The Project Manager can assess the design in near real time by tracking technical

parameters and equipment costs rather than actual documentation. It is easier to determine the level of design definition by knowing the parameters and values that have been defined than by trying to determine a level of design where the documentation is said to be 50% complete.

The tracking is accomplished with a simple spreadsheet program on the microcomputer. For those with the proper skills, a database manager can be used instead; however, consider the time required to prepare the database program if using this option. A spreadsheet can be set up easily and quickly without programming skills. The Equipment List is established in a hierarchical manner beginning at the system level. The major subsystems and their equipment are defined along with the parameters associated with the equipment. In addition to the technical parameters, the other important items are cross referencing (drawing and specification numbers), lead times, and costs.

Costs should include equipment, installation, testing, engineering, and any special costs contributing to total system/project cost. The costs can be those items identified on the Government Standard Form 1411 although this depends upon the accounting system/cost information required by either the contractor or customer. With the spreadsheet, total costs can be rolled up in columns to generate assembly, subsystem, or system costs and also summed by row to provide the total cost of the piece of equipment. This is important during cost reduction exercises when equipment additions or deletions are made. The other benefit is that it aids the team to focus on all costs other than purchase cost. For instance, procuring a motor/generator at a lower price may not reduce project cost if additional engineering is required for repackaging or changing an interface because of a new configuration. Representative parameters tracked during Phase 2 of the Vortec Vitrification Demonstration Plant Project are listed in Fig. 2.

Fig. 2.

Supplier Development

Working with the vendors actually begins during Phase 1. Because requirements are broadly defined, the activity is usually at a low level. It will benefit the project to become active in interactions with all potential suppliers. Some companies wait until all requirements and the design is neatly established before requesting quotes from suppliers. By actively interacting with suppliers, the design will proceed faster and can contribute to an increase in the excellence, and therefore quality, of the design.

Providing requirements and approaches to potential suppliers at an early date, allows them to become more familiar with the design issues and effective concerning their products. By participating in the design and costing activities with budgetary estimates during the early stages and refining these estimates as the design proceeds (See Fig. 1), an early warning can be obtained on potential cost problems. The usefulness of the microcomputer can be established during this process by having the latest documentation always available. Drawing changes or sketches are provided more quickly. Suppliers can be given key information at the end of a meeting when the computer to take notes during meetings.

Active cooperation with suppliers is a concept upon which all may not agree. There are many reasons companies state for keeping suppliers in the dark until design completion. They range from "The suppliers do not want to be involved until the design is completed" to "Our company policy prohibits it". Successful Project Managers continue to overcome these roadblocks and demonstrate that designs can be continuously improved and the costs can be reduced. This happens because suppliers want to provide a service to customers in order to obtain business and a better informed supplier can do this.

Interface Control Documentation

Definition and control of the interfaces during Phase 2 can improve Phase 3 success. In general, items of equipment from one supplier will usually operate successfully in a standalone mode. It is when equipment from different suppliers is brought together to operate as a system that the problems occur. Controlling interfaces and how they affect performance on both sides of the interface lies at the heart of system integration in ER projects.

The Interface Control Documentation (ICD) will be used to control these interfaces. While its use is primarily between major items of equipment from different suppliers (for instance a packaged Air Pollution Control System from Vendor A and the Process Monitoring and Control System supplied by Vendor B), the ICD can also be used for

other critical interfacing equipment under the design control of one vendor. The ICD results from the design drawings and specifications, but it focuses on the interfaces between pieces of equipment within the system or equipment outside the system that interfaces with the system.

Interfaces are defined, as appropriate, in the ICD prepared by the system integrator. This documentation is then reviewed and approved by all parties to the interface. It then becomes the binding document for the interface. Any changes to the interface, must result in a review and approval to changes to the ICD by all parties again. This is particularly important where control signals and timing are critical, but is also necessary where minor changes in physical interfaces can have a large impact on system performance (for instance a new seal at a pipe flange that results in only a material change but which could ultimately fail due to temperature extremes).

Red Team Review

The Red Team (independent) Review can result in raising emotions on a project. The benefits of avoiding adverse cost, schedule, and performance impacts will overshadow the emotions. Some Project Managers may initiate the independent review at critical events in the life of the project (at final design review for instance), but most result from an executive's initiative. The Red Team Review can be the Project Manager's best tool in the pre-implementation phase for assessing the design.

In carrying out the review, the reviewers are provided with the System Requirements Document, the major design drawings, a description of the system operation or flow, and any other major relevant information about the project, requirements, and design. This information should be provided at least two weeks before the review and earlier if possible. At the presentation to the reviewers, changes occurring since the documentation was provided are highlighted. All major project participants should be in attendance to hear the questions/comments of the reviewers. Subsequent to the review, the Red Team will provide written comments.

It would be nice to have a critique at each major design review, but this may not be cost effective. As a minimum though, a review should be held prior to the final design review with the customer.

SUMMARY

A new environment exists for managing Environmental Restoration projects. For projects requiring multidisciplinary technologies, "first time" design, and innovative equipment operation, the systems engineering approach provides a high confidence, reduced risk method for managing the project from the development of the concept through the implementation. Using the systems approach and the techniques and methods presented will help the Project Manager:

- Reduce total life cycle cost
- Integrate the project, and
- Anticipate and solve problems

46-11

ENVIRONMENTAL COMPLIANCE MANAGEMENT SYSTEM DEVELOPED BY THE DOW CHEMICAL COMPANY AT TEXAS OPERATIONS

Andy Cason
Larry Larrinaga
Dow Environmental Inc.

ABSTRACT

A cross-functional team of environmental regulatory experts, plant managers, and plant engineers have been working since 1991 on the development, implementation and maintenance of the Environmental Compliance Management System. The Environmental Compliance Management System is a practical and accurate method of determining the applicability of the state and federal environmental regulations and of establishing standard and straightforward procedures to meet these requirements. The Environmental Compliance Management System allows individual manufacturing facilities to avoid the additional manpower that would be required to read, digest and decide on the applicability and plan of action to meet the requirements of all the environmental regulations.

INTRODUCTION

In 1994, a record number of enforcement actions were brought and a record number of civil and criminal penalties were collected by the EPA.*

TABLE I

Voluntary compliance through self-auditing and pollution prevention programs offer an excellent alternative to achieving environmental compliance. However, the issue of understanding what a facility must do to be in 100% compliance with the applicable regulations in an area of ever changing regulations is complex given the fact that the federal environmental regulations have approximately 2,000 changes monthly.

A complete Environmental Compliance Management System is the best insurance to fight against fines, penalties, and business failure due to environmental non-compliances. The Dow Environmental Compliance Management System is consistent with the U. S. Sentencing Commission Environmental Guidelines and with ISO 14000.

Federal Operating Permit applications will require a comprehensive regulatory applicability assessment and a determination of the compliance requirements, including plans and schedules. Deadlines in a compliance schedule must be met because the schedule is the same as having an administrative consent order and the applicants can be fined or brought to court if the dates are not met. The Operating Permit program now is a program in which facilities must prove compliance--not one in which regulators are charged with finding noncompliances.

THE DOW SOLUTION

An environmental compliance system was developed by The Dow Chemical Company as a comprehensive management approach for environmental issues in chemical manufacturing facilities. The main causes of compliance deficiencies are inadequate operating discipline, inconsistent regulatory interpretations, and limited knowledge of the requirements

Dow has invested a considerable amount of time and resources in this project to document that its operating units are fully in compliance with existing laws and regulations pertaining to the environment. This system included the knowledge of its seasoned regulatory experts with specific know-how related to the interpretation of and the impact of the law. The Environmental Compliance Management System gives managers the tools to implement a comprehensive, multi-media, uniform, cost effective, plant level compliance program. Comprehensive, multi-media (air, water and solid waste) compliance requirements specific to an operation are customized via the Environmental Compliance Charts and documented via standard computer software (MS Excel spreadsheet and MS Word wordprocessor) for maintaining and reporting compliance data. This system defines the measures of environmental performance against objectives to allow the line managers to assume responsibility for compliance, in addition to the environmental staff. Typically, monthly Environmental Progress Reports are submitted to key stakeholders. In addition, it provides the tools necessary for line managers to be fully knowledgeable about their environmental obligations and to manage their responsibility, authority, and accountability for the environmental performance of their operations. The day-to-day compliance requirements are incorporated in the routine operating discipline making manpower available to focus their efforts on more cost effective concerns.

To ensure compliance, Dow developed compliance modules for each state and federal regulation. Some 60 modules currently cover these regulations. A few of these modules are still in the development stage. They provide a vehicle to communicate between environmental and production personnel by giving a clear and consistent understanding of the implications and requirements of the regulatory laws. The Environmental Compliance Management System allows individual manufacturing facilities to avoid the additional manpower that would be required to read, digest, and decide on the applicability and plan of action to meet the requirements of each law.

A module condenses the consensus of the experts and gives feed back on resolutions of compliance concerns. They provide consistent interpretation of what is needed to document compliance and by their nature become a useful roadmap for environmental self-audits. The Environmental Compliance Management System is a practical and accurate method for determining the applicability of the law and of establishing standard procedures to meet these requirements. Standard compliance checklists help new personnel gain an understanding of the requirements with minimum training. With this system in place, process changes can be made without allowing the unit to be out of compliance.

MODULE CREATION OVERVIEW

The Environmental Compliance System was developed by The Dow Chemical Company, Texas Operations to achieve compliance with federal and state laws and regulations. The

key component of the Environmental Compliance Management System is the Environment Compliance Module. The purpose of these modules is to provide plant personnel with a practical tool to ensure alignment and consistency between their function and the overall process for maintaining compliance.
The utilization of an environmental compliance module can be divided into five facets, starting with the issue of a new environmental law or regulation up to the full documented compliance with the new requirements.
Regulation Issue Management
The Regulation Issue Management Team studies each new or proposed regulation or interpretation and applies Dow resources to develop a compliance plan that minimizes the cost impact. The approach involves representatives from the potentially regulated plants and environmental regulations experts within Dow.
Module Development
The Regulation Issue Management Team submits to the environmental compliance team all new environmental laws and regulations to be converted into workable modules. The module development team analyzes final regulations and associated documentation for the specific compliance requirements. These compliance requirements are documented into a modular format.
Fig. 1.
Field Application & Training
The field application and training facet involves customizing applicable modules and compliance requirements for the unit involved, listing those requirements on an Environmental Compliance Chart, and training employees to implement the compliance requirements.
Self Assessment
The self-assessment facet is a "spot-check" performed by plant management and plant environmental personnel to verify compliance. Self-assessment provides the assurance that the assigned personnel perform the required compliance tasks in a timely manner.
Compliance
Compliance is achieved when all the technical, monitoring, and reporting requirement are met and a working plan is in place committed to the continuance of the program.
DEVELOPING AND MAINTAINING AN ENVIRONMENTAL COMPLIANCE CHART
The Environmental Compliance Chart (ECC) is the core of this system and it summarizes the applicable compliance requirements at the plant or department level.
All required documentation (recordkeeping and reporting) applicable to the facility appears as individual tasks.
Specific form number and/or name are shown.
The regulation, permit, law, or policy requiring the task is listed.
All the paperwork supporting the completion of the task is filed and the file number is listed.
The name of the personnel responsible for the completion of the task is listed.
A column is dedicated to note the verification of records when continuous monitoring is required.
The ECC provides to management at a glance the key information to verify the facility environmental compliance status. All the compliance requirements are listed in one place with the names of personnel assigned to perform the compliance tasks. In addition, the frequency of the tasks is shown with indication of when it was last performed.
The ECC includes a frequency section (e.g. daily, weekly, monthly, etc.) showing the total number of tasks completed and not completed for each respective period. For example, one of the monthly tasks is an inspection by the department head of the status of the items due that month.
Environmental personnel use the ECC information as a basis to certify that a plant is in compliance. All the information is referenced with checklists, special forms, and documentation files.
DEFINING APPLICABILITY
The initial task of the Module Project Leader is to establish the applicability of the environmental regulation. Applicability is a process to determine the scope of the regulation and to identify what elements of the production facility are affected.
The applicability process is done via the interaction of production representatives and regulatory experts. During this process the scope of the modules is defined,

tailoring each of them to the needs of a production facility. All the requirements of the environmental regulations are listed and plant personnel identify which ones affect their site.

FIELD IMPLEMENTATION AND TRAINING

The implementation of the Environmental Compliance Management System starts with the identification of the applicable modules and compliance requirements for a given plant. The requirements or tasks are listed on the Environmental Compliance Chart and plant personnel are assigned to those tasks after a training session.

The steps of the implementation process are:

- Identify modules pertaining to the manufacturing plant
- Determine and document modules for applicability
- Assign personnel for the implementation of tasks
- Train personnel in the implementation of tasks
- Change module applicability if necessary
- Identify units, areas, equipment, subject to regulation
- Identify the compliance requirements
- Complete reporting requirements and note completion on the ECC
- Document required process changes
- Develop specific operating procedures for each required task
- Develop, conduct, and documents training sessions

SITE INSTALLATION

Applicability

Analyze the applicability of the environmental regulatory compliance requirements at the plant level.

Conversion

Customize the Environmental Compliance Modules consisting of an environmental encyclopedia with detailed operating discipline. With this system in place, line managers can look to much leaner corporate and business units with environmental staffs only for specialized expertise and service that cannot be provided cost effectively on a decentralized basis.

Training

Train plant personnel to incorporate the Environmental Compliance Management System into the company's operating discipline. The company operating culture is incorporated during the module conversion process and delivered to the company representatives charged with implementation.

Maintenance

Institute a system maintenance process capable of incorporating new and amended regulations as they are promulgated and adjusts to reviews made of capital projects regarding applicable regulations and interpretation.

CYANIDE MIXED WITH RESIDUAL RADIOACTIVE MATERIALA UNIQUE REGULATORY COMPLIANCE PROBLEM*

G.G. Neff
D.G. Koch
A.M. Houska
Rust Geotech
U.S. Department of Energy
Grand Junction Projects Office
Grand Junction, Colorado

ABSTRACT

In 1981, the U.S. Department of Energy (DOE) Grand Junction Projects Office (GJPO) was assigned responsibility for the Uranium Mill Tailings Remedial Action Grand Junction Vicinity Properties Project. This project required planning, characterization, design, and remediation of more than 4,000 properties in and around Grand Junction, Colorado. These properties were contaminated with radioactive uranium mill tailings (residual radioactive material) as a result of milling operations conducted for the U.S. Government during the 1950s and 1960s.

During the remedial action activities conducted by DOE-GJPO and its contractor, Rust Geotech, a number of Resource Conservation and Recovery Act issues were identified at some of the vicinity properties. One of these vicinity properties was a machine shop whose principal operations consisted of manufacturing, repairing, and distributing drilling and other types of heavy equipment. As part of the operations,

a sodium cyanide bath was used in a metal heat-treating and case-hardening process. This process produced cyanide contamination that was commingled (mixed) with the soil and residual radioactive material surrounding the heat-treating area. This contamination posed a unique mixed-waste problem that required concurrence from the Colorado Department of Health and Environment (CDPHE) for the hazardous waste determination decisions before site remediation could be initiated.

OVERVIEW

The U.S. Department of Energy (DOE) Grand Junction Projects Office (GJPO) administers the Uranium Mill Tailings Remedial Action (UMTRA) Grand Junction Vicinity Properties Project in and around Grand Junction, Colorado. These properties were contaminated with radioactive uranium mill tailings (residual radioactive material [RRM]) as a result of milling operations conducted for the U.S. Government during the 1950s and 1960s.

Several Resource Conservation and Recovery Act (RCRA) issues have been identified during remedial action of these vicinity properties. One of these vicinity properties is a machine shop operation, which has been in operation for approximately 40 years. An area outside the machine shop was used for heat-treating and case-hardening metal parts. Commingled waste was identified in the heat-treating operation area (see Fig. 1).

Fig. 1.

The commingled waste presented an unique mixed-waste problem that required Colorado Department of Public Health and Environment (CDPHE) concurrence for the hazardous-waste determination decisions before site remediation could be initiated.

DEFINITIONS

Commingled Waste: Commingled waste is defined as material composed of RRM, or RRM and a solid waste, as defined in Title 40 Code of Federal Regulations (CFR) Part 261.2 (1), commingled with a RCRA hazardous waste or a Toxic Substances Control Act (TSCA) regulated substance (specifically polychlorinated byphenyls [PCBs]). RRM is excluded from the RCRA definition of a solid waste in 40 CFR 261.4, "Exclusions," (2).

RRM: The Uranium Mill Tailings Radiation Control Act of 1978 (UMTRCA), as amended, 42 United States Code, Section 7901 to 7925 (3), defines RRM in Title 1, Section 101, Definitions(7)(A), as "Waste . . . in the form of tailings resulting from the processing of ores for the extraction of uranium and other valuable constituents of the ores . . . ."

METAL HEAT-TREATING PROCESS

The following process describes the metal heat-treating operation conducted at this site:

Granular sodium cyanide is placed in a heat-treating vat, where it is heated to approximately 927C. Sodium cyanide is the only ingredient in the heat-treating vat.

Metal parts connected to a pull tool (or some other lifting mechanism) are lowered into the molten solution in the heat-treating vat.

The hot metal parts (after several hours) are extracted from the solution and transferred to an adjacent container of water for quenching. Sometimes this quenching bath is located approximately 3 to 5 meters away from the heat-treating vat.

Sodium cyanide residue (in the heat-treating vat) is treated on site by mixing it with chlorine bleach. The resultant substance is then sent off site for disposal or recycling.

The quenching bath is cleaned periodically. The wastewater sludge is sent to an off-site facility for recycling.

The following field observations were noted as a part of the hazardous-waste investigation:

Molten sodium cyanide was observed dripping onto the concrete slab as the metal parts were transferred from the heat-treating vat to the quenching bath.

The quenching bath container does not have a mechanism for preventing liquid drift. Drift occurs when the hot metal is placed into the quenching bath.

POSSIBLE HAZARDOUS WASTE SOURCES

Potential hazardous-waste sources that may have contaminated the soil and RRM on this vicinity property are

Spills or discards of pure, unused sodium cyanide.

Spills or drips of molten sodium cyanide solution and drift from the quenching bath.

Spills or disposal of sodium cyanide residue waste generated during cleaning of the heat-treating vat.

Wastewater or sludge from the quenching bath discarded on site.

ASSESSMENT OF HAZARDOUS WASTE SOURCE

Following is an evaluation of the applicability of the RCRA regulations to the potential hazardous waste sources identified:

Pure, unused sodium cyanide is a listed RCRA hazardous waste if spilled or discarded. Under these circumstances, its hazardous waste number is P106. In the event that pure, unused sodium cyanide is spilled or discarded in a manner that contaminates the soil, any concentration of the sodium cyanide contained in the soil will be a P106 listed hazardous waste.

The molten sodium cyanide solution used during the metal heat-treating process is not regulated as a listed waste; however, it qualifies as a characteristic hazardous waste if it is spent and it exhibits the characteristic of reactivity. Therefore, any spills from this source will not be considered to be a listed waste; however, any material contaminated by the spill will be regulated as a characteristic reactive waste (hazardous waste number D003) if it meets the regulatory definition. Specifically, reactivity is established if the waste reacts violently with water or generates toxic gases, vapors, or fumes in a quantity sufficient to present a danger to human health or the environment when exposed to pH conditions between 2 and 12.5. Reactivity can also be assessed by determining the concentration of total releasable cyanide in a waste sample. The regulatory limit for this determination is 250 milligrams of hydrogen cyanide per kilogram of waste in soil.

NOTE: Once used, sodium cyanide will not qualify as P106 (a pure chemical product).

The quenching bath water will only be regulated as a hazardous waste if it is spent or discarded and meets the definition of a reactive waste. Therefore, drift from this source will not be considered to be a listed waste. However, any material contaminated from this source will be regulated as a reactive waste (D003) if it meets the regulatory definition.

The sodium cyanide residue generated from vat cleaning could be identified as a listed waste with a waste number of F011. The residue contains spent cyanide solutions left in the vat after the heat-treating process and material generated during the actual cleaning of the vat. The hazardous constituent for which F011 is listed is cyanide (salts).

At this vicinity property, the sodium cyanide residue is treated on site and subsequently managed off site. Any spills resulting from the vat emptying or cleaning process could potentially result in soil containing a listed waste (F011) as determined by any detected concentration of cyanide (salts). If the spent sodium cyanide solution or residue is considered not listed, this same solution or residue and any material discarded or contaminated from a spill could be considered a reactive waste (D003) if it meets the regulatory definition.

Although it does not meet the definition of a listed waste, wastewater from the quenching bath could be a reactive waste (D003). Soils contaminated by spilled or discarded quenching bath wastewater will be regulated as a reactive waste (D003) if they meet the regulatory definition.

Wastewater sludge generated in the quenching bath is a RCRA-listed hazardous waste (hazardous waste number F012). If the sludge is, or has been, inadvertently spilled or discarded on site, soil that contains any concentration of the listed waste will be considered a listed waste. The hazardous constituent, for which F012 is listed, is cyanide (complexed).

ASSESSMENT OF SOIL CONTAMINATION SOURCE

Listed-Waste Sources

Possible listed-waste sources for the cyanide identified in the soil at this site include P106 from spilled or discarded pure product, F012 from spilled or discarded quenching-bath wastewater sludge, and F011 from spilled or discarded sodium cyanide residue generated during emptying or cleaning of the heat-treating vat. Process knowledge for the metal heat-treating operation does not demonstrate mismanagement of any of these listed waste streams. The owner or operator relies upon off-site recycling or disposal of the quenching-bath wastewater sludge and the discarded sodium cyanide residue generated during emptying or cleaning of the heat-treating vat.

Characteristic Waste Sources

Process knowledge for the metal heat-treating operation does not demonstrate

mismanagement of the sodium cyanide residue from the heat-treating vat. However, the molten sodium cyanide was observed dripping onto the concrete slab as the metal parts were transferred to the quenching bath. Drift during the quenching process was also observed. These sources, along with the possible discarding of the wastewater, are the probable sources of the total cyanide detected in the soil samples collected in the vicinity of the concrete slab. Therefore, the soil will qualify for management as a characteristic hazardous waste if it meets the definition of reactivity.

SITE CHARACTERIZATION ACTIVITIES

Sampling was performed to evaluate the potential of hazardous waste commingled with RRM. This sampling was restricted to locations of assessed radiological contamination determined most likely to contain hazardous waste. Factors considered in this determination included drainage areas for waste materials generated inside the machine shop (the concrete sumps); process knowledge of the activities and materials used in the heat-treating area; visibly stained or discolored soil in the heat-treating area; and anecdotal evidence about the existence of potential waste in areas of assessed radiological contamination. The metal heat-treating area was targeted for investigation on the basis of process knowledge from observation of on-site operations.

A series of site-specific sampling and analysis plans was developed and implemented with a combination of authoritative and systematic sampling techniques. Analyses performed during these investigations included Target Compound List (TCL) volatiles, TCL semivolatiles, Toxicity Characteristic Leaching Procedure (TCLP) metals, flammability, and the characteristic of reactivity with regard to cyanide content.

Phase 1

The first phase of the site characterization effort consisted of investigating the sumps inside the machine shop, the water meter pit, and the soils adjacent to the heat-treating area. Because no residues were discovered in the machine shop sumps, only liquid samples could be collected. These samples were analyzed for TCL volatiles, TCL semivolatiles, TCLP metals, and cyanide. The sump samples are designated as Locations 1 and 2 on Fig. 1.

No liquid was present in the water meter pit; therefore, a grab sample of soil was collected from the bottom of the pit and analyzed for flammability. This sample location is designated as Location 3 on Fig. 1.

Soils adjacent to the concrete pad in the heat-treating area were characterized by collecting a composite sample consisting of four aliquots. The positions of these aliquots are denoted on Fig. 1 as Locations 4 through 7. These soil samples were analyzed for TCLP metals and cyanide. A cyanide concentration of 30.6 parts per million (ppm) was detected in the composite sample collected from Locations 4 through 7. This detection prompted further characterization of soils in this area to define the areal extent of elevated cyanide concentrations. To complete this characterization, discrete samples were collected from Locations 8 through 13. The applicable reactivity test for soils collected from this site should evaluate the total releasable cyanide concentration (e.g., in an extract). The regulatory limit defines reactivity as 250 milligrams of hydrogen cyanide per kilogram of soil (ppm). This regulatory limit is specified in EPA's Test Methods for Evaluating Solid Waste, Chapter 7, Volume IC (4).

Phase 2

Because the analytical results from Locations 8 through 13 and those from the composite sample collected at Locations 4 through 7 indicated that elevated cyanide concentrations were mixed with radiologically contaminated soils, a second sampling activity took place. Locations 4 through 7 were resampled individually to quantify the cyanide concentrations at each discrete location. In addition, samples were collected from the concrete cuttings from the concrete pad in the heat-treating area and in the soils immediately beneath the pad. These samples were analyzed for cyanide content.

Results of analytes, equal to or exceeding typical contract required detection limits, are presented in Table I (Phase 1) and Table II (Phase 2). These analytical data were reviewed for compliance with laboratory quality control and data acceptance procedures. Those departures, from standard laboratory quality control measures, that did occur did not impede the effective evaluation of the analytical data for the presence of hazardous waste on this property.

TABLE I

TABLE II
Depth is reported in inches to reflect actual measurements taken at this UMTRA vicinity property.
SUMMARY OF SITE CHARACTERIZATION RESULTS
Evaluation of Characteristic Hazardous Waste: Sampled materials that met the regulatory definition of a waste and contained elevated cyanide concentrations potentially qualified as being hazardous in relation to the characteristic of reactivity. The sources of the elevated cyanide concentrations in the sampled material were identified in a previous section.
Elevated cyanide concentrations were noted in the soil samples collected from Locations 4 through 14 and in the concrete cuttings sampled at Location 14. However, total releasable cyanide concentrations in all of these samples were less than the regulatory limit of 250 ppm; therefore, these materials do not exhibit the characteristic of reactivity.
The toxicity characteristic is measured by analyses using the TCLP. Samples from Locations 1, 2, and 4 through 7 (composite) were analyzed for TCLP metals. None of the metals on the TCLP-metals list were detected in these samples as leachable concentrations exceeding contract-required detection limits.
The characteristic of ignitability was not suspected on basis of the absence of potentially ignitable-free liquids in any of the sampled areas. Although not a characteristic waste concern, a soil sample from the water meter pit (Location 3) was investigated for flammability to determine if the material had been affected by petroleum products and if it would present a hazard during any future transportation off the property. Results indicated the material tested does not present a flammability hazard.
There was no reason to suspect that radiologically contaminated materials on this site were excessively corrosive; therefore the characteristic of corrosivity was not investigated.
Evaluation of Listed Hazardous Waste: Several cyanide-based listed wastes that were potential sources of the elevated cyanide concentrations in the soils and concrete in the heat-treating area were identified. These possible sources could have included pure sodium cyanide that was spilled or discarded; spilled or discarded sodium cyanide residue generated during emptying or cleaning of the heat-treating vat; and spilled or discarded wastewater sludges generated in the quenching bath. Observations and historical research of site operations and the heat-treating process demonstrated that these waste streams are handled through off-site recycling or disposal; there was no evidence of spillage or mismanagement. Therefore, it was concluded that listed hazardous wastes were not the source of the cyanide contamination in the soils and concrete in the heat-treating area.
The contents of the two sumps inside the machine shop area (Locations 1 and 2) were analyzed to determine the chemical composition of these waste materials. If these materials were concluded to be hazardous, their leakage from the sumps into surrounding radiologically contaminated soils would have created the potential for commingled waste. The analytical results indicated the presence of detectable concentrations of the following TCL volatiles: acetone, chloroform, xylene (m, p), and bromodichloromethane. In addition, a number of tentatively identified compounds were detected during the TCL-volatile and TCL-semivolatile analyses. The minuscule concentrations of the positively identified contaminants (with the acetone from the sump [Location 1] being the largest concentration at 0.094 milligrams per liter [mg/L]) suggests that these constituents were present in the samples as a result of laboratory contamination rather than from on-site machine shop operations. The radiologically contaminated soils in the area of the sumps did not contain listed hazardous waste.
Evaluation of Toxic Substances (PCBs): No samples were analyzed for PCBs because there was no process-related information that would indicate spills or dumping of materials containing PCBs. There was also no reason to suspect the presence of any other toxic substance regulated by the EPA under TSCA.
CONCURRENCE OF STATE REGULATORY AGENCY
To enable DOE-GJPO to remediate the RRM on this property, concurrence was required from the CDPHE Hazardous Materials and Waste Management Division. A technical discussion document, prepared and presented to CDPHE, detailed the initial evaluation of this property. This evaluation included site background and process information, assessment of possible waste sources, assessment of hazardous waste

source, and the results of the Phase 1 site characterization activity. The technical discussion document scrutinized the materials and activities associated with the heat-treating process; assessed potential cyanide-based waste streams; addressed regulatory issues associated with the potential cyanide waste streams by examining the relevant classification of these wastes with regard to RCRA regulations; reported the results of the Phase 1 investigation; and recommended a course of action for a further investigation (Phase 2) on the basis of the regulatory conclusions.
This cooperative effort resulted in DOE receiving written concurrence from the section chief of the CDPHE Hazardous Materials and Waste Management Division accepting the regulatory determinations presented in the technical discussion document and approving the recommendation for conducting a Phase 2 site characterization. The results of the Phase 2 site characterization did not identify either characteristic or listed hazardous wastes. The results of the Phase 2 site investigation were submitted to CDPHE along with a recommendation to remediate the RRM on this property.
This vicinity property has subsequently been remediated of RRM. The radiologically contaminated materials were excavated and removed from the property. The disposal site for the RRM was the UMTRA Cheney Disposal site southeast of Grand Junction, Colorado.

Mound Plant
ABSTRACT
The Department of Energy (DOE) Mound and Pinellas Plants are part of the DOE nuclear weapons complex current reconfiguration effort and have been designated for transition from operational facilities to Environmental Restoration Programs and private industry ownership. A critical element during the initial stages of transitioning is proper identification and classification of materials, equipment, and wastes. A logic process was developed and incorporated as a tool to provide direct guidance to the site's transition and environmental management programs. The intent of the logic process is to help identify and establish the correct sequence for decontamination and decommissioning (D&D) of buildings, routing of materials and equipment, and disposition of any waste generated. Each plant used the logic process to develop site-specific transition plans.
Mound and Pinellas Plants have realized benefits from establishing a formal logic process that includes only contaminated materials are processed for decontamination, better management of hazardous materials, reduced cost, improved regulatory compliance, and effective use of resources and time.
INTRODUCTION
The transition effort at the Mound and Pinellas Plants is described below to demonstrate the magnitude of the remediation, material, and waste management problems associated with transition. The logic process reduces the potential for

radioactive and hazardous cross contamination of buildings, equipment, and materials. When cross contamination does occur it can result in generation of a radioactive RCRA contaminated mixed waste. This increases the decontamination and disposal costs.

SITE DESCRIPTION

The Mound Plant identified 72 buildings for transition. The buildings are in various stages of remediation and range in size from 25,700 to 183,000 square feet. Some of the buildings are being demolished, a few are in the process of decontamination, and other buildings have already been signed over to the Miamisburg community for industrial development. These buildings contain production areas, storage areas, office areas, various chemicals, laboratories, materials, process equipment, personal property, and building systems, all requiring transition.

The Pinellas Plant used a slightly different approach and identified 110 areas to be characterized and cleaned. These areas range in size from 100 to over 21,000 square feet. Most of the areas are in a single building and are at various stages of remediation; some are completed and are currently being leased by private companies for industrial development. Included in the Pinellas areas for transition are production areas, storage areas, office areas, various chemicals, materials, laboratories, process equipment, personal property, and building systems.

PLAN PROCESS DESCRIPTION

Development of the logic process began in May 1994 in Miamisburg, Ohio. The original concept focused on the development of waste minimization (WMin) procedures to help reduce or eliminate the volume of waste generated during the transition process. The resulting process, illustrated in Fig. 1, began with selection of a representative building, a potential waste material such as a chemical or process equipment, and the building systems (air handlers, mechanical pumps, and air duct systems).

The chemicals were determined to be either non-radioactive (clean) or radioactive (dirty). The chemicals were then determined to be reusable or recyclable. The question to reuse or recycle was always asked regardless of whether the chemicals were clean or dirty. If the chemical could not be reused or recycled, the final decision was disposal.

Using the plan logic process, equipment was evaluated in much the same way as chemicals, but the greater cost of equipment encourages the user/owner to try to decontaminate, reuse, or recycle equipment before declaring it waste.

In considering a building's systems, the building manager should anticipate the building's planned future use and what processes it will house. The future use of a facility may be identical to past operations and require minimal decontamination, or the opposite may be true. Decisions concerning the building's systems are typically the same as for the equipment: planners must identify which systems are contaminated and require decontamination, and which systems can be left in place or processed for disposal.

Fig. 1.

CHEMICAL INVENTORY EVALUATION FOR DISPOSITION

Every effort should be made to reuse or recycle a material and not dispose of it as waste. A number of reuse opportunities are identified in Fig. 2. For example, if a chemical has been used in a Radioactive Material Management Area (RMMA), the user must determine if the chemical is radioactive. Sampling and analysis may be required to make this determination. If the chemical is clean, a determination can be made concerning its suitability for reuse. If the clean chemical can be reused, it may be transferred to a new user. If it cannot be reused, the next decision is to determine whether the chemical is RCRA regulated and required to meet RCRA disposal requirements.

At the RMMA decision block, if the chemical is determined to be radioactive (dirty), a determination is made whether the chemical is also RCRA regulated. If it is not RCRA regulated, it is low-level radioactive and not mixed. The next decision is to determine whether the dirty chemical can or should be decontaminated. If it cannot be decontaminated, the decision is made whether the chemical can be reused. If the dirty chemical can be reused, transfer to the new user is required. If it cannot be reused, a declaration is made that the dirty chemical is now a low-level waste (LLW) and can be processed for shipment to a DOE-approved disposal site. If the dirty chemical is decontaminated, a decision is made whether the clean chemical can be reused. If so, it may be transferred to a new user. If not, the chemical can be prepared for proper treatment and disposal.

If the dirty chemical is determined to be RCRA regulated and radioactive, it is mixed, but not necessarily a waste. A decision is now required to determine whether the mixed chemical should or can be decontaminated. If it cannot be decontaminated, a decision is made that the chemical is a mixed waste (MW). The MW is included in the site's plan for mixed waste treatment and disposal.
If the mixed chemical can be decontaminated, the next decision is whether to reuse. If the chemical cannot be reused, it is prepared for shipment for treatment and disposal at an approved treatment, storage and disposal (TSD) facility. If the chemical can be reused, it may be transferred to the new user.
Fig. 2.
PROCESS EQUIPMENT EVALUATION FOR DISPOSITION
If the process equipment is clean of radioactivity, a decision is made regarding RCRA contamination, as illustrated in Fig. 3. If there is no RCRA contamination, a decision is made whether the equipment can be reused locally. If the clean equipment cannot be reused locally, it is declared Excess Property and formal procedures implemented to offer it for reuse off site. If the clean equipment can be reused, it may be transferred to the new user. If the clean equipment is RCRA contaminated, a decision is made whether the equipment can or should be decontaminated. If the equipment can be decontaminated, it is considered for reuse or declared as Excess Property. If the RCRA contaminated equipment cannot be decontaminated, a decision is made whether it can still be reused. If it can be reused, it may be transferred to the new user. If it cannot be reused, it is prepared for RCRA treatment and disposal.
If the equipment is radioactive the next decision is to determine whether the equipment is also RCRA contaminated. If the radioactive equipment is not RCRA contaminated, it is radioactive only and the next decision is whether it can be decontaminated. If it cannot be decontaminated, the next question is whether there is a user for the radioactive contaminated equipment. If there is, the equipment is transferred to the new user. If the equipment cannot be reused, it is declared low-level waste and requires disposal at an approved DOE facility. If the dirty equipment can be decontaminated, a decision must be made whether the equipment can be reused. If it cannot be reused after decontamination, then the equipment is Excess Property. If the equipment can be reused, it can be transferred to the new user.
If the radioactive equipment is also RCRA contaminated, it is mixed but is not necessarily declared a waste. The decision is made whether it can be reused as-is. If not, then a decision is whether the equipment requires decontamination. If the equipment cannot be decontaminated, a decision is made that the equipment is a mixed waste (MW). The MW is included in the site's plan for mixed waste treatment and disposal. If it can be decontaminated, an effort is made to reuse or recycle the equipment. If the decontaminated equipment can be reused, then it can transferred to the new owner. If the decontaminated equipment cannot be reused, it is prepared for RCRA treatment and disposal.
Fig. 3.
BUILDING SYSTEMS EVALUATION FOR DISPOSITION
The same basic logic process is used with a building's systems, as illustrated in Fig. 4. If elements of a building's system (air handlers, mechanical pumps, or air duct system) are clean, the decision is made whether the system is RCRA contaminated. If the system is not RCRA contaminated, it can possibly stay in place. If the clean system is RCRA contaminated, a decision is made whether to decontaminate. If the clean system can be decontaminated, the question is whether the system can stay in place. If the clean system cannot be decontaminated, a decision is to be made whether the system is to be reused or dismantled for proper RCRA treatment and disposal. If the clean system is not to remain in place, dismantling and packaging for RCRA treatment and disposal are required.
If the building system is determined to be radioactive a decision is made whether the system is also RCRA contaminated. If it is not RCRA contaminated, a decision is made whether the system can be reused as is or whether it requires decontamination. If it can be reused as is then the system can stay in place. If the radioactive system can only stay in place if decontaminated then an effort is made to decontaminate. If the radioactive system cannot be decontaminated then the system is declared LLW and packaged for proper disposal at a DOE-approved facility.
If the radioactive system is determined to be RCRA contaminated, it is declared

mixed, but not necessarily declared a waste. A decision is made whether the system can stay in place as is or if it requires decontamination. If it can stay in place as is no further action is required. If the mixed system requires decontamination but cannot be decontaminated, a declaration is made that the system is now a mixed waste (MW). The MW is included in the site's plan for mixed waste treatment and disposal. If the mixed contaminated system can be decontaminated, a decision is then made whether the system can stay in place.
Fig. 4.

CONCLUSION

The ultimate goal of facility transition includes the proper disposition of materials, equipment and building systems. In this capacity, the logic process ensures reduction of waste, maximum reuse or recycle, and D&D only of building systems and materials that require it. The benefits of this process include improved Health and Safety, reduced cost, timeliness, efficient use of resources, and recovery of materials and equipment for reuse or recycle.

EVALUATIONS OF NATURAL GAS HAZARDS AT THE FORT ST. VRAIN ISFSI

Engineering Analysis Inc.
Huntsville, Alabama

ABSTRACT

Public Service Company of Colorado (PSC) is considering repowering the Fort St. Vrain generating station with natural gas-fired combustion turbines and heat recovery steam generators. The Nuclear Regulatory Commission had concerns over potential natural gas hazards associated with repowering. PSC contracted Westinghouse to make an assessment of these hazards. Natural gas hazards evaluated by Westinghouse were potential explosions of unconfined vapor clouds from postulated gas line ruptures and a detonation within the Turbine Building and their impact on the Independent Spent Fuel Storage Installation Modular Vault Dry Storage (ISFSI). A series of analyses were performed using the state-of-the-art Vapor Cloud Explosion Damage Assessment Model (VEXDAM) (1) developed by Engineering Analysis, Inc. Our results showed that both the ISFSI and repowered Fort St. Vrain station could co-exist without a nuclear safety threat.

BACKGROUND

PSC is in the process of decommissioning the Fort St. Vrain High Temperature Gas-Cooled Reactor. Upon completion in 1996, there will be only one on-site facility containing radioactive material. This is the Independent Spent Fuel Storage Installation Modular Vault Dry Storage Facility (ISFSI). This facility currently stores the spent fuel from the Fort St. Vrain Station.

The ISFSI is a massive, reinforced concrete structure that is designed to withstand a 360 mph design-basis tornado.

Natural gas hazards in the vicinity of Fort St. Vrain have been previously analyzed. These hazards were associated with nearby natural gas wells and associated collection pipelines. The results of the analyses showed that there was no compromise to the ISFSI's nuclear safety function.

PSC has obtained Colorado Public Utilities Commission approval for repowering the site with natural gas-fired combustion turbines and heat recovery steam generators. The natural gas hazards considered included explosions of unconfined vapor clouds resulting from postulated gas line ruptures and a detonation within the Turbine Building and their impact on the ISFSI. The effects of the postulated natural gas explosions on the Reactor Building were not evaluated because significant quantities

of radioactive materials will no longer be available for release from the reactor building when natural gas is introduced.
Figure 1 shows proposed routing of gas lines at the Fort St. Vrain site. The following locations are relevant to the evaluations:
Fig. 1.
Point T is the tie-in location of the 12 inch service line feeding the combustion turbines to the 26 inch main supply header. The nearest approach is conservatively estimated to be 1,400 feet south of the ISFSI.
Point A is a routing option for the 26 inch Main Supply line, estimated to be located 5,280 feet southwest of the ISFSI.
Point C is located 4,300 feet to the west of the ISFSI and represents the closest approach of the 26 inch main supply header to the ISFSI.
Point Z is the location of the Fort St. Vrain Turbine Building where a confined natural gas explosion is postulated. The detonation was modeled at 1,737 feet from the ISFSI.

METHODOLOGY

The unconfined vapor cloud explosion analyses were performed in three steps. First, the amount of gas released from the pipeline ruptures was determined. Next, the downwind transport of the natural gas was evaluated with the DEGADIS (2) dispersion modeling code for several different wind speeds (2.0, 2.2, 4.5 and 6.7 mph) to determine the worst case scenario. This yielded the shape and extent of the unconfined flammable vapor cloud for the various wind speeds selected. The mass of natural gas available for an explosion was then determined for the plume considered to pose the most severe threat. This mass was adjusted upward for the elevated vapor cloud scenarios to account for the reflected shock wave (Mach region effect). Finally, the VEXDAM code was used to model the vapor cloud explosion and its impact on the ISFSI from both overpressure and impulse.
The confined vapor explosion in the Turbine Building was performed by determining the maximum amount of natural gas that could be present in the Turbine Building in a stoichiometric mixture with air. The VEXDAM code was then used to determine the overpressure and impulse at the ISFSI, assuming ignition of the mixture and confined detonation at ground level.

WORST CASE SCENARIO

To illustrate the methodology, a detailed description of the worst case, the 12-inch service line release will be presented. The results of all the other scenarios will then be summarized.

Natural Gas Release

The worst case release analyzed is the potential rupture of a 12 inch service line feeding the combustion turbines and a postulated unconfined vapor cloud explosion. The main supply line pressure is 875 psig and the service line was also evaluated at this pressure. A 20 foot diameter hole was assumed to be created as the gas jets from the rupture through the soil to the atmosphere. After time exceeds six seconds, the service line will depressurize and a steady state flow of 10,500 ft.3/sec. will result. A rupture with a release duration of three minutes was modeled to allow for full development of the flammable cloud. During this time interval, a total of 89,920 lbm of "Northern Colorado Standard" gas is released to the atmosphere.

Dispersion Model

The jet plume module of the DEGADIS dispersion modeling code was used to determine the trajectory of the flammable cloud. The flammable cloud is the volume of gas whose gas concentration is between the upper flammability limit (UFL) (15% vol) and the lower flammability concentration limit (LFL) (5% vol). The initial task was to evaluate the meteorological conditions, i.e., stability class and wind speed, that would yield the most conservative results, (i.e., the most severe damage to the ISFSI). Dispersion analyses were performed to estimate the flammable cloud volume for the following meteorological conditions:

- 2 mph, F stability
- 2.2 mph, F stability
- 4.5 mph, F stability
- 6.7 mph, F stability

Based on those analyses, the 6.7 mph and F stability resulted in the formation of the largest volume cloud, 3.3 million cubic feet, and this cloud was located closest to the ISFSI. In all cases, the wind was assumed to be blowing directly from the rupture to the IFSI.

The natural gas exits the ruptured pipe initially at sonic velocity. The upward momentum of the gas jet is included in the dispersion model. In addition, natural gas is buoyant (calculated molecular weight of 17.7 versus 28.8 for air) and this was also modeled. Near the rupture, the gas is at a concentration much higher than the UFL of natural gas and will not explode. As the vapor cloud is transported upward and downwind toward the ISFSI, the volume of the natural gas cloud in the flammable region (between 5% to 15%) increases due to atmospheric mixing. As the gas continues to be dispersed and diffused, the flammable volume decreases, finally reaching a point downwind where the volume drops below the LFL concentration and the gas cloud will not explode.

Figure 2 depicts the trajectory of the LFL and UFL clouds. The DEGADIS code does not provide instantaneous concentration profiles of the cloud. Rather it records the maximum concentration of the LFL cloud over time resulting in a tracing of the plume path. The DEGADIS code output can be used to determine the cross-sectional concentration profile at any height. Performing successive profiles (slices) permit development of the cloud (plume) profile. Additionally, the area of each slice can be determined and the total cloud volume estimated by multiplying the areas by the differential height. The net flammable volume was estimated by subtracting the volume above the UFL from the LFL volume. A review of these estimates indicated that the F stability and 6.7 mph conditions resulted in both the largest flammable cloud with the closest approach to the ISFSI. This volume was used for the detonation-damage estimation. The flammable cloud volume was determined to be 3.54E6 ft3. Assuming the flammable mixture to have an average concentration of 10% natural gas in air, this corresponds to 12,448 lbm of natural gas in a flammable concentration. Based on the dispersion analyses, the maximum downwind distance from the release point to a flammable concentration is 965 feet at an elevation of 358 feet. The center of the LFL cloud was estimated by determining the elevation in the cloud where one half of the cloud volume was above it, and one half was below. The area of the plume slice at this elevation was then estimated to determine the downwind distance where half the area was in front and half was behind the point. Based on this analysis, the center of the flammable cloud would be at 264 feet elevation and 361 feet downwind. At this point, the cloud center is 1,039 feet from the southside of the ISFSI. Under no conditions could a flammable gas concentration enter the ISFSI's natural cooling inlets from the 12 inch service line rupture (this is also the case for the other scenarios postulated in this study).

Fig. 2.

The VEXDAM Multi-Energy Model

VEXDAM has been designed to allow the rapid evaluation of damage experienced by each structure within a facility as a result of a primary vapor cloud explosion located on the surface, and any accompanying secondary vapor cloud explosions. Its primary application has been siting analysis of petrochemical storage and manufacturing facilities. The code can also be used to evaluate terrorism and sabotage threats to a facility.

The program has the capability to model an unlimited number of structures, and each with different dimensions and structural properties, including elevated structures by means of pressure-impulse diagrams. VEXDAM utilizes recently developed dimensionless curves of overpressure and pulse duration versus range, based on the Vandenberg multi-energy method (3), to predict overpressure and impulse at each structure location.

In VEXDAM, structure shielding, based on the three-doublet advanced shielding algorithm, is calculated, as well as damage levels. VEXDAM produces output in the form of damage tables, before-damage and after-damage displays, pressure, cumulative impulse and damage contour plots, and damage-versus-distance graphs.

Damage levels from vapor cloud explosions have traditionally been expressed in qualitative terms, with the adjective "severe", "moderate", and "light" most commonly used (4).

Severe damage corresponds to "degree of damage that precludes further use of the structure or object for its intended purpose without essentially complete reconstruction. For a structure or building, collapse is generally implied".

Moderate damage represents "degree of damage to principal members that precludes effective use of the structure or object for its intended purpose unless major repairs are made".

Light damage corresponds to "degree of damage to buildings resulting in broken

windows, slight damage to roofing and siding, blowing down of light interior partitions, and slight cracking of curtain walls in buildings. Minor repairs are sufficient to permit use of the structure for its intended purpose".
In order to produce a more quantitative description of damage, a numerical value has assigned to each such level. Based on past studies [5, 6] the following values have been used for VEXDAM:
TABLE
VEXDAM was developed for vapor cloud explosions located on the surface. The elevated vapor cloud explosion under consideration occurs at an altitude which falls in the Mach reflection region, for the horizontal ranges of interest. In such a region the incident peak overpressures can be approximately twice the values produced by a surface explosion. To take this Mach reflection region effect into account, the actual mass of the vapor cloud formed from the 12 inch service line rupture was multiplied by a factor of 3.9 to double the overpressure at the ISFSI for this scenario. This produced an adjusted mass of 48,485 lbm. The mass multiplier is unique for each of the elevated vapor cloud explosion scenarios modeled.
For purposes of the explosion analysis, the vapor cloud was modeled as a single sphere with its center coinciding with the center of the LFL region described earlier. The ambient temperature was assumed to be 70F and the ambient pressure 12.0 psi corresponding to an elevation of 5,500 ft above mean sea level. An explosive strength of 10, corresponding to a fully confined detonation, was assumed. The likelihood of such a detonation for an unconfined vapor cloud is extremely remote. By comparison, the most probable magnitude of the explosive strength of an unconfined vapor cloud would be two.
Based on available structural descriptions, the ISFSI facility was modeled as 22 individual components. This model was used for all cases in this study. Each component was described by its dimensions, location, orientation and structural resistance to blast.
VEXDAM Results for 12 inch Service Line
The output of the VEXDAM software consisted of a tabulation of damage to each structure of the ISFSI, as well as graphical displays and contour plots depicting the distribution of overpressure, impulse, and damage levels. Figure 3 shows the three dimensional distribution of peak overpressure from the 12-inch service line scenario. Figure 4 presents the three dimensional distribution of the 3.0 psi overpressure for this same scenario.
Fig. 3
Fig. 4.
The total composite damage level to the ISFSI facility is given as 13.8%, corresponding to light to moderate damage. The damage levels sustained by the reinforced concrete components were minimal, ranging from 0% to 0.9%. These percentages correspond to very light damage levels, which would not prevent such components from performing their structural, cooling and shielding functions. The corrugated metal components sustained higher levels of damage, ranging from 2.4% to 94%. Such percentages constitute light to severe damage levels. Because these metal components do not perform a safety function, such damage levels would not interfere with the performance of the ISFSI.
VEXDAM results indicate that the ISFSI would be exposed to a maximum incident overpressure of slightly greater than 3.3 psi for the 12-inch service line scenario. Also the ISFSI would be exposed to a cumulative impulse of 252 psi ms.
Based on the results produced by VEXDAM, damage levels to the reinforced concrete components of the ISFSI facility should be minimal. The structural, subcriticality control, cooling and shielding functions of such components would be unaffected. Essentially, no repairs would be necessary for the reinforced concrete.
The damage levels to the corrugated metal components would be significantly greater. Portions of these components would be destroyed with much of the remainder bent or buckled. The corrugated metal components do not perform any safety function, and thus, such damage would not in any way interfere with the mission of the ISFSI. The ISFSI could continue to function, although maintenance and security personnel might experience some inconvenience or discomfort due to exposure to external weather conditions, resulting from the absence of the corrugated metal. Considerable structural repairs to the corrugated metal would be necessary to repair or replace the damaged surfaces.
SUMMARY OF ALL SCENARIOS

The calculated overpressures and impulses are as follow:
TABLE
The results of these analyses show that a potential rupture of the 12 inch service line at Point T could create the highest overpressure at the ISFSI. The maximum overpressure was calculated to be 3.3 psi. A potential rupture of the 26 inch main supply line at Point C could create the highest impulse at the ISFSI. The maximum impulse was calculated to be 267 psi ms based on the pressure-impulse diagram analysis. The ISFSI can withstand these conditions.
The results of the VEXDAM damage assessment are as follow:
TABLE
The metal cladding of the ISFSI does not perform a nuclear safety function, but rather serves as a weather enclosure for workers' comfort. Damage to concrete components in all cases was light.
CONCLUSION
Based on the above values, there is no compromise in the mission of the ISFSI to provide containment boundaries for the irradiated fuel and its fission products, maintain the fuel in a subcritical array, provide for natural circulation cooling of the fuel storage containers and shield the public and ISFSI workers from the irradiated fuel. We conclude that even with the extremely conservative assumptions made, the ISFSI can safely withstand the impact of all natural gas scenarios postulated for the repowering of the Fort St. Vrain station.

ABSTRACT
The DEcommissioning Waste CHAracterization Program (DEWCHAP) has been developed to aid nuclear plant owners in projecting the amount and classification of the radioactive waste that will be generated during the decommissioning of a facility. This innovative computer program is built around statistical simulation techniques used for critical areas of data. This data includes radioisotope concentrations, quantities, volumes, and development of a level of accuracy reflecting the level of detailed information existing at the time of compilation.
The program is designed to use Monte Carlo techniques and various selectable

distribution functions to calculate waste characteristics. Default contamination levels and concentrations of radioisotopes have been built-into the program and can be used when site specific data is not available
The program allows the user to performance of "what-if" waste characterization calculations based on system, type of component or location in the plant.
Program results can be presented in a variety of formats: i.e. spreadsheets, defined reports listing radioactive waste volumes, weights, and class, or the add-on ability to design your own report.
The Decommissioning Waste Characterization Program (DEWCHAP) has been developed to aid nuclear plant owners in projecting the amount and classification of the radioactive waste that will be generated during the decommissioning of a facility. This computer program is designed to incorporate statistical simulation techniques for critical areas of data. This data includes radioisotope concentrations, quantities and volumes, to be used to develop a level of accuracy that reflects the level of detailed information existing at the time of compilation.
The program is designed to use Monte Carlo techniques and various distribution functions to calculate waste characteristics. Default contamination levels and concentrations of radioisotopes have been built-into the program and can be used when site specific data is not available.
The predictive windows-based computer program was developed using the simplified development model shown in Fig. 1. It was recognized that the information necessary to determine the waste characteristics from the decommissioning operations is heavily dependent upon plant specific data. Therefore, the program must be capable of handling a large number of variables from the plant, and requires them to be able to be changed or modified. In addition, to cover the situations where a minimum amount of information is available, a default set of data was prepared for each of the databases to allow the user the opportunity to manipulate data from a zero ground state.
TABLE I
A default set of information has been included in the following main databases:
Radiological,
Decontamination,
Component, and
Systems.
RADIOLOGICAL DATABASE
The radiological database is a table of the isotopes. It contains the isotope name, atomic number, atomic weight, and half life. An example of the database information is shown on Table I.
This information is important for several reasons. First, the half-life is essential in determining the specific activity of an isotope at the time of decommissioning. Second, it is important when determining the waste classification for the component since the isotope is used per the instructions in 10 CFR 61.55 Table I and Table II.
DECONTAMINATION DATABASE
The decontamination of a system, component or area in the plant will provide for the reduction of the radio nuclide concentration on the affected surface. The reduction of the concentration varies depending on many different parameters. A table was prepared for each of the different types of decontamination methods that exist in the industry today. Some examples of these decontamination methods are presented on Table II.
TABLE II
Each method has been given a range of decontamination effectiveness or a decontamination factor (DF). The DF range is based on published literature covering the subject and experiential data. In addition, it should be noted that the decontamination of a component or system will not reduce the total radio nuclide concentration in the plant. It will only move the contamination from one point to another. Therefore this program has been developed to keep track of the system wide decontamination method employed and to transfer the radio nuclide concentration to a designated waste volume for the particular method. An excerpt from this database is presented in Table III.
TABLE III
COMPONENT DATABASE
The components to be evaluated are imported into the program from various databases. The structure of the database is developed to optimize the information that exists

in a plant's master equipment list. An example of the structure of one of these databases is shown as Table IV.
For purposes of waste characterization, the important parts of master equipment list are the data that are used to determine weight, volume, system and location. The other information will be used in future programming to support the development of the decommissioning plan and component removal work packages.
TABLE IV
The waste characterization is developed at a component level. The process theory is based on several simplifying assumptions. First, the only radio nuclides that exist are those that are present in the reactor coolant system. This is valid for most non-transuranic elements that would be found in the plant. In addition, it assumes that any fuel failure has released a minimum amount of fuel into the system.
Second, the concentrations or specific activity of radio nuclides will vary depending on the interface between the system being evaluated and the reactor coolant system (RCS). The transfer of radio nuclides between systems can be measured in the actual plant situation. However, this information is transient and not normally available. Therefore, a System Activity Transfer Factor (SATF) has been developed for each system. This factor is used to develop the radio nuclide concentration in the component as a function the system's relationship to the RCS. The program allows for this factor to be developed using simulation techniques, thus providing upper and lower levels of confidence about the factor.
Third, radio nuclides can concentrate differently in different components. This effect is handled through the Component Activity Transfer Factor (CATF). Like the SATF, this factor can be determined through simulation techniques to improve the confidence level in the value and the calculation results.
Default values for these factors have been placed in the component and system databases.
The program proceeds to take the component, apply the SATF and CATF to determine the radio nuclide activity at the time of removal. In addition, if some method of decontamination is employed, the data is modified in accordance with the high and low decontamination factors to determine the final activity level of the component. The activity along with the component weight and displaced volume is provided in the output listing.
SYSTEM DATABASE
The system database contains the information about the radio nuclides and their concentrations as they exist in each system. The concentration can be developed by using simulation techniques, like those found in @RISK. This information is most important in developing the waste characterization and has been provided with the maximum ability for modification and change as the data associated with the end of plant life becomes available.
WASTE CLASSIFICATION
The information developed in the calculations is used to compare the activity levels and the radio nuclides present in the waste with the 10 CFR 61 requirements. The two tables used by the CFR are shown in Table V and Table VI.
The results of the evaluation are place in the output in a format determined by the user.
TABLE V
The process used in the determination is presented in Fig. 2.
TABLE VI
CONCLUSION
With the continuing uncertainties associated with the ability to dispose of radioactive waste and with the continued rise in the cost for disposal when available, the ability to accurately predict the amount of waste arising from decommissioning becomes increasingly important. The use of a program like DEWCHAP, that uses probabilistic techniques to predicting the amount of radioactive waste will aid the owner in determining the cost for its disposal. The program was designed to provide the information necessary to support the decommissioning planning of a nuclear plant. The preliminary results of the analyses has indicated that the accuracy of the information is greatly enhanced when a complete and detailed master equipment list exists. Even with this detailed list the probabilistic techniques are important in increasing the level of confidence in the accuracy of the results.

CADMIUM CONTROL/SAFETY ROD DISPOSAL AT THE SAVANNAH RIVER SITE

Steve McInnis
Bechtel Savannah River, Inc.
802 East Martintown Road
North Augusta, SC 29841

ABSTRACT
A total of 862 activated cadmium control/safety rods will be removed from four heavy water moderated reactors at the Savannah River Site. The cadmium rods are mixed waste and must be disposed of in accordance with the Resource Conservation and Recovery Act (RCRA). Determining a viable design plan for a 40-year-old facility while meeting today's standards, at a moderate cost, proved to be quite a challenge. First, a method to remove, handle and load these long, small-diameter cadmium rods from the reactor tank had to be determined. Second, a shielded cask which could fit in the small transfer pools and which could hold the control rods, had to be located or designed. Third, the waste acceptance requirements, the RCRA requirements and the logistical difficulties in meeting these requirements had to be addressed. These difficulties were resolved through close interpretation of the RCRA laws, involved management, strong communication, and detailed engineering.

INTRODUCTION

Four heavy water reactors will undergo activated cadmium control/safety rod removal. Du Pont designed and built these reactors in the early to mid 1950s. Although these Savannah River Site (SRS) reactors are forty years old, they offer several basic advantages for decommissioning. First, the equipment is still in some sort of operable state. Second, the reactor is below the floor in a large process room, which will allow access. Third, control/safety rods can be handled by existing components (fuel) handling equipment, which is a remote control robotic system. Finally, a radiologically shielded removal path exists for these cadmium control/safety rods. With these positive aspects, preliminary decommissioning steps (transitional steps) should be much easier.

The Savannah River reactors still had numerous constraints. First, the reactors are forty years old. Equipment operability and spare parts are a potential problem. Second, improvements in technology caused incompatibility problems. With improvements to technology came more stringent modern standards. Applying these modern standards to this 40-year-old facility took some detailed engineering and environmental guidance. To compound the plant's problems, the project had to comply with environmental regulations, such as RCRA.

PROCESS SELECTION

The progress of the project involved radical changes during the first couple of months. The process, the cask, and the RCRA interpretations needed to be clarified. The solution to any one item would impact the others. After initial investigation of the total project, it was decided that the rod removal process was the first problem to resolve.

The first approach was to bring a cask into the process room (or the reactor room) for loading. Problems quickly developed. Initial forecast of the cadmium rod activity indicated that a 35 ton (32,000 kg) cask would be the minimum weight for a shielded container for one reactor's compliment of rods. (Fabrication and manufacture investigations showed smaller casks that hold half or a quarter of the reactor's complement of rods was not cost effective.) Per discussions with structural engineers, the floor in the process room could not support this type of concentrated loading. In addition, the rods are lifted vertically by the components handling equipment. However, the ceiling was not high enough to vertically load a

vertical oriented cask. The cadmium rods were long and thin (approximately the diameter of a quarter) (2). The cadmium rods did not have enough structural rigidity for a single point of contact to rotate the rods from the vertical position to the horizontal orientation. Another group onsite had two very capable titanium robotic arms that could be used. However, investigations showed the arms could not be used in unison to rotate the cadmium rods from vertical to horizontal. As the more practical answers faltered, the proposed approaches became more radical. One solution suggested removing one leg of the reactor coolant loop, boring out its hole in the concrete floor, inserting a specially designed cask in the hole and loading the cask with the titanium arm attached to the components handling equipment.
After investigation and research, it was determined that the reactors used a different type of control/safety rods at one time (1). These rods were removed by the components handling equipment, were run through a canal to the disassembly basin, and then were processed through the disassembly basin, broken up, and removed from the basin via small casks. This was a possible process solution. However, cask selection became critical to the success of this proposed approach.

CASK SELECTION

The next critical link in the project chain was the cask. The cask had to be submersed in the disassembly basin pool to allow shielded loading. The cadmium rods were activated and had estimated fields up to 25 rad/rod (7). As the rods accumulated in the cask, the radiation field would become tremendous. Ideas were proposed such as cutting a hole in the disassembly basin roof and dropping a cask in the pool with a crane. Investigation of the area showed that the best approach was to use existing equipment and the existing transfer bay to remove the cask from the pool.

However, the transfer bay had several problems. The canal from the disassembly basin to the transfer bay was narrow, 1'-2' (30 cm-60 cm) wide. Three of the four reactors had a curved canal, which presented an obstacle with DOT-approved casks. (Most DOT-approved casks are loaded from the end, like a gun barrel. However, as discussed later, most SRS casks are loaded from the top, like a shoe box.) Second, the pool in the transfer bay was small. In fact, the largest pool dimension was one foot (30 cm) shorter than the length of the cadmium rods. The overhead crane was a dual point lift and was limited to 85 tons (77,300 kg). An approach for tilting the cask in the transfer bay pool was discussed. A tilted cask approach was unacceptable for two reasons. First, there were structural concerns about the floor and wall loading. Second, the cask would need to be handled in two orientations: horizontal (on the transportation vehicle) and tilted (in the transfer bay pool). Handling in two orientations presented some engineering problems. The transfer bay building was too small to allow use of a second crane of sufficient capacity. Loading the cask above water meant designing all new rod handling and cask loading equipment. This would be expensive and would impact the schedule. Plus, if the equipment broke with a rod unshielded, a repair person would receive significant dose. The best solution was to use the existing equipment in an as-normal-as-possible manner.

In parallel with the cask handling investigation and with the process selection investigation, a usable cask search was initiated. The project manager recommended a search of all the available casks in the US. A site group kept a database of the DOT-approved casks for this country. The initial search was to find a cask long enough to hold a full length rod. None was found. An alternate investigation of the characteristics of the cadmium rods (inventory count, length, diameter, make-up, etc.) had revealed the cadmium portion made up only the lower two thirds of the length of the cadmium rods (2). One offsite, DOT-approved cask was found to be long enough to contain the cadmium portion (the bottom 2/3s) of the rods. However, several obstacles still remained with the DOT-approved cask. Although this cask was large enough to contain 862 rods, it was very heavy and exceeded the transfer bay crane's capacity. This would require unshielded loading. Second, use of this cask would require cutting the cadmium rods, which violated the RCRA requirement of "no treatment". (RCRA defines treatment as cutting, bending, etc.)

A decision was made to look more closely at the Savannah River Site's (SRS) casks. The first contacts were the site transportation committee and the cask custodial group, and they assisted in locating two casks that could be used. The first cask was long enough to receive the full-length cadmium rod, so it required tilting in the transfer bay pool. Also, it was not DOT-approved and it required modification for dewatering, and it could hold only half of the total rods. Since detailed

drawings of this cask were not in the site's document control system, and the cask fabricator had not maintained drawings files over the last forty years, this cask would still require a detailed design. This meant an expensive and time consuming procurement cycle (as long as three years). This was not acceptable because the components handling equipment would further degrade and the technician staffing could not be held for a three year wait.

A search of old operating documents was initiated, and a second cask, a spent fuel cask, was located. It was compatible with the existing cask handling equipment. It could easily fit in the transfer bay pool, and it was large enough to contain all 862 rods. Also, it could be modified to meet the project needs. An inspection with the construction technicians of the cask exterior confirmed the ability to modify the cask. However, a detailed search of the document control archives failed to find any purchase order or purchase specification, so it was uncertain what the cask was capable of withstanding (factors of safety, heat transfer ability, crash strength, etc.).

The design requirements were important since the Department of Energy required a DOT-approved cask (or the equivalent). Old documents were searched again, one of which was a 1959 engineering description of the spent fuel cask (6). In this document, the two Du Pont engineers detailed their heat transfer calculations and performance testing. They discussed fabrication difficulties and structural capacity and had designed the cask to withstand a 4 g stop/crash. Also, in the event of a rolling accident, the cask was designed to withstand a complete roll of the cask attached to its railroad flat car. This was the engineering data needed to justify the safe use of this cask without having to pay for expensive engineering evaluations. In preliminary discussions, the site transportation committee felt that this cask, with this documentation, could be accepted as DOT equivalent for onsite use under controlled conditions. The spent fuel cask was a viable approach except that use of this cask would require the cadmium rods to be cut. This would again be "treatment" by the RCRA guidelines.

RCRA INTERPRETATIONS

If the SRS spent fuel cask was to be used, it must comply with environmental regulations. Since the Savannah River Site previously removed, cut, and transported its control rods (before the use of cadmium control rods), and since the site still performs similar actions with other materials, the state authorities accepted cutting the rods as normal operation. Since the site performs similar actions with existing functional equipment, no additional training was required, and no new procedures had to be writtenthe task required only minor changes to existing procedures. The rods could be cut above the cadmium portion (the bottom two-thirds) without disturbing the cadmium, and then they would be short enough to be placed in the spent fuel cask.

Now the project plan could be determined. It was presented to the site authorities and tentative approval was received. Then the plan to cut the rods above the cadmium portion was approved by the state, although with some constraints. The 90-day RCRA clock was implemented in a more conservative manner than expected. (RCRA allows the waste owner 90 days from the declaration the material is waste, until the waste is properly encapsulated and properly disposed of.)

The cadmium rods had a stainless steel outer covering swaged over the an aluminum core cladded with cadmium (2). After the top non-cadmium section of the rods was trimmed off, one could possibly argue that capillary action would draw the water between the swaged metals, ultimately reaching the cadmium. Now, the proposed spent fuel cask was something of a fortress. It had an outer wall of 0.5" (1.27 cm) thick stainless steel, 8.5" (21.5 cm) of lead for shielding, and a 0.25" (0.63 cm) stainless steel inner wall (2). Possible leak paths for this cask were the lid, four penetrations and five thermowells (2). (Since the thermowells penetrated the cask interior, and since the cadmium rods may shift during transport, welding the thermowells would provide a secondary barrier if a thermowell was damaged or broken.) If all penetrations and the lid were welded closed at the completion of the project, this would serve as "macro-encapsulation". The project team voiced concern about the difference between what is sealed, and what is contained. It was acknowledged that everything leaks. Leakage is a function of pressure and size of the molecule. Code of Federal Regulations 10 CFR 71.71 (DOT Transportation Requirements) (3) state that the cask must not leak during two inches of rain in one hour's time. ANSI 14.5 (Radioactive Leak Rates for Transportation) (4) stated

acceptable leak rates for radioactivity. The project team felt that "no leaks" would be the only acceptable leak rate.
The characteristics and details of the waste were looked at thoroughly. The radioactivity in the cadmium rods was activated cobalt. Cobalt was a trace element in the stainless steel cladding. Therefore, the radioactive cobalt would not "leak" out of the container, and ANSI 14.5 was not applicable (4). Since radioactive leakage was not a concern, and since RCRA does not provide clear guidance, cadmium (a toxic element) was studied. Cadmium leaches into water, which makes it similar to lead. If water can be kept from entering and leaving the cask, the cadmium rods will be "macro-encapsulated". To determine the pressure to seal against, calculations were performed. These calculations included the effects of ideal gas expansion of air (seasonal temperature changes), hydrolysis of water (gamma radiation causes a hydrogen atom to be driven off from the water molecule) and pressurization effects from evaporation of residual water (partial pressure changes). After discussions with the site environmental and non-destructive exam (NDE) groups, it was decided to use a conventional piping hydro test at 150% of the maximum expected pressure. Visual observation of the exterior, with no leaks, was the acceptance criteria. The penetrations used to perform the leak test will be welded and dye-penetration tested. The proposed test criteria was written up with extensive justification and was signed by engineering, environmental, and NDE authorities.
The final criteria to satisfy was "no free liquids". The site equipment engineering group was given the task of injecting 100 pounds (45 kg) of Sorbond UG (a clay based desiccant) to absorb any free liquids. The clay based absorbent was not as aggressive as petroleum based products; however, it did not degrade under heavy gamma radiation from the cobalt 60. The petroleum based products would break down and emit hydrogen gas, which would pressurize the cask. First, an absorbent was inserted in the low point drains to remove any liquid in the drain line. Second, using compressed air with an eductor and a low pressure relief standpipe, the desiccant was injected through the low point drain. Two complications encountered with the low point drain were that two long radius elbows eliminated the use of any screw type delivery, and the desiccant pile had built up on top of the low point drain entry point. To verify that these complications were overcome, the equipment engineering group made a full scale mockup to qualify its performance.
CURRENT PROJECT STATUS
The modifications to the spent fuel cask have been made. However, the welding of the lid and the final penetrations will not be complete until the cadmium rods are loaded in the cask. Before the cadmium rods were removed from the four reactors, the project team obtained verbal acceptance of the project plan from the waste acceptance custodians (8). Then, the cadmium rods were removed from the reactor tanks at all four reactors, and they are now in the disassembly basins awaiting cutting and loading into the cask. The project has received written approval from the waste acceptance custodians for the spent fuel casks as waste containers. Very soon, one spent fuel cask will proceed through all four reactors' transfer basins and collect all 862 cadmium rods. The projected excess cross-sectional area in the spent fuel cask is 27% (5). However, it is anticipated that the majority of the excess cross-sectional area will be taken by bent cadmium rods. Once the cask is loaded, welded, leak tested and desiccant injected, it will be transported to Waste Management via a railroad car. The total trip will be 15 miles (24 km) in length. The cask will be lifted off of the railroad car and placed on a transuranic waste pad (5). The cask will be disposed of when the mixed waste vaults are built.
LESSONS LEARNED
Research into previous documentation and human experience proved to be valuable in solving several key problems with the project. Also, good communication was essential. Many groups and individuals were involved with this project, and asking the right questions, and sometimes asking detailed questions, prevented derailment of the project. For future projects, verify information by checking drawings, by asking others, or by sight inspection. Many reviews should be expected because of the project's significance, because of the vast amount of unknowns, and because of the 90-day RCRA regulatory clock. Project management should work to minimize risk, cost, time, and therefore embarrassment.

PHASE II MICROWAVE CONCRETE DECONTAMINATION RESULTS*

Terry L. White
Don Foster, Jr.
C. Thomas Wilson
Chuck R. Schaich
Oak Ridge National Laboratory

ABSTRACT

We report on the results of the second phase of a four-phase program at Oak Ridge National Laboratory (ORNL) to develop a system to decontaminate concrete using microwave energy. The microwave energy is directed at the concrete surface through the use of an optimized wave guide antenna, or applicator, and this energy rapidly heats the free water present in the interstitial spaces of the concrete matrix. The resulting steam pressure causes the surface to burst in much the same way popcorn pops in a home microwave oven. Each steam explosion removes several square centimeters of concrete surface that are collected by a highly integrated wave guide and vacuum system. We call this process the microwave concrete decontamination, or MCD, process. The MCD process is fast, generates little dust, and avoids mechanical impacts. The concrete particles from this steam explosion are small enough to be removed by a vacuum system, yet less than 1% of the debris is small enough to pose an airborne contamination hazard. In the first phase of the program the principle of microwaves concrete removal concrete surfaces was demonstrated (1). In these experiments, concrete slabs were placed on a translator and moved beneath a stationary microwave system. The second phase demonstrated the ability to mobilize the technology to remove the surfaces from concrete floors. Area and volume concrete removal rates of 10.4 cm2/s and 4.9 cm3/s, respectively, at 18 GHz were demonstrated. These rates are more than double those obtained in Phase I of the program. Deeper contamination can be removed by using a longer residence time under the applicator to create multiple explosions in the same area or by taking multiple passes over previously removed areas. Both techniques have been successfully demonstrated. Small test sections of painted and oil-soaked concrete have also been removed in a single pass. Concrete with embedded metal anchors on the surface has also been removed, although with some increased variability of removal depth. Microwave leakage should not pose any operational hazard to personnel, since the observed leakage was much less than the regulatory standard.

SCOPE AND PURPOSE

The purpose of Phase II of the microwave decontamination system development was to demonstrate the ability to mobilize the equipment necessary to remove concrete surfaces from floors. This required the integration of all necessary subsystems on a mobile cart. The cart was designed to move in a straight line with limited manual steering capability. Tests were carried out on noncontaminated surfaces, simulating various conditions expected to be encountered in actual decontamination scenarios. These included painted concrete surfaces, oil soaked concrete surfaces, and concrete

surfaces with imbedded metal anchors. Different operating parameters were studied to provide a basis for the design of a Phase III prototype. The Phase III prototype will be fully robotic for deployment in a real-world decontamination demonstration. Estimated capital and operating costs for a final machine were generated from the fabrication of the prototype system and the concrete removal rate obtained with the unit.

SYSTEM DESCRIPTION

Figure 1 shows the overall MCD system used in Phase II testing. This system consists of a microwave high-voltage power supply, instrumentation, and controls.

Fig. 1.

Electrical power (480 V 3-phase, 120 A) and plant cooling water (15 gal/min) are supplied to these systems. The smaller, fully mobile cart contains the microwave tube and wave guide system along with a vacuum system and a 55-gal drum for collecting the concrete debris. The mobile cart is tethered to the main power supply that supplies the electrical power and cooling to the cart. A PC-based data acquisition system and rack-mounted controls for the cart speed and microwave power are located near the power supply.

Microwave Frequency

The frequency of the microwave generator chosen for this series of tests was 18 GHz. This is a much higher frequency than the 2.45 and .896 GHz used in previously published work (2,3) and higher than the 2.45 and 10.6 GHz frequencies used in the Phase I experiments. The higher 18-GHz frequency preferentially heats near the concrete surface compared with the wave amplitudes of all lower frequencies as shown in Fig. 2.

Fig. 2.

This causes the uppermost 5 mm of concrete, where most of the surface contamination resides, to be removed very efficiently. The 18 GHz generator was available for loan from the U. S. Department Of Energy (DOE) Fusion Program at no cost to the DOE Waste Research and Development Program. In addition, the 18-GHz, 15-kW generator was considerably more powerful than the 10.6-GHz, 10-kW generator or the 2.45-GHz, 6-kW generator used in Phase I. Therefore, higher removal rates and speeds were predicted. The rectangular wave guide size for transmitting microwave energy from the 18-GHz generator (1.78 by 1 cm) is considerably smaller than the wave guide used for 2.45-GHz generator (7.62 by 3.81 cm) and is therefore more compact and lightweight for integrating into a robot arm for positioning the applicator on floors and walls.

Microwave Applicator

The applicator used in Phase II represents a significant improvement over Phase I. Besides spreading the microwave energy over a larger area, 10 by 14 cm compared to the 3-cm diameter spot in Phase I, the applicator minimized any reflected microwave energy and eliminated the need for a bulky, expensive microwave circulator (protection device). Scattered microwave energy off the concrete floor that could constitute a safety hazard was also minimized due to the efficient design of the applicator. The microwave applicator was highly integrated with a 350 ft3/min vacuum collection system for concrete debris. In addition, the applicator design had unrestricted real-time video monitoring of the actual removal process, which allowed for greater operator control and improved understanding of the dynamics of the removal process.

EXPERIMENTS

In the Phase II dynamic tests, a mobile cart was used to remove concrete surfaces. Initial tests were carried out in the high bay area of Building 9201-2 at the Oak Ridge Y-12 Plant. An aluminum stage 5.48 m long by 78.7 cm wide by 26.7 cm high was built to support the weight of the cart (680 kg) and to elevate the cart so that cut slabs of concrete could be placed along the stage flush with the top of the stage, as shown in Fig. 1. The slabs were supported off the floor by a system of aluminum braces that allowed the underside of the slabs to be accessed. A microwave transmission diagnostic was placed in this region to measure the amount of microwave energy that might penetrate through the slabs. The slabs were 1.2 to 3.6 m long and 35 to 61 cm wide. The top surfaces of the slabs had a typical sidewalk finish, and the sides were smooth as a result of the diamond saw cutting required for slab removal. The bottoms of the slabs were rough and irregular due to the uneven gravel beds employed during the fabrication of the slabs. Because of this, the slab thickness varied from 12 to 18 cm. The age of the concrete slabs could not be

precisely determined, but they were estimated to be approximately 20 to 30 years old. The shorter length concrete slabs came from old sidewalks at ORNL, and the longer length slabs came from concrete parking pads at the Oak Ridge Y-12 Plant. The slabs did not contain any steel reinforcing rods. However, the Phase I results showed that the presence of steel reinforcement had a minor effect on the microwave removal of concrete at 2.45 GHz. This is because the steel mesh and rods lie normally 5 cm or more beneath the surface of the concrete and the microwave fields have decayed to low levels at this depth, as shown in Fig. 2. This rationale is even more true for the 18-GHz frequency. Final field testing was conducted in Building 3034 at ORNL. The MCD system was used to remove selected concrete surfaces from the building floor. The building drawings indicate that the concrete floor was poured around 1960.

RESULTS

Forward and reflected microwave power was measured to determine the net power incident on the concrete surface. An array of three detectors located around the applicator measured the scattered power leaking from around the applicator. A microwave detector on the 55-gal vacuum collection drum measured the amount of microwave power present in the drum. Power transmitted through the slab was also measured. Cart position and speed were controlled and documented for each test. A sensor monitored the vacuum in the applicator (4~6 in. of water) during operation. Also, a thermocouple measured the applicator temperature. A color video camera and pickup microphone recorded the concrete removal process during the experimental runs. All data was recorded on a 486 PC running Labview 2.5 for Windows. Data were displayed and processed with Mathcad 4.0 for Windows. Figure 3 shows a typical steam explosion.

Fig. 3.

Concrete Removal

To estimate the volume of removed concrete debris the clean trenches in the concrete were filled with fine sea sand. The sand was leveled with the surrounding slab surface so that all cavities in the slab were filled. Excess sand was carefully scraped and brushed away from the filled cavities. The sand was vacuumed up and the weight gain of the filter bag was measured. The weight of the sand was divided by its measured density to calculate the approximate volume of removed concrete. These measurements were conducted for the first few long runs. To obtain the volume removal rate the measured volume was divided by the duration of the run. To obtain the average depth of removal the volume was divided by the average width and length of the run. To obtain the area removal rate the speed was multiplied by the average width of the trench. The new Phase II applicator produced trenches 9~10 cm wide by 4~5 mm deep at speeds as high as 1.1 cm/s. This gave an area removal rate of 10.4 cm2/s and a volume removal rate of 4.5~4.9 cm3/s. The area removal rate was about 250% higher than that obtained in Phase I, and the volume removal rate was about 210% higher than it was in Phase I. The cross-sectional shape of the trenches in Phase II is flatter than that of the trenches cut in Phase I because the heated concrete surface has more uniform illumination. Other factors affecting the removal efficiency include the translation speed and the way in which the microwave power is distributed over the area to be heated.

Microwave Leakage

The microwave leakage at 18 GHz from the applicator was well below the American National Standards Institute (ANSI) standard (4) of 5 mW/cm2. This was true even if 5-mm trenches were cut between the applicator and the surface of the slab for the microwave energy to propagate. The low leakage may be explained by the high losses in concrete at 18 GHz and the fact that almost all the energy is absorbed in the first pass due to the efficient applicator design. After several dozen runs the drum detector and two of the scattered microwave detectors were removed because they did not reveal any hazardous leakage levels and their removal simplified the cart instrumentation and data acquisition. The remaining scattered microwave detector was retained as a personnel safety interlock but was seldom tripped in any tests.

Painted Surfaces

Historically, some rad-contaminated concrete surfaces have been painted to fix the contamination present at the surface. To investigate the effect of paint on the microwave removal process, a 20-cm-long section of concrete was painted with a two-part epoxy paint sealer commonly used to fix contamination to concrete surfaces. The paint was allowed to cure in order for the paint to reach its full bond

strength. The cart was started at 0.9 cm/s on bare concrete and driven over the painted section. Upon heating, the paint could be observed to soften, and then the paint and concrete were explosively removed in much the same fashion as unpainted (plain) concrete. The speed of the applicator was lowered from 0.5 to 0.7 cm/s to achieve removal depths similar to those of plain concrete. Some microwave energy was absorbed in the paint. However, the amount of energy deposited in the paint was insufficient to cause any fire or smoke from the heated paint. The concrete debris appeared to have a larger particle size as a result of the paint's binding some smaller pieces together.

Oil-Soaked Surfaces

Concrete contaminated with Polychlorinated Biphenyl's (PCBs) can be found at many DOE sites. To investigate the effect of oil on the microwave removal process, a 40-cm-long section of concrete was soaked with standard hydrocarbon pump oil and allowed to stand for 24 h. The cart was started at 0.9 cm/s on dry concrete and driven over the oil-soaked section. Upon heating, the surface oil bubbled and then the oil and concrete were explosively removed in much the same fashion as plain concrete is removed. No significant reduction in speed was required, indicating that the oil did not directly absorb significant amounts of the microwave energy. After the trench was cut, the oil was observed to have penetrated to a depth of 2~3 mm. A single pass removal of 5 mm was observed. Again, no smoke or fire was generated by microwave-heated oil.

Metal Anchors

Surface metal structures in the concrete may affect the reliability of the microwave removal process as a result of metal objects changing the applicator electric fields. To investigate this effect four 0.5-in.-diam holes were drilled into the concrete slab, and a steel bolt anchor was placed in each hole, flush with the surface, to simulate a typical floor or wall attachment to the concrete. Concrete was removed to 5 mm around two holes and partially removed around the remaining two holes. No arcing was observed with any of the holes, but water boiled from the holes during microwave heating (no water was added during the drilling). This caused a reduction in the steam generation because the hole provided an efficient pathway for the water to escape. The reduction in steam pressure reduced the reliability of the microwave removal process.

ECONOMIC ANALYSIS

The cost analyses in Tables I, II, and III give a rough estimate of the capital and operating costs associated with a potential Phase III MCD system.

TABLE I

TABLE II

TABLE III

The configurations vary with respect to the number of microwave tubes on a single mobile system and the frequency and power of each tube. These costs are relative and will be revised as the program progresses to later phases.

Capital Cost Basis

The estimated capital costs consist of two categories of costs. One category of costs includes those for subsystems obtained from various vendors off the shelf. The estimated costs for these subsystems are based on quotes from the manufacturers and include the high-voltage power supply, and high-power microwave tube(s); the vacuum system; and the robotic vehicle. These costs do not include discounts for multiple purchases. A second category of capital costs involves system integration costs. Integration systems include the wave guide transmission system and the instrumentation and control system. Costs for these subsystems are based on costs associated with the Phase II mobile system scaled as appropriate to fit the other potential configurations.

Operating Cost Basis

The estimated operating costs are based solely on operating the equipment. The costs are expressed as cost per area removed and cost per volume removed. Costs do not include maintenance costs or waste disposal costs. Phase II equipment has operated thus far without an equipment failure, so maintenance costs have not been determined. These operating costs are based on the concrete removal rates achieved by the various equipment configurations and the assumption that one person would operate the equipment at a cost of $95.73/hr. Concrete removal rates for all of the single microwave tube configurations, except the 15-kW 2.45-GHz unit, have been determined experimentally as part of this program. The removal rates of multiple

microwave MCD systems are projected rates, some of which will be verified in Phase III of the program. Volume removal rates are based on experimental results obtained by previous published work (2). This study determined that two microwave systems in parallel had a volumetric removal rate 30% greater than that removed by two single systems. The same study showed that by using three microwave systems in parallel the volumetric removal rate was 14 times the removal rate of a single system. The previous study did not show the effect of multiple microwave systems on area removal rates. Therefore, the area removal rates for multiple microwave systems are assumed to be as much as 30% greater for two in parallel versus two operating independently and as much as 60% greater for three in parallel versus three operating independently. The effect of multiple magnetrons on area removal rates will be determined in Phase III. To estimate operating costs the hourly labor rate is divided by the area removal rate. Electrical costs are negligible compared with labor costs.

Other Cost Considerations

The total cost of decontaminating concrete structures must consider other factors besides the cost of concrete removal. Currently, disposal of low-level waste at ORNL is $85/ft3. If transuranic-contaminated low-level waste disposal costs were the same, the microwave decontamination system would offer a potential savings of $43.5/ft3 in disposal cost over other technologies that produce concrete debris (powders) that do not meet the Waste Isolation Pilot Plant Waste Acceptance Criteria. Those wastes in powder form that do not meet these criteria must be immobilized (i.e., grouted), which could result in a 50% volume increase.

COST RESULTS

Based on the work completed to date, this preliminary cost analysis shows that a MCD system can easily be developed to remove 3/16 in. of concrete at a cost of $2/ft2, when company personnel are used. Vendor quotations of $2.50/ft2 for 1/16 in. concrete floor removal using conventional scabbling are typical. Phase II resulted in a greater than 200% increase in concrete removal rates over Phase I results. As the final configuration and operating parameters of the Phase III MCD system are defined, further increases in concrete removal rates are expected, and reduced operating costs are anticipated. The MCD operating cost is also well below vendor quotations of $50~$70/ft2 for removal of 1/4 in. from concrete hot cell walls.

CONCLUSIONS

ORNL has completed Phase II testing of a mobile MCD system to remove concrete surfaces. Continuous-area and volume concrete removal rates of 10.4 cm2/s and 4.9 cm3/s, respectively, at 18 GHz were demonstrated. These rates are more than double those obtained in Phase I. The mobile prototype produces high removal rates, generates little dust, avoids mechanical surface impacts, and generates no liquid waste. The concrete particles generated by the MCD process are small enough to be removed by a vacuum system, yet less than 1% of the debris is small enough to pose an airborne contamination hazard. Deeper contamination can be removed by using a longer residence time under the applicator to create multiple explosions in the same area or by taking multiple passes over previously removed areas. Both techniques have been successfully demonstrated. Small test sections of painted and oil-soaked concrete have also been removed in a single pass. Concrete with embedded metal anchors on the surface have also been removed, although with some increased variability of removal depth. Microwave leakage should not pose any operational hazard to personnel because the observed leakage was much less than the 5-mW/cm2 ANSI standard (4), and the Phase III MCD system will be operated remotely. A preliminary operating cost analysis shows that the MCD system can easily be developed to remove 3/16 in. of concrete at a cost of $2/ft2.

CHEMICAL DECONTAMINATION: THE ROLES OF PROCESS CONTROL AND PLANNING IN WASTE MINIMIZATION

Michael A. Rollor
ALARON Corporation

ABSTRACT

Chemical decontamination has been used successfully by ALARON Corporation in the decontamination of metals for free-release. Initially, however, secondary waste volumes associated with these applications ranged from expected minimum volumes to significantly higher waste volumes. Operational records from the first 15 metric tons of process material revealed that waste variances resulted from only six types of errors -- some relating to specific operational difficulties while others were due to shortcomings in the initial planning stages of these projects. Errors were analyzed for root cause(s) and for effect upon both processing effectiveness and waste volumes generated. The secondary waste volumes resulting from specific errors were compared to waste volumes produced during ideal process operation, thereby quantifying the effect of each error on overall secondary waste generation. The information obtained was then used to implement effective measures for controlling and minimizing secondary waste volumes produced during chemical decontamination operations.

INTRODUCTION

Over the last several years, ALARON Corporation has used its patented fluoroboric acid (HBF4) process for the decontamination of radioactively contaminated metals to achieve free-release. The specific characteristics and effectiveness of this process have been presented previously (1,2) and, therefore, are not provided in this paper. In general, however, fluoroboric acid provides excellent corrosion rates for almost all metals and, more importantly, can be regenerated and reused, thereby minimizing secondary wastes from the chemical decontamination process. Despite these advantages, early full-scale applications of this process produced varying degrees of success. The initial problems and errors resulted in relatively wide fluctuations in secondary waste volumes produced during various chemical decontamination campaigns.

In order to understand these fluctuations and the underlying reasons for higher-than-expected waste volumes produced at that time, operational data from more than 40 of ALARON's earliest chemical decontamination campaigns, involving approximately 15 metric tons of metal, were analyzed. The metal included stainless steels, carbon steels and aluminum contaminated with mixed fission and activation products. The primary objectives of this evaluation were to:

- identify major problems and errors resulting in abnormally high secondary waste volumes
- identify the origin of each error and/or problem
- provide some quantitative measure of the relative impact of each error and/or problem on final waste volumes.

Understanding the nature and origin of these errors, as well as their respective impact on secondary waste generation, was an important first step in recommending and implementing procedural changes consistent with effective secondary waste minimization practices.

INCOMING MATERIAL

Contaminated metals are generally evaluated for chemical decontamination processing at ALARON's facility based on specific surface characteristics which reflect the overall availability of the contaminated surface area to the chemical decontamination medium and to survey instrumentation. As a general rule-of-thumb, materials exhibiting no more than 5 - 10% "permanently inaccessible" surface area are considered "good" candidates for chemical decontamination. Surfaces may be "permanently inaccessible" due to surface geometry as well as due to the presence of paints and other coatings. Although many metal surfaces are, as received, inaccessible to survey instruments, these surfaces are readily exposed or rendered "accessible" by simple segmentation techniques. Therefore, "permanently inaccessible" refers only to those surfaces that cannot be made accessible with a reasonable amount of effort and within a reasonable amount of time.

In addition to surface accessibility, contaminated metals are also screened for

relatively uncommon surface characteristics resulting, usually, from harsh environmental conditions over an extremely long period of time (e.g., 20 years). Strong oxidizing environments, thermal cycling, and other stress-inducing phenomena can result in surface and oxide chemistries which, unlike most contaminated metal surfaces, are strongly resistant to chemical decontamination. Stress cracking, chrome-rich oxide layers and other atypical conditions produce metal surfaces that are not "amenable" to acid etching -- due to some unique resistance to the acid process or, more typically, to the relatively large volumes of waste generated during the decontamination of these surfaces. Although ALARON routinely screens for these surface phenomena, historical information accompanying most metal received for decontamination is generally incomplete and, as a result, the presence of such conditions is difficult to detect prior to actual receipt of the material for processing.

For the purposes of this evaluation, operational data and records from the first 15 metric tons of metal processed through ALARON's chemical decontamination process line were compiled and reviewed. In general, this material exhibited the following characteristics:

- a range of common metal types -- from 304, 304L and 316 stainless steels to structural-grade carbon steels to various anodized and non-anodized aluminums.
- a wide variety of sizes, shapes, configurations and original functions -- including hand tools, spent fuel racks, structural I-beams, galvanized roofing material, pipes, stands, valves, angle iron, tanks and vessel components.
- a range of surface contamination levels -- from 20,000 - 1,0000,000 dpm/100 cm2 "smearable" beta-gamma contamination and from 300 - 1,000 cpm "fixed" beta-gamma contamination.
- less than 10% of surface area classified, upon receipt, as "permanently inaccessible"
- close to 100% of material classified, upon receipt, as generally "amenable" to chemical decontamination.

The material was, for the most part, processed in a series of operational "campaigns" designed to separate metal and secondary wastes by customer and metal type (i.e., carbon steel vs. stainless steel vs. aluminum). Typical chemical decontamination unit processed batch sizes were 100 - 1,000 kilograms depending upon the configuration and density of the metal processed.

PROCESS FLOW SCHEME

Formally, the term "chemical decontamination" denotes only one of several specific unit processes used collectively in the decontamination of metal to achieve free-release. The flow of incoming material (metal) and the resulting secondary waste-streams are depicted in Fig. I. The metal received for "chemical decontamination" was first sorted and segmented to remove "permanently inaccessible" surfaces. The material removed included, specifically, metal with severely damaged surfaces and/or surfaces which, due to their configurations and geometries, could not be easily modified by further segmentation to provide ready-access by the decontamination media and/or survey instruments. These metal pieces were collected, further reduced in size and, when possible, embedded within the chemical stabilization matrices produced during the solidification and stabilization of chemical decontamination process waste (described below).

Fig. 1.

Since most metals received for decontamination exhibited relatively high levels of "loose" or "smearable" contamination (generally exceeding 60,000 dpm/100 cm2), a rinse step using hot (90o C) water at 100 - 200 kg/cm2 pressure was employed to reduce "loose" contamination below 50,000 dpm/100 cm2. In some cases, the rinse-water also contained a surfactant to remove grease, oils and other residue from the metal surface. Reduction of "loose" contamination levels and removal of chemical residues enhanced the performance of the subsequent chemical decontamination process step by:

- minimizing radionuclides in the chemical bath which may, at high concentrations, "recontaminate" the metal by redepositing on exposed metal surfaces
- minimizing chemical interferences associated with greases, oils and other coatings.

Liquid waste from the rinse step was volume-reduced through evaporation and the remaining residue solidified using cement-based chemistry prior to disposal or storage. The liquid waste from the rinse step contained no appreciable levels of

chromium (from stainless steels) and, therefore, required no stabilization to render the material non-hazardous.
Following the rinse step, the pretreated metal was then subjected to the chemical decontamination unit process. Typically, the metal was immersed in 5 - 25% fluoroboric acid at 60o - 90o C and allowed to undergo an "etching" or "pickling" process for 15 - 60 minutes. The acid was then drained from the tank to allow a 5 - 10 minute rinse with fresh water. Once saturated with metal, the acid solutions was then chemically or electrochemically regenerated and reused for processing additional incoming metal. The resulting liquid waste was volume-reduced through evaporation and the remaining residue solidified using cement-based or pozzolanic chemistry prior to disposal or storage.
Metal from the chemical decontamination unit process was then surveyed for free-release. Materials that did not meet ALARON's standards for free-release were returned to the chemical decontamination or sort & segment unit processes for further processing as "rework". In general, most material exiting chemical decontamination was free-released without additional processing. Survey rejection rates during normal periods of operation averaged roughly 7 - 10% by weight.
MINIMUM SECONDARY WASTE VOLUMES (MSWV)
The data and records associated with the first 15-metric tons of metal processed through chemical decontamination at ALARON's facility were reviewed and analyzed to reveal those specific process batches and campaigns in which no errors or problems were noted and which, accordingly, produced the lower quantities of secondary wastes. These "ideal" batches accounted for roughly 35% of the total 15-metric tons considered in this evaluation.
Typical minimum secondary waste volumes (MSWV), expressed as cubic centimeters of secondary waste per kilogram metal received for processing, are summarized in Table I. MSWV ranges and median values are provided for each of the three major unit processes specified previously in Fig. I -- sort & segment, rinse and chemical decontamination. The MSWV values reflect final, solidified and stabilize waste volumes per kilogram of metal as received at the front-end of the process sequence.
The MSWV values provided in Table I reveal that, under relatively ideal operating conditions:
  total MSWV produced by the entire process sequence was roughly 47 cm3 per kilogram of incoming metal; this corresponds to approximately 1.5 ft3 secondary waste per ton (short) of metal received.
  the chemical decontamination unit process accounts for the lion's share (>70%) of total MSWV
  roughly 20% of the total MSWV resulted from removal of "permanently inaccessible" surfaces or surfaces not "amenable" to chemical decontamination during the sort & segment unit process
  less than 10% of total MSWV was attributed to the rinse unit process
TABLE I
OPERATIONAL AND PLANNING (O/P) ERRORS
Information from the remaining, non-ideal batches and campaigns was reviewed to identify and pinpoint specific operational and planning (O/P) errors or problems noted throughout the course of process operations. Of the approximately 25 batches reviewed, all were characterized by at least one of the six O/P errors presented and described in Table II.
Of the six major O/P errors identified, three were associated with the sort & segment unit process, two with the chemical decontamination unit process, and one with the rinse unit process. The six O/P error types are listed in Table II in descending order of frequency recorded -- with " volumetric contamination from torch cutting" during sort & segment representing the most commonly encountered error and "incorrect process specification" for chemical decontamination representing the least frequent error. The underlying cause(s) for each O/P error, as well as the effects on unit processes and secondary waste production, are also summarized in Table II.
TABLE II
RELATIVE IMPACT OF O/P ERRORS ON SECONDARY WASTE VOLUMES (SWV)
Quantities of secondary waste produced by the unit processes affected, respectively, by each of the six O/P errors outlined in Table II were recorded and compiled. Ranges and median values for the secondary waste volumes (SWV) produced during process batches in which each of the O/P errors occurred are summarized in Table

III. In addition, a comparison (difference) is provided for each non-ideal unit process median SWV against the corresponding median MSWV from Table I. Finally, Table III includes a comparison of each error-induced secondary waste impact as a percent of the ideal, corresponding MSWV (again from Table I):
The data provided in Table III indicate:
the more grievous errors in terms of additional secondary waste produced were due to "incorrect process specifications" for the chemical decontamination and sort & segment unit processes; both of these types of errors were due to improper or incomplete characterization of the metal surface used to specify the treatment sequence for decontamination (see Table II) -- in other words, chemical decontamination should never have been selected for these materials.
the "volumetric contamination" and "excess splatter" from torch (plasma arc) cutting during the sort & segment unit process produced significant quantities of additional secondary waste and given their relatively high frequencies of occurrence in the study, represented areas of particular concern.
"process control variance" for both the rinse and chemical decontamination unit processes had relatively little impact on additional secondary waste volumes; considering their low frequencies of occurrence, these errors were found to be of relatively minor importance when compared to errors committed in the sort & segment unit process.
TABLE III
CONCLUSIONS AND FOLLOWUP
The results of this investigation illustrate the overall importance of good planning and preparation in order to minimize secondary wastes generated by chemical decontamination operations. Prior to this evaluation, wastes generated during the rinse and chemical decontamination unit processes were thought to represent the major waste volumes associated with the decontamination of metal for free-release. Under that assumption, major emphasis in limiting waste production was placed on maintaining good process control during the operation of those two unit processes. As the data indicate, however, the more significant waste volumes were produced by errors unrelated to rinse or chemical decontamination unit process control. In fact, the more serious errors in terms of waste production were attributed to poor planning. Further, significant waste volumes were also attributed to improper metal preparation (i.e., cutting techniques) prior to the rinse and chemical decontamination steps.
Using this information, ALARON Corporation devised and implemented procedural changes which, based on more recent operational data, maintain unit process secondary waste volumes routinely consistent with the MSWV's provided in Table I. More awareness of potential problems and greater diligence in characterizing incoming materials have all but eliminated excess waste due to incorrect process specification. Technologies used in the sort & segment unit process have been modified to enhance downstream processing by chemical decontamination. Greater emphasis on non-torch cutting method (e.g., saws and "nibblers"), as well as the use of "shields" to prevent the deposition of splatter from torch cutting on metal surfaces, has contributed to greater control of excess secondary waste volumes.

U.S. Department of Energy
ABSTRACT

The Savannah River Site (SRS) has been actively proceeding with the decontamination and decommissioning (D&D) of various facilities and structures which were instrumental in the success of past missions at the site. The most ambitious of these efforts involves the subcontracting of the complete D&D of the first SRS Tritium Extraction Facility, identified as building 232-F. This facility operated in the mid 1950's and discontinued operations permanently in 1958. The approach utilized for this effort attempts to invoke the novel principle of "As Commercial As Reasonably Achievable" or "ACARA". This concept of ACARA applies only the minimum essential requirements necessary to successfully perform the D&D task. Integral to this approach is the subcontractor provision for maximum flexibility in the identification of and adherence to the requirements of applicable DOE Orders, federal, state and local laws and regulations, as well as site specific procedures without violating the site contractual requirements. The technical specification prepared for this effort provides the basis for a competitively bid contract to perform the entire D&D evolution, including initial facility characterization, waste stream characterization and certification, D&D and waste disposal. Preparation and development of this specification and the subsequent Request For Proposal (RFP) was a successful team oriented endeavor. The schedule for this fast-track undertaking took three months to complete. Successful completion of this task will be the first D&D of a facility containing both radioactive and hazardous material at an operating site within the DOE Weapons Complex.
The strategy for preparing the D&D subcontract for the 232-F structure was facilitated by applying the ACARA principle. This approach resulted in the accelerated development of the specification and RFP documents, as well as minimized the complexities of proposal evaluations.♀

INTRODUCTION

The old Tritium Extraction Facility, at SRS, known as Building 232-F, was the first Process and Production Facility of its kind in the 1950's to exist in the early Atomic Energy Commissions (now Department of Energy, DOE), Weapons Complex. At a time critical to National Defense and Security, 232-F produced tritium, a vital component in the development and manufacture of thermonuclear weapons. In the 36 years since 232-F ceased production, no activity of any production significance occurred in the facility. The building has remained vacant with the primary contaminated processing system purged and flushed and, over the years, useful non-contaminated ancillary equipment scavenged for use elsewhere on the site.
In recent years, the facility has been restricted from access, except under controlled entry conditions involving respirators and/or protective clothing. This was mainly due to the radiological condition of the facility and the industrial safety concerns resulting from building deterioration. Furthermore, a report by the DOE Office of Nuclear Safety registered 232-F as a concern over "increasing spread of contamination within the facility (1)."
In February of 1994, the decision to D&D the facility by the use of an independent subcontractor was made. This was the first major undertaking of the SRS D&D Department in making progress on an ambitious, site-wide decommissioning schedule. The process by which a strategy was developed to begin the procurement activity on this subcontract, is the focus of this paper. The intent from the beginning of this activity was to maintain this effort as a commercial endeavor, invoking only the minimum essential requirements necessary to perform a successful D&D effort. An ACARA concept was conceived and pioneered during this procurement which involves allowing the subcontractor maximum flexibility in the identification of and adherence to the regulatory laws and requirements, as well as site specific procedures, applicable to the D&D effort.

FACILITY AND PROCESS HISTORY

The 232-F Facility is comprised of 1765 m2 of building area with approximately 1579 m2 being an enclosed structure. The facility consists of two butting sections, a process wing and a laboratory/administrative wing. The process wing is 40 meters by 25 meters while the laboratory/administrative wing is 27 meters by 21 meters. The remaining open building area consists of approximately 198 m2 of concrete loading dock and access bay area as well as an outside exhaust fan area with stack. The building frame is of structural steel with exterior walls of Transite. All floors are poured concrete with asbestos bearing tile in the laboratory/administrative areas. Interior walls are Transite except where radiation levels required concrete, steel and lead as shielding materials. The floors and walls in process areas are

coated with Amercoat.
The building is a one-story structure except in the center where a second story and basement were required to house sections of the process equipment. The roof is a cement slab of built up construction on top of structural bar joints. The roof surface is tar mopped on saturated tar felt and covered with gravel. Roof areas were utilized in the placement of ventilation equipment. Ductwork from the roof leads to a concrete fan platform on the southside of the main building. The fans are connected to a reinforced concrete stack 60 meters tall, 3 meters in diameter at the base and 1.5 meters in diameter at the chimney cap. (See Floor Plan, Fig. 1) The air intake ducts are galvanized sheet and the exhaust ducts are stainless steel. The heating and ventilation supply ducts are insulated with bitumen coatings.
In the 1950's, tritium processing did not require the stringent seismic codes of today's structures, therefore, structural steel, cement slabs and Transite walls were used as the common building material (2). Other building materials used during construction (later defined as hazardous) were asbestos insulation, asbestos floor tiles, lead-based paints and lead brick used for personnel radiation shielding. The process used elemental mercury in process pumps and diffusion pumps. The process pumps used were the Sprengel brand. These pumps contained some Inconel parts. Process equipment and designs were drawn from experience at the Hanford Works and tritium process flows were extrapolated from the initial tritium production conducted at the Los Alamos Scientific Laboratory.
The 232-F process equipment was enclosed in a single stainless steel cabinet with panels. As previously mentioned, the process area is a two story section with basement integrated with the single story layout. This large vertical height , over 8 meters, was required to house the thermal diffusion column, hold tanks and process pumps that were critical to the tritium production. The panels, associated with the steel cabinets, were framed and held plexiglass windows for visual inspection of equipment. The panels were mounted on tracks to permit opening for access to equipment for maintenance or replacement.
Fig. 1.
Irradiated targets, supplied from other SRS facilities, were received as canned "slugs" about 30 centimeters in length and 5 centimeters in diameter. The slugs were removed from a shipping cask by a remote manipulator. Using the manipulator, the aluminum sheeting or hull was separated from the Li-Al target slug (called decanning) through a die. The hull was crushed to conserve space and placed in another shipping cask for eventual processing and shipment. The target material was placed in a crucible and charged to one of the two extraction furnaces. The furnace was placed under a vacuum and heated in excess of the target-melting point. Tritium, Helium and small concentrations of ordinary hydrogen were extracted from the target during the diffusion heat cycle. In addition, fission products were entrained in these flows. A diffusion pump delivered the gases through a palladium metal barrier where the heavier tritium was extracted from the bottom and captured in a hold tank for analysis. The by-product line containing Helium-3, Helium-4, Nitrogen2 and trace Tritium2 was pumped to storage tanks for analysis and later pumped through a zeolite bed to a cylinder trailer for shipment.
The success of a D&D activity involving contaminated facility and process systems is dependent, by and large, on the known or documented process history records maintained during the facility's operational existence. Unfortunately, due to the short operating life of 232-F, approximately two years, and the excessive time lag between facility shutdown and this D&D effort, approximately 36 years, limited information existed to document the periodic processing of this facility during the 1950's time frame. Health Physics documentation was available from the 1950's and the proposed facility shutdown procedure was found. This documentation provided useful historical information, but was limited in assisting the development of the specification for the D&D Procurement.
To develop a working knowledge of this facility, the project utilized retired Westinghouse (DuPont) personnel that had worked in the facility to recall, document and develop a process and information history of the 232-F facility. This source of information was beneficial during preparation and execution of the contract specification.
The major radiological and hazardous chemical constituents associated with the 232-F Facility are tritium, mercury, lead and asbestos (3). Tritium is the only radioactive isotope of hydrogen. It has an atomic weight of 3 and exists by itself

as a gas or in combination with oxygen (tritium oxide) as a liquid. Tritium has a relatively short radiological half life of 12.3 years. Tritium decays to Helium-3 by the emission of a low energy beta particle. Tritium is readily dispersed in air and is a highly diffusible element that will penetrate a wide variety of substances including rubber, plastic, and metal. Tritium can be inhaled and is considered an internal hazard.
Beta-gamma radioactivity was introduced to the facility from impurities in the LiAl target slugs. Beta particles are charged electrons emitted by decay of some radioactive elements, such as tritium and strontium. Gamma radiation is a highly penetrating electromagnetic radiation of extremely short wavelength similar to x-rays. Gamma-emitting nuclides, such as those of cobalt and iridium, are a hazard both when ingested or inhaled and when external to the body. The majority of the beta-gamma impurity contaminant in 232-F are expected in the process furnaces.
Mercury is a Resource Conservation and Recovery Act (RCRA) regulated hazardous metal. Mercury was used in the process pumps and the process column to transport gases through the equipment. It is highly probable mercury contamination exists throughout the process piping and equipment. Lead is also a RCRA regulated hazardous metal. Lead bricks are used for shielding in the process room furnaces and the stack. The decanning room viewing windows consist of oil-filled, lead glass layers. Lead buttons are used on the building exterior to hold transite panels in place. Paint throughout the facility is suspected to be lead-based paint.
Asbestos is regulated under Toxic Substances Control Act (TSCA). The building exterior and interior walls are transite panels. Floor tile and mastic in the administration and process areas are suspected to contain asbestos. Wall, piping and ductwork insulation is suspected to be asbestos insulation. Electric control panels, electric boxes, breaker panels, etc. are suspected to contain asbestos components.
Polychlorinated Biphenyls (PCB's), also regulated under TSCA, may be present in lighting ballasts and transformer oils. Oil is contained between the lead glass layers of the decanning room viewing windows. Hydraulic oil may be present in pumps and other motor driven components. Freon may be present in drinking fountain cooling systems and the process cooling water system may have utilized chromated water.
During operation, the process likely generated little waste for disposal, with the exception of the radioactive spent metal (the LiAl target slug) and the day to day controlled wastes such as personnel protective clothing. Other than mercury and process cooling water, no liquids or chemicals were introduced to the process during normal operation. Mercury was used in the pumps and in the process column, and thus, there is sound basis for considering the process piping to be mercury contaminated. Tritium is practically insoluble in mercury, and therefore, any mercury remaining in the facility would be expected to have nil to trace amounts of residual tritium. Chromated water may have been utilized in the process cooling water system.
The most comprehensive radiological survey involving the entire facility was conducted in 1990. The results of the 1990 radiological survey for radioactive contamination are as follows:

Maximum transferable contamination of <500 d/m alpha and <1x105 d/m beta-gamma 0.1 m2 detected in the Decanning Room. Maximum dose rate of 5 mr/hr detected in the Decanning Room.

Swipes throughout the remainder of the building were <500 d/m alpha and 1 x 104 d/m beta-gamma 0.1 m2. Dose rate of 1 mr/hr (background) detected in the general area. Disc smears were <10 d/m alpha and <80 d/m beta-gamma except for the decanning room which was 10 d/m alpha and 1475 d/m beta-gamma 100 cm2.

The tritium survey detected minimum observable readings of 145 d/m and a maximum reading of 5.3 x 105 d/m in the Process Room.

Currently, no areas have airborne contamination of any kind. As indicated in Fig. 1, the building has some areas that do not require radiological work permits for access. No personal protective equipment is required to enter these areas.

D & D SCOPE

The Scope of this project involved the complete subcontracting services of all aspects and support functions of a D & D activity. These services include planning, preparation, equipment, engineering, material, labor, tools, and management for the D&D of the 232-F Facility. the D&D effort includes the existing building structure, exhaust stack, outside equipment, and contaminated systems within the process area. The procurement documents were to encompass all sampling and analysis, including laboratory work, waste characterization and waste certification. A formal D&D plan

was expected which would provide direction and a technical accounting of all D&D techniques to be used during the job. Various plans and reports, as well as site specific safety and health documentation, were expected from the successful subcontractor. Waste disposal of all generated waste from this activity through final release and acceptance of the remaining grounds of the facility area were also included.

PROCUREMENT PLANNING AND STRATEGY

The DOE indicated a strong desire to exercise SRS's abilities in obtaining the services of commercial D&D subcontractors to further the sites mission in environmental remediation and waste management activities. Procurement of subcontracting services of this type is also beneficial to SRS. First, these tasks permitted technically, qualified, experienced organizations to perform their services and promote technology transfer and development while at SRS. Second, these tasks allowed multiple D&D tasks to be performed at full capacity while minimizing SRS site resource involvement. Thirdly, this activity would initiate progress on a site wide D&D schedule proposed to D&D other site facilities adopting the same procurement format. The challenge presented with the 232-F procurement was time. In as much that a service procurement of this type had not been attempted previously at SRS, there where no previous examples to model. Thus, from a specification and requisition viewpoint, the development of these documents did not have the benefit of previous models or similar procurements nor was there ample time to search in great detail for industry wide sources. The time frame to develop, approve, competitively bid and eventually procure the award for this contract was four months. This ambitious schedule was proposed to support DOE-Savannah River direction for Waste Management activities.

Considering the magnitude of the task, including the cross organizational involvement required to construct the RFP, a team approach was adopted and used through the entire RFP development. One of the key successes to the effort was the team approach. A list of organizational entities integral to the SRS RFP included:

- Construction Engineering Services
- Design Engineering and Management
- D&D Project Management
- Industrial Hygiene
- Site Operations Engineering
- Safety and Health Department
- Site Facilities Management
- Environmental Protection Department
- Procurement Management
- Radiological Protection Department
- Quality Engineering
- Waste Management Engineering
- Systems Group Engineering
- Office of General Council

Frequent, scheduled meetings of all team members were held to review the initial revisions of the RFP specification and review, concur and incorporate comments into the final document. Over the course of the specifications development, nearly 1100 comments were addressed, responded to and/or incorporated into the document.

The basic requirements of the RFP involved a listing of subcontractor responsibilities and a document submitted schedule. The typical subcontractor responsibilities consisted of:

- Facility Characterization - this involves the facility Sampling and Analysis Plan (SAP); waste certification documentation; required inspections and radiological surveys to determine isotopic quantities; and surveys to quantity all hazardous, mixed, TSCA waste, sanitary, and other wastes requiring removal.
- Decontamination and Decommissioning Planning - this involves the development of the Decontamination and Decommission Plan for decommissioning the facility.
- Engineering Services
- Development of the detailed work procedures and work specifications necessary to achieve project objectives.
- Quality Assurance Program
- Waste Disposal - this involves preparing the shipping manifest, supplying all shipping containers, waste classification and certification activities, packaging, and waste preparation services required to meet disposal facility waste acceptance

criteria.

Project Performance and Controls - this required the development and utilization of a Project Management Plan to perform all direct management of subcontractor and lower tier subcontractors to achieve the project objectives.

Labor - requires the subcontractor to provide all labor to perform the D&D of the 232-F structure and contaminated systems.

Occupational Safety/Industrial Safety and Health - involves the development of a project specific Health and Safety Program (HASP) that covers the entire scope of work including potential hazards as they affect SRS employees, other subcontractors, and the public.

Environmental Protection - involves the documentation of all onsite monitoring during D&D and preparing the required waste management, sampling, analysis, and reporting in accordance with the applicable federal, state and local environmental laws and regulations.

Health Physics - requires that all health physics services including radiological surveys, personnel monitoring, radiation training, radiological records and inventories, and as low as reasonably achievable (ALARA) coordination be supplied by the subcontractor.

Contract Close-out activities consisting of a site radiological survey, final grading of any parts of the disturbed site, and a final report providing an overview of the project activities, accomplishments, final site status and lessons learned.

Document submittals for the proposal evaluation required outlines of the D&D Plan SAP, Waste Management Plan, Environmental Compliance Plan, and Safety documentation.

Minimizing excessive requirements or unnecessary site requirements and restrictions was another key factor in the success of this effort. The concept of ACARA was developed and implemented on this task. What ACARA attempts to do is apply only the minimum essential requirements necessary to safely and successfully perform a task. With respect to SRS, and this 232-F D&D, the attempt was made to treat this procurement activity as a commercial activity. This meant minimizing the influence of the many DOE Orders, existing site procedures and requirements and allowing the subcontractor maximum flexibility in the identification of and adherence to the codes, laws and regulations necessary to do the work. The experience of the subcontractor is utilized to the maximum extent. The responsibility remains with the subcontractor for identification and compliance with all governing regulations, codes and standards that are applicable to the D&D effort.

In this instance for 232-F, SRS established a base of minimum required documents that the successful subcontractor could build upon. These documents included Titles 10, 29, 40 and 49 of the Code of Federal Regulation (CFR), Chapter 61 of the South Carolina Code Laws, the DOE/EH-0256T (Radiological Control Manual), DOE Order 5400.5 (Radiation Protection of the Public and Environment) and Regulatory Guide 1.86 (Termination of Operating Licenses for Nuclear Reactors). During the writing of the RFP, and in keeping with the ACARA concept, the radiological release criteria for this D&D activity was purposely kept as an open item with the intent to have the competitive bid process develop a creative approach to this seemingly arbitrary choice. Even though a choice for release criteria was suggested in the RFP, the criteria established in the DOE RCM provided the limits best suited for the SRS Mission. This was eventually adopted as the release criteria to use for this D&D.

The overall ACARA approach provided a cost effective means to issue a complicated procurement activity in a very short period of time. These practices allowed the RFP to be prepared in less than six weeks and resulted in an approved package ready for bid solicitation in approximately twelve (12) weeks. Our 232-F specific schedules allotted perspective subcontractors twenty-two (22) days to submit their proposals. The detail of the bid requirements in the RFP (plan requirement submittals and technical requirements) provided enough information that a technical evaluation of the bids was virtually eliminated. This streamlined the bid evaluation process by providing a successful "checklist" type means of quickly and accurately evaluating proposals. This effort was solicited as a fixed price contract.

Only two (2) days were required to review the lowest competitively submitted proposal. It was determined that the proposal complied with the technical specification of the RFP and that it was a valid proposal for contract award. The entire cycle from conception to technical acceptance of a viable bid proposal was approximately 15 weeks.

CURRENT STATUS AND LESSONS LEARNED

At the present time, it has been announced publicly that the Virginia based firm, Babcock and Wilcox Nuclear Environmental Services, Inc., has been awarded this D&D contract for a fixed price of 1.6 million dollars. Activities are underway to begin mobilization of the company onto the SRS work area. Waste certification activities are the initial tasks which will take place. This will involve sampling and subsequent laboratory analysis, followed by waste characterization and certification determinations. The sampling activities are scheduled to begin in April/May 1995 with D&D activities beginning in September/October 1995.

Lessons learned from this task include the following:

The team approach to the RFP and technical specification development is critical and very positive to the success of the effort.

Education, understanding and application of the ACARA thought process is essential. Allowing a greater dependency on subcontractors to be responsible for and complying with governing standards and regulations within the work scope, in this instance, worked well and was cost effective by providing a streamlined bid evaluation process.

It must be recognized up front, that it takes time to change established practices and thought processes that the ACARA concept attempts to overcome. Valuable time can be wasted until this concept becomes a viable way of doing business.

Choose a definitive release criteria versus leaving the choice as part of the contract. The choice for this task was the limits found in the DOE RCM.

Top management must give proactive support for a task as schedule sensitive as this RFP.

Recognize that vision and flexibility are the key elements in ACARA. Ask how the task at hand would be done if there were no site regulations and requirements or what would be required for the task if the D&D facility was in an offsite "greenfield" area.

Established start-up practices, procedures philosophies be directly applied to D&D activities. Must develop this direction on an "As Required" basis.

Foster DOE counterpart support of the ACARA approach.

DECONTAMINATION OF A MANUFACTURING FACILITY CONTAMINATED WITH THORIUM OXIDE

Arthur E. Desrosiers
Bartlett Nuclear Inc.
Plymouth, MA

ABSTRACT

Bartlett recently decontaminated a facility that had previously been a site for the fabrication of radar tubes. The facility was uniformly contaminated with loose thorium oxide contamination. In order to minimize the cost of the decontamination, minimize the volume of radioactive waste, and minimize exposure risks associated with airborne or loose thorium oxide contamination, Bartlett and the facility owner decided to apply strippable coating to all accessible surfaces and all contents of the rooms. Loose thorium oxide was reduced below detectable levels.

DECONTAMINATION PROCESS

Bartlett Nuclear Inc. (BNI) recently decontaminated a facility that had previously been a site for the fabrication of radar tubes. Several models of the radar tubes were fabricated with cathodes of thorium metal. The facility had been established during World War II and had been in use for approximately 50 years. The construction of the facility included wooden floors, some with several layers of subsequent flooring, and plasterboard walls. The owner of the facility had negotiated a contract for the sale of the property and desired to terminate the nuclear material license. The scope of the decontamination included removal of ventilation ducts and the removal or decontamination of process and sanitary drains. The facility was uniformly contaminated with loose thorium oxide contamination at levels below the action level guidelines of USNRC Regulatory Guide 1.86. Nevertheless, the owner

decided to decommission the facility by removing the loose contamination and reducing fixed contamination below the action levels as much as practicable.
In order to minimize the cost of the decontamination, minimize the volume of radioactive waste, and minimize exposure risks associated with airborne or loose thorium oxide contamination, Bartlett and the facility owner decided to apply strippable coating to all accessible surfaces, including walls, floors, and all contents of the rooms. The contents included benches, sinks, electrical apparatus, cabinets, and process equipment. The strippable coating was applied and removed in two days in a 2000 square meter facility. As a result, loose thorium oxide was reduced below detectable levels. There was no airborne radioactivity encountered, and no personnel or clothing were contaminated.
Subsequently, Bartlett performed a complete survey of accessible surfaces for elevated levels of alpha and beta/gamma contamination. We found that elevated levels of beta/gamma contamination generally indicated subsurface alpha contamination, presumably due to ingrowth of thorium progeny. Ventilation ducts, drains, electrical conduits, and process equipment, were treated on a case-by-case basis.
The total cost of the decontamination was less than $100,000.

CONCLUSION

In conclusion, the results indicated that the use of strippable coating for decommissioning of facilities contaminated with loose metal oxide contaminates could be remarkably cost effective from the perspectives of labor, cost, time, waste volume, and health protection.

DECONTAMINATION OF STAINLESS STEEL HEAT EXCHANGERS WITH OZONE-ENRICHED FOAM TO ALLOW STEEL RECYCLING

ABSTRACT

The enhanced decontamination properties of nitric acid with Ce(iv) additive on stainless steel are well known. This paper discusses an application of the method (COMODIN process) to decontaminate five heat exchangers with recirculating foam. A sixth heat exchanger was also decontaminated by the same method, but with ozone-enriched foam. The process allows continuous regeneration of Ce(iv) without complex facilities, and its effectiveness was more than tripled. The process is a very promising development that minimizes the liquid waste volume, the dry residue requiring conditioning as an ultimate waste form, and the occupational dose rate.

INTRODUCTION

In a paper presented at Waste Management '92 in Tucson (1), one of the authors described the use of suitable foam compositions to decontaminate hollow components in the nuclear industry, notably those with complex shapes such as valves and heat exchangers.
Contamination of metal surfaces by fission products or by activation products and actinides is known to occur at two levels:

- contamination is deposited as metallic oxides are formed or develop on the surface of stainless steel and inconel alloys; the oxide compositions depend on the environmental conditions at the time of formation;
- a small fraction of the contamination penetrates into microcracks and intergranular gaps in the metal itself.

Equipment maintenance procedures call only for removal of the oxide layer and its contaminants, to avoid initiating corrosion processes in the metal. The residual dose rate continues to represent an occupational hazard. For decommissioning operations, however, the second layer of contamination must also be eliminated, implying removal of the metal surface to a depth of several micrometers. This operation not only virtually eliminates the occupational irradiation hazard, but also allows the steel to be reused for other purposes after melting in a specialized steel mill. An effective method for achieving this difficult erosion on stainless steel and inconel alloys is to employ nitric acid with Ce(iv) additive.
Even when adequate amounts of Ce(iv) are dissolved in acid mixtures, however,

in-depth decontamination of Fe, Cr, Ni steels is a very slow process that consumes large (and expensive) quantities of Ce(iv); yet acid etching of the metal substrate is indispensable to ensure a very low residual contamination level that would allow the steel to be recycled. Moreover, adding Ce(iv) progressively as it is transformed into Ce(iii) causes ions to accumulate in solution. This increases the quantity of dry residue obtained after treatment, e.g. coprecipitation of the liquid waste generated by the operation. The dry residue, which contains all the initial contamination, will be conditioned for long-term disposal, and the cost is directly proportional to the quantities produced. In addition, electrolytic regeneration of Ce(iv) from Ce(iii) in ferrous alloys is made difficult by the fact that the Fe(ii) Fe(iii) reactions predominate at the electrodes.

In this context, the use of ozone was considered to regenerate Ce(iv) from Ce(iii) directly in the decontaminating foam. The foam is an ideal active medium for ozone, which exhibits very limited solubility in water. The immensely larger liquid surface area, due to the thin films in the foam bubbles, enhances ozone dissolution and therefore its oxidizing effect.

DESCRIPTION OF CONTAMINATED HEAT EXCHANGERS

Six identical heat exchangers (Table I) were contaminated on the shell side by the pool reactor primary cooling fluid. The contamination was estimated by the Radiological Protection Department when the primary system was isolated from the reactor in December 1992: samples were taken from two of the heat exchangers and dose rates were measured around the circumference of the units. Each sample consisted of a disk with an area of 23 cm2 weighing 57 g, together with swarf from the contaminated inner face. Samples were taken from a highly radioactive portion (1.8 mGyh-1) of heat exchanger 4 and from a slightly radioactive section (0.2 mGyh-1) of heat exchanger 6. The total activity was 70.9 GBq, or an average of 11.8 mGBq per unit; the mean dose rate was 875 mGyh-1.

TABLE I

Figure 1 indicates the radioactivity spectrum for heat exchangers 4 and 6 at the time of decontamination in December 1993. The total activity and dose rate diminished significantly thereafter (200 mGyh-1) because of the short half-lives of the contaminant radionuclides.

Fig. 1.

THE COMODIN PROCESS

Foam, created in a generator where reactants are mixed with gas, is continuously circulated through the contaminated unit from the bottom up until foam flows out from the top of the unit and is recovered for recirculation. The liquid runoff from the unit and the foaming gas are recovered in the recirculation device to create additional foam. The same quantity of liquid, filtered and/or regenerated at each cycle, can thus be used indefinitely until complete decontamination is obtained. The gas contained in the foam is also partially recycled.

The COMODIN recirculation unit comprises mainly a tank and hydropneumatic pumps suitable for use with liquids and foams. The system is maintained under slight negative pressure by filtered exhaust blowers.

The contaminated heat exchangers were installed three at a time in the basement of the G2 reactor at Marcoule, which has been decommissioned to Stage 2. They were inclined on a cradle (Fig. 2) to prevent the internal heat exchanger baffles from hindering the fluid circulation. Foam was injected at the base of each unit through a safety valve, and flowed out of an orifice at the top for recovery by the COMODIN device. During each decontamination cycle, 50 ml liquid samples were taken from the foam and liquid return lines to measure their dose rates and total Fe concentrations, indicative of the extent of metal dissolution. Between each cycle, the contact dose rates were measured at three points (top, middle and bottom) of the heat exchanger shell.

Fig. 2.

Decontamination Reactants

The reactants used here were similar to those employed for the decontamination of the Rapsodie reactor primary system (2); the same AISI 304 stainless steel grade was used in both cases.

Alkaline and acid foams were used in turn, for periods of 4 hours each. The first was a 12% NaOH solution; the second was a mixture of 0.5N sulfuric acid and 2N nitric acid together with 0.04 moll-1 of Ce(SO4)2 additive. The alkaline fluid was filtered across 100 mm PALL filter cartridges, and the acid fluid was filtered to 10

mm. The filters were replaced whenever the dose rate reached 1 mGyh-1. The operation was terminated by two foam rinses. The surface-active agent (0.8 vol%) was a biodegradable mixture of betaine and glycoside covered by a CEA patent.
On completion of the operation, the filtered liquids were pumped into interim storage tanks. The alkaline and acidic liquid wastes were mixed to obtain a neutral fluid (pH 6) and sent via special flow lines to the central liquid waste treatment plant on the site. The salt resulting from this mixture constitutes an effective foam breaking agent.

Decontamination Procedure

The operation was conducted between December 1993 and February 1994, with the working temperature maintained at 20C.

Example 1. This work involved decontamination of five heat exchangers using air-generated foam. The Ce(iv) additive was regularly consumed by oxidation of the metal (about 2 g of iron were found per liter of solution) and had to be renewed continuously, for a total of 16 kg per cycle. Decontamination was satisfactory based on the drop in the dose rates (14 mGyh-1). Only a small quantity (1 m3) of liquid waste was produced for each heat exchanger.

Example 2. Heat exchanger 5 was decontaminated using ozone-enriched oxygen foam (100 g of O3 per Nm3 of O2) with 6 kg of Ce(iv). The reaction progressed some 50% faster than in the preceding test. Both acid foam steps provided better decontamination and the dissolved iron quantity was twice as high (4 gl-1). The residual heat exchanger dose rate was lower (< 8 mGyh-1), while the quantity of liquid waste was comparable to the previous test.

The ozone process uses relatively little cerium, requiring only an initial load. Any increase in the dry residue in the liquid waste is due exclusively to the larger quantity of metallic ions dissolved by the combined effects of Ce(iv) and the acid reactants.

The surface-active agents used to prepare the foam are slowly decomposed on contact with the ozone. It could be necessary to add a small quantity of surface-active agent during the decontamination operation, which may last for several hours. However, this drawback is minor in comparison with the advantage of the phenomenon: the surface-active agents are destroyed during interim storage of the liquid waste prior to transfer to the treatment station. The foaming power, which could be a nuisance at this stage, is considerably weakened.

RESULTS

Activity of the Decontamination Liquid Waste

The liquid waste generated by the decontamination operations were collected, sampled and diluted for analysis by the Marcoule Radiological Protection Department. Seven analyses were conducted as part of the waste management procedure to determine the total activity and spectrum for the following waste streams, where the alphabetic suffix A, B or R indicates the type of treatment (acid, basic or rinse) and the number of letters corresponds to the number of the treatment (AA: second acid treatment):

Analysis 1:	Heat exchanger 2:	basic treatment (2B)
	Heat exchanger 4:	basic treatment (4B)
Analysis 2:	Heat exchanger 2:	3 acid treatments (2A, 2AA, 2AAA)
	Heat exchanger 4:	2 acid treatments (4A, 4AA)
Analysis 3:	Heat exchanger 1:	2 acid treatments (1A, 1AA) & basic treatment (1B)
	Heat exchanger 2:	rinse (2R)
	Heat exchanger 4:	acid treatment (4AAA) & rinse (4R)
	Heat exchanger 6:	basic treatment (6B)
Analysis 4:	Heat exchanger 1:	2 rinses (1R, 1RR)
	Heat exchanger 3:	basic treatment (3B)
	Heat exchanger 6:	2 acid treatments (6A, 6AA) & rinse (6R)
Analysis 5:	Heat exchanger 5:	acid treatment (5A)
Analysis 6:	Heat exchanger 5:	acid treatment (5AA)

Analysis 7: Heat exchanger 5: basic treatments (5B)

The acidic liquid waste from heat exchanger 3 and the rinse from heat exchanger 5 were not analyzed. The liquid waste streams collected and analyzed therefore represent the decontamination of five of the six heat exchangers (1-6).
The analysis results are summarized in Table II. The liquid waste activity was calculated by multiplying the activity concentration (determined from the sample) by the liquid waste volume and the sample dilution factor. The total activity of the liquid waste, i.e. of the contamination removed from the heat exchangers, was thus 16.1 GBq. As the analysis results cover only 5 of the 6 heat exchangers decontaminated, the mean contamination removed from each unit may be estimated at 3.22 GBq, and the total contamination was therefore 6 3.22 = 19.32 GBq.
TABLE II
Estimated Residual Steel Activity prior to Melting
The activity remaining after decontamination was estimated from samples of the shell and internal tube bundle of heat exchangers 4, 5 and 6.
Sample Representativity. The heat exchangers were cut up into four elements (two end sections and two center portions). Samples were taken from one of the center portions of each heat exchanger. Each sample included disk obtained from the shell using a crown saw, and ten tube sections each about 10 cm long. The sampling positions were determined after radioactivity mapping around the tube bundle and on the inner portion of the shell using a Berthold 123 portable surface contamination detector to identify zones of average contamination levels, representative of the actual contamination of the given heat exchanger section.
Analysis Results. The specific activity values measured on the samples are indicated in Table III. The shell mass was 370 kg, and that of the tube bundle nearly 2330 kg; the total calculated activity in heat exchangers 4, 5 and 6 is also indicated in the table.
TABLE III
The activity in heat exchanger 5 appears to be appreciably lower than in the others. This is not unexpected, considering the dose rates observed after decontamination: the mean dose rate for heat exchanger 5 was 7.75 mGyh-1, compared with an overall mean of 14.2 mGyh-1 for all the units.
Estimated Residual Activity. The mean residual activity of heat exchangers 4, 5 and 6 was 65 MBq. The representativity of the samples means that this mean value can be applied to the other three units. The total residual activity was therefore 390 MBq, or about 0.4 GBq.
Decontamination Factor. The decontamination factor obtained by the COMODIN process was calculated from the mean activity removed from the six heat exchangers and from their residual activity:

Residual activity:		0.40 GBq
Removed activity:		19.32 GBq
Calculated initial activity:		19.72 GBq
Decontamination factor:	19.72/0.40	= 49.3

The overall decontamination factor was therefore approximately 50.
Note:The residual activity was calculated from the sample analyses performed at the end of July 1994, i.e. over four months after the decontamination liquid wastes were at the beginning of March. If allowance is made for this delay in estimating the residual activity, the actual decontamination factor drops to 41.
Heat Exchanger 5. Analyses 5, 6 and 7 are of particular interest, as they concern a single heat exchanger, No. 5. The activity removed by the decontamination process amounted to 3.49 GBq, and the residual activity was 0.022 GBq, for a decontamination factor of nearly 160, three times higher than the overall factor. Unlike the other units, ozone-enriched oxygen was used during the acid decontamination treatment for heat exchanger 5.
The radioactivity of the tube bundle was 100 times higher than the shell for heat exchanger 4, and 60 times higher for heat exchanger 6, but only 14 time higher for heat exchanger 5. As the shell activity was comparable for all the units, the residual activity of the tube bundle was therefore appreciably lower in heat exchanger 5.
Secondary Liquid Waste Spectrum
The liquid waste spectra are compared in Fig. 3. The spectra for heat exchanger 5

(analyses 5, 6 and 7) are distinguished by their very high 144Ce content, while the other spectra (for units 1, 2, 4 and 6) are more homogeneous.
Fig. 3.
Table IV indicates the concentrations of the three principal radionuclides (ruthenium, cerium and cobalt) found in the liquid waste streams. The basic treatment effluents contained significantly greater amounts of ruthenium (26 to 49%) than the acid treatment effluents (9 to 19%); basic treatments are thus apparently more effective for 106Ru decontamination. The opposite appears to be true for 60Co, which is more effectively eliminated by acid treatment. The situation is less clear for 144Ce decontamination, with comparable values for both basic and acid treatments, but with a high degree of residual cerium entrainment in the rinses.
TABLE IV
Residual Activity Spectrum
Figure 4 shows the radioactivity spectrum of the samples taken after decontamination and before melting. The mean spectrum was determined by calculating the average of the mean spectra for the shell and tube bundle, with allowance for the weight differences between them.
Fig. 4.
The most significant radionuclides were 60Co (30.4%), 106Ru/Rh (17.5%), 110mAg (32.4%) and 144Ce (8%). Note the high percentage of 110mAg, which did not predominate in the spectra recorded before decontamination.
CONCLUSION
At the request of a pool reactor operator, the CEA's nuclear facilities decommissioning unit (UDIN) submitted six stainless steel heat exchangers to a decontamination and decommissioning treatment consisting of the following operations:
  foam decontamination by the COMODIN process (with ozone-enriched foam for one of the units);
  cutting of each heat exchanger into four sections for dimensional compatibility with the specialized melting facility at Marcoule;
  melting;
  reutilization of the very low-level contaminated steel in the nuclear industry.
Radiological monitoring was conducted throughout the treatment:
  radioactivity assessment by dose rate measurements and application of transfer functions corresponding to the contamination spectrum prior to decontamination;
  quantitative laboratory analysis of the liquid waste generated by the decontamination process;
  assessment of the residual radioactivity after decontamination and before melting on samples taken from the tubes and outer shell of three heat exchangers for laboratory analysis.
The occupational dose rate was 1.2 man-mSv for the entire operation.
The COMODIN Ce(iv) foam decontamination process yielded a mean decontamination factor between 40 and 50, for an initial radioactivity level of about 20 GBq. Ozone-enriched oxygen in the process applied specifically to heat exchanger No. 5 significantly increased the decontamination factor to 160 for that heat exchanger; ozone management raised no major difficulties. Basic treatments proved more effective than acid treatments in eliminating 106Ru. The metal ingots are suitable for recycling, in view of the additional decontamination factor of 3 provided by the melting process itself.

ABSTRACT
The objective of this investigation was to examine the effect of decontamination of the building materials by simultaneous application of various species of micromycets and decontamination clay covering (DCC). Taking into account the abilities of some micromycetes to decompose "hot" particles and to adsorb radionuclides and using sorption properties of DCC the effectivity of decontamination can be greatly improved. In this study it was examined the ability of micromycetes to grow in different clay media under the condition of radioactive contamination of the tested surface of materials. More than two hundred strains of micromycetes belonging to 30 species and 10 genus were isolated, but only 28 strains of microorganisms were capable to grow on the surface of building materials, 10 demonstrated the ability to decompose "hot" particles. The best results in terms of decontamination were obtained when the species of the culture "Arthrinium mortagnei" and "Cladosporium" were used. The results of the test performed under the laboratory conditions showed that the decontamination using micromycetes decreases the contamination level from 55% to 120% compare to only DCC treatments. This corresponds to decontamination factor of 1.8 to 2.7.
INTRODUCTION
In recent years there has been observed increasing public and scientific concern with the problems of contamination and cleanup of terrestrial environments near Chernobyl Nuclear Power Plant (NPP). After the Chernobyl accident a number of the reviews and reports of the research on decontamination techniques available for cleanup of urban and supplement areas have been published (1-6).
The new composition of coatings for decontamination of radioactive deposit on buildings and structures was developed at the Ukrainian Academy of Science (7-8). Decontamination using a clay coating is suitable for large scale decontamination operations in urban environment, since it is safe, practical and cost effective. However, in many cases the residual contamination remains rather high. This is due to the contaminant level, the depth of contaminant penetration in porous substrates and the physical-chemical conditions of the surface of the building materials.
The analyses of relevant publications shows that the application of fungal organisms or their subcellular components along with associated process technology applied to manufacturing service industries and environmental management has received much attention in recent years (9,10). Several treatment approaches have been proposed for the cleanup of contaminated materials. One of the most promising is the biodecontamination using micromycetes. These fungi have been extensively studied (11-17) in the laboratory testing systems which permit observing and fixing interaction of the fungi with a radioactive source. The authors (14) have examined five species (six strains) of micromycetes isolated from radionuclide-contaminated soils and fifteen "hot" particles. These fungi are of interest for environmental cleanup research, because the combination of such properties as ability to overgrow and to destroy "hot" particles, and to adsorb radionuclides are ideally suitable for application with the decontamination clay coating (DCC). Clay minerals have been reported to influence microbial and enzymatic transformations on a variety of substances ranging from ammonium and sulfur to carbohydrates, organic phosphorus compounds. Such minerals have also been variously claimed to increase, decrease, or not affect microbial growth and activity. The literature on these subjects has been reviewed by Stotzky (18). In this study it was tested the ability of micromycetes to grow in the clay medium under different physical-chemical conditions and of radioactive contamination of the tested surfaces.
MATERIALS AND METHODS
Sampling Areas
The specificity of the Chernobyl accident and the features of release favored a widespread distribution of activity, throughout the variation of meteorological conditions and wind regimes. The levels of contamination and activity distribution by the multiple plumes on the surface varied widely. A large amount of studies of the radioactive contamination of the environment has been carried out (19-22). Objects of our monitoring include ground depositions (soil, buildings) on the exclusive zone. Data were collected from two different types of environmental

contamination regions - the city of Chernobyl and in the site areas within the range of 5-20 km from Chernobyl NPP. The measurement showed that the contamination level was formed by products discharged from the reactor, mainly in the form of "hot" particles derived from the fuel and activated matter. Radiographic, radiochemical and gamma-spectrometric analyses showed intrusion of "hot" particles having considerable specific activity 2.0-7.0103 Bq/particle and dominance of such elements as 90Sr, 134Cs, 137Cs, 144Ce and 241Am. In the other, more remote region, village of Vladimirovka of Polesky district, 65 km from the destroyed reactor the deposition of Chernobyl debris was carried in the lower parts of the atmosphere and was washed out by rain. 134Cs and 137Cs were prevalent in the radionuclide contamination.

Sampling

The most common town and farmhouses building roofing materials (clay roof tiles, roofing asbestos cement slate) were chosen as principal subjects for laboratory experiments. The orientation of the roofs was found to be important concerning the level of contamination. In the village of Vladimirovka samples of clay roof tiles were collected from the north-sides roof. Slate samples were taken from the north-west sides of the roofs of the houses in the city of Chernobyl in accordance with preliminary measurements. Complete characterization of the contamination on building materials requires a detailed sampling investigation. The degree and character of contamination were assessed by analyzing samples for b- and g-activity. Samples were analyzed for b-activity by measurements using the KRK-1 type radiometrically equipment. The activity of the samples was measured as "count per second, cps". The date of activity samples are given in Table I.

TABLE I

Gamma measurements were made using a Ge-detector spectrometry system. The gamma-spectrometric analyses of the two different samples are given in Table II.

TABLE II

Micromycetes

The micromycetes were obtained from the different sampling locations. The distribution sites are given in Table III. This species are common soil fungi of widespread distribution (23,24). More than two hundred strain of micromycetes belonging to 30 species and 10 genus were isolated. Simple techniques, such as dilution plating are commonly used for isolating micromycetes from the soil or from the surface layer of building materials. Ordinary bacteriological media has been used to prepare and cultivate the experimental suspension of the fungi.

TABLE III

Clay Minerals

The physico-chemical properties of the clay minerals including chemical composition, cation exchange capacity and swelling are shown in Table IV.

TABLE IV

EXPERIMENTAL

The objective of this investigation was to examine the effect of decontamination of the building materials by application of various species of micromycetes and DCC. Determining the most appropriate combination of the clays with electrolyte for prepared media was central problem of investigation applicable to the fungi growth. The matrix presented in Table V showed different testing combinations. All micromycetes have been studied under relatively similarly conditions.

TABLE V

An aqueous fungal solution (106 conidio/ml) was applied on the surface of each sample and covered the liquid clay medium.

Effect of Clay Medium

Experiments were made for determination of the relationships between the physicochemical characteristics of clay minerals, the ratio solid/liquid and fungi the growth activity. Initially on the surface of building samples micromycetes were added. They were covered with wet clays media. Gradually the water evaporates and that lead to a change of gel to pore texture. In this case the process of exhalation of the pore water is very slowly. Fast drying of the clay composition media is serious problem, because shrinkage of covering. For clays media the fast drying had damaged the coating surface. Swelling clay composition are dense and very hard in the dry state due to shrinkage stresses. This clay covering contain a maze of shrinkage cracks ranging from hairline to different widths and depths. Shrinkage cracks considerably influence the rate of growth of micromycetes. The shrinkage problem can be avoided when the coating is protected against water evaporation.

Factors such as the type of clay (montmorillonite or palygorskite), void ratio, method of preparation had significant effect on the water content. The sensitivity of tested micromycetes to various combinations medium show in Table VI. In this study expert values were used, because of difficulties to obtain cardinal number.

TABLE VI

As seen in Table VI all the species showed highest ability to grow in clay medium number 3-m-1. The species of Alternaria alternata, Mycelia sterilia were grown most efficiently. During their metabolism the fungus can produce acids able to degrade the contaminated surfaces of building materials. Fungal strains of Mycelia sterilia, that were producing gluconic and malic acid were found to increase more efficiently the decontamination factor.

Effect of Different Species State

The most important physical factors for micromycetes growth are: temperature, hydrogen ion concentration and various clay media characteristics: texture, structure, water and gaseous exchange. The experiments have been performed to determine the effect of different species state. The examined micromycetes were separated into two groups. The first group consisted of micromycetes which had been preliminary prepared to be in active form. The second group has been composed by dry spores. All micromycetes were examined at similar conditions using medium number 10-mp-05. The latent period also is affected by different factors, such as hydrogen ion concentration and temperature. The temperatures of 295 K and pH were common there. Clays medium were well buffered, with little variation in the pH media. For many fungi swelling of the spore accompanied the enchanted respiration. The rate of respiration is dependent on the water content. The presence of mixture montmorillonite with palygorskite in the medium allows better gas exchange for the fungi. In Table VII the effect of the growth ability micromycetes using expert values are illustrated.

TABLE VII

Cleanup

In order to determine the efficiency of the decontamination procedure the colonies micromycetes were removed using self-stripping DCC. This procedure involves covering of the contaminated surface with grown micromycetes. After drying it cracks, flakes, peels and fall off as a solid with entrained in the peelings loose surface material, removing the fungal layers. Loose contamination immobilized by clay coatings is in a form ready for collecting and disposal. Decontamination factor (DF) was defined as the original amount of radionuclide (A0) divided by the final amount (Af). The results of the test performed under the laboratory conditions showed that decontamination by using micromycetes decrease of the contamination level from 55% to 120% compare to only DCC treatments. This corresponds to a decontamination factor between of 1.8 to 2.7. The best results in terms of decontamination were obtained when the species of the culture "Arthrinium mortagnei" and "Cladosporium" were used.

CONCLUSION

It was concluded that using of micromycetes offers a potentially efficient method of removal of radionuclides from surface of building materials and is a technical feasible method. Micromycetes can function as effective immobilized and sorbent systems together with DCC. Mycelia of fungi are used as sorbent for retaining the products within their pores. The results of these studies confirm that clay minerals (montmorillonite) coating stimulated the growth fungi and activity of the fungi. Results of the studies presented here are preliminary.

COMPARATIVE ANALYSIS OF DECONTAMINATION METHODS FOR THE REMEDIATION OF MIXED RESIDUE TANK SYSTEMS AT THE ROCKY FLATS ENVIRONMENTAL TECHNOLOGY SITE

Steven R. Hughes
Terry A. Kuykendall
Parsons Engineering Science

ABSTRACT

The Rocky Flats Environmental Technology Site (RFETS) is currently in the process of closing a number of Mixed Residue Storage Tank Systems which are subject to the Colorado Hazardous Waste Act closure requirements. A study was conducted to identify and evaluate the available methods and technologies for removal of characteristic and/or listed hazardous constituents (as defined by 6 CCR 1007-3) from identified plutonium processing tanks. In addition to the listed and characteristic Resource Conservation and Recovery Act (RCRA) constituents, these process tanks are contaminated with residual radionuclides (primarily plutonium), which also were considered in the study.

The purpose of the study was to identify, and recommend, a course of action for performing the decontamination of the targeted tanks based on risks, compliance with specified requirements, and relative costs. The study involved detailed analysis of potential methods for decontamination and/or removal of the mixed waste residues. Once the methods had been identified, recommendations were to be made with respect to the most appropriate decontamination approach(es).

In an effort to provide thoroughly evaluated recommendations, a methodology was developed by which the study elements were conducted. The methodology is unique due to its multi-step, multi-faceted evaluation which continually addresses the relative risks associated with a given decontamination method as relate to; health and safety, technical feasibility, and cost and schedule.

BACKGROUND

The Rocky Flats Environmental Technology Site (RFETS; formerly the Rocky Flats Plant) is a Department of Energy (DOE) owned facility which is managed and operated by EG&G Rocky Flats, Inc. (EG&G). EG&G is preparing for systematic decontamination and decommissioning (D&D) of process tanks to remove hazardous and radioactive constituents. The Decontamination Methods Study was conducted in support of this effort in order to identify a recommended course of action for decontamination which will result in the safe and cost-effective disposal of the identified tanks in compliance with all applicable regulations.

ROCKY FLATS ENVIRONMENTAL TECHNOLOGY SITE BACKGROUND

The Rocky Flats Environmental Technology Site (RFETS) is located in northern Jefferson County, approximately 16 air miles northwest of Denver, Colorado. The site area is approximately 11 square miles. The primary production mission of the RFETS, prior to shutdown, was the manufacture of nuclear weapons components fabricated from plutonium and other metals. Since January 1992, the mission of RFETS has been changed from involvement in national defense programs to environmental remediation and cleanup. The transition of buildings, systems, and components of RFETS from Defense Programs (DP) to Environmental Management (EM), which includes D&D activities, began in 1993.

As an element of the Department of Energy's Decontamination and Decommissioning objectives, the RFETS is tasked with developing D&D programs, including budgets and estimates, for the remediation of onsite facilities and areas. As the primary site support contractor to the DOE Rocky Flats Field Office (DOE-RFFO), EG&G is directly involved in the development and implementation of D&D projects for RFETS. The transition of RFETS surplus facilities is addressed in the EG&G Rocky Flats Mission Transition Program Management Plan, dated March 11, 1993.

The RFETS is currently in a cold shut-down (transition) mode and is developing D&D program processes, procedures, and protocol. No full-scale field activities for D&D programs presently are underway. The management structure to accomplish the transition and implementation of D&D programs and policies is developmental; specific programs elements are under internal review at this time. The management structure to be implemented is being developed to organize, staff, direct, and control activities necessary for managing and implementing D&D program requirements and to assist in the site-wide transition. Subsequently, the RFETS will be

transformed from its previous operational mode of nuclear weapon components production to a condition of deactivation, decontamination, and environmental restoration.

PURPOSE

The purpose of the Decontamination Methods Study was to identify and evaluate the available methods and technologies for removal of characteristic and/or listed hazardous constituents (as defined by 6 CCR 1007-3 part 261) from identified plutonium processing tanks. The specific RCRA hazardous constituents to be removed include spent solvents (e.g. carbon tetrachloride, 1,1,1-trichloroethane), cadmium, chromium, and lead. In addition to the listed and characteristic RCRA constituents, these process tanks are contaminated with residual radionuclides (primarily plutonium), which also were considered in the study.

The ultimate goal of the study was to recommend a course of action for performing the decontamination of the targeted tanks based on health, safety and environmental risks, compliance with specified requirements, and relative costs. The study involved detailed analysis of potential methods for decontamination and/or removal of the mixed waste residues. Once the methods had been identified, recommendations were to be made with respect to the most appropriate decontamination approach(es).

SCOPE

The Decontamination Methods Study addressed the decontamination and/or closure of 228 tanks located in Buildings 371, 771 and 777. This study was limited to identification of decontamination methods which may be applied to the process tanks housed in the identified buildings which have been designated as `mixed residue' storage tanks. Residue, by definition is a waste which contains plutonium in sufficient quantities to warrant treatment for material recovery. Mixed residue is defined as residue mixed with hazardous waste or hazardous waste constituents that are regulated under RCRA.

Since these mixed residue tanks contain constituents that are regulated under RCRA, the tanks are subject to the closure requirements of RCRA. Based on these requirements, it was necessary for the analyses performed in the Decontamination Methods Study to consider whether the candidate decontamination methods would satisfy the RCRA closure requirements.

BACKGROUND FOR THE STUDY

The mixed residue tanks under consideration are of three types: Raschig ring-filled tanks (or Raschig ring tanks); annular tanks; and pencil tanks. The Raschig ring-filled tanks are the largest volume tanks of the three types. These tanks provided criticality safety for processing of fissile materials by filling the tank volume space with Raschig rings, which are hollow, cylindrically-shaped borosilicate glass rings. The volume taken up by the Raschig rings within the tank space typically is approximately 30 percent of the total available tank volume. Annular tanks are tanks of double wall construction, which creates an annulus, or uniform spacing between the inner and outer tank walls. In these tanks, the process material is contained in the annulus, which provides criticality control. The annulus is created by welding the tank walls together at a typical spacing of 1.5 to 2 inches. Pencil tanks are so designated because these are long, thin tanks of limited capacity. The small diameter (typically four inches) of these tanks provides the required criticality safety.

These mixed residue storage tanks contain (or have contained) both "characteristic" and "listed" types of hazardous wastes. Characteristic hazardous waste are those wastes which exhibit the characteristic of ignitability, corrosivity, reactivity and/or toxicity. Listed wastes are so designated if the particular waste form is included in the listings in 6 CCR 1007-3 part 261.33. The only waste forms processed in the tanks addressed within this study were "characteristic" or "F"-listed hazardous wastes. Of the 228 tanks within the scope of the study, 210 tanks contained "characteristic" wastes, while 18 tanks contained "F-listed" wastes. All of the tanks which managed "characteristic" wastes are located in Buildings 371 and 771 while those that managed "F-listed" wastes are in Building 777.

The following characterizes the tanks in Buildings 371, 771, and 777 to be decontaminated.

1. There are 228 tanks to be decontaminated. Of these, there are 107 Raschig Ring tanks; 93 Pencil tanks; and 28 Annular tanks.
2. The contaminants include: plutonium, chromium, cadmium, lead, carbon tetrachloride and freon.

3. RCRA hazardous waste involve both listed and characteristic wastes. Tanks which stored listed waste are only in Building 777 and include six Raschig Ring tanks and 12 Pencil Tanks. The remaining tanks only stored characteristic wastes.
4. The contaminants are anticipated to be found as passivation films covering the wetted surfaces. Scale deposits are expected to be found at the "mean" gas-liquid interface.
5. The majority of the tanks are of stainless steel construction; some are kynar-lined. These tanks were used in highly corrosive nitric acid based systems. A limited few of the tanks are of fiberglass reinforced plastic or carbon steel construction. These tanks were used in caustic systems such as off-gas treatment systems.
6. Tank sizes vary for each type of tank. Raschig Ring tanks range in capacity the largest of which is 7,000 liters. The largest Annular tank can store approximately 525 liters. Pencil tanks are typically small volume tanks the largest having a capacity of approximately 100 liters.
7. Buildings 371 and 771 contain a sequence of typical continuous flow chemical processing systems involving plutonium recovery. Building 777 is a support facility involving Research and Development. Beyond filtering waste organics to remove particulate plutonium, no treatment was performed in Building 777. The tanks in Building 777 were used solely for waste storage. However, the chemical processes in Buildings 371 and 771 involved treatment and storage tanks which were manifolded together in complex series/parallel arrangements. These complex arrangements allowed for flexibility in operating the chemical processes.
8. All of the many interconnections are valved while only a few vacuum pumps were used to transfer solutions.
9. Non-destructive assay has shown that the plutonium hold-up in the tanks range from zero to 773 grams. However, there are only 26 tanks with plutonium hold-up in excess of 100 grams. Since the majority of the tanks have less than 10 grams of plutonium hold-up, it is postulated that the small amounts are present as wall films. It is anticipated that those tanks having hold-up greater than 10 grams contain a large amount of sludge which could not be removed by conventional tank draining methods. In order to achieve effective decontamination, these residual sludges must be removed from the tanks.

These characteristics constantly must be considered when attempting to select the more appropriate decontamination methods to be applied to these tanks.

Selecting decontamination methods involves a system approach, in that it requires considering all items necessary to perform the task rather than only the costs associated with equipment; reagents; secondary waste treatment; disposal; etc. This implies conceptualizing all of the facilities required to support a given decontamination method to include modifications to existing facilities.

STUDY WORK PROCESS

The study work process consisted of the following:

Literature Search

Perform a literature search and obtain relevant information on existing and developmental technologies potentially capable of removal of the mixed residues and contamination from the tanks;

Identify and interview key personnel at RFETS and at other selected locations within the DOE Complex to identify decontamination methods that have been utilized on similar tank systems;

Use the literature search and interviews to identify required equipment, radiological containment, and any other special requirements.

Ensure compatibility of the identified decontamination methods with DOE Orders 5480.23, 5480.24, 5480.25, and American National Standards (ANS) Section 8 (for nuclear criticality) and;

Verify the capability of the identified decontamination methods to satisfy the RCRA Closure requirements;

Evaluation of Options

Develop criteria for the evaluation of the decontamination methods, including handling techniques, radiological contamination control techniques (for both personnel and the surrounding area), throughput estimates, waste generation estimates (separate by liquids and solids, RCRA hazardous and non-hazardous), equipment required, feasibility of methods for plutonium processing, and cost estimates;

Specify evaluation criteria that includes RFETS Tank Closure Performance Standards, and the requirements for radionuclide handling and removal;

Perform separate evaluation of the identified decontamination methods for Raschig ring tanks, annular tanks, and pencil tanks;

Perform separate evaluation of the identified decontamination methods for large versus small tanks;

Include an assessment and listing of required equipment, engineering, and construction activities required to initiate the decontamination processing;

Prepare a conceptual cost estimate;

Prepare an estimate of liquid generation and waste type to be anticipated during decontamination operations; and

Identify vendors and/or consultants with appropriate expertise and experience in the evaluated technologies; including rationale for evaluation of these companies (e.g., reason for listing the company, previous work efforts, qualifications of staff, etc.).

Recommendation of Optimal Methods

Provide a formal report (with supporting documentation) on the recommended decontamination processes for the tank systems.

STUDY APPROACH AND METHODOLOGY

The basis for the study was comprised of two elements. The first involved establishing the process and basic methodology by which the study was to be conducted and the options were to be evaluated. The second element was the implementation of the process, which involved development of assumptions, selection and screening of technologies, and ranking of favorable technologies. Decisions and evaluative information were introduced throughout the process to establish, develop, and support the baseline of the study. These sequential elements of the methodology and process, referred to as the Process Ranking System, are depicted in Fig. 1.

Fig. 1.

Basic Assumptions

Once the methodology for conduct of the study was established, and prior to ranking the candidate decontamination methods, it was necessary to define the assumptions that represented the fundamental basis of the study. These assumptions were used as the general parameters for researching the literature and information sources for potential decontamination technologies. Those technologies that in no way met the general intent of these assumptions were eliminated as not applicable to this Study.

Identification of Regulatory Requirements

The next step of the ranking process involved identifying RCRA Regulatory Requirements associated with "closing" the mixed residue storage tanks. As previously discussed, the tanks under investigation were utilized for processing solutions containing plutonium and other hazardous constituents. These nonradiological hazardous constituents included both "characteristic" and "F-Listed" chemical forms. The hazardous waste constituents of concern were identified as cadmium, chromium, lead, carbon tetrachloride, freon and 1,1,1-trichloroethane. An evaluation of RCRA regulatory requirements was conducted to establish the decontamination goals with respect to these waste constituents.

Field/Facility Investigations

As a part of the preliminary definition of the existing conditions, field visits were conducted. These visits were conducted in order to obtain an accurate assessment of the actual working conditions for the project, and of the physical condition of the tanks and associated piping. Buildings which contain approximately 70% of the tanks within the scope of this study were visited and considered representative of all of the tanks that would be decontaminated.

Identification of Potential Technologies

Once the baseline criteria had been established with regard to basic assumptions and regulatory requirements, a comprehensive investigation was conducted to identify potentially applicable technologies that could be evaluated in more detail for utility in decontamination of the mixed residue tanks. The comprehensive investigation included: use of on-line computer-access data bases; library/literature searches; interviews with professional personnel knowledgeable in relevant decontamination areas; and contacts with vendor/supplier companies that manufacture, install and/or operate identified decontamination technologies.

Clarification of Assumptions

As the study progressed, interactions with site personnel and representatives from

the organization directing the study resulted in refinement and clarification of original assumptions and working parameters. These clarifying assumptions involved issues associated with the levels of contamination and space limitations as relate to skid-mounted decontamination equipment.

Applicability Check/Screen

The next analytical step in the process consisted of identifying the available technologies that may be applicable to the decontamination scenario under evaluation, and performing an applicability check. This preliminary screen was performed to eliminate technologies based upon inherent, perhaps obvious, shortcomings. These shortcomings included issues relating to complying with existing permit conditions, or the likelihood of obtaining permits, to immediately recognizable risks posed to the worker, the public or the environment.

This applicability check was a basic `yes/no' validation conducted to verify that identified technologies were worthy of further consideration, and were not so unapplicable or esoteric as to be not feasible in possible decontamination scenarios. This screening was conducted on the basis of professional judgement of a licensed professional engineer responsible for corporate decontamination and decommissioning technology analysis, development, and transfer.

The initial technology searches resulted in the identification of over 100 various technologies that had some level of potential application to decontamination of the mixed residue tanks. The applicability check/screen winnowed this listing to 59 decontamination technologies warranting further evaluation.

Technology Groupings

In order to adapt the remaining technologies into a more manageable system, groupings were selected in order to assign each technology to a category of similar technologies. Upon completion of the applicability screen, candidate technologies were grouped into categories of decontamination methods, which included physical methods, chemical methods, process enhancements, and cutting techniques.

Preliminary Screening

The preliminary screening process utilized nine prepared "go/no go" (or "yes/no") questions to eliminate technologies that had the potential to manage the waste forms in question, but that did not meet established screening criteria selection for the study. The preliminary screening process narrowed the list of candidate technologies from 59 to 47.

Numerical Ranking

Once the noncompliant methods were eliminated by the screening process, the remaining candidate decontamination methods were subjected to a semi-qualitative ranking. This process involves the second step of the Process Options Ranking System. The semi-qualitative ranking process involved evaluating each decontamination method in specific detail. Details included evaluation of the technology with respect to: the risks posed to health, safety and the environment; technical feasibility; and cost/schedule. Each of the evaluative categories were assigned numerical rankings relative to the importance of the factor to this study. The numerical ranking process involved the most rigorous evaluation of the potential decontamination methods in that numerous areas of risk associated with health and safety, technical feasibility, and cost and schedule were considered. This numerical ranking, coupled with the cluster evaluation discussed below resulted in identifying the decontamination methods presenting the least risks under consideration.

Cluster Evaluation

The cluster evaluation provided a method to select the most feasible groupings of technologies. In this technique, a `cut-off' point was assigned to the weighted, ranked technologies. This cut-off point was chosen on the basis of the statistical `breakpoints' at which clusters of technologies were situated.

Comparison Model

In order to provide a benchmark against which to compare and contrast remaining candidate technologies, a theoretical comparison scenario in the form of a `model' problem was developed. The model problem was required in order to allow expedient and orderly examination of the remaining technologies, which would have been otherwise difficult due to the fact there were three tank types and two RCRA waste types to be assessed.

The model problem allowed preferential ranking of each of the candidate decontamination methods. Without the model problem, each method would have had to be evaluated under six scenarios to accommodate each tank and waste type. This

divergent number of analyses would have been unwieldy and nearly impossible to compare on an equivalent basis

Comparative Analysis

With the technologies identified that had the highest probability of success for the study scenarios, a comparative analysis was conducted to evaluate the positive and negative features among the remaining technologies. This [somewhat qualitative] comparative analysis required a consensus of knowledgeable engineering and technological experts. The result of this evaluation was the identification of the technologies that were the most feasible for the given conditions and requirements associated with the study.

Configuration of Technology Systems

Another consideration for the study was that the combination of technologies into a treatment systems might perform superior to single technologies. For this reason, an evaluation was conducted to identify possible sequences of the preferred technologies that would result in the optimum performance criteria.

Identification of Recommended Technologies

The evaluation of individual technologies and consideration of technology systems allowed the selection of optimal treatment schemes, and the identification of the technologies that could be recommended on the basis of this study.

CONCLUSIONS

Application of the methodology presented above allows for the determination of technological approaches presenting the lowest risk approach to decontamination, or any activity, through the up-front consideration of all associated risks which may be encountered through the various approaches. This methodology is extremely versatile in that it allows the decision makers to assign the relative numerical rank weightings based upon criterion specific to their requirements. For instance, if health and safety is of utmost importance; the highest weighting can be imposed on this area with lower weight placed upon technical feasibility and/or cost and schedule. This approach is unique in that it has the ability to accommodate specific areas of relevance in the selection of preferred approaches to given problems since, rather than simply choose a pre-determined approach; the most appropriate approach can be selected upon considering all associated risks given their respective risk weightings.

SCHEDULING AND IMPLEMENTATION OF FIELD ACTIVITIES FOR DECONTAMINATION AND DECOMMISSIONING PROJECTS AT DEPARTMENT OF ENERGY NUCLEAR FACILITIES

Edward F. Krohn, Jr.
Terry A. Kuykendall
Richard M. Millikin
Parsons Engineering Science, Inc.

ABSTRACT

The mission at the U.S. Department of Energy (DOE) nuclear weapons facilities has changed from weapons production to environmental cleanup and restoration. A number of the former production facilities/buildings are contaminated with or contain radiological and/or hazardous substances. Facilities targeted for Decontamination and Decommissioning (D&D) include uranium enrichment facilities; plutonium production facilities; metal fabrication and machining shops; laboratories; waste processing facilities; and metal recovery facilities.

In order to properly plan and implement D&D field activities at facilities within the DOE complex, it is beneficial to develop a process and precedence network/logic diagram of the generic field activities which would be performed during a facility D&D project. The sequences of and relationships between these activities are governed by criteria such as: technical feasibility; safety and health protection; minimization of contamination spread; accessibility; environmental protection and regulatory acceptability; site scheduling and operational constraints; and ultimate disposition.

Decontamination activities are to be performed on individual pieces of equipment, such as tanks, gloveboxes, entire rooms, and systems which are no longer useful (in their present state) and have been transitioned for D&D. Materials generated include asbestos; PCB's; concrete; steel; copper wire; glass; plastics; fabrics; and contaminated solutions. Some of these materials are uncontaminated and may be

selected for reuse, recycle, disposal in a sanitary landfill, or free-release/reuse. Some of the equipment and materials will be decontaminated to low-level waste or low-level mixed waste for appropriate storage or disposal. Ultimate disposition of facilities depends upon whether or not a future use has been identified for the facility or equipment following decontamination, and the success or feasibility of performing the decontamination.

Establishing a D&D program necessitates the evaluation of the integral parts encountered when conducting field activities for a typical D&D project. Past D&D projects at various DOE and U.S. Nuclear Regulatory Commission (NRC) regulated sites were evaluated to determine the critical elements of D&D field activity processes. The proposed, generic D&D network encompasses more than 100 activities, beginning with the issuance of an approved readiness review report. These activities include both decontamination and disassembly/dismantlement, and are time-phased into the major D&D elements/categories of Internal (equipment, utilities, etc.); Structural; Subgrade; and Closeout and Verification.

By utilizing facility-specific parameters such as: materials and equipment types; the type, location, and degree of contamination; and the selected ultimate disposition, facility-specific schedule networks can be prepared. By applying labor loading estimates to the activities, projected costs to perform the field activities are obtained. This process was developed as a PrimaVera schedule network of generic field activities to be performed during a facility D&D.

BACKGROUND

The U.S. Department of Energy (DOE) has focused internal efforts for the decontamination and decommissioning (D&D) of surplus facilities within the DOE office of Environmental Restoration and Waste Management (ERWM). This Office is challenged to develop a total system within the DOE complex to resolve issues associated with site and facility cleanup activities. The scope of the D&D program is to address the removal of contamination associated with buildings and equipment in order to support programs for continued use, reuse for nonradioactive missions, or release for unrestricted use. Specifically, the D&D program will consist of: 1) Recycling reusable raw materials and products; 2) Decontaminating and recycling recoverable internal building components and equipment; 3) Implementing an asbestos abatement program; 4) Managing, treating, and packing non-recoverable materials, equipment, and other building components for disposal; 5) Refurbishing buildings for future unrestricted use; 6) Dismantling surplus buildings; and 7) Properly managing the waste generated by D&D operations to limit future liabilities. Although all of these elements were considered, this poster focuses heavily on the activities required to accomplish items (2) and (6).

The basic requirements for D&D programs for radioactively contaminated facilities are contained in DOE Order 5820.2A, Chapter V; the Decommissioning Handbook (March 1994); and the Decontamination and Decommissioning Guidance Document (January 1994). These documents require that DOE manage radioactively contaminated facilities in a safe, cost-effective manner to assure that release of and exposure to radioactivity and other hazardous materials comply with Federal and State standards. In addition, facilities, equipment, and valuable materials are to be recovered and reused when practical.

Consistent with these documents, D&D efforts must:

Eliminate or reduce to acceptable levels the hazards and risks associated with facility/equipment contamination to ensure worker protection during the dismantling of surplus facilities;

Remove building components in phases to minimize the potential for spreading contamination and to ensure proper management of waste materials;

Eliminate one or more of the contaminant hazards to allow the facility, building, and/or equipment to be subject to less stringent controls and to be reused for other purposes (as much as possible)

Figure 1 presents the following major steps which are performed as part of a site D&D project:

Fig. 1.

D&D PROGRAM AND PROJECT PLANNING

Each DOE field organization must prepare and maintain a complete list of contaminated facilities (both operational and excess). In order to implement these requirements for facility inventory and to establish the D&D program goals, the responsible DOE field office must conduct programmatic actions, including:

Establishing and maintaining a master D&D schedule;
Transferring landlord responsibility from operations to D&D programs;
Developing waste management strategies;
Evaluating existing D&D technologies and developing specific applications;
Establishing free-release criteria; and
Identifying ultimate material disposition.

The surplus facility inventory will be used for establishing the phasing of overall D&D activities. The ultimate land use of the facility, utilization of buildings to support D&D operations or other restoration programs, and the need to maintain utility services for on-going plant operations need to be considered when developing the master schedule.

Following the establishment of program components, the development of plans for implementation of individual subprojects can commence. These efforts consist of plans preparation and completion of critical pre-D&D Operations activities, including the Subproject Management Plan; Facility Operation History; Baseline Characterization Plan; and Facility Characterization.

Next, D&D Engineering and Implementation Planning is performed. These efforts include the preparation of the Decommissioning Subproject Plan for the facility; Regulatory Integration; and Procedures Preparation. These activities form the basis for completion of planning activities prior to the initiation of D&D operations and field activities.

Specific procedures must be prepared that are specific to the facility and actions in question. These procedures could include:

Procedures for residual waste removal activities for wastes contained in process equipment, tanks, piping, sumps, drains, and other locations;
Procedures for implementation of decontamination techniques including contact and non-contact methods for equipment, building structures and surfaces, piping, tanks, and other ancillary equipment;
Procedures for decontamination verification sampling for equipment and building surfaces, rinsates, and decontamination fluids for both radioactive and non radioactive contaminants;
Procedures for dismantlement and size reduction procedures for building structures, vessels, piping, utilities, and other ancillary equipment;
Procedures for waste sampling and analysis for treatment, storage, and/or disposal determinations;
Radiological control procedures to be employed during decontamination and decommissioning;
Waste packaging and transportation procedures; and
procedures for verification sampling and analysis following D&D.

As soon as final engineering and implementation planning has been completed, procurement of items and services that have been identified as required for the D&D efforts should be initiated. This is especially critical in regards to long-lead procurement items.

REMEDIATION/D&D OPERATIONS

D&D operations include decontamination, dismantlement, disassembly, packaging, storage, and disposal of facility structures, components, systems, and equipment. These activities should be conducted in compliance with the Decommissioning Subproject Plan, which is established in the D&D Engineering and Implementation Planning project phase.

Decontamination activities are to be performed on individual pieces of equipment, such as tanks, gloveboxes, entire rooms, and systems which are no longer useful (in their present state) and have been transitioned for D&D. Materials generated from these D&D operations include asbestos; PCB's; concrete; steel; copper wire; glass; plastics; fabrics; and contaminated solutions. Some of these materials are uncontaminated and may be selected for reuse, recycle, disposal in a sanitary landfill, or free-release/reuse. Some of the equipment and materials will be decontaminated to low-level waste or low-level mixed waste for appropriate storage or disposal. Ultimate disposition of facilities depends upon whether or not a future use has been identified for the facility or equipment following decontamination, and the success or feasibility of performing the decontamination.

Past D&D projects at various DOE and U.S. Nuclear Regulatory Commission (NRC) regulated sites were evaluated to determine the critical elements of D&D field activity processes.

Major elements/typical activities to be considered for D&D operations which follow the issuance of the Readiness Review Report include:
1. Internal Activities
Decontamination Activities
- Chemical Cleaning
- Systems Flushing
- Non-Chemical Cleaning
- Partial Removal of Components
Removal of Radioactive Equipment
- Decontamination to the extent possible
- Isolation of the contaminated system and cutting pipe
- Sampling and characterization of radioactivity
- Sampling and characterization of RCRA/CERCLA contaminants
- Size/Volume Reduction
- Removal and packaging
- Onsite transportation
- Offsite transportation
Removal of Nonradioactive Equipment
- Segmentation and removal of large vessels and components
- Removal of other equipment
- Sampling and characterization of RCRA/CERCLA contaminants
- Verification of uncontaminated status
- Size/volume reduction
- Packaging and transportation
- Salvage or disposal
Major Systems Removal
- Segmentation and removal of large vessels and components
- Removal of other equipment
- Verification of uncontaminated status
- Size/volume reduction
- Packaging and transportation
- Salvage or disposal
Removal of Power and Control Systems
- Decontamination
- Operations interfaces
- Switch-over to construction/auxiliary power
- Verification of uncontaminated status
- Salvage or disposal
2. Structural Activities
Decontamination Activities
- Chemical Cleaning
- Systems Flushing
- Non-Chemical Cleaning
- Partial Removal of Components
Removal of Contaminated Concrete and Porous Materials
- Walls, floors, and structures
- Removal controls
- Removal methods
Demolition and Removal of Structures
- Removal of contamination
- Removal techniques
- Verification of uncontaminated status
- Salvage or disposal
3. Subgrade Activities
Treatment of Contaminated Soils
- Excavation
- Treatment processes (chemical/non-chemical treatment; flushing)
- Sampling and characterization of contamination
- Verification of clean status
- Final disposition
Waste handling activities are included in the requirements for Internal, Structural, and Subgrade activities. Considerations here include:
Liquid Radwaste Processing

- Present capacity and capability
- Additional services needed/required
- Solidification

  Solid Radwaste Handling, Packaging and Disposal

- Low specific activity (LSA) containers and casks
- Packaging and transportation
- Disposal
- Interim storage/staging

  Radioactive/Hazardous Mixed Waste

- Stabilization
- Packaging and transportation
- Disposal

  Nonradioactive Hazardous Waste Handling and Disposal

- Transportation
- Disposal or stabilization

  Clean Waste Handling and Disposal

- Identification of Laydown Areas
- Traffic management of waste site
- Local landfill site

POST-DECOMMISSIONING ACTIVITIES

After the completion of remedial/removal activities and related D&D operations, Project Closeout and Verification will be performed. This includes the preparation of a final radiological and chemical survey (or an independent verification survey) report.

Generic activities to be performed during the Closeout and Verification phase include:

  Closeout Documents

- Final Report
- Contracts
- Financial Records
- Safety Analysis Report
- Record of Completion
- Public Notices
- Project Data Package
- Long-Term Surveillance and Maintenance Plan

  Verification

- Independent Verification Documentation
- Approved Closeout

DEVELOPMENT OF THE GENERIC SCHEDULE

The generic activities discussed above were arranged into a time-phased integrated schedule/network of elements, after identification of dependency data and sequencing of events. The network, developed using PrimaVera Project Planner, is provided on the exhibited poster.

The D&D network starts with the issuance of an approved readiness review report and ends with the verified D&D closeout. Activities are time-phased into the major D&D elements/categories of Internal (equipment, utilities, etc.); Structural; Subgrade; and Closeout and Verification.

From this generic network, decisions may be made and facility-specific schedule networks can be prepared. The application of labor loading estimates for the activities in the facility-specific schedule network yields the projected costs to perform the field activities at the particular facility.

ABSTRACT

The Field Lysimeter Investigations: Low-Level Waste Data Base Development Program is obtaining information on the performance of radioactive waste forms. Ion-exchange resins from a nuclear power station were solidified into waste forms using Portland cement and vinyl ester-styrene. These waste forms are being tested to obtain information on survivability of waste forms in a disposal environment and to develop a low-level waste data base. Radionuclide releases from those waste forms during the first 9 years of sampling have been evaluated. Also, upward migration of radionuclides was recently discovered. Lastly, lysimeter data are applied to a performance assessment source term model.

INTRODUCTION

The purpose of this paper is to present the experimental results of the two instrumented lysimeter arrays over 9 years of operation and to compare these soil leaching results to bench leaching results from similar waste forms and to predictions of the Disposal Unit Source Term (DUST) code. While results of this program have been presented at previous WM meetings, this paper gives an update of the study, which includes further discussion of the upward migration of cesium-137 and cesium-134 in one unit of the Oak Ridge National Laboratory array. Results of

analysis of sand cores from that lysimeter are presented and discussed. Also, cumulative radionuclide release from the waste forms to the leachate water passing through the soil columns is presented and compared to bench leach test cumulative fractional releases from similar waste forms.

Concern over the practices associated with the disposal of low-level radioactive waste has resulted in a very real need to obtain accurate data on the long-term field performance of these wastes. The U.S. Nuclear Regulatory Commission (NRC) has enacted regulations that link low-level radioactive waste acceptance criteria to the long-term satisfactory performance of the disposal facility. Under Code of Federal Regulations (CFR) 10, Part 61, "Licensing Requirements for Land Disposal of Radioactive Wastes" (1), commercially generated low-level radioactive waste is classified as Class A, B, or C. Wastes classified as either Class B or Class C must be stabilized for a minimum of 300 years.

To verify the 300-year stability of waste forms, the NRC specifies the use of short-term standardized tests with the intention that such tests would provide information relevant to near-surface disposal performance objectives. Those tests, which were initially published in the NRC Branch "Technical Position on Waste Form" (2), and have been revised in Revision 1 of the Technical Position (3), continue to undergo critical reviews to determine their applicability to the 300-year stability requirements.

A central requirement for disposing low-level radioactive waste is the need for a detailed understanding of the waste form behavior. That is necessary because the radionuclide source is the driving force behind the site performance. A major requirement in any site licensing is the site performance assessment, which is used to evaluate whether or not a proposed disposal site will meet performance objectives. Assumptions regarding the performance of the buried waste form have a direct bearing on the outcome of the performance assessment.

The objective of the Field Lysimeter Investigations: Low-Level Waste Data Base Development Program is to compare the results of short-term laboratory leach testing, performed earlier by the INEL, with actual leaching in the field. Also, the waste forms are being field-tested to develop a low-level radioactive waste leach rate data base. This program, funded by the NRC, has been operating lysimeters for over 9 years to obtain information on the performance of radioactive waste forms in a disposal environment and to investigate waste form stability per requirements of 10 CFR 61. The experiment measures the releases of radionuclides and chemical species from the waste forms and the subsequent transport through soil columns to sampling locations within the lysimeters. This study was developed to field test waste forms composed of solidified ion-exchange resin materials from EPICOR-II* prefilters used in the cleanup of Unit 2 of the Three Mile Island Nuclear Power Station (4). Wastes used in the study are significant because they have high loadings of radionuclides and are comprised on ion-exchange media of the type used by the nuclear industry.

EXPERIMENT DESCRIPTION

Wastes used in the experiment include a mixture of highly loaded, nuclear-grade, synthetic, organic ion-exchange resins from EPICOR-II prefilter PF-7 and a mixture of organic-exchange resins and an inorganic zeolite from prefilter PF-24. Solidification agents employed to produce the 4.8 x 7.6-cm cylindrical waste forms used in the study were Portland Type I-II cement and DOW vinyl ester-styrene (VES). Seven of the waste forms were stacked end-to-end and inserted into each lysimeter to provide a 1-L volume. The PF-7 waste contained 89% of the radionuclide activity as cesium-137, while PF-24 contained 94% cesium-137. The PF-7 waste also contained 5% strontium-90, and PF-24 contained 1% strontium-90. There were also measurable amounts of cesium-134, cobalt-60, and antimony-125 found in those wastes. Details on waste-form descriptions, formulations, and technical position testing are given in Refs. (4) and (5). A listing of lysimeter waste form and fill material types are given in Ref. (6).

Ten lysimeters were used in this study: five at Oak Ridge National Laboratory (ORNL) in Tennessee and five at Argonne National Laboratory-East (ANL-E) in Illinois. The lysimeters were designed to be self-contained units that will be disposed at the termination of the study. Each lysimeter is a 0.91 3.12-m right-circular cylinder divided into an upper compartment that contains fill material, waste forms, and instrumentation, and a lower compartment for collecting leachate (Fig. 1). Four lysimeters at each site are filled with soil; a fifth, used as a control, is filled

with inert silica oxide sand. The lysimeters at ANL-E contain soil indigenous to the site, while the ORNL lysimeters contain soil taken from Savannah River Laboratory in South Carolina. The soil columns are 2.21 m deep.
Fig. 1.
Instrumentation in each lysimeter includes moisture cup soil-water samplers and soil moisture/temperature probes. The probes are connected to an onsite data acquisition system (DAS), which also collects data from a field meteorological station located at each site. Porous cup soil-water samplers and the leachate collection compartment comprise the water sampling components of each lysimeter (Fig. 1). Incoming precipitation moves downward through the soil column to the waste form, then on to cups 3 and 1, and finally to the leachate collector at the bottom. Moisture entering the soil at the edge of the lysimeter encounters cups 5, 4, or 2 as it moves downward. Samples of moisture are withdrawn from the cups and the collector. Radial movement of waste form releases are detected in cups 5, 4, and 2, while vertical release is observed by cups 3 and 1. Lysimeter design, installation, instrumentation, operation, and data acquisition are explained in Ref. (6).
Monitoring of the lysimeters at ANL-E and ORNL began with the collection of liquid samples in September 1985 (3 months from the time of placement) and has continued with sample collection on approximately a quarterly basis thereafter. Samples of liquids were taken from locations near the waste forms and from the leachate collectors to track the migration of radionuclides, primarily cesium-137. The water samples were analyzed for strontium-90 and gamma-producing nuclides. Each month, data stored on a cassette tape in the DAS were retrieved and translated into an IBM PC-compatible disk file. Soil moisture and temperature at three elevations in each lysimeter, along with a complete weather history, were recorded on a continuing basis by the DAS. Testing results are presented in Reference (7) as well as in this paper.
RESULTS AND DISCUSSION
Weather and Soil Data
Precipitation, air temperature, wind speed, and relative humidity were recorded continuously by the ANL-E and ORNL DAS during the experiment. The cumulative volume of leachate from the lysimeters since the initiation of field work, and examples of the lysimeter soil temperature and moisture data obtained at ANL-E and ORNL can be found in Reference (7). Data recorded in FY-94 indicate that the lysimeter soil columns at both sites have remained moist during the last reporting period.
Radionuclide Data
Figures 2 and 3 show examples of data on the cumulative amounts of nuclides as determined in water samples obtained from ANL-E and ORNL leachate collectors, respectively. Other data show that not all nuclides consistently appeared in the water obtained from the moisture cups or the leachate collectors. The nuclide that appeared with the most regularity at both sites was strontium-90. Table I contains a comparison of the cumulative fractional release of strontium-90 and cesium-137 found in the moisture cups and leachate water. Consistent significant occurrences of strontium-90 have been observed in all the number 3 cups (22.4 cm below the waste form in the soil column) at both ANL-E and ORNL.
Fig. 2.
Fig. 3.
TABLE I
At both ORNL and ANL-E, recovery of strontium-90 in cups 3 and the leachate collectors indicates a varied waste form performance (Table I). Recovery of strontium-90 in the ORNL cups is comparable for those lysimeters containing the cement waste forms and one of the two containing VES waste forms. However, the cups at ANL-E are recovering much more strontium-90 from the VES waste forms compared to the cement waste forms. These data indicate that releases from the cement waste forms are generally larger than from VES waste forms.
Movement of the nuclide into the leachate collectors of the inert, sand-filled control lysimeter 5 is much greater than that of the other lysimeters and thus provides evidence of the moderating effect of soil (versus the inert sand) in those lysimeters. During the past several years, leachate collector water from the control lysimeters at each site has contained amounts of strontium-90 at least an order of magnitude larger than releases from the soil lysimeters (Figs. 2 and 3) (7). The total strontium-90 being measured in the leachate collector waters remains somewhat inconsistent between the two sites (Table I). It is suspected that this represents a

difference in how the environment at the two sites affects the movement of strontium-90 being released from the waste forms. The higher release of strontium-90 from the ORNL control lysimeter waste form reflects the nearly 50% higher rainfall experienced at that site over that seen at ANL-E.

Gamma-producing nuclides continue to occur with regularity at both sites (Table I). However, only waste forms at ORNL are releasing detectable amounts of cesium-137 to the leachate waters (Table I). It is not possible to make a comparison of cesium-137 releases from cement and VES waste forms at this time due to the small releases.

Table II is a comparison of cumulative fractional releases from field testing EPICOR-II waste forms in lysimeters to releases from bench-leach-testing similar waste forms as reported in Reference (5,8). Releases observed in the lysimeter is at least four orders of magnitude less for strontium-90 and at least five orders of magnitude less for cesium-137 in soil. It is interesting to note that release of strontium-90 in the sand-filled lysimeter is only one or two orders of magnitude less than bench test results. At the present rate of increase (see Figs. 2 and 3), these cumulative fractional releases will be of similar magnitude in a couple of years.

TABLE II

Upward Migration of Radionuclides at ORNL

During previous samplings, the presence of both cesium-137 and strontium-90 were discovered at the surface of lysimeter ORNL-5, which is the sand-filled control. Radionuclide activity was first detected during a routine gamma survey of the lysimeter's surface in 1991. At that time, more activity was found near the center than at the edges. Core samples were obtained from the center of the lysimeter at depths from 0 to 2.5 cm and from 2.5 to 5 cm for analysis of cesium and strontium-90. Scientists detected 1,760 pCi cesium-137, 10 pCi cesium-134, and 0.5 pCi strontium-90 per gram of sand in the 0 to 2.5-cm core, and 306 pCi cesium-137, 3 pCi cesium-134, and 0.1 pCi strontium-90 in the 2.5 to 5-cm core material. These data showed that more radionuclides were at the surface, suggesting some type of an active deposition mechanism. There remained a question, however, concerning the source of the radionuclides. In August of 1992, samples were again taken from the lysimeter and analyzed for cesium-137 and cesium-134. The results were similar to the previous sampling, with 1,533 pCi cesium-137 and 6 pCi cesium-134 being found per gram in the surface, and 574 pCi cesium-137 and 2.4 pCi cesium-134 per gram in the 2.5 to 5-cm sample. A comparison was made between the ratio of cesium-137 and cesium-134 in the surface material and the ratio in the buried waste form. It was concluded that the contamination of cesium came from the waste form.

On January 31, 1994, two cores of sand 80 cm long were collected from lysimeter 5. One core was taken from the side of the lysimeter near the wall and has not yet been analyzed. The other core was removed from the center of the lysimeter directly above the buried waste form (located approximately 100 cm below the sand surface). This sand core was sectioned into 5-cm segments. Radiocesium and strontium activity were measured for each segment.

The analyses show that cesium-137 is present throughout the length of the core (Table III). There are three peaks seen in the cesium content: one at 30 to 35 cm, a large peak at 45 to 50 cm, and a smaller peak at 70 to 75 cm. These peaks may be indicative of some sort of periodic movement of the cesium, but further laboratory study is necessary before the cause of this movement can be determined.

TABLE III

During the sectioning of the core, it was noticed that there was a fine plant root present throughout the depth of the core. The root material was extracted from each segment and counted (Table III). Cesium-137 activity is associated with the root, and the peaks in the root data occur at the same depths as do the peaks in the sand activity. It can be seen that there are higher concentrations of cesium-137 associated with the root than with the sand. Sand from the deepest three segments was analyzed: each whole segment was analyzed, and two subsamples of each segment were analyzed. Segment 2 (Table III) has a fairly wide range of activities between the whole segment and the two subsamples, suggesting that the activity in the sand is not evenly distributed. This could be a result of the root being involved in the transport process.

Strontium-90 analysis results show that there is significant strontium throughout the entire depth of the core (Table III). Peaks occur in the distribution at the same depths as for cesium in both the sand and roots. This suggests that the same

mechanism may be involved for transporting strontium upward as cesium. Strontium and cesium behave very differently chemically, suggesting that the process of migration is more physical than chemical, such as evapotranspiration enhanced by the presence of the root. The fact that the sand has a very low cation-exchange capacity is probably the reason that the physical aspect of migration is so evident. Further analysis of soil cores is planned. ORNL scientists performed gamma-radiation surveys of gravimetric soil cores collected annually, and determined that soil-filled lysimeters are not experiencing upward migration of radionuclides.

SOURCE TERM MODELING OF LYSIMETER RELEASES

The Disposal Unit Source Term (DUST) (9) code was used to model the release of the radionuclides cesium-137 and strontium-90 from the lysimeter waste forms. DUST is a one-dimensional code that accounts for container performance and waste form leaching (including diffusion-controlled release). Transport can be modeled through finite differences or by a multi-cell mixing cascade approach. The finite difference method was used in the simulations reported in this paper because it is more general than the mixing cell approach and permits modeling of dispersive transport. Use of these data in the DUST code was examined in detail in a paper presented at WM '93 (10).

The releases of cesium-137 and strontium-90 from Portland type I-II cement located in the inert, sand-filled lysimeters 5 at ORNL and ANL-E were chosen because releases from other lysimeters were substantially lower; therefore, the data were not yet sufficient to model. At ANL, lysimeter 5 contained resin waste from PF-7 solidified in Portland type I-II cement; at ORNL, lysimeter 5 contained resin waste from PF-24, which was also solidified in cement (Table I). Diffusion coefficient values measured in laboratory testing of these waste forms were 9.6E-10 cm2/s for strontium-90 in Portland cement (8) and 5E-11 cm2/s for cesium-137 in Portland cement (5). The Darcy velocities ranged from 2.59E-6 cm/s at ANL-E to 3.6E-6 cm/s at ORNL (7). The soil bulk density values were 1.55 g/cm3 at ANL-E and 1.60 g/cm3 at ORNL (6). Moisture content values were calculated using the effective soil porosity and the fraction of saturation values found in Reference (7). The dispersivity and retardation (Kd) coefficients have not been measured for strontium-90 or cesium-137 in this sand; therefore, they were estimated based on data in References (11) and (12) and by fitting the model predictions to the data. The cumulative activity collected in the lysimeter leachate water over the first 9 years of operation of the experiment, which was used to make comparisons to the DUST code predictions, represented cumulative fractional releases of about 0.0012 and 0.00017 of the strontium-90 in lysimeter 5 at ORNL and ANL-E, respectively (Table I).

As shown in Fig. 4, the actual data for strontium-90 from ORNL lysimeter 5 are compared with the DUST code predictions of releases in case 1 using zero dispersive flux BC, Kd = 24, and dispersivity = 8.5. Also shown are predicted releases of case 2 using zero concentration flux BC, Kd = 10, and dispersivity = 0.6. The measured waste form diffusion coefficient of 9.6E-10 cm2/s was used. The predicted releases show a very good fit to the actual data after initial stabilization of the test data. Case 2 releases less activity over 4 years than case 1; however, over 20 years, case 2 will have released 33% of the total strontium-90 inventory, whereas case 1 will have released 3.3% of the total strontium-90 inventory. The lack of measured dispersivity and retardation coefficient necessitates obtaining cumulative release data over a longer term.

Fig. 4.

CONCLUSIONS

The radionuclide that has appeared with most regularity at both sites is strontium-90, although cesium-137 is observed regularly in the leachate of all ORNL lysimeters. A comparison of total strontium-90 found in leachate of the control lysimeters shows that environmental effects have resulted in a much higher release at ORNL. The data indicate that Portland cement and VES waste forms have comparable releases of strontium-90.

Cesium-137, cesium-134, and strontium-90 are present throughout the upper 80 cm of the inert sand in ORNL lysimeter 5 directly above the waste form. The ratio of cesium-137/cesium-134 indicates that the radionuclides are from the buried waste form and not from an outside source and were transported vertically upward by some physical mechanism enhanced by the presence of a plant root.

DUST-predicted cumulative release of strontium-90 from ORNL lysimeter 5, which was plotted over the first 9 years of data collection, show a reasonable fit to the field data for Kd = 24. The accuracy of the DUST modeling study was limited,

however, by the lack of measured soil dispersivity and retardation coefficients. Further testing will provide larger cumulative releases to better model the release patterns from the lysimeters.
Data provided by these lysimeter experiments have been shown to be useful in computing many parameters used as input to performance assessment codes. The utility of this reliable source of data will be demonstrated through continued operation of the lysimeters with application of the results to source term models such as DUST. NRC planning recommends that this experiment be augmented by experiments containing solidified decontamination wastes and activated metals from commercial nuclear power stations.

PROCESS KNOWLEDGE EVALUATION AT LLNL*
Stan Starkey
Kern Hainebach
Lawrence Livermore National Laboratory
ABSTRACT
A system for evaluating the process knowledge provided by radioactive waste generators has recently been implemented at the Lawrence Livermore National Laboratory (LLNL). This paper describes the formal mechanism used to evaluate and track the processes that have the potential for generating low-level or transuranic waste and to determine whether the waste contains RCRA- or California-regulated hazardous components. The heart of the system is a set of standardized forms completed by the waste generator and an environmental analyst and reviewed by the waste certification official. The system allows all interested parties to look at an operation in detail, evaluate the input and output constituents, and determine if the waste stream meets the waste acceptance criteria. It also gives all parties a chance to evaluate waste minimization and waste segregation, as well as identify any additional training for the generator and any additional controls that may be

required for the specific process. The evaluation results in a documented list of pre-approved components for each waste stream that have already been evaluated for hazardous constituents and waste acceptance criteria, and thus in a more efficient final processing of the waste. The documentation for this evaluation system, the Process Knowledge Form, is kept on a 4th Dimension database and is reviewed and updated annually.

OBJECTIVE

In most cases the people who design and operate a process are the ones most knowledgeable about it and are the best source for evaluating whether it is being conducted safely and effectively. In the same light, these people are the ones best qualified to evaluate and characterize the materials that end up in the waste generated by the process. This is especially true with the small research and development projects that represent most of the activities that generate radioactive waste at LLNL The majority of low-level radioactive waste and over 90% of the transuranic waste is generated in the research laboratories of LLNL's Plutonium Facility. This facility is staffed by highly knowledgeable chemists, physicists, engineers, and technicians. It is only natural to rely on these experts as the primary information source when evaluating the waste stream.

This is not new. It is the way research has always been conducted. What is new, in today's climate, is a requirement to formalize this process in such a way as to assure regulators and ultimately the general public that the research is being conducted safely and in compliance with all established controls. In addition, this formalized process assures that oversight is documented in such a way that it can meet all of the requirements of a Quality Assurance program.

At LLNL we look at the control of waste generated by R & D work as a three-level process involving the following:

1. The researcher (waste generator)
2. An environmental analyst
3. The waste certification official.

The environmental analyst works closely with the researcher and is the one who has the specialized knowledge of hazardous materials as well as the environmental rules and regulations. The environmental analyst also is able to stand back from the work of the researcher and take an objective look at the process, evaluating input materials, material changes that may occur in the process, and what materials come out both as product and as waste.

The waste certification official is the one ultimately responsible for certifying for LLNL that the waste is properly characterized, meets all waste acceptance criteria, and is being disposed of safely.♀

PROCESS KNOWLEDGE EVALUATION FORM

Section I - Process Information Provided by the Researcher (i.e. Waste Generator)

Fig. 1.

Entries 1, 2, 3. Location identification - For transuranic (TRU) waste, this evaluation is done for each glovebox or work station. For low-level waste, it is done for each room or area as considered appropriate.

Entry 4. Identifies Decontamination and Decommissioning activities. These are one time procedures with a prescribed duration and a specific set of controls, distinct from on going research programs. Entries 5 through 13

Describes the process, any hazardous materials, and how they are used.

Entries 14 and 15. Lists the types of radionuclides used.

Entries 16,17,18 and 19. Cover the details of the waste including type, detailed component list, comments and sign off by the waste generator.

Section II - Environmental Review Conducted by an Environmental Analyst Familiar With the Process

Fig. 2.

In addition to completing entries 20 through 25, which include a thorough inspection of the area and review of written procedures, the environmental analyst reviews Section I with the waste generator to assure there is a complete understanding of the process and the anticipated waste stream. Entry 24 is where environmental analysts can write as much as they feel necessary on special problem areas and prescribe any controls they feel are appropriate for this area.

Section III - Waste Certification Official Sign Off.

Fig. 3a.

Fig. 3b.

After discussion and clarification with the generator and the environmental analyst, the waste certification official signs, signifying agreement with the information provided and that it is complete, accurate, and sufficient to define the waste stream.

WASTE STREAM EVALUATION FORM

Once the Process Knowledge Evaluation form has been completed and signed off, the waste generator and the environmental analyst prepare the Waste Stream Evaluation form. There are separate, slightly different, Waste Stream Evaluation forms for transuranic and low-level waste, but in both cases they provide the same information.

Entries 1, 2 and 3. Identify the waste form, describe the steps taken to prevent producing mixed waste whenever possible, and give a detailed description of required controls.

Entry 4. is a list of authorized components that have been pre-approved and may be placed in the waste stream without any additional review. This list is a subset of the waste generator's list under entry 17 on the Process Knowledge Evaluation form. The goal is to have all of the components pre-
approved but in practice this is not always possible. For example, used HEPA filters may contain fine particles above the allowable limit and can not be pre-approved. Components that do not appear on this authorized list must be reviewed and authorized by the environmental analyst and the waste certification official before being placed in a waste container.

When signed off by all three parties the Waste Stream Evaluation form becomes a controlled document and is posted in the laboratory. It specifies the controls applying to the waste stream from that area.

STANDARDIZED COMPONENTS

With the Process Knowledge Evaluation forms and the accompanying Waste Stream Evaluation forms, it is desirable to standardize the descriptions of waste components whenever possible. For example we use the description "paper wipe" instead of trade names such as Kleenex, Kimwipes, etc. With this procedure waste stream components are restricted to those that are on the authorized list and appear on the Waste Stream Evaluation form for that particular work station. If a waste generator wishes to dispose of an item not already authorized, the form must be updated and the change approved before that item can be discarded. With this in mind, the authorized components list should be as generic as possible while at the same time precise enough to not let unwanted substances enter the waste stream undetected. Choosing component descriptions that meet these criteria is critical.

DATABASE

The Process Knowledge Evaluation and Waste Stream Evaluation forms are stored on a 4th Dimension relational data base. The database makes it possible to easily standardize component descriptions and to keep track of those that have been pre-approved. Although not presented on the forms, the database also provides a convenient method of keeping track of the hazardous material in a waste component as well as quantities and other identifying information. The forms are reviewed and updated annually.

The 4th Dimension database and its report programs were originally developed by an administrative assistant over a period of a few months. It has since been revised and upgraded by a programmer working part time for six months- The database presently handles about 300 Process Knowledge Evaluation and Waste Stream Evaluation forms and can operate on a Macintosh system with 8 MB of RAM.

CONCLUSION

With this review process and the documentation created by the Process Knowledge Evaluation and Waste Stream Evaluation forms we have established a method of assuring that the process knowledge of the waste generator is sufficient to guarantee that waste entering the waste stream meets all waste acceptance criteria and that we have an auditable documented paper trail to support this guarantee.

ABSTRACT
The Low-Level Radioactive Waste Management Office in conjunction with SENES Consultants Limited of Richmond Hill, Ontario, have developed a computer assisted surface gamma radiation survey system. The system has been designed to collect detailed, objective surface gamma radiation data in a cost effective and efficient manner. The use of this data collection system results in large amounts of data that are not easily handled manually. A number of statistical techniques have been developed to summarize these data and assist in the detection and delineation of radioactive contamination. These statistical methods and the large amount of data improve the ability to detect and delineate areas contaminated with low levels of radioactivity, and are routinely capable of detecting localized contamination containing 7400 Bq (0.2 mCi) Ra-226 (in equilibrium with its progeny) or less, and distributed contamination with concentrations of approximately 74 mBq/g (2 pCi/g) Ra-226 or less.
INTRODUCTION
The LLRWMO
The Low-Level Radioactive Waste Management Office (LLRWMO) was established in 1982 to carry out the responsibilities of the Canadian federal government for low-level radioactive waste (LLRW) management in Canada. The LLRWMO is operated by Atomic Energy of Canada Limited through a cost recovery agreement with Natural Resources Canada, the federal department which provides the funding and establishes national policy for LLRW management. Part of the mandate of the LLRWMO is to resolve historic radioactive waste problems that are a federal responsibility. Historic wastes are LLRW for which the original owner can no longer be held responsible and which are managed in a manner no longer considered acceptable. If they are wastes for which the federal government accepts responsibility, their management comes within the mandate of the LLRWMO. In fulfilling this mandate, the LLRWMO must frequently conduct outdoor, environmental-level gamma radiation surveys at sites across Canada for investigation, cleanup and compliance purposes.
Manual Gamma Radiation Surveys
Traditionally, these surveys have been conducted by field personnel using hand-held analog scintillometers. Gamma radiation readings are taken at evenly spaced points on a site, usually on a 3 by 3 metre grid. The area between the grid points are generally scanned by the surveyors, and any anomalous readings detected during the scan noted. All data collected are recorded manually on paper, and analysis of these paper records is used to determine the results of the survey.
This "manual" method of conducting surface gamma radiation surveys has several limitations. It is labor intensive, and large quantities of data (particularly for larger sites) must be managed by hand. As well, the scanning operation is quite subjective and can vary from surveyor to surveyor. More desirable is a system that increases objectivity in data collection and analysis, reduces manual data handling, and is more amenable to quality assurance procedures.
The Computer Assisted Large Area Surface Gamma Radiation Surveying System
In 1991 the LLRWMO contracted SENES Consultants Limited to assist in the development of a portable computer-assisted gamma radiation detection system capable of surveying large tracts of land in an efficient and reproducible manner. Using off-the-shelf gamma radiation detection instruments controlled by a portable computer with custom software, SENES and the LLRWMO were able to develop a system that i) increased the objectivity in data collection and analysis, ii) reduced manual data handling, and iii) provided a system more amenable to quality assurance procedures (1).
SENES Consultants Limited is an environmental consulting firm with experience ranging from solid waste management to risk analysis, and with extensive specific expertise related to occupational and environmental radiation and radioactivity, including low-level radioactive waste management, uranium mining and milling,

naturally occurring radioactive materials (NORM), radiological surveys, statistical analysis and interpretation, and especially the analysis of risk associated with exposure to radon and its progeny.
Four years of subsequent prototyping have lead to the development of a system consisting of two electronic radiation meters each using a two by two inch cylindrical sodium iodide scintillation detector. The meters are controlled by a portable computer, and a twelve volt battery is used to supply power to the instruments and computer. To provide portability in the field, these components are then mounted on a frame (initially a golf cart, which has lead to the system becoming known as the "cart"). Custom software collects and analyzes the data in real-time. The data analysis is aimed primarily at the detection of above-background radioactive material by identifying readings that are statistically high compared to other local readings. There are currently three configurations in use: a three-wheeled cart, a two-wheeled cart, and a backpack based system. The three-wheeled cart is shown in Fig. 1.
Fig. 1.
The main configuration (the three-wheeled cart) consists of the electronics mentioned above mounted on a large, three-wheeled frame. Its primary use is for surveying large, open areas such as parks, school yards and undeveloped areas. A two-wheeled configuration has been developed for smaller areas such as private residential properties. There is also a third configuration for use in difficult terrain, where the wheeled carts cannot be used. In this configuration, each probe is held to either side of the surveyor using customized "handles", one of which includes a simple control, and the remaining electronics are carried in a backpack on the surveyor's back.
The computer assisted gamma radiation data collection system produces larger amounts of more densely spaced data than the traditional manual surface gamma radiation surveying methods. Typically, the spatial density of this data for the computer-based system is two to four readings per square metre, but has been as high as eight readings per square metre in small area investigations. Statistical techniques have been developed and applied to assess objectively the presence and extent of radioactive contamination based on this large amount of data.
TYPES OF CONTAMINATION
Sources and Amounts of Radioactivity
The contaminated sites managed by the LLRWMO contain several types of radioactive materials that are in either disperse or discrete particle form. Some examples of disperse materials on these sites include: process wastes from uranium, radium, and rare earth refineries, incinerator wastes and soil contamination from air deposition. Discrete particle contamination includes pieces of uranium ore, dials and other materials painted with radium, and industrial equipment used in the uranium refinery industry.
The amount of radioactivity present in these contaminated materials varies greatly. For example, radium-226 concentrations range from soils with elevations of less than 37 mBq g-1 (1.0 pCi g-1) above the local background to refinery wastes exceeding 37 Bq g-1 (1000 pCi g-1). Radium-226 activity in discrete particles ranges from less than 7.4 kBq (0.1 mCi) to more than 7,400 kBq (100.0 mCi).
Most of the radioactive materials contain radionuclides that emit gamma radiation. Since the contaminated materials are often found at, or near, the surface, gamma radiation surveys have been used to locate contaminated areas. Detection of the contamination with gamma radiation surveys is relatively simple at those sites with high concentrations of disperse materials or discrete particles with high activity. However, the detection of contamination at sites that only contain materials with low levels of radioactivity requires extensive gamma radiation surveys and statistical analyses.
Spatial Distribution of Contamination
For the purposes of detection and delineation using gamma radiation survey equipment, contaminated areas can be loosely classified into two categories based on the spatial extent of the surface expression: localized and distributed. Localized contamination areas consist of a few (or possibly, one) discrete radioactive particles or a small volume of disperse radioactive material or both. Regardless, the contamination is present over spatial areas on the order of 30 by 30 cm or less. This definition of localized contamination arises because appreciable elevation in gamma radiation levels would be seen at only one, maybe two, measurement point with

the typical grid spacing used during the gamma radiation surveys. Distributed contamination areas consist of radioactive material, either discrete particles or disperse materials, spread out over larger areas. The extent of these areas ranges from the 30 by 30 cm localized area to a few square meters to hectares depending on the site.

These two types of contaminated areas have certain gamma radiation characteristics (or "signatures"). Both types of contaminated areas exhibit elevated gamma radiation levels; however, the elevation for localized contamination areas is expressed over a much smaller spatial extent. The incremental gamma radiation field from a single discrete particle, or a compact volume of disperse material, decreases rapidly with distance since the inverse-square law applies. For example, the incremental gamma radiation field at a distance of one metre from moderate activity particles, say, about 37 kBq (1.0 mCi) radium, is operationally indiscernible. Only a few, perhaps just one, gamma radiation measurement taken on a fairly dense grid, say 50 cm by 50 cm, would show elevated readings and, if the activity were small or a grid point did not coincide with the location of the discrete contamination, the elevation could be small compared to counting statistics or natural variability.

Areas of distributed contamination exhibit elevated gamma radiation levels at several points using a similar grid spacing since the spatial extent is larger than for the localized contamination areas. For most properties surveyed to data using the computer-based system, the radioactive contamination has not been uniformly distributed in areas of distributed contamination. Although gamma radiation levels were generally elevated at the grid points, there was variability in gamma radiation levels between grid-points due to the non-uniform spatial distribution of the contaminated materials.

SURVEY PROTOCOL AND DATA COLLECTION

All three of the survey system configurations make use of a similar surveying protocol. First, larger sites are broken down into smaller "blocks" (typically 30 by 30 meters) to make the field work more manageable. For smaller sites, the entire area to be surveyed can be defined as a single block.

Within each of these blocks, ropes and markers are used to help guide the surveyor. Data are continuously collected along specified lines and integrated readings stored every second. These lines are generally spaced either one half or one metre apart, depending on the detail of data required. The computer system determines spatial coordinates using the method of dead reckoning. This begins with the surveyor entering the starting coordinate of the line of data about to be collected. Knowing that the surveyor will travel at a constant rate (generally one metre per second), the computer can calculate the current location based on the time elapsed since the beginning of the line. To assist the surveyor in travelling at a constant speed, ropes or markers are placed at even intervals along the line, and the computer beeps when the surveyor should be passing these markers. As well, the computer constantly displays the current calculated position, which allows the surveyor to make continuous adjustments to his or her pace in order to stay synchronized with the computer. If a particular line of data is collected particularly poorly, that data can be erased and the line resurveyed. Figure 2 shows a surveyor collecting a line of data.

Fig. 2.

Data collection on a typical 30 by 30 metre block generally takes a single surveyor approximately one half hour to complete. Often, a second surveyor will assist with laying out ropes and markers, drawing site maps, and, when surveying residential properties, talking to home owners about the surveying process.

Once a survey is complete, the site record consists of the electronically recorded gamma radiation and spatial coordinate data along with a hand-drawn site map. The site map is used to record the locations of the site boundaries, areas on the site that were not surveyed (such as buildings), the type of terrain (such as grass, asphalt, bare earth, etc.), possible natural sources of anomalous readings (such as fieldstone or brick), and any other information of interest.

Use of this computer assisted surveying system results in the objective collection of a large number of relatively evenly spaced gamma radiation readings. Visualization and analysis of these large data sets requires the use of automated and statistical methods.

DATA ANALYSIS METHODS

Statistically based methods of data analysis have been developed to: i) consistently

analyze and summarize the large amounts of gamma radiation data collected; ii) improve the detection limits over other gamma radiation surveys; and, iii) accommodate variation in background gamma radiation levels.
A large amount of data is collected during the gamma radiation survey process. Upon completion of each 30 by 30 m survey block, up to 4,000 individual gamma radiation measurements are collected along with the northings and eastings (spatial co-ordinates) for each measurement. A consistent and relevant summary of these measurements is required for decision-making.
For some radium contaminated sites, the gamma radiation level at the clean-up criterion is within the range of natural background gamma radiation level. At one site, the soil criterion was 74 mBq g-1 radium when the local background was 37 mBqg-1; therefore, the incremental gamma radiation level from the contamination is 0.012 mSv h-1 (2.0 mR h-1) or lower. This increment is within the range of natural variability in gamma radiation levels from changes in soil moisture content and washout of radon decay products during precipitation events (2). The natural variability in gamma radiation exposure rate levels between survey locations is higher due to additional variability of other factors such as soil type. In fact, the background gamma radiation levels at one site were generally lower on the contaminated site than on the background properties located less than a few kilometers from the site. The effect of natural variability on assessment can be reduced by considering the variability in gamma radiation levels within the property instead of basing the assessment on absolute gamma radiation levels.
Localized and Distributed Contamination Statistics
Two statistics are calculated from the gamma radiation measurements on individual properties or survey blocks. First, the elevation in gamma radiation level above the local background is calculated for each measurement point and transformed to a statistically applicable measure. High values of this measure are indicative of discrete contamination. The detection limit for discrete particles depends on several factors including; depth of the discrete particle under the soil, local background gamma radiation level and the selection of acceptable false positive rate.
Figure 3 shows the probability of detection under normal conditions by activity and depth under the soil. Detection probabilities decrease rapidly for discrete particles buried deeper than 10 cm due to the combination of increased soil attenuation and increased distance between the particle and detector. Discrete particle detection limits do not change rapidly over the range of natural background gamma radiation levels.
Fig. 3.
The second statistic is calculated from the variability in gamma radiation levels over small areas, approximately 3 m2, on the property and, along with the localized contamination measure, is calculated for each measurement location. High values of this statistic are considered indicative of distributed contamination.
Discriminant Analyses
At many waste sites, locations with high values of either the localized or distributed contamination measures are immediately investigated and the appropriate remedial actions are completed. At other waste sites, the computerized gamma radiation survey has been used as a screening tool to identify properties, or areas, that have a high probability of containing contamination. Follow-up delineation on these properties is comprised of soil sampling, comprehensive hand-held gamma radiation scans, portable gamma spectroscopy or a combination of the methods. These follow-up investigations are costly; hence, an objective method for allocating follow-up effort, referred to as discriminant analysis, was developed.
Discriminant analysis has proven to be useful in the screening level applications. In this statistical technique, an empirical relationship between the quantitative variables and the classification of an object are established from a calibration set. This relationship is then used to predict the classification for previously unclassified objects from the corresponding quantitative variables (3). In this application the quantitative variables were the largest localized contamination measure and a summary of the distributed contamination measures on the individual properties. The classification variable was whether the property was contaminated or not.
The discriminant function was calculated during the first half of the survey program. The calibration set for background, or uncontaminated, properties were

randomly selected from local areas without contamination. The contaminated set where properties were previously known to contain localized or distributed or both types of contamination. The discriminant function suggested contamination on properties where either the localized or the distributed measure or both were relatively large. The appropriateness of the discriminant function was investigated by calculating the cross-validation error rate. This procedure involves removing, in turn, one calibration observation, recalculating the discriminant function, and comparing the predicted classification using the new discriminant function against the true classification of the removed observation. The cross validation error was small which indicates that the selected discriminant function was reasonable.

The discriminant function was applied to all properties and provided a single number summary of the gamma radiation measurements collected on each property. Discriminant scores for background properties were generally lower than scores for contaminated properties. The distribution for unclassified properties lies between the background and contaminated properties. This suggests that the unclassified properties are comprised of both background and contaminated properties. Previously unclassified properties with high discriminant scores were identified for more intensive investigations.

Geo-statistical and Visualization Analyses

Gamma radiation maps were constructed for some applications to aid in the interpretation and understanding of contamination on individual properties. Some of these maps showed choropleths of the gamma radiation levels on the property along with locations of highly localized and distributed contamination measures. Other maps showed only one statistic such as the distribution of highly localized contamination measures. These maps were useful in understanding the nature of contamination, in directing follow-up investigations and in communicating the gamma radiation survey findings to property owners.

Figure 4 is an example of a gamma choropleth map of a public school property. The areas occupied by buildings (one large and three small) are shown in white indicating that they were not surveyed. Although there are no indications of contamination on this property, there are other points of interest shown on this map. Note the lower areas (with gamma radiation exposure rates of approximately 3.0 to 4.0 microroentgen per hour (mR/h)) surrounding most of the main building and extending to the south-west corner of the map. These areas are a roadway, parking lot and playground, and are all covered with asphalt. The grassed areas to the north-west, along the north edge, and in two areas to the south are easily distinguished from the asphalt covered areas by their generally higher exposure rates (approximately 4.5 to 5.5 mR/h). Another interesting feature is the elevated area immediately surrounding the main building, particularly along the south face of the west wing. These exposure rates (up to 8 mR/h) are the highest found on site, and are due to the naturally occurring elevations found in the brick used in the construction of the school building.

Fig. 4.

Maps of over-all property discriminant score were also constructed during the site survey program. Spatial clustering of properties with high discriminant score was visually evident from these maps. This information facilitated the prioritizing of further efforts to ensure that those properties adjacent to those properties with contamination were adequately surveyed.

Geo-statistical techniques were also employed. The spatial structure of contamination at this site was investigated by constructing the semi-variogram of discriminant scores. Semi-variogram plots show the mean squared difference of the discriminant function at paired locations as a function of the distance between the paired locations. The semi-variogram showed spatial correlation up to about 40 m (or three properties). This information assist in the statistical sampling design for the properties surrounding the contaminated site.

Discriminant scores were predicted for unsurveyed properties using simple kriging (4). The patterns of high likelihood of contamination were similar to the subjective, or visual, assessments of the pattern on the maps. Both analyses provided estimates, during the survey program, of the number of follow-up surveys required and preliminary estimates of contaminated material volumes.

PROJECT EXPERIENCES

Survey of Properties in Scarborough, Ontario for the Investigation of Possible Ra-226 Contamination

In the fall of 1980, mildly contaminated soil was discovered in the residential community of Malvern in Scarborough, Ontario. The contaminant identified was Ra-226 from a radium recovery operation that took place in the 1940s on a farm site that was subsequently developed in the 1970s. At the recovery operation, waste materials from dial painting facilities (cardboard, rags, brushes, etc.) were reportedly incinerated to reduce the volume and provide a waste residue suitable for the chemical extraction of radium.

Traditional radiological investigations of the area identified approximately 3500 m3 of soil contaminated with above background concentrations of Ra-226. The areal extent and depth of the contamination were determined with the use of hand-held scintillometers. Gamma radiation surveys were conducted on approximately 130 residential lots in the area of the former farm site. A 3 by 3 metre grid was applied over each lot and gamma radiation exposure rates were recorded at each of the grid intersection points. As part of these gamma radiation surveys, the area between the grid points was scanned and any anomalous readings detected during the survey were recorded and investigated in detail to confirm the source of the elevated gamma radiation.

In addition to the bulk soil contamination, the results of the gamma radiation surveys and scans also identified discrete sources of radium-contaminated waste. These pieces of waste ranged in size from small particles of soil to pieces of 3mm diameter plastic tubing, approximately 1 to 5cm in length. Soil grading and spreading operations during the construction of the residential lots appear to have spread these small artifacts beyond the limits of the original farm site.

In the spring of 1990, a second accumulation of radium contamination was discovered within Malvern at a site located approximately one kilometer north of the old farm site. Investigations of this new site indicated the primary source of the radioactivity to be radium impregnated pieces of plastic tubing similar to the tubing found at the 1980 site. During the late summer of 1990 a remedial clean-up program was conducted and approximately 20,000 pieces of Ra-226 contaminated tubing were identified and recovered from 2500 m3 of soil.

The discovery of the second site of radium contamination prompted concern that additional radium waste may have been discarded at other locations within the Malvern community. To address this concern the LLRWMO contracted SENES Consultants Limited to assist in the development of a portable computer-assisted gamma radiation detection system. The design objectives were to provide a portable gamma radiation detection and recording system capable of surveying large tracts of land in an efficient and reproducible manner. The result was the first prototype cart system.

In 1992 and 1993 investigations were conducted using the cart system on 15 school properties and approximately fifty residential sites throughout the Malvern area, but not in the immediate vicinity of the old farm site. Although the expectation was that no historical radioactive contamination would be found, these surveys were to document surface gamma radiation levels on each site and to verify the absence of radium artifacts. No historic radioactive contamination was found during these surveys. However, a single piece of uranium ore (approximately 3 cm across) buried just below the surface of a schoolyard was detected and recovered.

In 1994, the cart system was used to complete an intensive survey program covering approximately 420 residential properties in the area of the original farm site. The purpose of these surveys was to document surface gamma radiation levels on the properties and to examine each for radium artifacts or radium contaminated soil that may have been deposited on the site as a result of historic soil moving operations. For each property surveyed, a discriminant function was applied to the data. The resulting "discriminant score" was used to select properties for further investigation. Follow-up investigations were performed on approximately 270 of the 420 properties. Hand-held instrument readings (both gamma spectroscopic and gross gamma) were collected over selected areas of each of the properties. In some cases, soil samples were taken from the surface and from shallow (less than 1.5 metre) boreholes for laboratory gamma spectroscopy analysis. These selected areas were determined using analysis techniques designed to detect both localized and distributed contamination, as described earlier under the "Data Analysis" section. Ultimately, it was determined that approximately 17 of the properties required remedial action. A review of the data was performed manually as a check on the automated data analysis methods, and to make final decisions in a few borderline cases.

It is interesting to note that annotated gamma radiation choropleth maps of individual properties will be used in this project to help inform home owners of the results of their surveys and status of their properties. With some explanation, these maps can help the layperson visualize the data much more effectively than a simple grid of numbers or a few summary statistics based on the collected data.
A similar survey program is planned for the summer of 1995, and will encompass approximately 1000 residential properties in the surrounding area. The same data collection and analysis techniques will be used. There is no expectation that any historic radioactive contamination will be found based on the results of the work performed in 1993 and 1994. However, there is a need to verify that the extent of contamination has been reached.
A thorough manual analysis of the data in the project would have been very expensive and time consuming. As well, the consistency of the collection and analysis of data could not have been maintained throughout the project without well defined data collection methods and objective, automated analysis techniques. By the end of 1995, approximately 1500 residential properties will have been surveyed, the results analyzed, and follow-up investigations performed. This work has proceeded in a cost effective and timely manner with the help of the computer assisted data collection and analysis system.
Survey of Industrial Sites in Fort McMurray, Alberta for Initial Characterization and
Post-Remedial Compliance
During an investigation of an historic uranium transportation network from Port Radium, Northwest Territories to Fort McMurray, Alberta, a number of sites were identified as having been contaminated by spillage of ore and ore concentrates. This transportation network served mines operating in the 1930s and 40s, and carried ore along a 1400 mile water transportation system, through the barge to railcar transfer station in Fort McMurray, Alberta, and on to Port Hope, Ontario for further refining.
In 1992/93 the LLRWMO performed cleanup operations at sites in the City of Fort McMurray, Alberta covering an area of approximately 120,000 m2 and has characterized further areas totalling approximately 150,000 m2. The bulk of the remedial work was in the immediate vicinity of the rail line, neighboring warehouses and loading/unloading areas. These area were contaminated primarily through the spillage of the radioactive materials. The movement of materials on these industrial sites in Fort McMurray, be it due to grading, tracking by people and vehicles or other activities, has distributed discrete fragments of uranium ore over much of the site areas.
As part of the characterization of suspect properties in Fort McMurray, a representative 10% of the surface areas were surveyed using the three-wheeled cart system. These data generated were analyzed using the localized anomaly detection method described earlier in the "Data Analysis" section. The areas identified by this method were each investigated with a comprehensive hand-held instrument scan. Where historic radioactive contamination was found, remedial action was initiated.
On completion of the 1993 remedial work, the LLRWMO conducted a verification program to ensure that the established clean-up criteria had been met. A 100% surface coverage of each remedial property using the computer-based survey system was intended. However, excavation on the sites contributed to the rough terrain, areas of the site were wooded, and other areas were scattered with debris. The three wheeled cart, though not originally intended to travel on such abusive terrain, fared well but could not be used on the roughest areas. The backpack system was developed to tackle these areas. It allowed data in many of the more uneven areas to be collected and analyzed by the same method as that collected with the three-wheeled survey cart. Some areas could not be surveyed using any of the survey system variants so were surveyed manually using a one metre grid pattern and electronic, integrating instruments. The manually collected data was interpreted using similar algorithms to those used on the data collected by the cart or backpack systems.
For the verification program each site was divided into 30 by 30 m areas to make the cart surveying more manageable. After each smaller area was completed, areas identified by the localized anomaly detection methods were investigated by technical staff and the sources of the anomalies recovered and identified, where possible. This project saw the first use of a discrete source density map. Mapping of the

locations of recovered sources of anomalous readings by material type depicted trends in the movement of materials on the site. That most of the anomalous readings were attributed to small pitchblende fragments in the northern end of a Fort McMurray site was characteristic of the loading and unloading of materials in that area. Towards the southern end of the same site the anomalous readings were more often attributed to a lower grade ore and signified the movement of surface materials of apparently little worth or concern. Materials such as gneiss and granite were also recovered from areas of the site. These rocks are native to the area itself and although they are recovered sources of gamma radiation reading anomalies, they are not a contaminant. Mapping of the recovered materials according to their type indicated trends in their past movement. Analysis of these trends pointed to areas of possible contamination which may not have otherwise been considered. Further investigation in these areas uncovered a volume of contaminated material that was attenuated by 50 to 75 cm of overburden.

SUMMARY AND CONCLUSIONS

The computer-assisted methods of data collection and analysis described in this paper are more powerful than the subjective analysis of more traditional manual surveys using integrated gamma radiation measurements at grid points and surface scans between grid points. Surveys using the new data collection and analysis techniques have identified the location of contamination on properties where previous methods were unable to locate such contamination.

These methods have proven especially useful where the incremental radiation from contamination is similar in magnitude to the variability in background radiation. Localized contamination containing 7400 Bq (0.2 mCi) Ra-226 or less, and distributed contamination with incremental concentrations of approximately 74 mBq/g (2 pCi/g) Ra-226 or less have been identified.

The computer-assisted gamma radiation detection system is capable of surveying large tracts of land in an efficient and reproducible manner with: i) increased objectivity in data collection and analysis; ii) reduced manual data handling and, iii) greater quality assurance.

COST-EFFECTIVENESS EVALUATION OF SAMPLING PROGRAM TO SUPPORT PROCESS CONTROL, SAFETY, AND REGULATORY COMPLIANCE IN A MIXED WASTE EVAPORATOR SYSTEM AT THE HANFORD SITE

Jennifer Sheriff
Kenneth S. Redus
MAC Technical Services Company

ABSTRACT

A cost-effectiveness evaluation of waste characterization sampling and analysis programs for the 242-A Evaporator at the Hanford site is presented. Program selection is based on the greatest effectiveness-cost ratio. Cost is modeled in terms of sampling, analysis, and quality control costs. Effectiveness is defined as meeting all minimum requirements associated with the decision variables Process Control, Safety, and Regulatory Compliance expressed in terms of the statistical power of the test and confidence levels achievable.

INTRODUCTION

There is a need for rigorous, defensible, and easily implemented and understood cost-effectiveness approaches for high-level radioactive waste sampling and analysis programs. Often times, such programs are evaluated on cost merits without formal consideration to the effectiveness of the alternatives. A suitable tool for combining the program cost and the program effectiveness is cost-effectiveness analysis. Such an approach forces a complete and concise definition of the cost parameters and the effectiveness parameters. Based upon these definitions, the term

"cost-effectiveness" has meaning and is not vernacular.

STATEMENT OF THE PROBLEM

Several waste characterization sampling and analysis programs for the 242-A Evaporator needed to be evaluated for mid-FY-95 operations. Characterization of specific radionuclides and chemical constituents was required for selected evaporator process streams. Each program needed to provide sufficient analytical data to meet process control, operations safety, worker safety, and compliance with the Resource Conservation Recovery Act (RCRA) requirements.

The 242-A Evaporator, located at the Hanford Site in southeastern Washington State, uses a conventional forced circulation and vacuum evaporation system to concentrate mixed waste solutions. Candidate waste feed tanks must be characterized, pumped to the Evaporator feed tank and processed. The feed stream is separated into a slurry stream, a process condensate, and a gaseous process exhaust stream. Two non-hazardous effluent streams, steam condensate and cooling water, are produced and discharged to an evaporative pond.

The slurry stream consists of the concentrated bottoms and contain the majority of the radionuclides and inorganic constituents. The slurry stream is recycled until it is concentrated to target levels. It is then pumped to double shell tanks to be stored for further treatment. The condensed boiloff, or process condensate, contains primarily water, trace organic material, and a greatly reduced concentration of radionuclides. The process condensate is stored at the Liquid Effluent Retention Facility awaiting treatment capacity in the Effluent Treatment Facility. The process exhaust, or vessel vent stream, consists primarily of non-condensible gases drawn from the condenser system, is filtered and discharged through an exhaust stack.

TECHNICAL APPROACH

A cost-effectiveness approach was used to evaluate proposed waste characterization programs (1). This approach was chosen for several reasons. Evaporator operations management needed easily understood information to select among waste characterization programs for current and future operations. A major purpose of the 242-A Evaporator is to support delisting of various RCRA constituents. Sampling and analysis at the evaporator, therefore, needed to support similar requirements at the Effluent Treatment Facility which receives process condensate from the Evaporator. Finally, as retrieval and treatment operations mature at the Hanford Site, a historical database will be required to identify those waste characterization programs that offer the greatest cost-effectiveness in support of these operations.

Cost and effectiveness were modeled separately. The baseline waste characterization program was first defined. Alternative programs were then identified. The cost and the effectiveness of each alternative were determined and compared to the baseline program. Programs that were dominated, i.e., both the cost and the effectiveness parameters were less than at least one other program were eliminated from further evaluation. The remaining programs were then evaluated. The program with the greatest effectiveness-cost ratio was selected as the optimal program. Sensitivities to cost thresholds and effectiveness parameters were examined to determine the influence of these factors in the selection of the optimal alternative.

Baseline cost estimates were determined using sampling data, analytical services data, and quality control data from previous evaporator campaigns during FY-94 and early FY-95. Baseline effectiveness was estimated based on the statistical factors associated with the number of samples taken for the same campaigns. A Data Quality Objectives (DQO) process, including decision error tolerances, was used to identify mid-FY-95 sampling and analysis waste characterization program alternatives for the evaporator (2-4).

IDENTIFICATION OF WASTE CHARACTERIZATION PROGRAMS

Waste characterization program alternatives were identified as described below.

Baseline The Baseline case was the 94-1 evaporator campaign. The 94-1 campaign utilized an extensive sampling effort to determine the contents of certain feed tanks for processing. The sampling consisted of seven samples in the process streams. The baseline data was used as a historical estimate of constituent variability. A comprehensive suite of analyses was performed on the samples with extensive quality control checks.

Alternative 1 Alternative 1 was based on the waste characterization program used in evaporator Campaign 94-2. Five samples were taken in the process streams for this alternative. A comprehensive suite of analyses was also performed on the samples with equally extensive quality control checks.

Alternative 2 This Alternative has a reduced set of analytes, reduced number of samples, and fewer quality control checks. This Alternative was derived during the Evaporator DQO. One sample in each of the three process streams was identified as sufficient to meet process control, safety, and regulatory compliance requirements. Quality control checks were not as extensive as in the Baseline or Alternative 1.
Alternative 3 This Alternative also has a reduced set of analytes, reduced number of samples, and fewer quality control checks. This Alternative was also considered during the Evaporator DQO. Eight samples in each of the three process streams were identified as sufficient to meet process control, safety, and regulatory compliance requirements. Quality control checks were not as extensive as in the Baseline or Alternative 1.
Alternative 4 This Alternative is based on the implementation of DQO Process for Campaign 95-1 of the evaporator. Three samples taken in each of the three process streams were considered sufficient to meet process control, safety, and regulatory compliance requirements. Quality control checks were not as extensive as in the Baseline or Alternative 1.

COST MODEL

Baseline cost information was obtained from previous evaporator campaigns during FY-94 and FY-95. Originally, waste characterization program costs were to be modeled in terms of both direct costs and opportunity costs in discounted 1994 dollars. Direct costs were estimated based on sampling and analysis, sample preparation, and data package costs. Opportunity Costs were associated with schedule delays and impacts. In the course of cost data collection, we were unable to estimate opportunity costs with any degree of certainty. While these costs are integral to a complete cost estimate, we did not include such costs in our evaluation.
Costs associated with the Baseline and Alternative 1 are based on a comprehensive set of analyses and the maximum amount of quality control checks that would be accomplished by both the field samplers and analytical services personnel.
Costs associated with Alternatives 2, 3, and 4 are based on a reduced number of analytes and a reduced quality control checks. Use of the DQO Process helped evaporator operations personnel better define their needs and the value of the data requirements relating to process control, safety, and regulatory compliance.
Several methods were employed to arrive at cost figures when data was either unavailable or suspect. Cost estimating relationships were used to relate costs to operations variables. Specific analogy methods were used to estimate costs by comparison with known costs of similar items or services. Included in this cost factor are estimates for complexity factors or scaling laws. Expert assessment was used as a last resort when cost information was unavailable. Cost estimate uncertainty was determined to be + 10%. Table I summarizes the costs used for this investigation.

EFFECTIVENESS MODEL

Effectiveness is determined as a function of two factors associated with the results of any of the waste characterization program alternatives: (i) the confidence to correctly conclude the requirements are not met, and (ii) the risk associated with incorrectly concluding the requirements are not met (5). The requirements that must be met are process control, safety, and regulatory compliance. The minimum requirement is: the concentration of all analytes that represent a decision variable do not exceed a predefined threshold.
The waste characterization program alternatives were generated using a statistical hypothesis test of the mean value if one or more constituents for each of process control, safety, and regulatory compliance requirements. If the mean value exceeded a specific threshold, it was concluded that the requirements were not met. The confidence to correctly conclude the requirements are not met is commonly called the Power of the Test. The risk associated with incorrectly concluding the requirements are not met is called the Type I error, or the false negative rate. Therefore, the effectiveness measure is a function of the Power of the Test and the Type I error. We will use the convention of denoting the confidence to correctly conclude the requirements are not met as the power and the Type I error as the risk throughout the remainder of this paper. Therefore, the waste characterization alternative with the greatest power and smallest risk is considered the best alternative when both factors are equally weighted.
The general form of the effectiveness model is presented in Eq. 1.
Eq. (1)

where Ei is the effectiveness for waste characterization alternative i, w is the weight associated with the Power of the Test, and v = 1 - w, is the weight associated with the risk . Since there are usually several constituents that must be characterized for an alternative sampling program, the most conservative way to describe the effectiveness of any alternative is to use the minimum power, min (1-), the maximum risk, max (a), and weights such that w = v = 0.50.

For example, suppose three constituents are being examined in a specific waste characterization program. Let the power of the test for the three constituents be 0.90, 0.85, and 0.99, respectively. Let the risk for the three constituents be 0.20, 0.01, and 0.05, respectively. The minimum power is 0.85, and the maximum risk is 0.20. The conservative effectiveness value for the program is based on an 85% power to correctly conclude the requirements are not met, and a 20% risk associated with incorrectly concluding the requirements are not met. The optimistic effectiveness value for the program is based on an 99% power to correctly conclude the requirements are not met, a 1% risk associated with incorrectly concluding the requirements are not met. Both power and risk are equally weighted. The weights of the power and the risk are the basis for sensitivity studies of the effectiveness measure and subsequent trade-offs in the cost-effectiveness evaluation.

The power of the test, 1-, and the risk, a, for the Baseline and the remaining alternatives is presented in Table II. The values for the Baseline and Alternative 1 were computed based upon the number of samples taken and confirmed with evaporator personnel. The values for Alternatives 2, 3, and 4 were defined as part of the Evaporator DQO (2) to determine sampling requirements for process control, safety, and regulatory compliance.

EFFECTIVENESS-COST ANALYSIS

An effectiveness-cost ratio, ECi, was computed for each of the waste characterization sampling alternatives. For convenience, we will denote the effectiveness-cost ratio as the EC ratio. The alternative with the largest EC ratio was selected as the preferred alternative. The utility of this approach is that large values of cost, regardless of the effectiveness, will push the ratio close to zero, and small values of effectiveness, regardless of cost, will force the ratio to behave in a similar manner. The EC ratio is defined as:

Eq. (2)

Three activities were performed prior to the computation of the ECi value. First, we attempted to identify and assess any other decision factors that should be included in the effectiveness or the cost measures. Radiological worker safety was identified as a significant factor. The more samples taken, the greater the Radiological worker exposure. This meant that alternatives that had less samples were preferred to alternatives with more samples from a radiological worker safety perspective. We did not include this as a specific element in the effectiveness measure, but we did consider it in evaluation and selection of the preferred alternative.

Second, all alternatives were examined in terms of any one alternative dominating another alternative for all effectiveness or cost values. For example, suppose Alternative A had a cost of $100K, a maximum power of 90%, and a maximum risk of 10%. Suppose Alternative B had a cost of $200K, a maximum power of 60%, and a maximum risk of 20%. Suppose Alternative C had a cost of $100K, a maximum power of 90%, and a maximum risk of 20%. We would say that Alternative A dominated Alternative B. Alternative B would be eliminated from further evaluation since ECA > ECB in all cases. Since Alternative A and Alternative C tied in cost, we could not eliminate Alternative C although the maximum risk for Alternative C exceeded that of Alternative A. No one alternative dominated any other alternative.

Finally, we identified any minimum power required or any maximum risk allowed. It was determined that risk was the key concern. If any alternative had a risk that exceeded 0.10, the alternative would not be evaluated. This criteria resulted in Alternative 2 not being included in the evaluation since the maximum risk prescribed by Alternative 2 was 0.20.

Results of the waste characterization sampling program effectiveness-cost values are presented in Table III. The effectiveness value, the cost value, the EC ratio, and the marginal change between the baseline cost and the baseline effectiveness for each alternative is provided.

Using only the EC ratio, the preferred alterative is Alternative 4 (EC = 21.1). The next preferred alternative is Alternative 3 (EC = 10.0). Alternative 4 is preferred over all alternatives because it requires the least number of samples (three) and

displays the smallest cost.
Alternative 4 offers a relatively small marginal change over the Baseline (DE/DC = 2.0) when compared to Alternative 3, (DE/DC = 4.5). This clearly indicates that Alternative 4 is the preferred waste characterization alternative in the absolute sense, but Alternative 3 offers the greatest marginal return. Interpreted in terms of the effectiveness and cost measures, this implies that the alternative with the smallest risk is preferred given (i) equal weights for power and risk, (ii) if the power is the same for all alternatives, and (iii) if the cost model remains the same.
Sensitivities were performed by varying the weights from the base case of w = v = 0.50. Two cases were examined: w = 0.20 and v = 0.80, and w = 0.40 and v = 0.60. The ordering of the preferred alternatives did not change.

CONCLUSIONS

An easy to implement cost-effectiveness evaluation of waste characterization sampling and analysis programs for the 242-A Evaporator at the Hanford site has been presented. The utility of this approach is its relative simplicity and understandability. Data requirements include (i) estimates of cost in terms of sampling, analysis, and quality control costs, and (ii) statistical hypothesis measures in terms of the Power of the Test, the Type I error, and their associated weights.

ACKNOWLEDGEMENTS

We would like to acknowledge numerous personnel who supported the 242-A Evaporator DQO and their invaluable participation. Particular thanks go to Brian H. Von Bargen, Process Engineer, Westinghouse Hanford Company (WHC) and Paul Carter, Analytical Services Program Manager, Department of Energy, Richland Operations (DOE-RL). Mitzi Miller, Environmental Quality Management, Oak Ridge, TN, deserves specific recognition for her outstanding facilitation of the DQO. We would also like to express sincere appreciation to: Joel Cooper, George Miller, Mark Bowman, Charles Mulkey, and Patty Morant (WHC); Clay Smith, IT Corporation; Brian Tucker, Stone and Webster; and, Kurt Silvers, Pacific Northwest Laboratories.

RECHARACTERIZATION OF BACKLOG MIXED WASTE AT ROCKY FLATS

Pamela W. Edrich
EG&G Rocky Flats, Inc.

ABSTRACT

During 1994, an effort was undertaken by EG&G Rocky Flats, Inc. to review previous RCRA hazardous waste determinations and characterizations for almost 33,000 containers of backlog waste (waste generated before 1992) in storage at the Rocky Flats Environmental Technology Site (RFETS). The goals of this recharacterization project were as follows:

gather all existing process knowledge and analytical data concerning backlog waste generation and characterization into a central location,

build consensus between the waste generators and technical and regulatory experts on the correct waste characterization for all backlog waste,

verify the RCRA regulations regarding hazardous waste determination and characterization are applied consistently, and rectify any characterizations made in the past that were overly conservative or incorrect,

update all container labeling and computer records to reflect the new characterization,

publish a controlled document that concisely summarizes all backlog waste generation and characterization information gathered, and update the document as new information is obtained, and

build a basis for identifying future sampling and analysis requirements and storage, treatment, and disposal options.

The recharacterization effort was completed in late 1994 and has resulted in many changes to the characterization of the waste in storage at RFETS. Nearly 970 containers of waste previously considered to be nonhazardous waste were determined to be hazardous waste, and over 5000 containers previously considered hazardous waste were determined to be nonhazardous waste. All waste has been characterized consistently and container labeling and computer records are in agreement, resulting in a higher degree of RCRA compliance and a more accurate RCRA operating record. The information gathered during the recharacterization effort has better defined the extent of sampling and analysis required for groupings of backlog waste. This effort has been reviewed by and received praise from the facility owner, the Department of Energy, and the state regulating agency, the Colorado Department of Public Health and Environment.

HISTORY OF WASTE GENERATION AT ROCKY FLATS

Waste has been generated at Rocky Flats since the beginning of plant operations in the early 1950's. Until the late 1980's, the primary concern with waste generation was proper segregation based on type of material (glass, metal, combustibles, etc.) so that the nuclear material content could be properly measured. Each type of material was identified by a three digit Item Description Code (IDC) and a title; for example, a drum containing stainless steel pipe would be identified as IDC 480 - Light Metal, and lead shielding from a glovebox would be identified as IDC 321 - Lead. Based on the nuclear material content, the waste would then fall into one of four categories: nonradioactive waste, low level waste (waste containing less than 100 picocuries/gram), transuranic (TRU) waste (waste containing greater than 100 picocuries/gram and less the economic discard limit), and residue (material containing levels of special nuclear material deemed economical to recover).

In 1986, a compliance agreement was signed by the Department of Energy (DOE), the Environmental Protection Agency (EPA), and the Colorado Department of Public Health and Environment (CDPH&E), regarding the regulation of waste considered hazardous under the Resource Conservation and Recovery Act (RCRA). Initially, only nonradioactive hazardous and low level hazardous (mixed) waste was regulated. In 1988, further compliance agreements began regulating TRU mixed waste, and by 1991, various agreements and court orders began regulating mixed residue.

Since 1986, Rocky Flats has been working to bring hazardous and mixed waste into compliance with the RCRA regulations. It took until the 1991-1992 timeframe to implement a sitewide system that characterized and documented that characterization of all waste being generated at the Site, and to train all waste generators to properly use the system. All waste generated before that system was in place is called "backlog waste" and the accuracy of the characterization of these backlog wastes is extremely suspect.

Another problem that arose in the late 1980's was the cessation of offsite shipment of the majority of Rocky Flats waste. The Nevada Test Site stopped receiving low level and low level mixed waste in 1990 and the Idaho National Engineering Laboratories stopped receiving TRU and TRU mixed waste in 1989. Additionally, DOE stopped shipment of all nonradioactive waste because proper policies and procedures were not in place to determine what "nonradioactive" really meant. Finally, the shutdown of the Site's plutonium recovery facilities in late 1989 halted the reprocessing of residues. Rocky Flats was forced to store practically all waste generated after 1989.

THE NEED FOR RECHARACTERIZATION OF ROCKY FLATS BACKLOG WASTE

As previously mentioned, the accuracy of the characterization of backlog waste at Rocky Flats is suspect. Much of the backlog waste had been characterized by program support groups or by personnel storing the waste, not by the waste generator. Normally these "second-hand" characterizations were extremely conservative. The backlog waste had been characterized and recharacterized over the years by different groups of individuals having different levels of understanding of the RCRA regulations, resulting in poor consistency in how the regulations were applied. Most

times, the characterization of backlog waste was done by writing a letter, with no attempt made to verify that the waste containers actually got relabelled and the computer database that tracks the containers (the Waste and Environmental Management System - WEMS) was updated. Additionally, there was no systemized documentation of the rationale behind the characterizations of backlog wastes.

This approach in characterization of backlog waste had resulted in incorrect, overly conservative, inconsistent, and unreliable characterizations. The ability to properly store this waste in compliance with RCRA regulations was weakened by these problems. Long-term plans to treat and ultimately dispose of these wastes were severely compromised by the characterization problems. Additionally, the state regulating agency, CDPH&E, had little confidence in Rocky Flats' ability to properly characterize waste and regularly threatened enforcement action.

The "last straw" came when a drum of waste having one characterization recorded on the drum label and another characterization recorded in WEMS was almost treated at one of the Site's interim status treatment facilities. The facility did not have interim status for the treatment of one of the EPA waste codes recorded on the label. The question arose, which characterization is correct - the one on the label or the one in WEMS? It was decided that the only way to determine the correct characterization was to start at the beginning and review the generating process for this drum. The realization was then made that every backlog waste container needed to undergo this type of scrutiny before any of the backlog waste characterizations could be trusted. A project was initiated to "reassess" the hazardous waste determination and waste characterization of all backlog waste currently in storage at Rocky Flats.

THE REASSESSMENT PROCESS

Through review of the WEMS database, it was determined that approximately 33,000 containers fell into the "backlog waste" category. As previously discussed, after 1991-1992 a Sitewide system was in place which properly characterized and documented the characterization of the waste, so containers produced after this timeframe did not require reassessment. Fortunately, a majority of the 33,000 backlog waste containers were identified with an IDC which gave an initial clue as to what each container held. Containers having similar IDCs were grouped into waste forms. Table I lists the 44 waste forms into which all backlog wastes were grouped and the number of containers in each waste form. These waste forms were the starting point for the characterization reassessment.

In order to conduct the reassessment of the 33,000 backlog waste containers, a simple database separate from the very complex WEMS database was established. Thirteen pieces of important characterization-related information for each of the 33,000 containers were downloaded from WEMS into the dBASE IV Backlog Waste Reassessment (BWR) database. All queries, sorts, and groupings of containers for the reassessment project were conducted using the BWR database.

A technical person familiar with RCRA regulations and general waste processing was assigned as the lead "reassessor" for each waste form. The reassessor gathered all the information currently available for the waste form, including:

a listing of all the containers in that waste form, including container identification number, IDC, description of the waste, generation date, building and room in which the waste was generated, building and room in which the waste is currently stored, and the current characterization of the waste.

descriptions of the waste generating process, gathered from interviews with waste generators and technical experts or from review of operating procedures. Process information gathered included the process flow, chemicals used in the process, reactions that occurred in the process, materials of construction of the process equipment, and information regarding the handling and packaging of the waste produced.

any existing analytical data for the containers within the waste form, or similar containers of waste, or from any products or byproducts of the generating process. Due to the radioactive nature of the waste and the heterogeneity of many of the waste forms, analytical data was normally not available.

documentation of past characterizations and current characterizations of similar waste forms.

any relevant regulatory guidance.

Following a review of the information gathered, the reassessor determined the appropriate characterization for the containers included in the waste form.

Containers were divided into "subpopulations" of containers that had identical waste characterization. A subpopulation was defined as any group of containers that had the same IDC, EPA waste codes, compatibility code, Land Disposal Restriction status, and chemical constituent codes (a coding system used at Rocky Flats to track chemical usage). In some cases, thousands of containers would fit within the same subpopulation, and in other cases, a subpopulation would consist of only one container. Each container within the waste form was "tagged" with a population number and subpopulation letter to identify into which characterization subpopulation it fell.

The reassessor assembled all gathered information into a Backlog Baseline Book for that waste form. All Backlog Baseline Books followed an identical format which included an introduction, brief description of the waste form, detailed description of the generating process (many times including a process flow diagram), summary of any analytical data, discussion on the proposed hazardous waste determination and waste characterization, regulatory discussion, and a list of personnel contacted and reference materials used. Of greatest importance is the section discussing the proposed hazardous waste determination and waste characterization. This section begins with a table listing the subpopulations and the characterization of each subpopulation. Subsequent paragraphs explain the rationale behind the characterization of each subpopulation. Attached to each Book was a database listing of all the containers within that waste form, sorted by subpopulation.

The Backlog Baseline Book for each waste form was distributed to a group of reviewers including waste generators, technical experts on the generating process, personnel currently storing the waste (called "custodians" at Rocky Flats), regulatory experts, and quality assurance personnel. After allowing approximately a week for review, a meeting (normally 1 to 2 hours in length) was held to collect comments on the book and discuss questions. During the meeting, consensus was reached between all parties on the proper characterization of the containers within that waste form. Following comment incorporation, the final draft of the Backlog Baseline Book for each waste form was circulated for final review and concurrence signatures were gathered from generator representatives, custodians, regulatory experts, and the reassessor.

After each Book was finalized, it was issued to the current storage unit custodians so that any containers which changed characterization could be relabelled and information in the WEMS computer database could be updated. Each waste form Backlog Baseline Book was released separately over a 7 month period so that custodians would not be inundated with changes. All Books were released by December 8, 1994, and custodians are continuing to update container labels and WEMS. All 33,000 containers should be updated by September 1995.

All waste form Backlog Baseline Books (excluding the database listing of all the containers) have been combined into a single controlled document entitled the Backlog Waste Reassessment Baseline Book, which was distributed to affected Site personnel in mid-January 1995. This document represents the official characterization of all Rocky Flats backlog waste and will be updated as any new information becomes available.

BENEFITS DERIVED FROM THE BACKLOG WASTE REASSESSMENT EFFORTS

In total, the backlog waste reassessment project had taken over one year to complete at a cost of over $1.5 million, not including the relabelling and WEMS database updating efforts (which are considered part of the day-to-day requirements of maintaining compliant container storage units). However, the payoffs of the project will be great.

Correct, Consistent, and Reasonable Characterizations Leading to Improved RCRA Compliance

The majority of backlog containers had some change in characterization as a result of this project. Nearly 970 containers of waste previously considered to be nonhazardous waste were determined to be hazardous waste, and over 5000 containers previously considered hazardous waste were determined to be nonhazardous waste. Additionally, thousands of containers already considered hazardous or mixed waste had minor changes to EPA waste codes.

This project has provided consistency in characterization between containers of like wastes and throughout the entire population of waste inventory at Rocky Flats. Because of this project, the interpretation of how various EPA waste codes should be applied have been agreed upon between various groups at the Site and with DOE and

CDPH&E. The characterizations are appropriate, rather than the prior practice of being overly conservative. With the improved characterizations, a much higher degree of RCRA compliance can be reached in the container storage areas. This higher degree of compliance will earn a higher confidence level and better working relationship with CDPH&E and the EPA.

Characterizations are Well Documented and Defensible, and New Information Can Be Incorporated

The publication of the Backlog Waste Reassessment Baseline Book finally gives a single source that can be accessed to understand the generation processes and characterizations of the backlog waste. This Book will be used by the regulators, storage custodians, and waste personnel attempting to treat and dispose of backlog waste. If the characterization of a backlog waste is ever called into question, the information in the Book can be reviewed again and further debated. If new analytical data or process information becomes available, the information can be added to the Book, the waste recharacterized if necessary, and all affected containers can be identified, relabelled, and updated in WEMS.

Basis of Future Sampling and Analysis Efforts and Treatment and Disposal Options

This project compiled a wealth of information that will be useful for planning future sampling and analysis events. By grouping the containers in subpopulations, statistical methods can now be used to sample the waste form without sampling every container. The information gathered on each subpopulation is useful in determining which analytes must be requested when sampling, thereby eliminating costly testing for hazardous constituents that were never a part of the waste. Additionally, the information gathered during reassessment is extremely useful when planning for future treatment and disposal options. The form, volume, and characterization of the waste are all important considerations during this planning.

SUMMARY AND CONCLUSIONS

The historically poor characterization of Rocky Flats backlog waste resulted in a multitude of RCRA compliance problems and presented a barrier to future sampling and analysis events and the eventual treatment and disposal of the waste. The backlog reassessment project conducted in 1994 was successful in using available information to recharacterize 33,000 containers of waste on a subpopulation basis. The project brought together the organizations that could make the proper characterization of previously generated waste and then ensured that the container labels and WEMS database were properly updated consistent with the new characterization. The Backlog Waste Reassessment Baseline Book provides a concise description of the generating processes and characterizations of backlog waste and will be used in the future to determine required sampling and analysis, and for planning treatment and disposal options. The Book will also be updated as new analytical data and process information becomes available.

CONSIDERATIONS IN THE DEVELOPMENT OF GUIDANCE ON THE APPLICATION OF PROCESS KNOWLEDGE TO THE RCRA CHARACTERIZATION OF DOE'S MIXED LOW-LEVEL WASTE

Judith M. Weintraub
Donald C. Habib
Brown & Root Environmental
Susan Jones
U.S. Department of Energy

ABSTRACT

The United States Department of Energy (DOE) is considering the development of a guidance document on the subject of using "process knowledge" in Resource Conservation and Recovery Act (RCRA) waste characterization. Based on a study of RCRA waste characterization requirements, objectives, and practices, the authors believe that such guidance should consider that:

Both process knowledge and sampling and analysis data are usually necessary to fully characterize waste for future treatment, storage, and disposal.

Process knowledge data are more suitable for meeting some RCRA waste characterization objectives than others.

The level of accuracy that process knowledge characterization should achieve depends on the subsequent management of the waste.
Given regulators' bias toward sampling and analysis, it may be important for DOE sites to develop a rationale for waste characterization determinations based on process knowledge.
Many different types of documentation can be used to substantiate process knowledge.
Tracking knowledge concerning waste matrices, underlying hazardous constituents, and non-RCRA waste characteristics is just as important as tracking EPA codes.

INTRODUCTION

Characterization is fundamental to the proper management (that is, the treatment, storage, and disposal) of all types of solid waste, including radioactive, hazardous, and mixed waste. Characterization of hazardous and mixed waste is required by regulations promulgated under RCRA and involves assembling the data necessary to treat, store, and dispose of waste in accordance with applicable regulatory requirements.
Under RCRA, there are two basic types of data used to characterize waste: 1) sampling and analysis, and 2) "process knowledge." The term "process knowledge" is short for "knowledge of the hazard characteristic of the waste in light of the materials or the processes used." Process knowledge data usually mean all information pertaining to a waste that can be used to characterize it, except for sampling and analysis data.
DOE facilities tend to rely heavily on the use of process knowledge in characterizing mixed low-level waste. Due to the radioactive nature of mixed waste, reliance on process knowledge can be justified based on the desire to:
control mixed waste sampling and analysis costs;
avoid the possibility of spreading radioactive contamination through sampling and analysis activities; and
reduce the personnel radiation exposure associated with sampling and analysis activities so as to comply with DOE and Atomic Energy Act (AEA) requirements to keep personnel exposures as low as reasonably achievable (known as the ALARA principle).
While the Environmental Protection Agency (EPA), state regulatory agencies, and other stakeholders are sympathetic to these goals, they remain concerned that:
waste classified by DOE as low-level (non-mixed) waste on basis of process knowledge may actually contain hazardous constituents; and
process knowledge may not have adequately identified the hazardous constituents or hazard codes of mixed waste needing treatment.
Characterization based on process knowledge engenders greater concern than characterization based on sampling and analysis because of the lack of guidance, procedures, or protocols defining the appropriate methods, level of accuracy to be achieved, quality assurance/quality control measures, or documentation/recordkeeping requirements that should be associated with the application of process knowledge to characterize waste.
DOE may address these concerns by developing guidance for DOE sites to follow when process knowledge is used to characterize waste in accordance with RCRA requirements.

CONSIDERATIONS

This paper describes considerations for DOE's guidance based on:
RCRA waste characterization requirements and objectives;
the current application of process knowledge to RCRA waste characterization processes at DOE facilities; and
EPA and State comments on DOE's Interim Mixed Waste Inventory Report, which were critical of DOE's reliance on process knowledge in RCRA waste characterization processes.

Relationship of Sampling and Analysis and Process Knowledge to Waste Characterization

There has been a tendency in regulations, regulatory preambles, guidance documents, and DOE's information-gathering efforts (such as the Interim Mixed Waste Inventory Report and the data compiled for the final Mixed Waste Inventory Report) to present sampling and analysis and application of process knowledge as different methods of waste characterization. Typically, however, both sampling and analysis and process knowledge are needed to fully characterize a waste for future management.
At one extreme, process knowledge alone may be sufficient to determine that a waste

could not be hazardous and therefore that other RCRA requirements, including land disposal restriction (LDR) standards, are not applicable. At the other extreme, nothing beyond what can be learned from physical examination may be known about a waste. In this case, sampling and analysis is needed to establish the basic parameters for further sampling and analysis.

For example, initial sampling and analysis may establish that an unknown waste contains metals. Additional sampling and analysis would be necessary to determine if RCRA metals were present at levels that would fail the Toxicity Characteristic Leaching Procedure (TCLP).

The most common situations, however, fall somewhere in the middle. For example, the choice of a sampling and analysis strategy depends on the amount and presumed accuracy of knowledge of the process(es) that produced the waste and the way in which the waste was containerized. This knowledge defines the waste requiring characterization and determines which sampling strategy is most appropriate to characterize it (e.g., random sampling, systematic sampling, stratified random sampling, composite sampling), the number of samples that must be taken, and the types of analyses that must be performed.

There are also situations where sampling and analysis data may be considered process knowledge. This occurs when sampling and analysis is used to characterize a particular waste stream or a surrogate waste, and the sampling and analysis data are subsequently used to characterize another similar waste stream.

Sampling and analysis of a waste stream that has already been fully characterized may be required when a process change could alter the RCRA characterization of the waste. Consequently, it is process knowledge that determines when changes to a process (and consequently to the waste) require both recharacterization of the waste and additional sampling and analysis.

The suitability of process knowledge or sampling and analysis to meet various characterization objectives is affected by the types of regulatory standards on which the characterization objectives are based. In the RCRA program, concentration-based standards favor sampling and analysis. Standards identifying wastes as hazardous on the basis of chemical uses or the processes used to generate waste (these types of standards identify "listed" wastes) require process knowledge to make a determination as to whether the waste is really hazardous or non-hazardous. Standards based on technologies used to treat waste favor process knowledge.

Table I illustrates the relationship between different types of RCRA regulatory standards, process knowledge, and sampling and analysis when waste is characterized for the purpose of meeting each of the two fundamental RCRA waste characterization objectives.

Table I. Relationship Between RCRA Regulatory Standards, Process Knowledge, and Sampling and Analysis

Standards promulgated in other regulatory programs have also influenced the ability of DOE sites to use process knowledge to characterize wastes. The promulgation of the Occupational Safety and Health Administration's Hazard Communication Rule in the mid-1980s significantly strengthened DOE's ability to use process knowledge. The Hazard Communication Rule requires that information about the materials used in the workplace be in the form of material safety data sheets (MSDSs) and be made available to employees. This has resulted in a great increase in the availability of MSDSs, which describe the chemicals and hazards present in commercially purchased chemical substances used in the workplace. MSDSs typically list the principal chemical ingredients in a material by percent and contain other data on chemical and physical properties and hazards.

The relationship between process knowledge and sampling and analysis will continue to evolve as new regulations are promulgated under RCRA and other laws. For example, the future promulgation of a hazardous waste identification rule allowing low-concentration listed wastes to exit the hazardous waste system may favor earlier sampling and analysis of listed wastes to determine whether they meet exit criteria.

Relationship of Process Knowledge to the Objective of Waste Characterization

Under RCRA, wastes are required to be characterized to meet a variety of objectives, including the following:

Generators of solid waste are required to determine whether the waste is hazardous (40 CFR Part 262).

Facilities treating, storing, or disposing of hazardous waste must obtain

sufficient information about the waste to treat, store, or dispose of it in accordance with applicable standards (40 CFR 264 and 40 CFR 265).

Generators and facilities treating, storing, or disposing of hazardous waste must characterize the waste to determine the applicability of RCRA LDR requirements (40 CFR 268).

DOE sites that generate mixed waste also typically store this waste for long periods of time. (Long-term storage of mixed waste is a consequence of the limited availability of treatment and disposal capacity.) Some of these sites also treat mixed waste or expect to do so in the future. In addition, some sites may dispose of mixed waste. For DOE sites, RCRA waste characterization may therefore serve a wide variety of different objectives, most of which fall into one of the following five categories:

identification of the waste as hazardous or non-hazardous;

determination of requirements for compliant/safe storage;

determination as to whether the waste meets LDR standards (either before or after treatment);

performance of a treatability evaluation; or

determination as to whether the waste meets the waste acceptance criteria (existing or proposed) of an existing or planned treatment or disposal facility.

Other important characterization objectives for mixed wastes (and nonhazardous radioactive wastes) that are not addressed in this paper involve assessing the radioactive nature of the waste to determine the applicable requirements for containment, radiation protection, and avoidance of criticality.

In general, the suitability of using process knowledge data to meet RCRA waste characterization requirements is heavily dependent on the waste characterization objective. In the past, process knowledge has been adequate to determine whether many DOE radioactive wastes should be stored as mixed wastes and to choose storage configurations that comply with the requirements of RCRA, the AEA, and other laws. As a result of the use of process knowledge to make these determinations, however, some radioactive wastes that contain hazardous constituents but are not hazardous (e.g., if tested, the waste would pass the TCLP), are managed as mixed wastes until better information is available.

While this strategy adds to the cost of waste management (because it is typically more expensive to manage mixed waste than nonhazardous low-level waste), the additional cost may be justified in some situations. The additional cost of managing a waste as a mixed waste must be balanced against the costs of sampling and analyzing mixed waste, considering the probability that sampling and analysis could demonstrate that the waste is nonhazardous. In general, the higher the probability that sampling and analysis results will allow wastes to exit the RCRA hazardous waste system, the more cost-effective it is to perform sampling and analysis. The following expression demonstrates this relationship:

Cost-Effectiveness = f[($HW - $SW - $CHAR) x (%Prob)]

Where cost-effectiveness is a function (f) of the following variables:

$HW	=	the future cost to manage the waste as a hazardous (or mixed) waste
$SW	=	the future cost to manage the waste as a solid (or nonhazardous radioactive) waste
$CHAR	=	the cost of additional characterization to determine if the waste is hazardous
%Prob	=	the probability that additional characterization will determine that the waste is nonhazardous

If cost effectiveness is less than or equal to 0, additional characterization is not cost-effective. The higher the value of calculated cost-effectiveness, the more cost-effective it is to perform additional characterization. Similarly, the lower the value of the calculated cost-effectiveness, the less cost-effective it is to perform additional characterization.

While process knowledge is often adequate to determine the regulatory status and the storage requirements for a mixed waste, sampling and analysis data are typically required to meet other waste characterization objectives. Sampling and analysis is

required more frequently to determine whether waste meets LDR concentration-based standards, to evaluate wastes for certain types of treatment, and to determine whether wastes meet the waste acceptance criteria and requirements of waste analysis plans of proposed treatment and disposal facilities.

In September 1994, DOE announced a policy of applying the Data Quality Objectives (DQO) Process, developed by the EPA, to all environmental projects where significant environmental data must be collected. EPA developed the DQO Process to minimize expenditures related to data collection by eliminating unnecessary, duplicative, or overly precise data, and to ensure that data collected are of sufficient quality and quantity to support defensible decisionmaking. In the area of waste management, DOE sites can apply the DQO Process to minimize the need for sampling and analysis when characterizing waste for storage and to meet the waste acceptance criteria and requirements of waste analysis plans of treatment and disposal facilities.

Defining the purpose of the waste characterization effort corresponds to performing Steps 1 (State the Problem) and 2 (Identify the Decision) of the DQO Process.

Different Types of Waste Characterization Errors Have Different Consequences

The level of accuracy that waste characterization based on process knowledge needs to attain should be based on the purpose of the characterization and the possible consequences of an error. Determining acceptable levels of accuracy corresponds to performing Step 6 in the DQO process, Specify Limits on Decision Errors.

For example, a process-knowledge-based determination that a waste is not hazardous should achieve a very high level of accuracy, comparable to the 95% confidence level prescribed by sampling and analysis. An error in this determination may be a RCRA compliance issue and may pose a threat to human health and the environment.

However, a process-knowledge-based determination that a waste is hazardous does not need to be accurate for the purpose of compliant storage. Managing a nonhazardous waste as a hazardous waste does not pose a threat to human health or the environment. In most cases, further characterization for treatment will allow inapplicable EPA codes to be eliminated.

Waste Characterization Rationale

Given regulators' bias toward sampling and analysis, it may be important for DOE sites to develop a rationale each time a waste is characterized to determine whether it is hazardous or to assign EPA codes to hazardous wastes. For example, a waste can be determined to be nonhazardous based on the following rationale:

   No hazardous constituents entered or could have been formed in the process producing the waste.

Sometimes many EPA codes are assigned to waste destined for robust treatment (e.g., incineration) based on process knowledge. These codes are assigned because there is a possibility that hazardous constituents could be present. If incineration is the best demonstrated available technology (BDAT), considering the waste matrix and the codes that are assigned, the waste characterization rationale could be:

   All EPA codes that could apply to the waste have been assigned. Further characterization of this waste will be necessary to determine whether it meets the waste acceptance criteria of the treatment facility. EPA codes will be verified and corrected, if necessary, when waste is characterized for treatment. Residuals from treatment will be tested to determine whether they meet LDR treatment standards.

Documentation of Process Knowledge

Many different kinds of documentation can support waste characterization rationales that rely on process knowledge. Such documentation may include testing protocols, work orders, process descriptions, MSDSs, training records (of employees who generate and characterize waste), and procedures for waste accumulation and management.

The documentation that is available may vary according to whether the documentation was produced contemporaneously with the waste, whether the waste was produced by routine or nonroutine processes, the types of operations producing the waste (e.g., manufacturing, laboratory operations, maintenance, environmental restoration, decontamination and decommissioning), and the purpose of the original documentation. For nonhazardous waste, it is particularly important that the documentation show that administrative and other controls have effectively segregated the waste from hazardous waste.

For DOE, other important considerations with respect to documentation of process knowledge include:

  The information in the documentation should be traceable.

The documentation should be readily retrievable and formatted/managed so it can be shared among various site contractors, sites, and with regulators.

The documentation should be formatted/managed so it can be kept for many years and transferred to successor contractors.

Contents of Documentation

RCRA waste characterization involves more than determining whether a waste is hazardous or nonhazardous and, if hazardous, assigning appropriate EPA codes. Thus, adequate documentation of waste characterization information also requires identifying matrix, underlying hazardous constituents, and various chemical and physical characteristics.

Different LDR standards (and thus treatments) are applicable to wastes with different matrices (wastewater, nonwastewater, debris). Matrix identification may depend on process knowledge (including visual inspection) and/or sampling and analysis.

Under EPA's September 1994 Phase II LDR rulemaking, new LDR standards were established that require the identification and appropriate treatment of underlying hazardous constituents in ignitable, corrosive, and TC organic wastes. The regulations allow identification of hazardous constituents standards that must be achieved using process knowledge. (Determining whether these standards have been achieved, however, often requires sampling and analysis.)

Waste movement/transportation, treatment, and disposal in accordance with RCRA standards may require information on many non-RCRA chemical and physical waste characteristics, including viscosity, specific gravity, heating value, organics content, free liquid and moisture content, and the presence of non-RCRA contaminants (radionuclides, asbestos, PCBs). Information on these chemical and physical characteristics may be developed using process knowledge, sampling and analysis, or a combination of the two.

Because determining and documenting waste matrix, underlying hazardous constituents, and non-RCRA waste characteristics are often necessary for proper management of waste, they are just as important as determining and documenting EPA codes. This information is usually developed based on a combination of process knowledge (including visual inspection) and sampling and analysis.

CONCLUSIONS

The authors believe that DOE's process knowledge guidance should recognize that:

1. Both sampling and analysis and process knowledge data are usually necessary to fully characterize waste for future treatment, storage, and disposal.
2. The use of process knowledge data is generally more suitable to some waste characterization objectives than to others.
3. The level of accuracy that waste characterization based on process knowledge needs to attain should be based on the objective of the characterization and the possible consequences of an error.
4. Given regulators' bias toward sampling and analysis, it may be important to develop a rationale for waste characterization decisions involving process knowledge.
5. Many different kinds of documentation can support waste characterization that relies on process knowledge.
6. Documenting and tracking knowledge about the waste matrix, underlying hazardous constituents, and non-RCRA waste characteristics are just as important as tracking and documenting EPA codes.

The authors invite comments on these considerations or on other considerations that should be applied to the development of guidance on the application of process knowledge to the RCRA characterization of mixed low-level waste.

Aguirre Engineers, Inc.
RFETS
ABSTRACT
Five pyrochemical processes were used at Rocky Flats Plant (renamed to Rocky Flats Environmental Technology Site, RFETS). The pyrochemical processes produced a variety of pyrochemical salt residues. The five pyrochemical processes that produced these salts were: molten salt extraction, direct oxide reduction, electrorefining, salt scrub and pyroredox. Currently, there are approximately 3600 containers of pyrochemical salts in storage at RFETS. Most of these salts were conservatively characterized under the Resource Conservation and Recovery Act (RCRA) as having the RCRA characteristic of "reactivity" due to the presence of "reactive" metals such as magnesium, sodium, calcium and potassium. In addition, the salts were characterized as D007 (Chromium) based on conservative assumptions which considered that chromium could be present from incidental contact with stainless steel equipment and/or trace amount of chromium may have been present in the generating-process feedstock (site-returned plutonium). The regulated status of these salts is significant to the Department of Energy (DOE) due to the substantial costs associated with their storage, treatment and management as hazardous waste under RCRA.
Utilizing previously unreferenced chemical processing information, analytical tests on surrogate salts, newly developed objective criteria and regulatory analysis, RFETS determined that the definition of the RCRA "reactivity" characteristic does not apply to approximately 3200 of the 3600 containers of pyrochemical salts. The objective criteria resulting from this effort included information from operating experience and analytical data not collected under SW-846 (Environmental Protection Agency's waste analysis methodology) (1) and could serve as the basis for a standardized definition for RCRA "reactivity" for the Department of Energy complex. The D007 code was removed from all pyrochemical salts by the use of thermodynamic calculations. Process equipment was not constructed of stainless steel and the residue salts had no direct contact with stainless steel. Feedstock to the process contained only negligible quantities of chromium. The thermodynamic calculations conclude that, chromium could exist only in insignificant amounts in the residue salt after the pyrochemical reactions are concluded.
RFETS developed an economic model to estimate the potential savings resulting from the removal of these salts from RCRA regulation. The model estimates the potential cost savings across three different residue management pathways and time frames: a baseline new actinide separation facility pathway, a separate salt treatment facility pathway, and a salt repackaging pathway. Potential cost savings are due to reduced costs for storage, inspection, consolidation, permitting, treatment, and characterization. For each residue management pathway a comparison was made between the cost to manage the affected salts as RCRA regulated versus non-RCRA regulated. The model estimated a significant cost savings for managing the salts as non-regulated for all three of the residue management pathways. The potential savings ranged from $6.9 M to $20.1 M depending upon the management pathway assumed. Managing the salts as non-regulated also results in several additional benefits which include: reduced regulatory liability; opening up off-site treatment options; cost avoidance for other DOE sites; and regulatory good will.
INTRODUCTION
During the forty years of production at Rocky Flats various plutonium recovery processes produced spent pyrochemical salt waste streams. The pyrochemical salts were generated as by-products of several processes used to reduce plutonium oxide (PuO_2) to metal, refine Pu metal, and extract actinides from Pu metal. The specific processes utilized were molten salt extraction (MSE), electrorefining (ER), direct oxide reduction (DOR), pyroredox, and salt scrub.
The molten salt extraction process removes americium from plutonium by combining plutonium metal which has unacceptable levels of americium with a mixture of sodium chloride and potassium chloride with magnesium chloride. The mixture is heated until it melts. While the mixture is molten, the magnesium chloride oxidizes most of the americium along with some of the plutonium and the oxidized actinides report to the salt phase. When cooled, the salt and metal are separated. In 1989 a change was made to the MSE process by converting the use of magnesium chloride to dicesium hexchloroplutonate (DCHP).
Electrorefining purifies plutonium metal that does not meet foundry specifications.

Nonspecification plutonium metal is combined with magnesium chloride and an equimolar mixture of sodium chloride and potassium chloride. The mixture is heated until molten. A cathode and an anode/stirrer are lowered into the molten mixture and a current is applied to the anode/stirrer which flows through the molten mixture to the cathode. Pu ions migrate to the cathode and are reduced to purified metal. When the mixture is cooled, the salt, anode heel and purified plutonium metal are separated. Another reaction which occurs during the electrorefining process is that of the reduction of sodium chloride and potassium chloride to elemental sodium and potassium.

Direct Oxide Reduction reacts plutonium oxide with calcium in molten calcium chloride to produce a plutonium metal button by reducing the plutonium oxide to plutonium metal and oxidizing the calcium. The plutonium oxide is "calcined" by heating in a muffle furnace to remove moisture and drive off volatiles. The calcined plutonium oxide is then combined with calcium chloride and calcium metal and heated until molten. The molten material is stirred until the reduction is complete. When the material is cooled, the salt, calcium, and plutonium metal are separated.

Pyroredox is a two-step process for purifying impure plutonium metal. The impure metal is combined with sodium chloride, potassium chloride, and zinc chloride and heated until the mixture is molten. While the mixture is molten, the zinc chloride reacts with the plutonium metal to form plutonium chloride and zinc metal. The mixture is cooled and the salt and metal products are separated. The salt phase is then mixed with calcium metal and heated until molten. While molten, the calcium reduces the plutonium chloride to plutonium metal. The contents are cooled and the metal and salt separated.

Salt Scrub reduces and concentrates actinide ion metals present in spent MSE salt into a stable non-oxidizing metal alloy. The salts are combined with a reducing agent and an alloying agent such as magnesium and aluminum, calcium and gallium and calcium and cerium. The mixture is heated until molten. While in a molten state the plutonium and americium are reduced by the calcium or magnesium and the actinides are taken up in the metal alloy phase. When the mixture is cooled, separation of the salt and the alloy button occurs.

The pyrochemical salts contain recoverable amounts of plutonium and were therefore not considered to be subject to RCRA hazardous waste regulations until a Notice of Violation(NOV) was issued by the State of Colorado in 1989. The NOV identified the residues as mixed waste. DOE and the State of Colorado entered into a Settlement Agreement and Consent Order (2) establishing a responsible approach to identification, characterization and management of the mixed residues in storage. The 1992 Backlog Residue Hazardous Waste Determination Status Report (3) (a deliverable under the Order) identified all pyrochemical salts as RCRA hazardous and assigned the EPA codes D003 (reactivity) and D007 (chromium). The reactivity code was assigned because of the suspected presence of "reactive" metals (sodium, calcium, potassium and magnesium). The chromium code was assigned because it was suspected that chromium could be present in feedstocks to the pyrochemical processes or could be present in the spent salts due to incidental contact with stainless steel equipment.

REMOVAL OF D007 (CHROMIUM) CODE

Background

Two possible sources of chromium were elucidated in the Backlog Residue Hazardous Waste Determination Status Report (3), dated February 1992. The first source was thought to be incidental contact with stainless steel. The second was the possible presence of chromium in the feedstocks for the processes. Experimental analytical data from 1962 and 1963 on pyrochemical salts also indicated that chromium may be present. In April 1993, the State of Colorado requested reevaluation of the pyrochemical salt characterization for chromium.

Approach

Hazardous waste regulations state that the chromium present must be primarily hexavalent chromium in order for the waste to be hazardous for chromium. Process knowledge indicates that hexavalent chromium in the salt matrix could exist only in very small concentrations. Operating procedures indicate that the only sources of chromium are 1) chromium metal from the cell components or 2) chromium ions from the plutonium metal used as feed to the processing. If small quantities of chromium metal were present in the salt, they would not be oxidized to hexavalent chromium because the operating conditions did not allow for its formation. Utilizing standard

free energy of formation data and with the understanding that plutonium ions are always present in the salt and plutonium metal is always present in an immiscible phase, the free energy change can be calculated for the reaction:

PuCl3 + Cro = CrCl3 + Puo

The calculation results in a free energy change of +96.6 Kcal/mole. The positive result indicates that equilibrium favors the reactants over the product. Therefore, chromium in the metallic state will remain in that state and will alloy with plutonium metal.

The pyrochemical processes occur at extremely high temperatures (approximately 700 - 800oC) in an inert environment and, therefore, it is unlikely that significant oxidation of the stainless steel cell can occurred to form chromium oxide (CrO3). Hexavalent chromium compounds decompose at relatively low temperatures, and CrO3 will decompose at 250 oC to Cr2O3 and will then be reduced to chromium metal by the plutonium metal as indicated by the reaction:

4Cr2O3 + 6Puo = 6PuO2 + 8Cro

The standard free energy for the reaction is -105.7 Kcal/mole of Cr2O3 indicating that equilibrium favors to products rather than the reactants.

CONCLUSIONS

The thermodynamic calculations indicate that the pyrochemical salts do not exhibit the toxicity characteristic for chromium, and therefore, the D007 code was removed from the salts. The data was presented to the State of Colorado in May 1993 and the State concurred with the characterization.

REMOVAL OF THE D003 (REACTIVITY) CODE

Definition

The hazardous characteristic of reactivity is defined in the Code of Colorado Regulations 6CCR1007-6, Part 261.23 (4) as stated below:

A solid waste exhibits the characteristic of reactivity if a representative sample of the waste has any of the following properties:

1. It is unstable and readily undergoes violent change without detonating.
2. It reacts violently with water.
3. It forms potentially explosive mixtures with water.
4. When mixed with water, it generates toxic gasses, vapors, or fumes in a quantity sufficient to present a danger to human health or the environment.
5. It is a cyanide or sulfide bearing waste which, when exposed to pH conditions between 2 and 12.5 can generate toxic gases, vapors or fumes in a quantity sufficient to present a danger to human health or the environment.
6. It is capable of detonation or explosive reaction if it is subjected to a strong initiating source or if heated under confinement.
7. It is readily capable of detonation or explosive decomposition or reaction at standard temperature and pressure.
8. It is a forbidden explosive as defined in 49 CFR Sec. 173.51, or a Class A explosive as defined in 49 CFR Sec. 173.88.

Approach

Because the EPA definition is vague, objective criteria were developed to help Rocky Flats better define the conditions necessary for a waste to exhibit the characteristic of reactivity. Conditions that should be satisfied for determining the reactivity characteristic in pyrochemical salts included:

Are any of the containers bulging, signifying pressure buildup?

Is there evidence that any containers have ever exploded?

Are the containers vented? Does the design of the containers prevent gaseous buildup and gaseous mixing?

How long have the wastes been stored in the containers?

Have the wastes been exposed to water during their storage? What resulted?

Applying the objective criteria, knowledge of the composition of the pyrochemical salts gained from years of processing, handling, and storing them at Rocky Flats Environmental Technology Site and other sites within the DOE Complex with no "reactive" incidents demonstrates that pyrochemical salts do not meet the definition of reactivity as described by sections (1), (5), (6),(7), and (8). However, due to the possible presence of calcium, sodium, potassium, or magnesium metal which are known to generate hydrogen when mixed with water, sections (2), (3), and (4) were reviewed further.

The EPA definition of "water reactivity" is obscure, so efforts were made to clarify the meaning. EPA laboratories in Cincinnati and Las Vegas were contacted and it was

determined that the concern was twofold:
1. the amount and rate of hydrogen generation (i.e., whether the rate and volume of hydrogen generation is so large that it would blow off a barrel lid by pressure alone), and
2. the violence of the reaction (i.e., whether the reaction generates enough heat to cause an explosion).

Based upon this clarification, the salts were evaluated for water reactivity. Surrogate testing was performed using pure magnesium metal and salts which were produced by the molten salt extraction process without plutonium. Hydrogen gas bubbled slowly off the surface of the salt and the reaction was not "violent" and did not create enough heat to ignite the hydrogen that was produced. Operating experience was considered in addressing whether enough hydrogen would be generated to blow the lid off of the container. There are no documented cases at RFETS or other DOE sites of bulging drums or explosions relating to containers of any pyrochemical salts. D003 was removed from the Molten Salt Extraction (MSE) salts. The packaged salt would have to be immersed in water in order to generate sufficient quantities of hydrogen. For this to occur a pathway for the water to enter the container would have to be present and in such a case the drum would then be "vented" which would prevent it from becoming over-pressured. While the surrogate testing along with process knowledge removed the D003 code from the MSE salts, the remaining pyrochemical salts were considered to be reactive due to the presence of calcium and sodium metals which are known to react violently with water.

State of Colorado Clarification of Definition of Reactivity

The above information was presented to the State of Colorado in April 1994. During the presentation, the Colorado Department of Public Health and the Environment (CDPHE) provided additional clarification concerning the criteria used to determine whether a waste exhibits the characteristic of reactivity, as summarized below:

RCRA reactivity is a condition that requires the following three key elements:
1. a high reaction rate
2. containment of the reaction, and
3. an ignition source

and that there is a high probability of these elements occurring at the same time. Furthermore, reactive wastes are those that require aggressive management, such as being covered with oil or kerosene to shield the waste from contact with air or moisture, from the point of generation through storage and treatment.

Reevaluation

Additional objective criteria were developed to reevaluate the remaining pyrochemical salts which were considered hazardous for the characteristic of reactivity.The additional criteria included:
1. According to the Colorado Department of Public Health and the Environment, for a waste to be considered reactive, the reaction must be immediate. This presupposes that the reaction is vigorous and that a primary indicator of the vigorous nature of the reaction is a dramatic increase in temperature (e.g., a highly exothermic reaction) and, under contained conditions, a concomitant, significant rise in pressure. Do the containers during storage, or representative samples during testing, exhibit rapid temperature increase, indicating a highly exothermic reaction is occurring?
2. Are conditions which would increase the rate of reaction present, i.e. gas containment, temperature, ignition source, pressure increase, photosensitivity, presence of catalyst?
3. Since the residues and wastes are managed for the pyrophoricity of the Plutonium, what is the difference in the way these would be managed if they were removed from RCRA regulation?

Based upon these criteria and the clarification provided by CDPHE, the remaining salts were reevaluated for reactivity.

The Electrorefining salts (ER) and the pyroredox salts could contain sodium and potassium metal that was produced during the electrorefining process. However, there is a low probability that unreacted metal is still present in the salts. The CDPHE criteria that there be a high probability of a high reaction rate and a source of ignition occurring at the same time is not met because there is a low probability that any unreacted metal would be present. These salts would no longer be considered RCRA reactive. Subsequent sampling and analysis of the ER salts supported the process knowledge.

The DOR salts and the salt scrub salts remain reactive because of the presence of relatively large "buttons" of calcium metal or entrained cerium . These containers are "aggressively" managed in specially designed buildings, protecting the residues from the weather, water, and uncontrolled movement. Personnel access to the containers is strictly controlled. If containers of these salts were placed in an uncontrolled storage location, there is an increased probability that the three conditions of reactivity as defined by CDPHE would occur at the same time.

COST SAVINGS FROM THE RECHARACTERIZATION OF PYROCHEMICAL SALTS

The action to remove the D003 (reactivity) code resulted in the removal of 3169 containers from hazardous waste regulation. Utilizing an economic modeling technique developed by the Operations and Waste Management Organization at DOE's Rocky Flats Field Office, the cost savings/cost avoidance associated with the management of the pyrochemical salts as non-RCRA regulated were calculated.

It is estimated that the cost savings range between a minimum of $6.9 to a maximum $20.1 million over a 26 year period, depending upon which of the pyrochemical salt management options is used. Management options include construction of: 1) a baseline actinide separation treatment facility; 2) a salt repackaging facility; or 3) a separate salt processing facility. Savings were calculated based on reduced costs for storage, inspection, consolidation, permitting, treatment, and characterization for each management option.

Table I illustrates the results of the cost calculations for management of the pyrochemical salts over the 26 year period. The three management options for RCRA hazardous salts as well as the costs for management as non-hazardous are presented. Table II depicts the overall cost savings for managing the salts as non-RCRA hazardous as compared to the three options for RCRA hazardous salts.

FUTURE DIRECTION

First, Rocky Flats Environmental Technology Site now uses the objective criteria developed for the pyrochemical salts to define any "reactive" hazardous waste at RFETS. This provides a consistent basis for managing "reactive" hazardous waste at RFETS.

Second, RFETS issued a letter to the other DOE sites explaining the approach used and suggesting that the same objective criteria used to define a "reactive" waste at RFETS should be used throughout the DOE complex. The rationale for this is to minimize confusion and facilitate a consistent basis for managing these salts complex-wide.

Third, RFETS provided this information to a joint DOE-Headquarters/Environmental Protection Agency (EPA) Process Knowledge Project Team that is looking at developing nationwide guidance on the proper use and documentation of process knowledge to characterize waste throughout the DOE complex. Depending upon the scope of their guidance, RFETS has recommended that the objective criteria developed at RFETS be included in the guidance document to help the DOE complex achieve a consistent approach to managing its "reactive" hazardous wastes.

A MODEL FOR PREDICTING CHARACTERIZATION REQUIREMENTS AND FUTURE ANALYTICAL LABORATORY LOADS FOR ALPHA-CONTAMINATED WASTE*

C.D. Leigh
M.S.Y. Chu
Sandia National Laboratories
Albuquerque, New Mexico

ABSTRACT

Regulatory compliance and effective management of TRU waste in the United States requires a knowledge of the constituents present. With limited resources, the United States Department of Energy (DOE) needs a cost-effective characterization program.

In addition, the DOE needs a method for predicting the present and future analytical requirements for waste characterization so that it can provide facilities to meet the need. Thus, a model that can be used to predict the present and future waste characterization needs, using current knowledge of the TRU inventory, has been developed.

INTRODUCTION

Transuranic wastes have been generated, packaged, and stored at the United States Department of Energy (DOE) facilities, under a constantly changing climate of rules and regulations, for the past fifty years. Transuranic waste or TRU is defined as waste that contains more than 100 nCi/g of alpha-emitting, transuranic isotopes with half-lives greater than twenty years. Through the years, the rules and regulations in place at the time dictated the extent to which the wastes were characterized. Today, the DOE has about 300,000 m3 of transuranic waste stored at eleven facilities across the United States (1). This is equivalent to over one million 55-gallon (0.21 m3) drums of TRU waste. Using today's standards, only a small percentage of the DOE's transuranic waste inventory is believed to be adequately characterized. Continued storage, potential treatment, and ultimately disposal of transuranic waste will require a substantial characterization effort. Characterization is needed to safeguard worker health and safety and the environment, to protect and optimize potential treatment processes, to meet environmental regulations, and to satisfy the waste acceptance criteria for the disposal site. However, because TRU waste contains relatively high concentrations of alpha-emitting isotopes, characterization efforts must be conducted in specially designed facilities that limit worker exposure to alpha-contaminated waste.

The U.S. DOE is sponsoring the development of a model that can be used to predict the potential characterization requirements for TRU waste in the United States given a variety of possible management scenarios for the waste. The model has a three-fold value: first as a planning tool, second as a communication tool, and third as a decision tool. As a planning tool, the model will provide the DOE with information about the size, type, cost, and schedule required for transuranic waste characterization facilities given a variety of assumptions about the ultimate fate of the waste. As a communication tool, the model will provide the DOE with information about the consequences of any agreements concerning TRU waste characterization that may be reached with the regulatory agencies involved. As a decision tool, the model will provide the DOE with information that will help it decide between building new or retro-fitting old waste characterization facilities, or using commercial facilities.

OBJECTIVE

The model discussed in this paper is designed to provide an estimate of present and future analytical requirements for TRU waste characterization. It provides a defensible technical basis for predicting the amount of sampling and analysis that will be required for the TRU waste inventory in the United States over the next five to fifty years. The model is flexible and can account for the planned management scenario for the waste inventory and also can account for the current state of knowledge about the waste. In this context, "management" encompasses all of the steps involved from the time a material becomes a waste until it is placed in a permanent disposal site. "Knowledge" encompasses any analytical data pertaining to the waste and any information about the process that produced the waste.

TECHNICAL APPROACH

Sandia National Laboratories in Albuquerque, New Mexico has proposed a strategy for analysis of potential characterization needs for TRU waste that involves the following steps:

1. the processes involved in managing a TRU waste stream (waste management scenarios) are identified;
2. the analytical tests required to characterize the waste for the management processes identified are determined;
3. the number of samples required for each analytical test in the least-informed case, without the benefit of process knowledge or existing analytical data, is calculated;
4. the quality and quantity of the existing knowledge about the waste stream (both process knowledge and analytical data) is determined;
5. the number of samples required for each analytical test in the least-informed case is reduced to reflect the quality of existing data;

6. the number of samples calculated in step (5) is recorded in a matrix format, where the rows correspond to the analytical tests, and the columns correspond to media and sample radiation handling protection classes; and
7. the number of tests in each analytical test/media class category is translated into an equivalent amount of laboratory space.

These steps represent the major components of the theoretical model being developed as a tool to estimate future analytical requirements for the TRU waste inventory. The following discussion concerns an example calculation designed to demonstrate each of the steps for solidified process residues at Rocky Flats.

ANALYTICAL REQUIREMENTS FOR SOLIDIFIED PROCESS RESIDUES AT ROCKY FLATS

Transuranic waste has been generated at the Rocky Flats Plant (RFP) in Colorado in past years from routine production support operations for the U.S. nuclear weapons program. Production operations at RFP were suspended in 1990. The primary radioactive contaminant in the waste streams is plutonium. The primary hazardous contaminants are heavy metals, organic solvents, and pyrochemical salts. Prior to 1986, RFP TRU wastes were shipped out of Colorado for storage. In 1986, waste shipments to storage were terminated, and TRU waste has been accumulating at RFP since then.

Six RFP waste streams were chosen in order to demonstrate the theoretical model. The six waste streams are all solidified process residues from RFP (2). Altogether the six waste streams represent 1235 drums of transuranic waste, a total volume of 260.3m3. Of the 1235 waste containers, 27 were generated between 1970 and 1986 and 1208 were generated between 1986 and 1993 as shown in Table I.

The Waste Management Scenario

Management of a waste typically begins with its designation as either high-level, low-level, or transuranic waste as well as its designation as either hazardous or non-hazardous waste. Further, management includes a combination of storage, treatment, and transportation steps leading ultimately to disposal of the waste. The six waste streams chosen for this analysis have been designated by RFP personnel as TRU waste. Three of the waste streams are believed to contain both hazardous and radioactive components (ID Nos. RF-W010, RF-W013, RF-W038); three contain only radioactive components (ID Nos. RF-T010, RF-T013, RF-T038).

The DOE's current management strategy for these waste streams involves disposal at the Waste Isolation Pilot Plant (WIPP), a deep geologic repository in southern New Mexico. The repository is still under development, and until it opens, the waste will continue to be stored at the RFP site in Colorado. When WIPP opens, the waste will be shipped in containers designed specifically for transportation of transuranic wastes. It is believed that the six waste streams chosen for this analysis will not require any treatment before they can be shipped and placed in the repository.

The Analytical Tests Required

Depending on the management scenario selected, the knowledge required about a waste will vary. For example, the characterization activities required to support transportation of a waste may be different from those required to support a given treatment technology for the waste. As a result, the types of chemical or radiological analyses required will vary with the management scenario.

Given the DOE's current management strategy for TRU waste, none of the six waste streams chosen for this demonstration analysis will require treatment. Consequently, characterization activities will focus on gathering knowledge to support storage, transportation, and disposal of the wastes. The DOE has issued a tentative plan for characterization of these waste streams. In its plan (3), the analytical tests required are a function of a group number assigned to the waste stream. Group 1 includes those waste categories for which the original materials used are the predominant component of the final waste. Group 2 waste categories include waste that results from a specific process or a final treatment option. The Group 3 waste category includes mixtures of Group 1 and Group 2 waste categories. Group 1 waste includes combustibles and noncombustibles, graphite, filters, Benelex and Plexiglass, firebrick and ceramic crucibles, leaded rubber, metal, glass, and supercompacted waste. Group 2 waste includes inorganic waste water treatment sludge, organic liquid and sludge, solidified liquid, inorganic process solids and soil, cation/anion exchange resins, and pyrochemical salts. Group 3 waste includes both solid and solidified materials. The group numbers assigned for the six waste streams are shown in Table I. All of the waste streams chosen for this analysis have been

assigned to either group 2 or 3 for sampling and analysis. Table II identifies the suite of analytical tests that will be performed for wastes assigned to each of the groups.

The Number of Samples Required in the Least-Informed Case

Once the suite of analytical tests required to characterize a waste stream for the management scenario under consideration has been established, the number of samples needed for each analytical test in the least-informed case is calculated. The least-informed case refers to a circumstance where no analytical data and a minimal amount of process knowledge are available regarding the analyte of concern. The number of waste samples required for characterization of a waste stream in this case represents a maximum amount of sampling and analysis for the waste. The amount and quality of existing analytical data or process knowledge are not factors in determining the number of samples.

An algorithm for calculating the number of samples was developed for this application. The algorithm is a statistical function of the waste volume, the number of containers, the homogeneity of the waste form, the precision of the analytical method, and the proximity of the expected result to the threshold limit of concern. The first portion of the algorithm is based on standard statistical theory for confidence interval estimation to arrive at an initial value for the number of samples needed. To address other sources of uncertainty affecting waste characterization (like homogeneity of the waste form), a set of factors based on expert judgement were used. Computations for the maximum number of samples (least-informed case) for specific analytic test/waste matrix combinations were performed using the algorithm. Results for the six RFP waste streams are shown in Table III.

Evaluating Existing Data Quality

The least-informed case can be thought of as an upper bound on the number of analyses that need to be performed. If existing information is taken into account, the number of analyses required can be reduced. TRU waste inventories, both current and projected, have been described with unknown degrees of accuracy in several databases and reports (4), (5). Characterization to date has relied primarily on process knowledge, while a minimal amount of characterization has been based on sampling and analysis. Both process knowledge and sampling and analysis will be needed to adequately characterize the inventory of TRU waste.

Four reduction factors have been developed for this application. The reduction factors scale the number of analyses required down from the maximum (least-informed case), depending on the presumed quality of existing data for the waste stream and the analyte of concern. The reduction factors and brief descriptions of the quality levels are given in Table IV.

In general, there is a correlation between the amount and quality of information about a waste and the time period that the waste was generated. Records for TRU wastes generated before 1970 are very poor. As environmental standards changed through the years, the quality of information recorded for the wastes increased. Working with site personnel, four quality time periods for RFP wastes were established. Containers in the six RFP waste streams were assigned data quality levels based on the time period in which they were generated. Wastes generated prior to 1970 (Time Period 4) were assigned to quality level four. Wastes generated between 1970 and 1986 (Time Period 3) were assigned to quality level three. Wastes generated between 1986 and 1993 (Time Period 2) were assigned to quality level two, and wastes generated after 1993 (Time Period 1) were assigned to quality level one.

The Number of Samples Required

Once the quality of existing data has been determined, the number of samples required in the least-informed case is reduced to reflect the benefit that may result from using existing analytical data and/or process knowledge to guide the sampling and analysis program. The results for the six RFP waste streams are shown in Table V.

The Analytical Matrix

The number and types of analytical tests predicted for a waste stream are stored in matrix format as shown in Table VI. Rows in the analytical matrix correspond to analytes, categories of analytes, or test methods identified as important for characterization of the six RFP TRU waste streams. Columns in the analytical matrix are divided into media classes. The columns are further divided into sample radiation handling classes. For example, distinctions are made for samples that must

be handled in a hot cell or a glove box rather than on a laboratory bench with a hood.
A media class includes all physical forms that are amenable to laboratory preparation using the same processes. Here, the same processes means the same facilities and processing equipment. Minor changes in glassware, consumables, and/or reagents will not constitute a different process unless there is a significant effect on the required processing space, storage space, or equipment required for safe and effective handling.
The first media class is a group of waste matrices which can be prepared for analysis in a laboratory using the same facilities and equipment that are used for standard methods of analysis such as those specified in EPA SW-846 (6) or other consensus compendia, as applicable to the analyte. The second media class is a group of waste matrices that must be prepared for analysis using demonstrated methods which require facilities or equipment which are known but different from those required for the standard methods or adaptations falling in the first media class. The third media class is a group of waste matrices which cannot be prepared using standard or demonstrated methods. A methods development effort is likely to be required, and the facility and equipment needs must be assumed from waste matrix characteristics. Based on information given by the site, it is assumed that all of the samples taken from the six waste streams must be processed in a glove box. Further, all of the samples have been assigned to the second media class.
Also, a distinction has been made in Table VI between analyses for high concentrations of a compound and low concentrations of the compound. Equipment used to analyze samples containing high concentrations of a compound can become contaminated, making detection of low concentrations of the compound difficult. Therefore, separate, equivalent pieces of equipment are frequently used for analysis of high-concentration and low-concentration waste samples. Concomitantly, the laboratory space needed to process both high and low concentration samples will be greater than that required to process either high or low concentration samples. The high and low designations were made by examining the hazardous constituents listed for the waste streams by the site.
TABLE VI
The Laboratory Space Required
Summing the rows and columns in the analytical matrix can provide the DOE with valuable information about its intended characterization program for TRU waste. For example, for the six RFP waste streams described above, 600 waste samples are needed for characterization of the waste. This is equivalent to sampling 9% of the 1235 waste containers. Applying the model to the entire inventory of TRU waste will tell the DOE how much sampling and analysis is required for characterization of its TRU waste. Application of the model to the entire DOE inventory of TRU waste is scheduled for completion in October of 1995.
For the purposes of this paper, the project staff considered a very crude extrapolation of the results for the six RFP waste streams to the inventory of TRU waste intended for disposal at WIPP (approximately 800,000 drums or 168,000 m3). The extrapolation is made in order to demonstrate the types of results that are expected from this program. The reader is cautioned to remember that the six RFP waste streams on which the extrapolation is based are not particularly representative of the DOE TRU waste inventory. For example, none of the containers chosen were generated before 1970, and very few of the containers were generated before 1986. In addition, all of the containers chosen are contact-handled, and there is little or no fission product activity. In reality, the DOE has a large volume of TRU waste that was generated before 1986. It has remote-handled TRU waste, and at some of the DOE sites, fission products are present in the waste. Overall, extrapolation of the current results to the entire DOE TRU waste inventory is likely an underestimate of the DOE's characterization needs for TRU waste.
If 600 samples are required for 260.3 m3 of waste, an extrapolation indicates that 387,244 samples would be required for the 800,000 TRU waste containers intended for disposal at WIPP. Therefore, 387,244 samples would be sent to the laboratory for analysis. Of the 387,244 samples, 89,066 samples will be analyzed for volatile organic compounds, 89,066 samples will be analyzed for semi-volatile organic compounds, 46,469 samples will be analyzed for polychlorinated biphenyls, 85,194 samples will be analyzed for toxic elements, and 77,449 samples will be analyzed for mercury.

Depending on the time schedule imposed on the characterization program, the size of the laboratory facility required can be determined. For this example, it is assumed that the WIPP disposal site will open in 1998 and characterization will take place over a five year period. An estimate of the number of glove boxes and chemical analysis units for volatile and semi-volatile organic compounds is summarized here.
Analysis for volatile organic compounds by EPA SW-846 methods requires purge-and-trap extraction of the waste samples followed by measurement using a gas chromatograph (GC) or gas chromatograph/mass spectrometer (GC/MS). The extraction and analysis can be done at an average rate of about one sample every two hours. Based on working one 12 hour shift a day for 250 working days per year, sample through put is 6 samples a day, 1500 samples a year, or 7500 samples in five years. Twelve extraction/analysis units would be needed to perform 89,066 analyses in five years. Each unit should fit in a standard 4 ft. (1.22 m) by 8 ft. (2.44 m) glove box. From this information, the amount of laboratory space required for analysis of volatile organic compounds can be estimated.
Analysis for semi-volatile organic compounds by EPA SW-846 methods also requires extraction of the waste samples and analysis by GC or GC/MS. These procedures, however, permit the extraction and analysis to be done at different locations and different times. Extractions can be done at the rate of about 10 per day per glove box or about 2500 per 250-day working year or about 12,500 in five years. Eight glove boxes would be required to extract all 89,066 samples in five years. The GC or GC/MS analyses can be done at the rate of about 10 samples per 12-hour shift per GC or GC/MS unit. Based on one 12-hour shift per day and 250 working days per year, the number of GC or GC/MS units required is the same as the number of glove boxes for extractions.
The EPA SW-846 method for PCBs has requirements that are very similar to those for semi-volatile organic compounds. Thus, the same through put rates (12,500 samples in five years) can be assumed for semi-volatile organic compounds. The result is that four extraction glove boxes and four GC or GC/MS units will be required to perform the 46,469 analyses in five years working 250 days per year. Altogether, for the organic analyses, twenty-four glove boxes and twenty-four GC or GC/MS units would be required to complete the characterization program for organic compounds.
The toxic metals of interest are the RCRA TCLP metals (As, Ba, Cd, Cr, Hg, Pb, Ag, Se) and Ni and Tl. Samples are digested and the metals determined by Inductively Coupled Plasma (ICP) spectroscopy or Atomic Absorption (AA) spectroscopy. Mercury is analyzed by a different method than the other metals and will be considered separately below. It is estimated that samples can be digested by SW-846 methods at the rate of about 4000 samples per year per glovebox. If ICP is used for analysis, about 24,000 samples per year can be analyzed for the nine metals (not Hg) listed above. This assumes a simultaneous, multi-element ICP instrument is used. It will thus require five gloveboxes to digest 85,194 samples in five years and one ICP spectrometer to analyze the 85,194 digestates in five years.
If AA is used for analysis, each metal determination becomes a separate analysis. Thus each sample requires nine analyses to determine the nine metals of interest. Throughput for Ca, Cd, Cr, Pb, Ag, Ni, and Tl is estimated to be 24,000 analyses (3,430 samples) per year per AA. As and Se require either different or additional processing. Estimated throughput for these two elements is about 10,000 analyses (5000 samples for As and Se) per year per AA. Using these assumptions and estimates, it will require nine AA spectrometers to analyze 85,194 samples for these nine metals in five years.
Determination of mercury by SW-846 methods requires sample digestion followed by analysis by manual cold vapor atomic absorption. About 8000 samples can be digested per year per glovebox and about 8000 samples can be analyzed per year per AA spectrometer. based on these assumptions, it will requires four digestion glovebox and four AA spectrometers to complete analysis of 77,449 samples for Hg in five years.
DISCUSSION
Implementation of the model described above has a three-fold value for the DOE. First, the DOE is interested in a planning tool. By changing the assumptions input into the model, the DOE can see the impact of a variety of "what-if" scenarios. To demonstrate, the assumption about the quality level of existing data for the six RFP waste streams will be challenged in this discussion. The results presented above were calculated assuming two quality levels for data depending on the time period in

which the waste was generated. However, the quality of existing data, both process knowledge and analytical data, and the extent to which existing data can be used in lieu of further characterization is currently a subject of debate between the DOE and the regulatory agencies.
A total of 600 samples would be required for the six RFP waste streams assuming two quality levels that change with time. If the assumption about data quality in this example is in error, the number of samples required would change. For instance, if it is determined that the quality of data at RFP is Level 1 for all six waste streams, the number of samples required would drop to 141. On the other hand, if the regulatory agencies decide that all of the existing data for RFP is poor (Level 4), the number of samples required would increase to 1908. Extrapolating these numbers to the 800,000 drums of waste intended for disposal at WIPP would mean only six extraction/analysis units would be required in the best case (Quality Level 1) and seventy-seven extraction/analysis units would be required in the worst case (Quality Level 4).
This insight highlights the second value of the model which is communication. Estimates generated using the model can be used to communicate the consequences of proposed characterization programs to the regulatory agencies and the public. In this example, it is clear that the extent to which existing data can be used in lieu of characterization significantly impacts the ultimate cost of the DOE's characterization program. This impact can be communicated to the regulatory agencies during negotiations. The DOE is in a much better position to negotiate with the regulatory agencies if it knows the consequences of future programs.
Finally, as a decision tool, the model provides the DOE with information about the need for analytical laboratory facilities. Most of the major TRU waste storage sites in the U.S. have requested funding for additional analytical laboratory space for processing TRU waste samples. Using this model, the DOE can perform a comparative analysis of the need for laboratory space at the various sites. With this information, the DOE can decide how best to meet the need.
CONCLUSION
The model described in this paper provides the DOE with a method for predicting the present and future analytical requirements for waste characterization. It has been implemented in an integrated software package that is connected to a database of information about TRU waste in the U.S. Using this package, the DOE can set guidelines for TRU waste characterization at the sites and allocate resources to meet its waste characterization needs.

A PROPOSED RISK-BASED RADIOLOGICAL CHARACTERIZATION METHODOLOGY FOR SOIL AND SEDIMENT INVESTIGATION DERIVED WASTE
Keith D. Anderson
EG&G Rocky Flats, Inc.
Golden, Colorado
ABSTRACT
Environmental field investigations, accelerated cleanup actions, and construction activities result in the generation of residual materials that may be contaminated with chemical and/or radiological constituents. Residual materials/waste may include drilling mud, soil and sediment drill cuttings, water and soil treatment residues,

and excavation spoils, and may be referred to as environmental media. The management of such material must be protective of human health and the environment, and comply with all applicable regulations.

At the Rocky Flats Environmental Technology Site (RFETS), a Department of Energy facility managed and operated by EG&G Rocky Flats, Inc. in Colorado, approval was obtained from Region VIII Environmental Protection Agency and the Colorado Department of Public Health and Environment to characterize soil and sediment investigation derived materials/waste (IDW) for chemical contaminants using a risk-based determination. In order to ensure that a comprehensive waste characterization is conducted for all identified contaminants in the IDW, a determination must be made concerning the radiological constituents present. Presently at RFETS, radiological waste characterization is performed according to the No-Radioactivity-Added (NRA) Program, in accordance with the Performance Objective for Certification of Non-Radioactive Hazardous Waste as required by the Department of Energy Office of Waste Operations, Environmental Restoration and Waste Management (EM-30). The NRA Program requires the radiological waste characterizations be performed using process knowledge for non-liquid and/or non-homogeneous materials that are suspected of volume/bulk contamination. Using process knowledge as the sole method for the radiological characterization of IDW and similar environmental media precludes the use of a significant amount of analytical data which has been or may be collected in association with the waste materials.

An alternative methodology for the radiological characterization of environmental media has been proposed which takes advantage of best available technology and statistical analysis of sampling data populations. This approach is similar to the risk-based characterization for chemical contaminants that was developed and implemented for IDW at RFETS. The proposed method stresses the utilization of analytical data results to perform a radiological characterization of the waste material. The method incorporates a conservative sampling data screening technique which compares results against background screening levels for radioisotopes of concern. Sampling data results greater than the established background screening levels are compared to human health risk-based concentration values. Material which exhibit an unacceptable risk are characterized as radioactive. With the implementation of this proposed method, a significant reduction in the amount of low level and mixed waste resulting from environmental restoration and construction activities will be realized as compared to the more conservative methodology.

INTRODUCTION

RFETS is a DOE facility managed and operated by EG&G Rocky Flats, Inc. The primary mission of the Site, from its inception until the early 1990s, was to produce metal components for nuclear weapons. Both radioactive and non-radioactive wastes were generated during the research and production processes, and past waste handling procedures involved both on-site storage and disposal of wastes. In 1992, the primary mission of RFETS changed from weapons production to stabilization of the radioactive material remaining on the site and environmental restoration.

In the late 1980's, DOE/Rocky Flats Field Office (RFFO) began environmental investigation to determine the extent of contamination at the site. As a result of these investigations, by 1993 a backlog of over 4,000 drums of IDW had accumulated at the site. Originally the IDW generated during environmental investigations was to be stored near its point of generation, and disposed of in accordance with the Record of Decision (RDO) for each individual Operable Unit (OU). However, due to the lengthy investigation period leading to each ROD, alternative means of handling the IDW were required. The alternative selected was to package the IDW and manage the drums according to appropriate waste handling requirements.

Purpose

This paper presents a proposed methodology for the radiological waste characterization of soil and sediment IDW utilizing regulatory guidelines and risk-assessment methodologies. The proposed methodology includes a proceduralized technique that utilizes site historical information, i.e. "process knowledge", available sampling data, a background comparison, and risk-assessment equations to characterize the radiological component of the soil and sediment IDW. A risk-based methodology for the characterization of chemical nonhazardous and hazardous waste has previously been developed.

Background

An agreement was reached between EG&G, DOE/RFFO, and the Colorado Department of Public Health and Environment (CDPHE) in February 1994 concerning the waste compliance issues related to the IDW drums. Inclusive to this agreement was that a waste characterization of the drums would be performed for the radioactive constituents. EG&G indicated that the radiological waste characterization was to be performed according to the Performance Objective for Certification of Non-Radioactive Hazardous Waste (herein referred to as the Performance Objective), as required by the DOE Office of Waste Operations, Environmental Restoration and Waste Management (EM-30). The RFETS No-Radioactivity-Added (NRA) Waste Verification Program (herein referred to as the NRA Program) was developed in response to the Performance Objective. The NRA Program presently has limited approval for the application to surface contaminated and suspect bulk/volume liquid-homogeneous contaminated waste (DOE/EM-30 Memorandum to DOE/RFFO 1994). However, except for the use of process knowledge, the approval did not extend to media similar to the soil and sediment IDW, except for the use of process knowledge.

DOE Headquarters (EM-30) will allow RFETS to amend the approved NRA Program to include non-liquid and/or non-homogeneous materials that are suspected of volume/bulk contamination. Therefore, a proposed methodology which provides for a risk based radiological characterization of the soil and sediment IDW will be submitted to DOE/EM-30 as a revision to the NRA Program.

REGULATORY GUIDANCE

The scope of the Performance Objective includes those wastes originating in Radiologically Controlled Areas (RCAs) or areas where there is a potential for radiological contamination. Such areas have also been defined as Radioactive Material Management Areas (RMMAs). Soil and sediment IDW are subject to the Performance Objective in that historical information concerning the operation of RFETS indicates environmental contamination by radioactive materials. According to the DOE, the IDW drums must meet the requirements for unrestricted release in order to be considered for non-radioactive disposal. The Performance Objective defines unrestricted release as:

> A release of property (e.g., waste), based on a formal, documented decision reflecting risk-based standards and associated implementing procedures, that the property must be utilized, treated, or disposed of by any party without concern for radioactive content.

In order to classify the material as available for unrestricted release, a program must be established which clearly defines how the Performance Objective is to be met. The program must include process knowledge, radiological survey, sampling, and analysis, shipping and handling, quality assurance, training, and records retention requirements. As the RFETS NRA Program has been approved as meeting these requirements, the proposed risk-assessment methodology will be amended to the existing program. The focus of the proposed methodology regards sample analysis and data management, a background comparison, and the risk-based analysis in the characterization of the IDW.

Regulatory guidance available for the radiological waste characterization of environmental media and materials similar to the IDW directs the generator to 1) identify the bulk/volume radioactive contamination concentrations, and 2) perform a risk-based assessment that quantifies the contributing dose to the public and the environment due to the radioactive constituents. This is seen in DOE Orders, Environmental Protection Agency (EPA) remediation guidance, and proposed rulings by DOE and EPA for regulatory requirements. Although the Performance Objective does not specifically allow for the release of waste characterized by risk-based levels, DOE/EM-30 does recognize the ongoing effort to generate such release limits which have an insignificant impact to the public health and the environment (DOE Performance Objective, 1991).

The EPA has provided guidelines for the cleanup of radioactively contaminated sites in The Radiation Site Cleanup Regulation - Preliminary Draft (EPA, 1994) The preliminary draft of Title 40 Code of Federal Regulations (CFR) Part 196 provides detailed guidance concerning remediation of radioactively contaminated sites. The proposed rule sets standards that limit the radiation dose received by members of the public from a formerly contaminated site. The limit is an annual committed effective dose of 15 mrem/yr in excess of natural background radiation levels for 1000 years after completion of the cleanup. The annual committed effective dose of 15 mrem/yr corresponds to a lifetime excess cancer risk of less the 3 x 10-4 over a

thirty year exposure period (EPA, 1994). The proposed dose limit is intended for the protection of the reasonably maximally exposed (RME) individual in the population at risk. Through the application of conservative, multiple exposure pathways and land use scenarios, a worst case contributing dose can be derived. The derivation of the contributing dose demonstrates the application of the As Low As Reasonably Achievable (ALARA) concept, which becomes inherent to the site cleanup process. The proposed ruling applies to radiologically contaminated environmental restoration clean-up actions. As such, it would be appropriate to apply the same requirements to the development of release limits for bulk/volume materials containing residual radioactive materials, the two subjects being essentially the same.

The Department of Energy Order 5400.5, Radiation Protection of the Public and the Environment, contains guidance concerning the generation of risk-based soil guidelines. The Order specifies the use of the Residual Radioactive Material (RESRAD) computer code to develop the risk-based soil guidelines. The code applies conservative multiple pathways with a long term exposure, residential use scenario. Derived soil guidelines are to be based upon a contributing dose of 100 mrem/yr, excluding background and medical contributions, with the application of ALARA. DOE's proposed rule 10 CFR 834, Radiation Protection of the Public and the Environment, Subpart D, Release of Property Having Residual Radioactive Material, continues the application of authorized limits that are arrived at through dose assessment techniques. The primary receptors for the residual radioactive material are isolated to the most probable receptors (the general public) and doses are not to exceed primary or supplemental limits. The application of worst plausible use and actual/likely use scenarios are also required. The dose limit is initially set at 100 mrem/yr with the application of ALARA. The proposed ruling stresses a reduction in dose to less than/or equal to 15 mrem/yr.

The EPA provides further guidance in the development of Preliminary Remediation Goals (PRGs) in the guidance for conducting baseline risk-assessment for Superfund sites (EPA, 1991). The risk-based PRGs are calculated for the identified contaminants of concerns that are suspected or known to be present at a site. These may be based on multiple use scenarios, with the site specific information supplementing the calculations. Exposure assumptions, toxicity information, and the development process of the calculations must be clearly stated. The methodology of the EPA guidance on the calculation of PRGs is very similar to DOE guidance in that worst case exposure scenarios are clearly established, with exposure pathways and parameters defined within conservative assumptions.

IDW RADIOLOGICAL CHARACTERIZATION PROCESS

The remainder of this paper provides a descriptive of the method for performing the radiological risk-assessment of the soil and sediment IDW. Using this method, radiological concentrations in soil and sediment IDW may be characterized either by analytical results from corresponding environmental investigation samples or by drum-specific samples. The IDW drums covered by the proposed process have previously been chemically characterized to determine if they were RCRA hazardous, or nonhazardous. The results of the IDW Radiological Characterization will be combined with this information to complete a comprehensive waste characterization.

Radionuclide Information Determination

Prior to the background comparison or the risk-assessment, a determination of the available radioanalytical data will be made. A decision will be made as to the suitability of the available data, or lack thereof, to perform the radiological characterization of the soil and sediment IDW. Information will be considered sufficient when each container has at least one validated analysis for each of the selected radionuclides or when it is determined that any missing data do not impact the characterization. It is at this point that process knowledge will play a key role in the suitability determination. As an example, if historical information does not indicate that the location from which the IDW originated is in a source area (i.e. an area not considered to be radiologically contaminated), the material will be considered "clean". However, consideration must be lent to determining the appropriateness of the assumptions made regarding process knowledge. It is essential to verify that the process knowledge is complete and reliable, as any misinformation could lead to a fallacy concerning the radiological characterization.

If sample and IDW drum associations are available, laboratory analysis results will be obtained electronically from the Rocky Flats Environmental Data System (RFEDS). For IDW drums with only one analytical result, that value will be used to

characterize the drum. If there is more than one reported analytical result for a particular radionuclide, the average concentration will be calculated. The average concentration is calculated by summing the results (both negative and positive) for the radionuclide and dividing by the number of results.

Background Comparison

In order to determine if a material may be suspect of contamination, a comparison will be made to an established background concentration for each radionuclide. This effort will determine if the soil and sediment IDW exhibits the potential to be radioactive waste. The Performance Objective defines a radioactive waste as:

> Contains a measurable increase in radioactivity (at a statistically defined confidence interval) above background in volume or bulk resulting from DOE operations except for waste specifically exempted by the EPA, DOE, or NRC regulations.

and,

> All procedures and criteria must be aimed at determining is there is any measurable increase in radioactivity (at a statistically defined interval) above background from DOE operations.

The Performance Objective provides criteria for determining the radioactivity of materials similar to IDW as follows:

> For potentially radioactive soils, comparing analytical results for the suspect soil to analytical results for native soils from areas well outside suspected contamination areas.

Background radiological concentrations for the soil and sediment IDW have been determined for the Rocky Mountain Region surface soils. Background surface soil samples were collected along the Front Range and in the vicinity of the Rock Creek Drainage area. RFETS is located to the east of the Front Range. The Rock Creek Drainage area is located in the northwest corner of Site, in the Buffer Zone. The prevailing winds for RFETS are from the northwest, inferring a nominal or imperceptible impact to the sampling locations due to their location upwind from RFETS. This infers a limited redistribution of contaminants from Site operations. The soil structure and the texture of the selected sampling sites are similar to that found in many locations throughout RFETS. This serves to duplicate the presence and/or mobility of analytes that would be affected by soil and sediment IDW characteristics.

The Rocky Flats Method (RFM) was used to collect the surface soil samples. The RFM involves the collection and compositing of ten discrete soil samples collected within a polygon area, using a sample jig and scoop. The jig collects with a sample configuration of 10 cm x 10 cm x 5 cm deep. This method allows for the collection of undisturbed soils, preserving the surface soil matrix. This allows for the actual fate and transport mechanisms of the contaminants (actinides, naturally occurring radioactive material, and fission fragments) to be preserved.

Samples collected as part of the background surface soil sampling effort were submitted to procured Vendors for radiochemical analysis. Laboratories (i.e., Vendors) providing analytical services to RFETS are required to meet specific minimal detection criteria and laboratory protocol (GRRASP, 1991).

The Performance Objective requires that defined confidence intervals be established for background. The application needs of the proposed method are to establish radionuclide specific concentration values which can be stated to contain the population mean with a high degree of confidence. The purpose of the background comparison is not to predict the upper limit of the event, i.e. the radionuclide specific concentration, but to establish what is representative of the population with some level of confidence. A 95% confidence level is a reasonable representative of a normal population, and is expressed as the mean of the population of sample size, n, plus two standard deviations, s.

The background surface soil sample data is presented Table I, Native Background Surface Soil Values for IDW Radiological Characterization. The radionuclide, sample mean, standard deviation, sample number, and upper 95% confidence level values are shown.

Risk Assessment Methodology

A conservative risk assessment methodology is proposed that assumes a long-term residential, multiple pathway exposure to the receptor population. Radionuclide specific Risk Based Concentrations (RBCs) are calculated for direct ingestion of soil, dermal absorption, inhalation of suspended soil, external gamma exposure, and

ingestion of home grown food. A target risk level of 1x10-4 is used for an exposure duration of 30 years (6 yr. childhood and 24 yr. adulthood). Unlike the chemical-specific RBCs, the radionuclide-specific RBCs do not use body weight or averaging time. The radionuclide slope factors used for the risk equations do not require corrections for intestinal absorption and lung transfer efficiency.
Most of the intake parameters are standard default values prescribed by the EPA for long-term residential exposure scenarios. For the chemical risk-assessment, the State of Colorado required that time-weighted averages be used for all pathways in order to account for the subpopulation group of children under the age of 6. This is applied in the factors selected for the radiological risk-assessment. The general exposure factors that are applied to the process are:

- Exposure Duration, child (1-6 yr) (EDc) = 6 yr,
- Exposure Duration, adult (7 yr and up) (EDa) = 24 yr, and
- Exposure Frequency (EF) = 350 day/yr.

The exposure factors for soil ingestion are:

- Oral Intake Factor, soil ingestion (IFo) = 1.26x103 g,
- Soil Ingestion Rate, child (1-6 yr) (IRc) = 0.2 g/day, and
- Soil Ingestion Rate, adult (7 yr and up) = 0.1 g/day.

The exposure factors for dermal absorption of soil; for radionuclides only applies to Tritium, all other listed isotopes are metals and therefore not a dermal pathway; are:

- Dermal Intake Factor, absorption from soil (IFd) = 3.47x104 g
- Skin Area (exposed), child (1-6 yr) (SAc) = 4.6x103 cm2,
- Skin Area (exposed), adult (7 yr and up) (SAa) = 7.10x103 cm2,
- Absorption Factor, soil (AB) = 0.5 (unitless),
- Adherence Factor, soil (AF) = 1.00 mg/cm2/event, and
- Exposure Frequency (EF) = 350 events/yr.

The exposure factors for the inhalation of soil particilates are:

- Inhalation Intake Factor, soil (IFi) = 4.41 x 10-2 g,
- Inhalation Rate, child (1-6 yr) (INc) = 0.73 m3/hr,
- Inhalation Rate, adult (7yr and up) (INa) = 0.83 m3/hr,
- Exposure Time (ET) = 24 hr/day, and
- Particle Emission Factor, soil (PEF) = 4.63 x 103 m3/mg.

The exposure factors for the ingestion of homegrown food (vegetables) are:

- Oral Intake Factor, homegrown food (IFf) = TC*461,160 g,
- Transfer Coefficient, soil-to plant (TC) = radionuclide specific, use Bv or Br,
- Ingestion Rate, homegrown food (IRf) - 1.22 x 105 mg/day, and
- Fraction Ingested, contaminated source (FI) = 0.36 (unitless).

And, the exposure factors for external radiation exposure from soil are:

- External Radiation Intake Factor, (IFe) = 24 yrs,
- Gamma Shielding Factor (Se) = 0.2 (unitless), and
- Gamma Exposure Factor (Te) = 1 (unitless).

Radionuclide specific slope factors that quantify the risk per pCi were selected from the EPAs Health Effects and Summary Tables (EPA 1994). The units for the slope factors are risk/pCi. The more restrictive slope factors for 240Pu, 90Sr, and 233U are used in the risk calculations. Slope factor for 137Cs, 226Ra, and 238U include the contributions from the decay progeny. Radionuclide specific slope factors are shown in Table II, Radionuclide Specific Slope Factors.
The general risk equations are:
(1) Risk = Intake * Slope Factor (SF), with
(2) Intake = Intake Factor (IF) * RBC.

To calculate the target excess individual lifetime risk of cancer (TR):
(4) TR = Intake * SF = (IF*RBC) * SF.
For the following RBC's, the target risk is set equal to 10-4. The Intake Factor (IF) and the Risk Based Concentration (RBC) equations have been developed for the five pathways. The equation for the soil ingestion pathway RBC is:
(5) Soil Ingestion (IFo) = [(IRc)(EDc) + (IRa)(EDa)](EF),
with the RBC calculated as:
(6) RBC Soil Ingestion (RBCs) = (TR)/{[IRc)(EDc) + (IRa)(EDa)](EF)SFo)}.
The equation for the dermal absorption pathway RBC is:
(7) Dermal Absorption (IFd) = [(SAc)(EDc) + (SAa)(EDa)(AB)(AF)(EF)(CF)(Sfo).
The equation for the external radiation exposure pathway is:
(9) External Radiation (IFe) = (ED)[1-Se)](Te)
with the RBC calculated as:
(10) External Radiation (RBCs) = TR/{[(EDc+EDa)(1-Se)(Te)](SFe)}
The equation for the inhalation of soil exposure pathway is:
(11) Inhalation of Soil Particles (IFi) = [(INc)(EDc) +
(INa)(EDa)](CF)(ET)(EF)(SFi)}
with the RBC calculated as:
(12) Inhalation of Soil Particles (RBCi) = [(TR)(PEF)]/{[(INc)(EDc)+
(INa)(EDa)](CF)(EF)(Sfi)}
The equation for the ingestion of homegrown vegetable exposure pathway is:
(13) Ingestion of Homegrown Vegetables (IFh) = [(EDc) + (EDa)](IRf)(FI)(EF)(CF)(TC),
with the RBC calculated as:
(14) Ingestion of Homegrown Vegetables (RBCh) = (TR)/{[(EDc) +
(EDa)](IRf)(FI)(EF)(CF)(TC)(SFo)]
The equation for the total of the five pathways combined RBC is:
(15) RBCt = (TR)/[(IFo + IFd + IFf) x SFo) + (IFi x SFi) + (IFe x SFe)].
The equations are based on the stochastic, carcinogenic effects of ionizing radiation. Stochastic effects (such as cancer or genetic mutation) are an "all or none" effect for an individual. Increasing the dose only increases the probability of the effect, not the severity. Alternatively, nonstochastic effects would be associated with health effects such as cataracts, skin burns (fibrosis), etc. Considerably large doses of radiation are required to cause nonstochastic effects; doses which are highly unlikely to be encountered when handling the IDW or the environmental media.
The risk of cancer is factored in by using the most recent Slope Factors available from the EPA (EPA, 1994). The ingestion and inhalation slope factors are "best estimates of the age-averaged, lifetime excess cancer incidence (fatal and nonfatal cancer) risk per unit of activity inhaled or ingested, expressed as Risk/pCi." External exposure slope factors are "best estimates of the lifetime excess cancer incidence risk for each year of exposure to external radiation from photon-emitting radionuclides distributed uniformity in a thick layer of soil." The risks from ingestion and inhalation are based on an estimate of fatal and nonfatal cancer incidence, while external radiation risk is based on an incidence of cancer risk. RBCs for gross alpha and gross beta/gamma are not calculated, as risk-based analysis is conducted by radioisotope specific information. The total RBC for all five pathways is presented in Table III, Total Risk Based Concentration.
PERFORMANCE OF THE IDW RADIOLOGICAL CHARACTERIZATION
The basic steps for performing the proposed IDW Radiological Characterization can be clearly stated as follows:
Step 1:
Determine which samples can be used to evaluate each drum, or determine if the drum did not originate from a source area. As stated previously, this may require no further characterization effort due to process knowledge.
Step 2:
Perform evaluation of the analytical data including data usability, flagging and discarding any non-qualified values. Determine if single sample points or multiple samples exist which may be utilized to characterize the IDW drum. If multiple samples exist, calculate that average concentration of the samples by summing the values (negative and positive) and dividing by the total number of samples.
Step 3:
Calculate the RBCs for each of the selected radionuclides using the equations with the given intake parameters, exposure pathways, and slope factors. It is important

to calculate each individual RBC so that contributing factors may be identified and evaluated. Calculate the total RBCs for all five pathways.
Step 4:
Compare the mean, or the single data point, of the radionuclide specific analyte to the corresponding background surface soil level. If any single analyte exceeds the background level, then perform a risk-assessment of the material. If no analytes exceed the background levels, then the IDW drum requires no further radiological characterization.
Step 5:
Calculate the radiological risk ratio for the IDW drums which exceed background for any of the selected radionuclides. This is accomplished by initially subtracting the background value from the corresponding analyte of concern, to quantify the material which is the contributing dose. This value is than divided by the radionuclide specific total RBC for all pathways. The ratios are then summed, with any drum exceeding a value of one being considered unavailable for unrestricted release, i.e. radioactive waste.
After completing the steps, a final decision will be made regarding the IDW drum contents. The results of the Radiological Risk Characterization will be combined with those from the previous chemical characterization effort. Based upon the results, it is assumed that the IDW drum will be characterized as one of the following:
Case No. 1:
If the soil and sediment IDW was previously determined to exhibit the characteristics of corrosivity, ignitability or reactivity or exceeded the adjusted Toxicity Characteristic Leaching Procedure (TCLP) regulatory level, and/or the RCRA risk analysis criteria, but did not exceed the radiological risk analysis criteria, then the IDW will be classified as a RCRA hazardous waste and must be managed and disposed of accordingly.
Case No. 2:
If the soil and sediment IDW was previously determined to exhibit the characteristics of corrosivity, ignitability, or reactivity, or exceeded the adjusted TCLP regulatory level and/or the RCRA risk-analysis criteria, and exceed the radiological risk-analysis criteria, then the IDW will be classified as a RCRA mixed (RCRA hazardous and low-level radioactive) waste and must be managed and disposed of accordingly.
Case No. 3:
If the soil and sediment IDW was previously determined not to exhibit the RCRA characteristics as discussed for Case No. 1 and Case No. 2, but did exceed the radiological risk-analysis criteria, then the IDW will be classified as a low-level radioactive waste and must be managed and disposed of accordingly.
Case No. 4:
If the soil and sediment IDW was previously determined not to exhibit the RCRA characteristics as discussed for Case No. 1 and Case No. 2, and did not exceed the radiological risk-analysis criteria, the then IDW will be classified as chemically and radiologically nonhazardous and may be disposed of as an unrestricted release.
SUMMARY
RFETS anticipates that the proposed Risk-Based Radiological Characterization method for the soil and sediment IDW will be submitted to DOE Headquarters in the Spring of 1995. If the method is approved, it will be applied to the IDW drums using exiting sampling and analysis data. It is essential that the method reflect current federal and state requirements regarding the release of bulk/volume materials that may contain residual radioactivity. However, the ultimate goal of the program will be to meet appropriately approved guidelines while protective human health and the environment.

ABSTRACT
The Subsurface Disposal Area (SDA) at the Department of Energy's (DOE's) Idaho National Engineering Laboratory is undergoing environmental remediation. A baseline risk assessment of the SDA is planned. To support the risk assessment, a comprehensive inventory has been compiled of the radiological and nonradiological contaminants in the disposed waste. The inventory was compiled by a new approach that stressed obtaining process knowledgeinformation about the processes that generated the waste. The paper reports numerous lessons learned, in compiling the inventory, that may be useful to other disposal sites undergoing remediation. Included are insights on the reliability of shipping records, creative approaches to obtain missing information, and methods for checking the reliability of the new inventory.
BACKGROUND
The DOE's Idaho National Engineering Laboratory (INEL) is on the National Priorities List of Superfund sites under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA). A Federal Facility Agreement and Consent Order (FFA/CO) governs activities conducted to investigate and, as necessary, remediate actual and potential release sites at the INEL.
One waste area group (WAG) under the FFA/CO is the Radioactive Waste Management Complex (RWMC). The RWMC SDA has been the INEL's primary disposal site for solid radioactive waste since opening in 1952. Transuranic and low-level wastes, including mixed wastes, have been disposed of in more than 90 pits, trenches, and rows of soil vaults, covering 88 acres.
A CERCLA baseline risk assessment (BRA) is planned under the FFA/CO for the pits, trenches, and soil vaults in the SDA. Knowledge of the identity and quantities of radiological and nonradiological contaminants (including uncertainties) in the buried waste is essential for preparing the BRA.
It is not feasible to quantify directly the contaminants in a large, highly heterogeneous disposal site such as the SDA by conventional means, i.e., drilling, sampling, and performing laboratory analyses. Therefore, an inventory of the radiological and nonradiological contaminants in the waste disposed of in the SDA was compiled (1) from many information sources for use in the BRA. The inventory includes information on the physical and chemical properties of the contaminants to help postulate release mechanisms and rates. The inventory information will also be used in engineering and safety studies of remediation alternatives.
PURPOSE OF PAPER
This paper describes the new, comprehensive method that was used to estimate the inventory of radiological and nonradiological contaminants in the buried waste. The results of the inventory compilation are discussed briefly. The paper then lists the lessons learned in performing this complex inventory task. The lessons may prove useful for personnel involved in similar inventory tasks at other environmental remediation sites.
SHIPPING RECORDS
Historically, shipping records prepared at the time of disposal have been the primary source of inventory information on disposed waste. The shipping records for the waste disposed of in the SDA have been compiled into a database known as the Radioactive Waste Management Information System (RWMIS). Prior to the development of the new inventory reported in this paper, RWMIS was the key source of information for the waste in the SDA.
When waste disposal began at the SDA 43 years ago, requirements and practices were much less rigorous than the current requirements for waste characterization. Consequently, complete information about the waste was not recorded on shipping records when it was generated. Many of the shipping records contain only minimal or incomplete information. For example:
- Little information was included on nonradiological contaminants.
- Many shipping records listed only generic radioactivity terms (e.g., mixed fission

products).
Many shipping records listed only some of the radionuclides that are present. Often, only the one or two radionuclides that contributed most to the radiation level during shipment were listed (e.g., Co-60, Cs-137). The list seldom included low-radiation, long-lived beta/gamma-emitting radionuclides (e.g., Sr-90, C-14, and Tc-99) that could be the primary contributors to the post-disposal risk via environmental transport pathways.
Many previous studies had addressed portions of the contaminant inventory disposed of in the SDA. The studies drew their information mostly from RWMIS and from the shipping records themselves. However, no existing compilation of the inventory was considered adequate for use in the BRA.

THE NEW APPROACH

A new approach was developed that built upon previous studies and provided the information necessary to complete the BRA. The new approach emphasized obtaining process knowledgeinformation about the processes that produced the wasterather than simply re-reviewing the shipping records.
The first step was to divide the INEL and non-INEL facilities that generated the waste into seven groups. Seven corresponding lead data-gatherers were appointed to direct the compilation of the information. In nearly every case, each lead data-gatherer had previously worked at the waste generator location whose information he was assigned to compile, and each was familiar with the operational activities that had generated the waste.
Figure 1 depicts the flow of information in this approach. The data-gatherers compiled information from each generator, using process knowledge, plant operating records, hundreds of technical and programmatic letters and reports (including previously classified information), interviews with present and former operations personnel, and nuclear physics calculations, in addition to the traditionally used information sources of shipping records and RWMIS.
To simplify the collection and use of all this information, the waste from each generator was subdivided conceptually into several waste streams. Basically, a waste stream was defined so as to reduce the nonhomogeneity within a portion of the waste. For example, one stream consisted of all of the beryllium reflectors from the Test Reactor Area at the INEL. Another stream consisted of all of the organic sludges received from the Rocky Flats Plant.
For each waste stream, a detailed data form was completed. The data form covered general information about the stream (generator, building number, years generated, volume, etc.), the physical and chemical form of the stream, the quantities (including uncertainties) and the physical and chemical forms of the radiological and nonradiological contaminants in the stream, and the sources and reliability of the information.
The completed data forms were reviewed, then entered into a new database called the Contaminant Inventory Database for Risk Assessment, or CIDRA. The CIDRA offers a wide range of search capabilities for presenting various rollups of the information.
The inventory information was collected and evaluated in two phases. The first phase covered the waste disposed of from 1952 through 1983 and comprises 232 waste streams. The report documenting that inventory (1) is available upon request. The second phase covered the waste disposed of from 1984 through 1993, as well as the waste projected to be disposed of from 1994 through 2003. The total number of streams is 99. The report summarizing this waste is in preparation. The data from both phases, totaling about 3,000 pages, have been entered into CIDRA.

THE INVENTORY RESULTING FROM THE NEW APPROACH

For the waste disposed of from 1952 through 1983, a total of 100 radiological contaminants and 77 nonradiological contaminants was identified. The radiological contaminants of greatest activity were Co-60, H-3, Fe-55, Cr-51, Ni-63, Cs-137, Sr-90, Pu-241, Ce-144, Mn-54, Co-58, and Am-241. The nonradiological contaminants of greatest mass were sodium nitrate, lead, potassium nitrate, aluminum nitrate nonahydrate, carbon tetrachloride, 1,1,1-trichloroethane, trichloroethylene, and nitric acid.
The new inventory exhibits many changes from the previous estimates of contaminant quantities. Some of the most notable changes are greatly increased quantities of Pu and Am; tritium; and C-14, Tc-99, and I-129.
The quantities of plutonium and americium increased about 10 times over those listed in RWMIS. The new information was based on previously classified, plant-wide

mass balances maintained at the principal generating site for the plutonium and americium in the SDA, the Rocky Flats Plant in Colorado.

The tritium activity is more than 20 times larger than previously estimated, due primarily to identifying a new waste stream containing approximately 1 million Ci of tritium entrapped in the beryllium reflectors from test reactors.

Increases of more than a factor of 1,000 were identified for some long-lived fission products and activation products (e.g., C-14, Tc-99, and I-129). The new results reflect the use of nuclear physics calculations to estimate the activities of radionuclides that are difficult to measure and generally were not reported on the shipping records.

The guidance that implements the CERCLA regulations requires the estimation of bounds on the contaminant quantities. The upper and lower bounds were developed by examining in detail the sources of uncertainty for each contaminant in each stream, estimating these uncertainties, and then combining and propagating them to obtain an overall uncertainty for the estimated total quantity of each contaminant, using standard statistical techniques. The bounding values are analogous to 95% upper and lower confidence limits on the estimated total quantity of each contaminant.

As a completeness check, the resulting inventory of contaminants was compared in detail against inventories found in RWMIS and in previous studies. As expected, the new inventory was much more extensive than previous compilations, particularly for nonradiological contaminants. The new inventory was also compared against the results obtained from sampling and analysis in environmental monitoring conducted at the RWMC, to determine if contaminants detected at the RWMC are also in the inventory. Reasons were determined for differences between the new inventory and other inventories.

CONTRIBUTIONS MADE AND LESSONS LEARNED

Far from being a routine process, the compilation of the inventory resulted in many new contributions to technical knowledge about the waste and many lessons learned. The lessons may benefit other organizations faced with compiling inventories at large burial sites in a complex environment of waste information records (or lack thereof).

The principal contributions and lessons learned are discussed below. The sequence in which they are listed is that in which the topics might be encountered during the compilation of an inventory of this type. The lessons include programmatic considerations, data management considerations, and technical considerations. Some of the lessons may seem obvious, but the subtleties involved became apparent as the information was being gathered.

1. The scope of the inventory to be compiled needs to be defined very precisely in terms of the time period covered, the disposal locations included, and the types of waste addressed.

2. The exact types of information to be gathered need careful definition and thorough documentation. All of the data-gatherers (no matter how experienced and highly educated) were required to complete a training course on exactly what information was to be collected and how the information was to be entered onto the data form. This approach minimized inconsistencies in data reporting from one generator to another and made possible meaningful comparisons and rollups of the data across multiple generators.

3. It was important that the data-collection approach accommodate major differences among waste generators in the types of records available. For some generators, the shipping records were virtually the only source of information. For other generators, the shipping records were of little value and other sources were used almost exclusively. In retrospect, it would have been a serious mistake to require that all data-gatherers follow exactly the same process. The selection of data sources was left to the judgment of the individual lead data-gatherers.

4. The waste generators represented several DOE contractors at the INEL (reporting to three Operations Offices), several other DOE sites, and non-DOE organizations. The data-gatherers represented several contractors. Therefore, special management coordination was necessary to deal with the differing work priorities and different recordkeeping systems of the various organizations. It was important that the time of the data gatherers be committed to completing the task, and that their management support the commitment. It was also important to advise each generator that they would be expected to review and approve the results of the task. In this way, all parties, including regulatory agencies, can place confidence in the results.

5. Numerous instances of inaccurate shipping records were found. One extreme example was a 1965 shipment that was recorded as containing 700 Ci of U-235 (constituting a total mass of 327,000 kg and a definite criticality issue if the quantity were correct!). Investigation of the operating records revealed that the shipping record should have read 700 Ci of mixed fission products with a trace of U-235. "Sanity checks" of shipping recordscomparing the listed radioactivity against the radiation level, the volume and weight of the shipment, etc.are strongly recommended.
6. Many types of process knowledge provided information on the waste. Incident reports, annual reports, health physics logs, in-process chemical inventories, and other types of documents were useful.
7. Important information about the waste from two generators had been classified for security reasons. In both cases, the data-gatherers worked successfully with generator personnel to produce nonsensitive summaries of the classified information and get those summaries declassified for use in the inventory report.
8. Interviews with former plant operators were helpful, but the results were used with caution. Operators' memories of events that occurred long ago tend to fade with time and can become distorted. Some former operators may even see an interview as an opportunity to "grind an ax" and put forth their personal view of what is really in the waste.
9. Nuclear physics calculations were essential to identify radionuclides not listed on the shipping records but expected to be present based on other reported radionuclides. (For example, the shipping record might list only U-235, but U-234 and U-238 also are almost always present, in ratios that depend on the enrichment of the uranium.) Varying amounts of information on the nuclear core operating histories and the materials of construction were available. This allowed the use of a wide range of nuclear physics evaluations to arrive at a more complete and accurate inventory of the radionuclides in the waste.
10. The waste generators' projections of future waste disposals were found to be systematically biased. Statistical evaluation of several recent years' projections versus actual disposals indicated an average upward bias of a factor of four in the radioactivity. Accordingly, current projections of the radioactivity in future disposals were reduced by a factor of four.
11. A method was devised to deal with situations in which a contaminant was known to be present but the quantity was not known. Such entries were dealt with outside CIDRA, separate from the entries with defendable estimates of the quantity. For the unknown entries, upper-limit estimates were made to allow comparison with the totals for the known quantities. This approach allowed a determination on whether the unknown quantities were important uncertainties.
12. Substantial effort was devoted to converting all generic radioactivity terms (e.g., mixed fission products) into distributions of specific radionuclides for use in the BRA. For such entries, the approach used a different radionuclide distribution for each waste generator, based on nuclear analyses of the waste or of the reactor operations.
13. Systematic corrections were needed to many of the original estimates of the radioactivity in containers of waste. Some of the instruments and procedures used to make those estimates, particularly in the early days, produced data that were biased. A simplified procedure, commonly used at some INEL facilities to estimate the radioactivity in waste based on radiation readings outside the container, had been found in laboratory tests to be biased (2-4). The amount and direction of the bias depend on (a) the geometric relationship of the radiation source and the detection instrument, (b) the density of the fill material inside the container, and (c) the particular radionuclides present compared with those for which the technique was calibrated. Data in the three cited references (2-4) were reviewed. It was concluded that the original estimates of radioactivity that were made using this method should be reduced by a factor of two.
14. Because the BRA calculations are based on the upper bounds of the contaminant quantities, the evaluation of the uncertainties resulting in those bounds is important. A considerable amount of data evaluation and statistical analysis was devoted to identifying and quantifying the sources of uncertainty in the contaminant quantities.
15. If at all possible, it is useful to identify whether each waste stream is RCRA-listed. The information may be important during CERCLA Feasibility Study evaluations and the associated identification of ARARs (Applicable or Relevant and

Appropriate Requirements).
16. A very thorough process of quality assurance, review by waste generator personnel, independent technical review, checking against other inventories, and "sanity checking" of the inventory information was essential. To confirm the completeness of the inventory, one particularly useful check was a comparison against the list of contaminants detected in environmental monitoring conducted at the disposal site.
17. Compiling a defensible inventory of the contaminants in a large waste disposal site that has been used for decades was a lengthy and expensive task. Unplanned-for issues arose frequently, and they often impacted the schedule and cost of the task. Most of the above lessons were learned during the first phase of the effort. The knowledge gained thereby was valuable for conducting the second phase of the inventory compilation.

CONCLUSIONS

For large waste-disposal units undergoing the CERCLA process, a sizeable effort may be needed to compile a defendable contaminant inventory upon which to base risk assessments. Creative approaches based on using a broad array of process knowledge can produce more complete and accurate inventory information than may be obtained from shipping records only. Careful planning and execution of the effort, factoring in the lessons learned at other remediation sites, can result in avoiding many of the pitfalls in compiling the inventory.

ABSTRACT

The U.S. Department of Energy (DOE) Headquarters and associated contractors have developed an IBM PC-based software package that estimates costs, schedules, and public and occupational health risks for a range of mixed-waste management options. A key application of the software package is the comparison of various waste-treatment options documented in the draft Site Treatment Plans prepared in accordance with the requirements of the Federal Facility Compliance Act of 1992. This automated Systems Analysis Methodology consists of a user interface for configuring complexwide or site-specific waste-management options; calculational algorithms for cost, schedule and risk; and user-selected graphical or tabular

output of results. The mixed-waste management activities modeled in the automated Systems Analysis Methodology include waste storage, characterization, handling, transportation, treatment, and disposal. Analyses of treatment options identified in the draft Site Treatment Plans suggest potential cost and schedule savings from consolidation of proposed treatment facilities. This paper presents an overview of the automated Systems Analysis Methodology.

INTRODUCTION

Activities mandated by the Federal Facility Compliance Act of 1992 and pressures to reduce budget expenditures led the U.S. Department of Energy's (DOE) Office of Program Integration (EM-33) to develop a model that simulates mixed-waste management activities for the entire DOE Complex. This model is based on the premise that waste management is an interdependent system and should be viewed as a complete system. Decisions on how to manage one part of that system (e.g., treatment at a particular site) must consider potential impacts on other parts of that same system (e.g., disposal at a different site).

The Mixed-Waste Systems Analysis Model (the Model) simulates DOE mixed waste-management as a complete system. It addresses several key requirements that are needed for informed decision making. The Model provides a consistent approach to the analysis of mixed-waste management options, and does not rely upon calculated results that have been developed using widely differing inputs and assumptions. It provides rapid analysis of a large number of options. Average turnaround time for an option analysis ranges from a few hours to a few days, depending upon the complexity of the option. The Model uses enhanced versions of DOE mixed-waste inventory and facility information, including the Mixed Waste Inventory Report and the Site Treatment Plan databases. It provides results in a variety of camera-ready graphical or tabular forms, depending on the requirements of the analysis.

This paper reviews the process used to develop the Model, describes its capabilities, provides examples of its output, and summarizes planned enhancements to the Model.

BACKGROUND

The Mixed-Waste Systems Analysis Model is the automated version of the Mixed-Waste Systems Analysis Methodology that has been under development for the last three years. The Methodology mapped all components of mixed low-level waste management, compiled data on these components needed for options analysis, and provided results of analyses that were performed prior to automation of the Methodology. Components of mixed-waste management that are included in the original Methodology and the automated Model are as follows:

- Storage (both before and after treatment)
- Characterization (both before and after treatment)
- Waste sorting (prior to treatment)
- Certification and preshipment activities
- Transportation
- Receipt and inspection (after any movement of waste)
- Treatment (including any additional pretreatment)
- Solidification/stabilization (produces final waste form)
- Disposal

These waste-management activities are evaluated relative to several criteria. All activities are evaluated in terms of cost, which includes technology development (where appropriate), facility design, permitting, construction and start-up, operations, maintenance, and decommissioning. Each cost component also can be scheduled, with costs distributed over that schedule. Public and occupational health risks associated with each waste-management activity are calculated so that the user can compare costs to risks as a form of cost-benefit analysis. Given that decisions on treatment will be influenced by disposal requirements, long-term disposal is modeled using the Pathways Analysis Model. Options are rejected when releases from the treated final waste form are found to exceed release standards. Finally, options are evaluated qualitatively for potential regulatory compliance issues.

Automation of the Methodology began in May 1994 and remains a work in progress. As of late February 1995, cost and schedule have been fully automated. Given the extensive base of information available when the automation effort began, the level of complexity coded into the Model, and the accelerated pace at which the programming effort has proceeded, the five-to- seven-person team used in automating the Methodology should be assumed to be the bare minimum required for programming

efforts such as this.

DESCRIPTION OF THE MODEL

The Mixed-Waste Systems Analysis Model is a PC-based program built around the Paradox database software package. The Model consists of three major componentsthe option-configuration module, the calculational module, and the reports module. The option-configuration module includes a series of menus that prompt the user in configuring a mixed-waste management option. These menus allow the user to group wastes with a common management "train" and to specify all of the waste-management activities to be included in that train. For example, a typical management train may begin with storage at the generator site, followed by characterization/sorting/certification prior to shipment off-site for treatment, then transportation to the treatment site, followed by treatment, followed by storage then final solidification/stabilization, followed by additional long-term storage, then transportation to the disposal site, and finally disposal. In a different option, the user may choose to configure a completely different management "train" for the same group of wastes. For each activity, the Model uses the volumes and masses of the waste streams involved to determine which existing or planned facilities are viable candidates and displays this information to the user. In the case of treatment and solidification/stabilization, wastes and facilities are matched based on "treatability group" compatibility. A "treatability group" is defined as a combination of radiological-component characteristics, waste matrix, and hazardous-component characteristics. At the completion of the option-configuration module, the option configuration is saved for future reference. Configuration of an option using the Model will take anywhere from a few hours to a few days to complete, depending on the complexity of the option.

Once all mixed-wastes have been accounted for, the user can instruct the code to calculate costs and develop schedules using the calculational module. No additional user input is required to run this module. The code automatically sums all wastes to be processed at each facility, sizes the facility based on the inventory work-off period specified by the user, calculates costs and develops schedules for that facility based on the treatment technology specified, and stores results in a detailed form to maximize reporting capabilities. Computer run times for these calculations range from 10 to 50 minutes, depending upon the complexity of the configured option.

The reports module provides the user with options for reporting cost/schedule results in either a graphical or tabular form. Results can be presented in any combination of the following cost/schedule accumulators:

- Waste-management activity
- Waste operation (preoperations, construction, operations and maintenance, and decontamination and decommissioning)
- Waste matrix (e.g., all costs for treating aqueous wastes)
- Site where activity will occur
- Generator site (allows costs for all activities required to manage a group of waste to be assigned back to the original "caretaker" of the waste)
- Treatment facility
- Year activity will occur.

The reports module provides a menu for the user to select the structure of the desired report. This menu gives the user the capability to specify up to 10 configured options on any report. Computer run time for each report is 1 to 2 minutes, once all configured options to be included in the report have been run through the calculational module.

EXAMPLES OF ANALYSES PERFORMED

The Mixed-Waste Systems Analysis Model has been applied to a variety of complexwide and site-specific applications. An example of the graphical presentation of results is provided in Fig. 1. An example of the tabular presentation of results is provided in Table I.

Fig. 1.

TABLE I

ENHANCEMENTS TO THE MODEL

Enhancements for the Mixed-Waste Systems Analysis Model could include addition of selected modeling of mixed-transuranic and high-level waste management and the automation of public/occupational health risk calculations and disposal-facility long-term performance. The cost and schedule modules of the Model will be refined

and further integrated as required by Model users. There are plans for a controlled distribution of the Model and for a user's network to share results of options analyses. Longer term, there are plans to include uncertainty analysis for cost and risk. There are also plans to expand mass/energy balance calculations that support the cost calculations for treatment.
In terms of the databases used by the Model, there is a continuous effort to expand and refine these databases based on information that becomes available. Updated databases will be included in each new version of the Model.

A SYSTEMATIC APPROACH FOR FUTURE SOLID WASTE ACTIVITIES AT THE HANFORD SITE
L. L. Dirks
H. S. Konynenbelt
Pacific Northwest Laboratory
K. L. Hladek
Westinghouse Hanford Company
ABSTRACT
The Hanford Site, an area of approximately 560 square miles in south central Washington State, was a major producer of plutonium beginning in the 1940's and lasting for nearly half a century. The production of plutonium generated large volumes of radioactive and hazardous wastes in both solid and liquid forms. Today, the U.S. Department of Energy (DOE) is in the process of restoring the Hanford Site. As defined in the Hanford Mission Plan (DOE 1993), "The primary Hanford mission is to clean up the Hanford Site, eliminate potential risks to the public and our workers, and serve as the DOE model in environmental restoration."
This paper describes the systematic approach to the treatment, storage, and disposal system (TSD) planning and management that has been developed and implemented by Hanford's Solid Waste Program.
The systematic approach includes:
- collecting the forecast and waste inventory data
- defining Hanford's TSD system
- studying and refining the TSD system using analysis tools
- documenting analysis results.

The customers responsible for planning, funding, and managing future solid waste activities have driven the evolution of the solid waste system.
Currently, all treatment facilities are several years from operating. As these facilities become closer to reality, more detailed systems analysis and modeling will be necessary to successfully remediate solid waste at the Site. The tools will continue to be developed in detail to address the complexities of the system as they become better defined. The tools will help determine which facility lay-outs are most optimal, will help determine what types of equipment should be used to optimize the transport of materials to and from each TSD facility, and will be used for performing life-cycle analysis. It is envisioned that in addition to developing the tools to be adapted to the more specific facility design issues, this approach will also be used as an example for other waste installations across the DOE complex.
INTRODUCTION
The Hanford Site, located in south central Washington State, was a major producer of plutonium beginning in the 1940's and lasting for nearly half a century. The production of plutonium generated large volumes of radioactive and hazardous wastes in both solid and liquid forms. Today, the U.S. Department of Energy (DOE) is in the process of restoring the Hanford Site. As defined in the Hanford Mission Plan, "The primary Hanford mission is to clean up the Hanford Site, eliminate potential risks to the public and our workers, and serve as the DOE model in environmental restoration" (DOE 1993).
As part of the restoration mission, the Westinghouse Hanford Company (WHC) Solid Waste Program is responsible for the management and final disposition of the solid wastes generated or received at Hanford.* The purpose of this paper is to present an overview of the Program's approach to analyzing and planning for future waste management activities.
As described in this paper, there are three major components to the Solid Waste Program planning approach: data collection; a treatment, storage, and disposal (TSD) system; and analysis tools. The results from development and use of these components are used by "customers" and Westinghouse Hanford Company (WHC), which operates the

Program, to successfully manage solid waste at Hanford and integrate system planning with other DOE installations.

As part of this overview, Section 2.0 outlines the types of customers that use this information and describes how these customers have influenced the analysis process. Section 3.0 provides an overview of the solid waste planning and management concept, including:

- collecting the forecast and waste inventory data
- defining Hanford's TSD system
- studying and refining the TSD system using analysis tools
- documenting analysis results.

Section 4.0 discusses the plans for improving the understanding of the solid waste management system.

CUSTOMERS OF THE DATA

The customers responsible for planning, funding, and managing future solid waste activities have driven the evolution of the solid waste planning and management concept. The current customers represent a wide array of individuals from different programs, ranging from representatives of the DOE-Headquarters to specific Hanford cognizant engineers who are documenting the design requirements for the future solid waste TSD facilities. As new customers are identified and additional requirements are recognized, new analysis techniques and tools will be applied to meet customer requirements. A summary of the main customers and their data requirements follows:

DOE-Headquarters and DOE-Richland Operations Office. DOE program managers request information from each DOE installation on the types of radioactive waste that is currently stored at the Site and how much is anticipated to be generated at, and/or shipped to, the Site in future years. This information is requested to determine how large the DOE waste management system is and the magnitude of waste volumes being generated at each installation. The information is transmitted through formal data requests, personal visits, and on an ad hoc basis.

Facility Planners. Facility planners are outlining the requirements of future TSD facilities. To perform this work, these planners require insights into how much waste is currently at the Site and how much will be generated in the future. In addition, these planners need specific waste characteristic information to help determine the types of examination equipment, treatment technologies, and disposal grounds that will be necessary for waste characterization and final disposition.

System Analysts and Solid Waste Program Managers. Hanford solid waste system analysts use the data to support system-wide TSD planning and to ensure all waste forms have a defined waste management path, eventually reaching onsite or offsite disposal. These data are also used to test the system sensitivity to alternative planning options. By understanding future TSD requirements, the information is also used by the Program to justify funding for facilities that are required to safely and expeditiously manage solid waste.

Financial Analysts. The financial system uses the data to set billing rates for onsite and offsite waste generators who will be sending waste to Hanford's Solid Waste Management System over the next year.

A SOLID WASTE PLANNING AND MANAGEMENT CONCEPT

Management of Hanford's solid waste is a complex mission. Many factors impact the success of this mission: complying with all laws and regulations; identifying technologies that are feasible and available; identifying future waste types and volumes that will be managed at the Site; ensuring worker and public health and safety; ensuring funding is available to carryout the mission; and identifying and managing uncertainties associated with future program missions, waste volumes, and funding appropriations. This section describes the systematic approach that has been implemented to address design and planning issues associated with Hanford's complex solid waste TSD system. Figure 1 illustrates the primary system components that constitute the solid waste management approach. Each of these components is described in the following subsections.

Fig. 1.

Waste Volumes

Each year information is collected on how much solid waste will be generated by and sent to Hanford in the future. This information is requested from the specific waste generating sites and is maintained in an evolving electronic database. Hanford also has large volumes of solid waste that were generated in the past and are currently being stored in trenches, caissons, and buildings. Waste characteristic information

for the waste currently stored at the Site has been maintained in a separate electronic database.
The information that is collected and maintained for both the forecasted waste and the stored waste is driven by the needs of the data users. The types of information currently available include the generating source, level of radioactivity, date of generation or shipment to the Site, volume of waste, the container types used for shipping and storing the waste, the physical matrix of the waste contents, and the hazardous constituents within each container.
The waste characteristic information serves several purposes. The information aids in determining waste management handling requirements. For example, large odd-shaped containers may require special devices to load the material to and from storage, disposal, and treatment. The specific container types also allow a planner to determine how many packages can be placed in a building and how the material can be stacked and organized. Containers that contain specific waste characteristics may need to be stored in special designated areas within a building. The radioactivity level, physical matrix, and hazardous constituents present within a waste package will also dictate the treatment and disposal requirements. In some cases, the waste may need to be shipped offsite for final disposition.
Treatment, Storage, and Disposal (TSD) System Description
A written description of Hanford's TSD system has been developed to narratively capture the future plans for TSD. This information is obtained from technical documentation, facility planners, program managers, and system analysts working within the Solid Waste Program. Consensus meetings are held to ensure that the system description adequately reflects all participants' points of view and documents a technical baseline from which sensitivity analyses can be performed. The latest system description contains multiple storage buildings, several treatment facilities, and both onsite and offsite disposal sites. Figure 2 illustrates the current state of the planned system, while Fig. 3 portrays Hanford's vision for the solid waste management system in the future. The vertical columns in the figures identify the waste sources, storage areas, characterization and treatment facilities, and disposal sites. Many of these components of the TSD system do not yet exist but will be constructed in phases, with the first major treatment facility (WRAP Module 1) planned to be on-line in 1997 and the last treatment facility scheduled for operations by 2013.
The waste sources shown in Fig. 3 include 22 offsite and 68 onsite waste generators who will be sending waste to Hanford over the next 30 years. Several storage areas are planned to store the waste arriving from these waste generators as well as the work-in-process waste that is awaiting additional treatment or shipment to disposal. Six treatment facilities are planned to treat the waste, and several disposal sites have been identified to receive the waste for final disposal. Each TSD component is subject to environmental regulations and treatment requirements that dictate what type of activities and functions will be performed.
Fig. 2.
Fig. 3.
Once this system has been described to the level of detail required by the customer, the information is documented in flow diagrams. An example of a flow diagram is shown in Fig. 4. These flow diagrams depict the system description in a more structured, analytical method, tracking each waste stream from point of generation to its final disposition. These diagrams provide a flow diagram model of the solid waste management baseline. The flow diagram model is imported into a computer model so that the system can be analyzed and sensitivity studies can be performed.
Fig. 4.
Analysis Tools
Several analysis tools are used to understand and refine Hanford's solid waste management system. Because of the large quantities of data that are collected, databases have been used to maintain and store the forecasted waste information and waste currently in inventory. The databases are updated as volume information is collected. Because this information is maintained electronically, specific information can be extracted to respond to data requests, to provide information to the financial department, and to create an electronic file to be used during modeling activities.
A second tool used at the Hanford Site is a simulation model that is based upon Hanford's TSD system description. The TSD functions are coded within the simulation

model, and the input data from the forecast and stored waste databases are fed into the model to analyze the baseline system and alternative operating strategies. A baseline is established to gain an understanding of how the system may operate in the future.

Once the baseline is understood, alternatives can be evaluated using the simulation model to determine if other operating strategies are more optimal than the baseline. For example, the baseline system may indicate that short falls will exist by the year 2000 in planned storage capacity; therefore, one may want to evaluate alternatives that could alleviate this problem. Model runs could be performed delaying the timing of the waste receipts so that less volume requires storage within a given time period, or increasing the capacity of one of the treatment facilities to process waste volumes waiting in storage more rapidly.

Another reason for investigating alternatives to the baseline system description is to evaluate the system's sensitivity to events not represented in the baseline that have a probability of occurring. For instance, one may want to determine the impacts to the system if the waste volumes received at the Site have the potential to be twice the amount forecasted over the next 10 years. Several alternatives could be analyzed to assess the optimal sizes and startup dates for the TSD facilities. This tool provides the flexibility to easily analyze and study alternatives before designing a full-scale system.

Data obtained from the simulation model are stored in a database that allows a user quick access to the end results. The database allows for model output results of different alternatives to be compared and viewed graphically. Each time an alternative is generated, the new results can be compared to previous results to determine how the TSD system components are impacted.

Results

Several types of formal results from the analysis work are generated and provided to the customers, including results obtained from the collection and organization of the forecast and inventory data and results obtained from the system description and simulation model.

Results From the Forecast and Inventory Data

Due to the large volume of forecast and inventory data currently maintained and the diversity of the customers requesting information, several reports and summaries are issued. The following list identifies a sample of these reports and summaries, and provides a brief description of the information contained in each document.

Solid Waste Forecast Volume Summary Report. The objective of the document is to provide a base line volume forecast that can be used for standard reporting, preparing input files for modeling Hanford's waste management facilities, establishing a basis for billing rates, and responding to special data requests from solid waste facility planners and system analysts.

Treatability Group Summary Report. This document describes the physical waste forms and hazardous constituents for the waste that will be shipped to Hanford's Solid Waste Complex and how these characteristics enable the mixed waste to be identified by nationally established treatability groups. This information provides insight into the treatments and capacities that will be required at the Site.

Container Volume Summary Report. This document describes the containers that will be used to ship waste to the Hanford Site and the volume of waste associated with each container type. This report is used primarily for planning the handling, storage, and disposal requirements at Hanford's solid waste complex.

Stored Waste Data Analysis Summary. This report analyzes the use of stored waste data to determine if past waste receipts provide insight into future waste shipments. It compares past waste volumes with the forecast volumes to identify trends among onsite and offsite waste generators for each waste generator from year to year and for each waste category. The report includes both the forecast data and stored waste data.

Additional Solid Waste Reports. The specific data requirements of the TSD planners often vary from year to year. For this reason, unscheduled reports are frequently generated to supply these data needs. These reports differ in subject matter and level of detail; however, the objective is to provide a documented data set that may be used consistently for short- and long-term planning.

Integrated Database Support. Every year Hanford is required to provide input to the DOE Integrated Database (IDB). A portion of the required information is extracted from the solid waste forecast database.

Results From the System Description and Simulation Model

Reports are developed that document the baseline system description and the baseline model results. Once the baseline assumptions and results are established, the system is analyzed with the simulation model by investigating "what-if" scenarios. The following list identifies the products delivered to the customers as a result of the system description and modeling activities.

TSD (Baseline) System Description. This document describes a cradle to grave approach for achieving the mission to manage Hanford's solid waste. The report includes detailed definitions about each treatment facility, each storage building, and each onsite or offsite disposal site. In addition, the report identifies the facilities' functional requirements, the system's and facilities' interfaces with other systems or facilities, and the operational constraints of the system.

Baseline Model Results and Systems Analysis. Once the baseline system description is established, the system is modeled using a simulation package to indicate how the current system plan meets the projected waste volume demands over the next 30 years. A report is issued that summarizes the results of this simulation. The results that are summarized include facility throughputs, storage requirements, disposal accumulations, and transporter movements. This information is presented in written descriptions, tables, and interim reports as well as through presentations to provide feedback to management and facility planners on the baseline system results. The analysis of the end results may introduce alternatives to be studied.

Alternative Operating Strategies. Feedback obtained from WHC management and facility planners allows for several alternative studies to be conducted to show how Hanford's system could be impacted and/or improved by varying the system components or input data. Such alternative studies have included increasing/decreasing a treatment facility's capacity, adding waste volumes to the system that have the potential of requiring treatment at Hanford, re-routing waste volumes through other treatment facilities, and never opening a disposal site. The information provided for these studies is specific to the study performed but primarily includes treatment facility throughputs and storage requirements.

Integrated Database Support. The simulation model has also been used to respond to the IDB in the past, as defined in Section 3.4.1.

CONCLUSION AND FUTURE VISION

Hanford has developed a systematic approach to accomplishing its mission to remediate solid waste. The four major activities performed toward achieving this mission are:

- collecting the forecast and waste inventory data
- defining Hanford's TSD system
- studying and refining the TSD system using analysis tools
- documenting analysis results and communicating these results to the customers.

Over the next year, Hanford will continue to analyze the solid waste management system by performing the above activities. These activities illustrate to system designers which areas need improvement or attention. Also, these activities assist Hanford in quantifying the complex pieces of the solid waste management system and in identifying those components of the system that can greatly impact the system. Currently, all treatment facilities are several years from operating. As these facilities become closer to reality, more detailed systems analysis and modeling will be necessary to support successful planning of solid waste remediation. The tools will continue to be developed in detail to address the complexities of the system as they become better defined. The tools will help determine which facility lay-outs are most feasible, will help determine what types of equipment should be used to optimize the transport of materials to and from each TSD facility, and will be used for performing life-cycle analysis. It is envisioned that in addition to developing the tools to be adapted to the more specific facility design issues, this approach will also be used as an example for other waste installations across the DOE complex.

National Low-Level Waste Management Program
Lockheed Idaho Technologies Company
Idaho National Engineering Laboratory

ABSTRACT

The Department of Energy's (DOE's) planning for the disposal of greater-than-Class C low-level radioactive waste (GTCC LLW) requires characterization of the waste. This paper estimates future volumes, radionuclide activities, and waste forms of GTCC LLW. It groups the waste into four categories, representative of the type of generator or holder of the waste: Nuclear Utilities, Sealed Sources, DOE-Held, and Other Generator. In the future, Nuclear utilities will probably generate the largest volume of GTCC LLW with 65-83% of the total volume. The Other Generators will generate 17-23% of the waste volume, while GTCC Sealed Sources are expected to contribute 1-12%. A preliminary review of current DOE-Held wastes indicates that they will not require management as GTCC LLW because of the contractual circumstances under which they were accepted for storage. In addition, this paper discusses the uncertainties that may affect the predictions of this kind. This paper concludes that the volume of GTCC LLW should not pose a significant management problem from a scientific or technical standpoint. The projected volume is small enough to indicate that a dedicated GTCC LLW disposal facility may not be justified. Instead, co-disposal with other waste types is being considered as an option.

INTRODUCTION

This paper estimates future greater-than-Class C low-level radioactive waste (GTCC LLW) volumes, radionuclide activities, and waste forms, and identifies potential waste generators. Information for this paper is taken from the report Greater-Than-Class C Low-Level Radioactive Waste Characterization: Estimated Volumes, Radionuclide Activities, and Other Characteristics(1). This report was originally published in 1991. Since 1991 there have been several additional studies conducted to further identify and quantify projected volumes and activities of GTCC LLW. The report was revised in 1994 to include new information affecting the estimated volume and activity projections for GTCC LLW. These estimates will provide information to the U.S. Department of Energy (DOE), the agency responsible for ensuring the safe disposal of GTCC LLW, to assist in developing long-term strategic planning for storage, treatment, fee assessment, and final disposal of GTCC LLW. The estimates in this paper represent the best available data for DOE planning.

The DOE began the GTCC LLW Management Program in response to a congressionally mandated responsibility, Public Law (PL) 99-240, the Low-Level Radioactive Waste Policy Amendments Act of 1985. Low-level radioactive waste (LLW) is defined in PL 99-240 as radioactive waste that is neither high-level radioactive waste (i.e., spent fuel) nor by-product material (i.e., mill tailings). In the absence of a concentration-based definition for high-level waste, there is currently no upper limit for the concentration of radionuclides in LLW.

The U.S. Code of Federal Regulations, 10 CFR 61, regulates the disposal requirements for three classes of LLW considered generally suitable for near-surface disposal: A, B, and C, with Class C waste requiring the most rigorous disposal specifications. The radionuclide concentration limits and calculation methods for determining Classes A, B, and C LLW are found in 10 CFR 61.55, Tables 1 and 2. Waste with radionuclide concentrations above Class C limits is identified as GTCC LLW. GTCC LLW is not suitable for near-surface disposal, except on a case-by-case evaluation and the U.S. Nuclear Regulatory Commission (NRC) approval of the proposed disposal method.

The waste generators described in this paper are licensed either by the NRC or a State agency. Commercial nuclear power plants are licensed by the NRC, regardless of the State in which they reside. Other radioactive waste generators can be licensed by the NRC, or a State regulatory agency that is accredited by the NRC. States that issue licenses in this manner are known as Agreement States. PL 99-240 assigns to the States the responsibility for providing disposal facilities for Classes A, B, and C LLW. The same law makes the Federal government (specifically, DOE) responsible for disposing of GTCC LLW.

This paper addresses GTCC LLW as waste that meets the following criteria:

- Exceeds the Class C limits as defined in 10 CFR 61.55, Tables I and Table II
- Is generated by radioactive waste generators licensed by the NRC or an Agreement State

Is not "owned or generated" by DOE, or generated as a result of nuclear weapons activities or decommissioning of nuclear powered naval vessels
Requires management or disposal under PL 99-240.

In this paper, GTCC LLW is divided into the following four categories, each of which is determined by the major industry that produces the waste or by the agency holding it:

Nuclear Utility
Sealed Sources
DOE-Held
Other Generators.

Nuclear Utility waste includes activated metals and process wastes generated by commercial nuclear power plants. Sealed Sources consist of radioactive materials contained in small, metallic capsules and used in devices for measurement or calibration. DOE-Held waste consists of commercially generated wastes that a) exceed Class C limits, and b) DOE has accepted for storage. Other Generators waste consists of sludge, activated metals, and other wastes that are generated by radionuclide manufacturers, commercial research, sealed source manufacturers, and similar types of operations.

In calculating volumes and activities for these GTCC LLW categories, this paper uses the following definitions:

Concentration averaging: 10 CFR 61.55 allows the radionuclide concentration to be calculated over the volume or mass of the waste. In practice, similar wastes of varying radionuclide content are packaged together for shipment to a LLW disposal facility. The total radionuclide content in the package is averaged over the total waste volume or mass in order to calculate the average radionuclide concentration per unit of volume or mass for waste classification. This method of calculation is known in the industry as "concentration averaging."

Unpackaged volume: This is the volume of waste before packaging for disposal. The unpackaged volume is often used as the foundation for applying the packaging scenarios that calculate the packaged waste volumes presented in this paper. For the Nuclear Utility category, estimates of unpackaged volume do not reflect the impact of concentration averaging. All other categories account for concentration averaging in the unpackaged volume estimates.

After-concentration averaged (ACA) packaged volume: This is the packaged volume of waste that is classified as GTCC LLW, after all other waste has been classified as Class A, B, or C LLW using concentration averaging practices.

Low, Base, and High Cases: Three cases are calculated for the volumes described above. These values are defined as the low, base, and high cases. The base case is the most reasonable volume and activity estimate, and is based on inventories, surveys, and industry production rates. High and low cases are considered upper and lower limits of the base case. Assumptions used to calculate the low, base, and high cases may be different for each category of waste. Specific definitions and assumptions used to make these calculations are described for each category in the appropriate sections.

NUCLEAR UTILITY GTCC LLW

The information on Nuclear Utility GTCC LLW was developed in order to project volumes and activities to 2055 for current-technology reactors. This projection will account for waste generated by some nuclear reactors that may apply for and receive a 20-year license extension.

Nuclear Utility data are divided into pressurized water reactor (PWR) and boiling water reactor (BWR) types. BWRs are designed and manufactured by General Electric (GE). PWRs are designed and built by three manufacturers: Babcock & Wilcox (B&W), Combustion Engineering (CE), and Westinghouse (W).

Waste materials, which are unique to each of the reactor designs, are generated during normal plant operations and at decommissioning. Operations wastes are routinely generated during the normal operation of a reactor. Decommissioning wastes result from the closure and cleanup of a nuclear reactor, a one-time event that accounts for the major volume of GTCC LLW generated.

Activated metal GTCC LLW, from both operations and decommissioning activities, consists of irradiated metal components from nuclear reactors. Hardware internal to the pressure vessel absorbs neutrons during reactor operation and becomes radioactive. If the hardware is exposed to a sufficiently high neutron flux, the radioactive constituents could reach concentrations above Class C limits.

Process wastes consist of the waste generated from the cleanup of liquids containing soluble and insoluble radioactive constituents. Those wastes are in the form of ion-exchange resins and cartridge filters.
The volume and activity of GTCC LLW from nuclear utilities depend on several factors:
- Life cycle for the operations and shutdown of commercial nuclear power stations
- Packaging factors used to calculate packaged volumes
- Extent to which waste can be packaged for disposal in a near-surface disposal facility by using concentration averaging.

Three possibilities exist to predict the time when operations and decommissioning GTCC LLW will be generated from commercial nuclear utilities: early shutdown of a reactor, operation for license duration, and license extension. In 1993, 109 commercial nuclear power plants (37 BWRs and 72 PWRs) were operating in the United States. Forty-six of those units will reach the end of their 40-year operating licenses by 2015. Because many of these plants have a relatively low capacity for generating electrical power, it may not be economically feasible to extend their lives past the end of their operating licenses. Several nuclear plants have recently shut down permanently before the end of their 40-year licenses. However, nuclear plants might choose to apply for license extensions to allow them to operate beyond 40 years. The following general assumptions were used concerning timing issues related to nuclear utility plant operations and decommissioning:

High Case: The high case uses DOE's 1991 National Energy Strategy(2) to predict the percentage of plants that will have a license extension, which could move shutdown and decommissioning dates 20 years into the future for many reactors.

Base Case: The base case assumptions and calculations represent the most probable waste generation timing using the most current projections in the DOE's Annual Energy Outlook 1993(3). Extension of licenses occurs less frequently in the base case than in the high case, and early reactor shutdown is assumed for some reactors in order to account for regulatory, political, and economic uncertainties.

Low Case: The low case establishes a lower bound for waste volume calculations. The low case, which also includes the possibility of early shutdown to account for regulatory, political, and economic uncertainties, presents a conservatively short projection for nuclear plant life. No plants will receive license extensions in the low case.

GTCC LLW will require packaging before disposal. For Nuclear Utility waste, this study uses a packaging factor (PF) to convert the unpackaged volume to a packaged volume. The PF is defined as the volume of the GTCC LLW disposal container divided by the unpackaged volume of the waste loaded into the container. Packaged volumes were determined for the low, base, and high cases. The base case is the most realistic value; the high case indicates a higher ratio of disposal container volume to waste volume; and the low case indicates a lower ratio.
This paper uses the following assumptions relating to the concentration averaging of nuclear utility waste:

High Case: The high case assumption is that no concentration averaging is allowed. This yields the maximum packaged volume estimate.

Base Case: The base case assumption is that the 1993 NRC draft Branch Technical Position (BTP) on concentration averaging will be the standard adopted by most LLW generators and disposal site operators. The base case assumes that concentration averaging will continue in the future. This volume is the base case ACA packaged volume.

Low Case: The low case assumption is that an additional volume reduction from the base case GTCC LLW will result because of the alternatives provision found in the 1993 NRC draft BTP on concentration averaging. The alternatives provision clarified the concentration averaging guidelines by stating that certain copackaging practices would be allowed on a case-by-case basis.

The low, base, and high case concentration averaging assumptions are used to determine concentration averaging factors for each of the Nuclear Utility components that exceeds Class C limits. The concentration averaging factor is used to calculate the volume of waste components that will be classified as GTCC LLW after all other LLW has been disposed of as Class A, B, or C. The packaged GTCC LLW volume remaining after concentration averaging is referred to in this paper as the ACA packaged volume.
In all three cases, the predicted unpackaged volume of Nuclear Utility GTCC LLW is

the foundation for estimates of ACA packaged volume.
The timing, packaging, and concentration averaging assumptions were used to project nuclear utility GTCC LLW to 2055. Nuclear Utility GTCC LLW projections are base case unpackaged volume of 1,144 m3 and base case ACA packaged volume of 1,347 m3. The core shrouds/baffles and lower core barrels are the major volume contributors. Table I shows the total Nuclear Utility GTCC LLW volumes in 2055. The base case activity of the Nuclear Utility GTCC LLW is estimated to be 88,400,000 Ci in 2055. The major portion of the activity will be from short-half-life radionuclides. The highest activity components result from the PWR core shrouds and baffles at decommissioning.

SEALED SOURCES GTCC LLW

Sealed sources are radioactive materials encapsulated in a metallic container. While the sources are small in volume, they are often highly radioactive. Sealed sources of concern to DOE and the GTCC LLW Management Program are those that exceed the Class C limits for waste classification and are not useful for their designed purposes.
A study of sealed sources was conducted to gather information concerning the types of sealed sources, the total number of licensed holders of sealed sources, the radionuclide activities, and to determine how many sources are in use.(4) This information was compiled in a database that was used to estimate the inventory of sealed sources in the year 2035. This information was collected and calculated for sealed sources held by both general and specific licensees. It is important to note that a high degree of uncertainty is associated with the data used to estimate the current inventory and future projections for sealed sources held by general licensees. For this reason, no attempt was made to add the totals for general and specific licensees.
In the base case, this study estimates that in 2035, 43,920 GTCC LLW sealed sources will be held by general licensees. These sources could have an unpackaged volume of 0.12 m3 and an ACA packaged disposal volume of 8 m3.
In 2035, a base case total of 54,278 GTCC LLW sources will be held by specific licensees. The estimated unpackaged volume will be 0.87 m3, and the ACA packaged volume for disposal will be 234 m3. Table II shows the estimated 2035 inventory of sealed sources.

DOE-HELD GTCC LLW

A number of commercial facilities have generated waste with radionuclide concentrations above Class C limits, and through contractual arrangements with DOE or for health and safety reasons, have stored these wastes at DOE facilities. This waste was identified as DOE-Held potential GTCC LLW. The GTCC LLW Management Program has investigated these wastes to determine the legal and contractual requirements for managing and disposing of the wastes.(5)
A decision process was developed to evaluate the legal and contractual arrangements by which DOE accepted waste for storage. That process was developed to determine which of the potential GTCC LLW wastes held by DOE would be classified and managed as GTCC LLW under PL 99-240. That decision process includes the following questions:
Does the waste exceed the Class C limits as defined in 10 CFR 61.55, Tables 1 and 2?
Is the waste generated by a radioactive waste generator licensed by the NRC or an Agreement State?
Is the waste "owned or generated" by DOE under PL 99-240 or generated as a result of nuclear weapons activities or decommissioning of nuclear powered naval vessels?
Is management or disposal of the waste required under PL 99-240?
In 1991 it was estimated there was 1,080 m3 of DOE-Held potential GTCC LLW. From 1991 to 1993, the GTCC LLW Management Program identified an additional 1,869 m3 of DOE-Held potential GTCC LLW for a total volume of 2,949 m3.(3) The decision process indicates that, because of contractual agreements and circumstances under which the wastes were generated, none of the waste identified as DOE-Held potential GTCC LLW falls under the requirements of PL 99-240. Therefore, these wastes are not included as GTCC LLW in this paper.
All current DOE-Held wastes will be classified as DOE Special-Case Waste (SCW). SCW is waste that is above Class C limits and is owned or generated by DOE for various reasons. For example, it was generated by DOE or by a subcontractor performing work for DOE, or DOE has taken ownership of it under provisions other than PL 99-240. The management and disposal issues for DOE SCW are being studied under another program.

OTHER GENERATORS GTCC LLW

The Other Generators category includes all GTCC LLW that is not generated by nuclear utilities or sealed source licensees, or held at DOE facilities. Generators include

- Manufacturers and users of 14C
- Industrial research and development firms
- Fuel fabrication and irradiation research (burnup) labs
- Academic nuclear research reactors
- Sealed source manufacturers
- Non-medical academic institutions.

Generator operating histories and estimates by the generators were used to determine annual production rates for each generator. The annual production rates were used to project the total volume and activity inventory to 2035. Table III shows the estimated 2035 inventory of Other Generators GTCC LLW.(1)

DATA SUMMARY OF ALL CATEGORIES

The following volumes of GTCC LLW are projected from all categories: (numbers presented here are rounded off to the nearest cubic meter from the calculated values presented in Table IV).

- A base case unpackaged volume of 1,380 m3
- A base case ACA packaged volume of 2,054 m3.

Table IV shows the low, base, and high case summary of all categories for future unpackaged and ACA packaged volumes. Table V shows the future total activity for each category.

AREAS OF UNCERTAINTY

This paper contains the best available data and information for projecting GTCC LLW volumes and activities for each of the categories. However, there are areas of uncertainty that must be considered when applying the volume projections presented in this paper. The following sections describe the uncertainties associated with each category of GTCC LLW.

Uncertainties in Nuclear Utility Areas of GTCC LLW Volume Projections

The actual volumes of GTCC LLW generated by nuclear utilities in the future can be affected by the following five areas of uncertainty:

- Concentration averaging practices
- The interpretation of the Standard Contract (10 CFR 961), that identifies the wastes which meet the definition of spent fuel
- Implementation of procedural controls to reduce the volumes of operations wastes generated
- The assumed concentration of cobalt, nickel, and niobium in the stainless steel making up the core components
- The construction of advanced-technology power reactors to supply future demand for electrical energy.

The following paragraphs discuss these five factors.

The first factor that can affect the total volume of Nuclear Utility GTCC LLW is future concentration averaging practices. The volume of potential GTCC LLW that can be disposed of at a commercial LLW disposal site is determined by the NRC or State regulatory agency (monitored by the NRC) who issues the license to the site. The LLW sites' licenses regulate the waste acceptance criteria, which define the concentration averaging practices that will be allowed. The only commercial LLW sites currently accepting radioactive waste are located at Barnwell, South Carolina, and Hanford, Washington. The Barnwell site has closed to all States except those in the Southeast compact region. The Hanford site is closed to all States except those in the Northwest and Rocky Mountain compact regions. The waste acceptance criteria for new LLW sites have not yet been developed or approved. Therefore, it is unclear what concentration averaging practices will be allowed in the future.

Concentration averaging practices that are acceptable to the NRC are described in the draft 1993 BTP on concentration averaging. Since one purpose of this BTP is to promote consistent concentration averaging criteria, the base case ACA packaged volume for nuclear utilities is calculated with factors based on the guidance provided by the BTP. The high case assumes that no concentration averaging will be performed. The low case assumes a further GTCC LLW volume reduction for some waste forms based on special exceptions that might be allowed under the alternatives provision in the BTP. The actual concentration averaging practices that will be adopted by the Agreement State licensees are unknown at this time and could be more restrictive than the NRC guidance.

The second factor that can affect the total volume of Nuclear Utility GTCC LLW is

the interpretation of the Standard Contract (10 CFR 961), which identifies the wastes that meet the definition of spent fuel. Studies are underway that may result in some fuel-related components being classified as high-level waste and eligible for disposal in a spent fuel repository when it opens. This reclassification may result in a decrease of the volumes reported in this document.

The third factor that can affect the total volume of Nuclear Utility GTCC LLW is procedural control implemented by the power plants. For example, a plant can change out filters, control rod blades, and instrument strings more often so that they will not be irradiated above Class C limits. Procedural controls can result in an overall decrease in operations GTCC LLW from nuclear utilities.

The fourth factor that can affect the total volume of Nuclear Utility GTCC LLW is the assumed trace concentration of cobalt, nickel, and niobium in stainless steel. The 10 CFR 61.55 classification of activated metals is driven by nickel and niobium concentrations. Standard waste classification techniques are based on assumed values for cobalt, nickel, and niobium in stainless steel. The assumed cobalt (Co) concentration is used together with the measured radiation readings to estimate the 60Co activity. Scaling factors are used to estimate the nickel and niobium concentration from the 60Co value. These assumed values are taken from Long-Lived Activation Products in Reactor Materials.(6) In type 304 stainless steel, nickel is a major constituent; its content can vary by +15% from the value reported in Reference 6. The uncertainty associated with this variance is not significant. This is not the case for niobium, which is also a trace metal in type 304 stainless steel. The actual trace quantity of niobium can vary by as much as +50% from the Reference 6 values. If the assumed value for cobalt, nickel, or niobium changes, the waste classification of the activated metals components could also change.

The fifth factor that can affect the total volume of GTCC LLW generated by nuclear utilities is the possible construction of advanced-technology reactors and the volumes generated from their operation of these reactors. The possible estimated volumes from operating these reactors are addressed in Reference 1 but are not included in the Nuclear Utility totals or in the GTCC-LLW totals from all categories presented in this paper. These volumes have not been included at this time because the future construction of these reactors is so uncertain. If advanced-technology plants are built and begin operation, the total volume of GTCC LLW from nuclear utilities could increase.

Uncertainties in the Sealed Sources GTCC LLW Volume Projections

The Sealed Source areas of uncertainty include possible changes in future concentration averaging practices and variances in the future production and recycling rates from the assumed rates used in making the volume projections for both general and specific licensed sealed sources.

Uncertainties in DOE-Held GTCC LLW Volume Projections

Future acceptance of GTCC LLW by DOE will be on a case-by-case basis until a final disposal option for GTCC LLW is identified. Any future wastes accepted into this category will come from one of the other categories. Therefore, the volume in this category may increase in the future, but that will not increase the total volume of GTCC LLW. A change in the legal interpretation of legislative requirements could also impact the estimated volume of GTCC LLW in this category.

Uncertainties in Other Generators GTCC LLW Volume Projections

Two factors can affect the volume of Other Generators GTCC LLW:

- Concentration averaging practices
- A major increase or decrease in waste generation.

Other generators of GTCC LLW have already performed concentration averaging as much as possible for their waste. Future projections assume that current practices will continue. Therefore, an area of uncertainty for the Other Generators GTCC LLW is the effect of concentration averaging. The reasons for, and effects of, this are the same as explained for the nuclear utilities. Until concentration averaging guidelines are better defined by the NRC and the Agreement States that will license future LLW disposal sites, the base case ACA packaged volumes reported are the best data available.

Another factor that could impact these volumes is a major increase or decrease in GTCC LLW generation rates in the future. No one can accurately predict the economic and political forces that could affect their production. The generation rates used in this paper are based on the best data currently available. In addition, reasonable assumptions are made about the future production rates and number of new

generators that will arise in the future. If the generation rates change, or the anticipated number of new generators differs from these estimates, the actual GTCC LLW volume from Other Generators could vary.

CONCLUSIONS

This study estimates a base case, unpackaged future GTCC LLW volume from all categories of 1,380 m3. If concentration averaging is performed, the base case ACA packaged volume of GTCC LLW is estimated to be 2,054 m3. Table VI summarizes the estimated future GTCC LLW from all categories.

The information and data in this study leads to the conclusion that the volume of GTCC LLW should not pose a significant management problem from a scientific or technical standpoint. The projected volume of GTCC LLW is small enough to indicate that a dedicated disposal facility for this waste may not be justified. Instead, co-disposal with other waste types (i.e. high level waste or DOE special case waste) is being considered as an option.

ABSTRACT

This paper presents a combined deterministic and probabilistic methodology for modeling hazardous waste transportation risk and expressing the uncertainty in that risk. Both the deterministic and probabilistic methodologies are aimed at providing tools useful in the evaluation of alternative management scenarios for U.S. Department of Energy (DOE) hazardous waste treatment, storage, and disposal (TSD). The probabilistic methodology can be used to provide perspective on and quantify uncertainties in deterministic predictions. The methodology developed has been applied to 63 DOE shipments made in fiscal year 1992, which contained poison by inhalation chemicals. Models have been applied to simulate shipment routes, truck accident rates, chemical spill probabilities, spill/release rates, atmospheric dispersion, population exposure, and health consequences. The simulation presented in this paper is specific to trucks traveling from DOE sites to their commercial TSD facilities, but the methodology is more general. Health consequences are presented

as the number of people with potentially life-threatening health effects. Probabilistic distributions were employed for several input parameters; namely, accident time (hour and season), amount(s) of hazardous material released and spill characteristics. The meteorological conditions for the location and time of each modeled accident are obtained probabilistically from a preprocessed meteorological database consisting of hourly records for 61 cities in the contiguous United States. The results show an approximate 98.6% probability that during 20 years of shipments (assuming the 63 DOE shipments of 1992 are made each year), no people would suffer potentially life threatening health effects. However, the last 1.4% of probability includes accidents that can have significant effects, although of very low probability of occurrence. For instance, over a 20-year period, there is approximately a 1 in 86,000 chance totaling 100 or more people and a 1 in 2,000,000 chance of accidents totaling 1,000 or more people suffering potentially life-threatening health effects. The deterministic prediction of risk for the 20-year period, 0.00348 people suffering potentially life-threatening health effects, was found to be at the 99.5th percentile of the probabilistic distribution, which is not surprising given the very skewed shape of the distribution. Expressing risk with a combined deterministic and probabilistic method is helpful to decision makers because a perspective of the uncertainty in the deterministic risk value is given when placed on the cumulative risk probability distribution.

INTRODUCTION

The U.S. Department of Energy (DOE) has approximately 45 sites in the United States that produce chemical hazardous waste (HW) from research and production processes. Much of this waste must be transported on public highways to commercial facilities that are permitted for treatment, storage, and disposal (TSD). During transit, a truck may become involved in a accident. Though rare, such accidents may lead to a hazardous material release which may result in potentially life-threatening health effects, increased probability of carcinogenic effects, and/or other adverse human health effects. As the generator of the waste, DOE must assume partial responsibility for the consequences of such an accident.

The DOE is considering various options (alternatives) for the management of this HW. These options are being evaluated and compared in terms of the relative risk associated with the three health endpoints mentioned above, as a function of the management scenario under consideration. The alternative scenarios differ mainly as to where the 45 DOE sites would transport their chemical wastes for TSD. Portions of the waste might be handled on-site or at regionalized DOE locations and the rest handled off-site at commercial facilities. Determining how to distribute the waste between on-site treatment and off-site TSD facilities leads to a comparison of multiple alternatives requiring the evaluation of human health risks, costs of treatment and transportation, and ecological, land-use, and socioeconomic impacts. The current cases under consideration by DOE include baseline or no action, decentralization, and 5-region and 2-region regionalization.

The need for quantifying the risk in these alternatives and the exigency for providing decision makers with a means for proper interpretation and understanding of these risks gives rise to the necessity to determine and communicate the uncertainty behind the risk estimates. Typically, risk assessments are conducted with deterministic methods that use single values or "point estimates" of parameters pertinent to the risk calculation. However, risk parameter values are often quite uncertain and/or variable, and may in fact fall within a range of possible values. Because deterministic methods do not account for this error, they have limited usefulness in providing a perspective on risk estimates for informed policy decisions. Therefore, an approach has been developed and applied that specifically accounts for key parameter variability and uncertainty. This approach is not intended to replace deterministic methods, but rather to supplement when appropriate information is available to develop necessary parameter data distributions.

This paper presents a state-of-the-art stochastic methodology for quantitatively expressing the distribution of HW transportation risks. When combined with a deterministic risk computation, an expression of uncertainty in the typical deterministic risk estimates can be obtained. The paper also presents results from applying this methodology to assess the risks of transporting HW generated by DOE in fiscal year 1992. The risk assessment methodology was applied only to DOE-generated HW that was transported under the baseline alternative, with the risk measure being the number of people with potentially life-threatening health effects. The candidate

hazardous chemicals in the DOE waste were identified for evaluation with the help of the poison by inhalation hazard (PIH) list from the U.S. Department of Transportation (DOT) (1). The risk assessment methodology developed can be routinely applied to the other health endpoints and waste management alternatives using the computer models developed as a result of the methodology provided in this paper.

HAZARDOUS WASTE DATABASE AND ROUTE PREDICTIONS

To analyze risk from off-site transportation accidents, the Hazardous Waste Risk Assessment Modeling Database (HaWRAM) has been developed at Argonne National Laboratory (2). This database is structured to manage information related primarily to DOE-generated HW that was transported to commercial facilities for treatment and/or disposal during fiscal year 1992. The 63 shipments with PIH chemicals to which the combined deterministic and probabilistic methodologies was applied have been identified by their chemical names, and these names have been entered into the records of the HaWRAM database.

A computer routing prediction model was used to determine routes traveled for each alternative. Routing information was predicted with the HIGHWAY 3.1 Enhanced Highway Routing Model (3) developed at Oak Ridge National Laboratory. This model takes as input the origin and destination cities (generator location and designated facility location) and supplies a detailed output of population densities at locations defined by latitude and longitude coordinates, mileage between successive locations, and interstate and local roads traveled. Several of the actual routes traveled for the baseline alternative were obtained from carriers and compared against routes predicted by HIGHWAY 3.1 to determine accuracy. Each of the predicted routes served as a good estimate of the actual route taken.

DETERMINISTIC RISK METHODOLOGY

Risk due to any one mile of transporting HW is defined as the product of the probability of a release of this waste in transit multiplied by the consequence of the release. The total shipment risk for any one shipment is calculated by summing each of the individual one mile risks along the entire route. The total risk for an entire scenario (management option) is computed by summing each of the shipment risks into one final risk number. Equation 1 defines the formula for computing risk over an entire hazardous waste management scenario:

Eq. (1)

where

S = number of shipments;

L = one-mile locations along the route traveled for the current shipment;

ARL = accident rate or probability of an accident in any one mile of travel (value depends upon the demographic region of the current location);

PRS = probability of a release given the occurrence of an accident (value depends upon shipment packaging, i.e., bulk or package freight);

EAS = exposed area in which the accident plume concentration is greater than the health criterion (exposed area depends upon the chemical properties of the HW released, meteorological conditions, release rates, health criterion, amount of liquid released that flashes or vaporizes directly to the atmosphere and liquid evaporation rates); and

PDL = average population density at the current one-mile location.

In Eq. 1, the product of ARL and PRS gives the probability of a release and the product of EAS and PDL gives the consequence of that release. The remainder of this section provides additional details about the probability of a release and the consequence.

The probability of a release is derived from the product of the probability of an accident in any one mile multiplied by the probability of a release given an accident. The probability of an accident in any one mile is a function of the demographic region (rural, suburban, or urban), and the probability of a release given the occurrence of an accident is a function of container type (package freight or bulk) and physical state of the waste (liquid or gas). The actual probabilities are given in Table I. Accident probabilities are based on California state truck

accident data, and conditional release probabilities are based upon Federal Highway Administration truck accident data. For further details, the reader is referred to Chapter 4 of Present Practices of Highway Transportation of Hazardous Materials (4).
Consequence is defined as the number of people impacted by the particular health endpoint considered. In this paper, the consequence is measured as the number of people with potentially life-threatening health effects. In future applications of the risk assessment methodology, consequence could be measured in terms of the number of people with carcinogenic or other adverse health effects. The number of people affected is computed as the exposed area in which the predicted accident concentration is above the health criterion (for that human health endpoint) multiplied by the average population density within that exposed area.
The average population densities for one of three population zones rural, suburban, and urban were determined by the HIGHWAY 3.1 routing model (3). In this analysis, all rural areas were assumed to have the same population density, and a similar assumption was made for urban and suburban areas.
The distribution for the areas covered by HW concentrations above the health criteria was computed using the Chemical Accident Stochastic Risk Assessment Model (CASRAM). CASRAM has two principal model components that are used to simulate each hypothetical accident: a source-term model and a dispersion model. By considering thousands of accidents for each shipment, a wide distribution of release scenarios is considered. For a deterministic model, each variable is treated as fixed; for the probabilistic version, there is a distribution of release rates and pool sizes (if a pool does form). If the container includes a gas, the release rate and duration of the gas release is predicted instead. The probabilistic method computes a probability distribution of such rates.
The CASRAM source model requires several input parameters such as the chemical(s) released, the total HW quantity shipped and container type for each chemical released, and ambient meteorological conditions. The output includes the release rate and duration from the container and, if applicable, an evaporation rate. These release rates serve as input to the dispersion model.
Prior to determining the release rate with the deterministic method, the source model quantifies the release amount of each hazardous material in the shipment by using average release fractions as a function of container type. These release fractions, shown in Table II, are based upon thousands of HW releases resulting from truck transportation accidents that occurred between 1985 and 1992. The accident data were supplied by the Hazardous Materials Incident Reporting System Database maintained by DOT's Research and Special Programs Administration (6). The average release fractions are small because most releases occur as a result of a damaged valve or receptacle, which leads to a small release.
An additional input parameter required for the dispersion model is the human health criteria. The health criteria refer to the air concentration (and duration) that, when exceeded, can lead to adverse consequences under the health endpoint considered. The health criteria parameter is a function of the duration of inhalation. Three values have been supplied for each health endpoint, a 15-minute, 30-minute, and 60-minute inhalation duration. Only a few chemical wastes in the HaWRAM database have the potential to cause lethal, carcinogenic, or other adverse human health effects (other adverse effects include nonlethal and noncarcinogenic effects such as respiratory problems). An example of a chemical (hydrogen selenide) released in a transportation accident is given in Table III. The results show that the concentration resulting in adverse health effects decreases as the inhalation duration increases.
The actual fixed input parameter values used for the deterministic risk assessment, all of which are either average or conservative, are as follows: stability class D; ambient temperature 95F; wind speed 4 m/s; inversion layer none; cloud cover 10/10 (completely cloudy); and humidity 50%. Potentially life-threatening concentrations are assessed for specific HW chemical components designated as PIH by DOT (Code of Federal Regulations, Title 49, Parts 173.115 and 173.132-133). Liquids and gases that have high toxicity based upon animal 50% lethal concentrations (LC50), as well as liquids with medium to high volatility, have been placed on DOT's PIH list.
Two possible toxicity values that are often available in the literature for estimating potential human life-threatening health effects are the LC50 and the LCLO. The LC50 is defined as the concentration of gas or vapor that causes death in

half the animals tested when administered by continuous inhalation. Because LC50 values are obtained only from animal tests, the results must be extrapolated for application to humans. The LCLO is defined as the lowest concentration of gas or vapor that causes death in any exposed species. The LCLO values may be obtained from animal tests or from actual accidental human exposures. When obtained from human exposures, the lethal concentration measurement may not be accurate.

When several chemicals are transported as part of one shipment on the same truck, additive health effects are modeled to determine the exposed area. This determination is based on the following inequality:

Eq. (2)

where

Ci = the air concentration of the ith chemical, and

Ti = the concentration threshold (health criterion) for the ith chemical

The plume area with concentrations above a particular human health criterion is computed via numerical integration starting at the emission source. Distances closer than 100 ft from the accident scene are omitted because people do not live that close to the roadways. At each downwind integration step, a crosswind integration algorithm is used. As crosswind distances are incremented, Eq. 2 is employed to determine whether or not the current location is included in the exposed area. If there are multiple chemicals in the same accident shipment, then the resultant area is usually a bit larger than the largest area obtained from treating each chemical separately. This method accounts for the additional dosage contributed by each chemical in the mixture released without accounting for synergistic effects.

A PROBABILISTIC METHODOLOGY

Four major parameters or categories of parameters meteorological conditions (atmospheric turbulence characteristics, wind speed, temperature, etc.), temporal conditions (time of day and month of year), release quantities, and health criteria are required to determine the plume area with chemical concentrations above a particular health criterion. Using the deterministic method, these parameters are treated with fixed values or point estimates, although they are truly stochastic. Meteorological and temporal conditions are clearly stochastic parameters because they are constantly changing; release quantities vary with the severity of the accident.

Most HW releases resulting from truck accidents involve only a damaged receptacle or valve leading to small, slow releases. However, more severe accidents can lead to more catastrophic releases where the entire cargo contents is released almost instantaneously. Similarly, there is uncertainty in human health criteria because humans have varying sensitivities to chemical effects, and because health criteria are based upon limited animal studies. A probability distribution for health criteria defined by the "potentially life-threatening health effects" endpoint could be determined on the basis of laboratory data (if available for a given chemical) regarding the concentrations causing death in 10%, 50%, 90%, etc., of an animal population. An uncertainty factor (converting animal data to human data) would have to be included to adjust those animal concentrations. Once that is done, a probability distribution of concentrations can be developed to represent potentially life-threatening health effects in humans.

The probabilistic methodology presented in this paper has been developed to account for variation in the key parameters. Meteorological conditions, temporal conditions, and release rates have been treated probabilistically. The health criterion has been treated deterministically at this time because it was beyond the scope of the current work to define its variation, which depends on the chemical to some degree. Future improvements to the methodology presented may include a stochastic treatment of the health criteria as well.

The probabilistic method is based upon a Monte Carlo algorithm in which a distribution of consequences is derived. The model can be split into two steps. The first step is to derive a distribution of risk for each shipment under consideration (for this application, 63 shipments of DOE-generated PIH HW and subsequently 63 distributions of risk). The results of this first step can be used to examine individual shipments carefully. The second step is to determine a single combined distribution of risk for the entire scenario (waste management alternative) based upon the 63 individual shipment distributions of risk.

Distributions of Risk for Individual Shipments as Determined in CASRAM

The CASRAM model was employed to determine the risk distribution for each of the 63 shipments mentioned earlier. In this section, we outline the CASRAM model to provide the reader some perspective on the Monte Carlo approach as applied in this study. A flowchart illustrating the Monte Carlo approach considered here is shown in Fig. 1. The probabilistic components of the Monte Carlo process illustrated in Fig. 1 are marked by the "Random " notation. As initial data, the model requires the route traveled, the shipment contents, and the population densities along the route. The model begins by looking at the first mile of the route, selecting a random number 'r' between 0 and 1, and determining if an accident occurs. If 'r' is less than the appropriate probability of an accident, then an accident occurs; otherwise, the location is incremented to the next mile. Similarly, when an accident occurs, another random number 'r' is selected between 0 and 1 and tested to determine if a release occurs. Once an accident occurs, a release is modeled and the consequences are recorded. To obtain a smooth distribution, the model continues until 100,000 releases are modeled.

The probability of an accident and the probability of a release given an accident are functions of demographic region and container type, respectively, as described in the section on the deterministic method. Similarly, these values are exactly those used in the deterministic method.

Distributions of time of day and month of year, given an accident, have been developed on the basis of data collected from thousands of actual HW releases resulting from truck accidents. These data are contained in the HMIRS database. Tables IV and V show the distributions numerically.

Two types of meteorological data from 61 cities distributed across the continental United States (Fig. 2) were used for the probabilistic treatment of meteorological conditions. These data were 1) surface airways data to specify the surface turbulence characteristics data (organized through the National Solar Radiation Data Base and essentially reproduced directly from the original National Climatic Data Center [NCDC] 3280 database) and 2) upper air data (NCDC 6201 format). The data are used for specification of hourly atmospheric boundary layer parameters which, with the morning temperature profile, allows for determining daytime inversion heights. Inversion heights during stable conditions were determined through diagnostic equations that are incorporated directly into the dispersion scaling. In the probabilistic modeling, the meteorological data used are those appropriate to the mile in which the accident occurs.

Five cumulative probability distributions of release fractions were developed using the data in the HMIRS database. Each distribution is representative of a different container type (see Fig. 3). The five container types accounted for include 1) small drums (capacity 20 gallons), 2) large drums (capacity >20 gallons), 3) pressurized cylinders, 4) pressurized bulk containers, and 5) nonpressurized bulk containers. Only package freight (pressurized cylinders, small drums, and large drums) distributions are presented in this paper because bulk containers were not used in packaging any of the HW in the 63 shipments of PIH wastes under consideration.

Due to lack of acceptable techniques, a simplified method for estimating pool size was employed. By considering a few representative chemicals for which data were available, equilibrium pool thickness was estimated on a flat surface. These estimates typically yielded coverage areas near 1 m2/gal. Most often, spills do not occur on flat uniform surfaces. To account for the large variety of surfaces with varying porosity and slope, a probability distribution for unit spill coverage area was selected.

In addition to typical atmospheric conditions, the source model also requires a surface temperature profile for accurate
determination of evaporation rates from pools of liquid. The surface temperature profile used differs from the usual ground temperature in that the energy balance at the surface does not include evaporation or transpiration from plants. This modification greatly affects the local energy budget, leading to large variations in surface temperature and conductive heat fluxes compared with those observed on normal ground. For the application presented in this paper, the surface temperature profile was based on the assumption that all evaporating pools are formed on pavement. Although the model does not require this assumption, it is believed to be the most conservative assumption considering the type of surface on which pools may form. Temperatures on the pavement can exceed those of other surfaces, such as soil, by as much as 20F.

The source model uses the release fractions, chemical property data, and information supplied by the meteorological preprocessor to determine release rates and evaporation rates for liquid spills onto the ground. Two types of releases are considered in the model. For gases, liquefied gases or liquids whose boiling point is below the pavement surface temperature, the released quantities are assumed to be released instantaneously. For cases when the pavement temperature is between zero and ten degrees above the boiling point, some liquid will flash and the rest will form a pool. Due to lack of available data, all liquid that is not flashed is assumed to form a pool on the pavement surface. Undoubtedly, this does not always occur in actual accidents.

The dispersion model uses local meteorological data, chemical release rates, and evaporation rates (if applicable) to determine the area downwind in which a particular health criterion is exceeded. The concentration downwind of the source is determined with a similarity-based method that uses nondimensional relationships for the ground-level, crosswind-integrated concentration together with relations for the horizontal plume spread. This method is superior to the Pasquill-Gifford-Turner curves because it appropriately accounts for the atmospheric boundary layer's physical structure and continuously relates the meteorological parameters to the downwind concentration estimates. Furthermore, model predictions agree well with a wide variety of studies, most notably the Prairie Grass atmospheric dispersion experiments. Besides standard plume releases, the dispersion model also has the capability of treating puff releases. Such capability is required because gaseous and flashed liquid releases are instantaneous (forming a puff), whereas evaporation from a liquid pool is continuous (forming a plume). For a more thorough description of the dispersion modeling methodology, the reader is referred to Statistical Determination of Downwind Concentration Decay for the 1993 Emergency Response Guidebook (5).

Distribution of Risk Values for Multiple Shipments

To determine the distribution of risk values for the multiple shipments scenario, an additional Monte Carlo algorithm was implemented. For this application, each of the 63 individual shipment distributions of risk was sampled. The consequence values, one from each of the 63 individual shipment distributions, were summed and recorded. The recorded number represents the total number of people at risk for one trial (at risk of potentially life-threatening health effects for the application presented in this paper). Several hundred or thousand trials are repeated to produce the desired distribution. For this application, the process was repeated 100 million times to guarantee sufficient sampling from the upper tails of the individual shipment distributions of consequence.

RESULTS AND DISCUSSION

Figure 4 shows the cumulative probability distribution of risk from the combination of all 63 shipments of PIH wastes transported to commercial TSD facilities in fiscal year 1992. For this run, the health endpoint under consideration was the number of people with potentially life-threatening health effects.

The cumulative probability distribution presented in Fig. 4 is heavily skewed. Although the probability of a release in any one mile of travel is a function of the demographic region (rural, suburban or urban) and the container type (package freight or bulk), its value is always less than or equal to 1.88E-7. As a result, the probability of no releases occurring along the entire route traveled for all 63 shipments of PIH chemical HW is greater than 97%. Furthermore, most releases are small, often leading to zero risk even though a release does occur (due to the 100 ft offset distance). This fact leads to a probability of zero risk for the entire scenario in excess of 99%. However, in the extreme tail of the distribution (the last 1% of probability), the number of people with potentially life-threatening health effects can be large. The large probability of zero risk coupled with the rare high-risk accidents heavily skews the distribution.

The mean of the risk distribution for the baseline waste management alternative (see Fig. 4) is approximately 3.48E-4 and the deterministic risk value was computed to be 1.74E-4 (nearly half of the mean). Although the deterministic value is half the mean, these two values are at the 99.941th and the 99.947th percentiles, respectively, on the cumulative probability distribution.

Accidents leading to one person or more with potentially life-threatening health effects can occur. However, its probability is 3.6E-5 or 1 in 28,000 over a one-year period for these 63 shipments. Accidents can lead to 10 people or more with

potentially life-threatening health effects, with a probability of 5.4E-6 or 1 in 180,000 for a one-year period of transporting hazardous waste under this scenario. Also, 100 people or more may be subject to potentially life-threatening health effects in a one-year period, with a probability of 5.8E-7 or 1 in 1,700,000 for that year. In summary, very serious accidents with catastrophic impacts could occur with these 63 shipments, but the probability is extremely low. Such accidents would occur under the very unlikely combinations of worst-case release rates (i.e., a very serious traffic accident) along with near-worst case meteorological conditions in highly populated areas. The probability of all such worst-case components occurring at the same time is extremely low, and the Monte Carlo method was able to quantify that probability and impacts on the population. Even after a 20-year period, the probability that no people would suffer potentially life-threatening health effects is approximately 98.6%. Similarly, over a 20-year period, the probabilities that more than 100 people and more than 1,000 people would suffer potentially life-threatening health effects are 1 in 86,000 and 1 in 2,000,000, respectively.
It is also interesting to note that the risk of physical trauma fatalities resulting from a truck accident is higher than the risk presented by a release of a PIH substance as a result of a truck accident. This means that cargo-related risks appear to be smaller than vehicle-related risks. On the basis of data supplied by the U.S. Bureau of the Census and the Federal Highway Administration, the fatality rate for truck accidents is estimated to be 2.02E-8 fatalities per truck mile traveled, leading to a risk of 6.3E-4 for physical trauma fatalities resulting from the 31,250 miles that would be traveled in one year to transport the 63 PIH shipments. This risk level is greater than the cargo-related risk of about 1.7E-4 (deterministic risk value) or 3.4E-4 (mean of the cumulative probability distribution of consequence for all 63 shipments in the entire baseline scenario).
Finally, it is interesting to note that both the probabilistic and deterministic methods show that risk is not uniformly distributed among the 63 shipments. In particular, shipments 3, 12, and 23 of the 63 shipments represent the highest risk. These three shipments alone account for 73% of the deterministic risk and have the most potential for a catastrophic release in which more than 100 people could be affected with potentially life-threatening health effects. These three shipments consist entirely of PIH wastes transported in a gaseous state.
Decision makers will be evaluating transportation risk predictions for the baseline, decentralized, regionalized number 1, and regionalized number 2 alternatives. Presentation of only a deterministic value for each alternative might lead to relatively small differences among the risk predictions. It is possible that the uncertainty in the risk predictions might be so large that it envelopes all the deterministic predictions of the alternatives. Without any clear quantitative understanding of the magnitude of the uncertainty, the decision maker cannot determine whether the predictions are essentially the same or whether they represent perhaps the 10th, 50th, 75th or 90th percentile of the risk probability distribution.
The Monte Carlo approach used in this paper is able to quantify much of the uncertainty in the risk. Questions regarding the completeness of the database of PIH shipments; the accuracy of the dispersion codes; the effects of fire, rain and water reactivity (hazardous waste released into a body of water); and the uncertainty in the health criteria were not quantified in this version of the Monte Carlo model. However, we believe that the bulk of the uncertainty has been captured and that conclusions based on the combined deterministic/probabilistic methods will be more supportable than from the usual deterministic modeling that has been done in the past. The presence of uncertainty in many aspects of the risk calculation needs to be accounted for in a quantitative fashion to make the best use of deterministic predictions for the benefit of decision makers.

ABSTRACT

The mixed low-level hazardous waste in the U.S. Department of Energy (DOE) complex consists of organic and inorganic solids and liquids comprising a wide variety of materials contaminated with radioactive substances. Treatment systems are needed to destroy the hazardous organic materials and to immobilize any hazardous inorganic materials, along with the treatment residues and radionuclides, in order to comply with the regulations promulgated by the Environmental Protection Agency (EPA), state agencies, and the DOE. This paper identifies the importance of final waste forms and the sensitivity of the cost of disposal to the waste treatment technology selected.

INTRODUCTION

The DOE's Environmental Management Office of Technology Development has commissioned an Integrated Thermal Treatment Systems (ITTS) Study to assess alternative systems for treating contact-handled, alpha and non-alpha, mixed low-level radioactive waste (MLLW). The purpose of the ITTS study is to perform a systematic engineering evaluation of a variety of integrated MLLW treatment systems. The emphasis in this study is on the total system, from the receiving dock through disposal of the treated wastes. A total system approach is critical since the selection of one treatment technology over another can have impacts elsewhere in a complete system, such as in waste sorting and sizing, immobilization of the residues, waste disposal volumes, and total life cycle costs.

A major cost component in the treatment of mixed low-level waste is the cost of disposal. In studies sponsored by DOE, total life cycle costs have been developed for a wide range of mixed waste treatment systems (1,2). These studies show that disposal costs can be between 10 to 40 percent of the total life cycle costs, depending upon the wastes being treated, the technologies used in waste treatment and residue stabilization, and the costs of disposal. This paper presents some of the results from the ITTS studies to demonstrate how these inter-related options can affect the choice of a treatment technology.

WASTE COMPOSITION

To identify appropriate waste treatments, knowledge of the physical and chemical makeup of the waste is needed. The waste composition used in this study was derived from a report (3) compiled for the DOE from inputs from 49 DOE sites. The data were known to be imprecise but represented the best possible inventory at the time. The waste in storage at the DOE sites comes from operations that span almost 40 years -- long before requirements for good record keeping, waste treatment, and disposal

existed. Consequently, the data on physical matrices generally do not have a significant level of detail. Furthermore, most of the waste is a very heterogeneous mixture of trash-like material. Little or no segregation of wastes into discrete types of physical matrices was performed. Consequently, the data normally used in the design of combustion or other chemical treatment systems do not exist. Nevertheless, for the purposes of this study, an effort had to be made to define the DOE MLLW in terms of physical matrices in order to get some estimate of the chemical composition of the wastes. The chemical composition can then be used to perform comparative mass and energy balances for each of the different treatment system concepts. The results of the study leading to the waste profile used for the ITTS study are documented in Ref. 4. The physical matrix data from each DOE site are summarized in Table I. These data represent an estimate of the "average" DOE waste arrived at by combining the data from all sites. After assigning a chemical composition to the physical matrices and combining the data, the final waste profile was developed for mass balance calculations; the input waste quantities are shown in Table II.

TREATMENT OPTIONS AND RESIDUE STABILIZATION

Over the last several years, numerous concepts for the treatment of DOE MLLW have surfaced from the DOE National Laboratories and private technology developers. The concepts typically focus on one aspect of a total treatment system -- usually the organic destruction operation or stabilization of the treatment residues. For a waste profile that is primarily organic, the volume reduction associated with thermal treatment is very large. For wastes consisting of inorganic material, volume reduction may be small. The ITTS studies were commissioned by DOE to examine the effectiveness of some of the technologies when combined into an integrated system for treatment of the "average" waste described above. The technologies and a brief summary of the key features of each system are shown in Table III. More details on the technologies are presented in a companion paper in this conference (5). The primary treatment technologies include conventional incineration as well as many non-conventional thermal technologies. For most incineration systems considered, the bottom ash, and usually the fly ash, is converted to a vitrified waste form for disposal. Other systems use polyethylene or grout for primary system residue stabilization. Some of the most innovative systems have the primary treatment combined with the primary stabilization.

In addition to the primary treatment systems, additional subsystems re required to treat the remainder of the waste (mercury, lead, and special waste; metal decontamination; and metal melting (Table II)). These subsystems, which are common to all systems in the study except those that provide the metal melting function in the primary system, also contribute to the total system waste residues.

STABILIZATION OPTIONS AND ADDITIVE REQUIREMENTS

As noted in Table III, the disposal waste forms include vitrified material, polymer stabilized material, and grouted material. For vitrification of the treatment residues, the requirement for glass forming reagents will vary depending upon the post-thermal treatment composition and the type of glass or glass-ceramic final waste form being produced. For this study, it was assumed that the vitrification would be conducted in a melter capable of operating near 1600C. The ash melts easily at this temperature and, depending on its composition, can become an acceptable waste form without any other additives (6). However, to ensure that the ash will be acceptable for disposal, additives are expected to be necessary. Soil is one such additive that has been considered because it can produce an excellent, leach resistant glass-ceramic when melted and cooled (7). Work on vitrification of surrogate waste residues has shown that for virtually any credible post-thermal treatment composition, a soil additive ratio of 40 to 60% (by mass, referenced to the post-combustion residue (ash)) produces a good final waste form (6,7). Thus, to establish an estimate of the disposal residues, a mass ratio of soil to waste residue of 0.5:1 was chosen for the ITTS mass balance calculations. If contaminated soil is used in the vitrification process, then additional benefits are achieved by treating two waste streams in one process.

For the ITTS systems that use polymer stabilization as the primary stabilization option, a mass ratio of post-thermal treatment residue to polyethylene of 1:1 was selected based on work done at the Brookhaven National Laboratory on polyethylene stabilization. As was the case for vitrification, sometimes a higher waste mass loading is possible with polyethylene but a conservative value was chosen for this

study.
For systems that use grout for stabilization, a mass ratio of cement to waste residue of 2:1 was selected. This mass ratio is believed to be suitable for ash waste streams that have minimal chloride residues. The ITTS air pollution control systems are configured to separate the flyash from the scrubber salt residues and should meet the low chloride requirement in the ash residues.
Systems that use polyethylene or grout as the primary stabilization agent do not require addition of soil to produce an acceptable waste form. However, polyethylene or cement must be added, which results in a greater mass and volume for disposal. For example, if a system produces 1000 lb of ash residue, 500 lb of soil would be necessary for vitrification, but 1000 lb of polymer or 2000 lb of cement would be necessary for polymer and grout stabilization, respectively.
All systems that produce a salt in the scrubber blowdown use polyethylene for salt stabilization. Systems producing calcium carbonate and calcium chloride also use polyethylene for stabilization of those salts.

CALCULATED DISPOSAL VOLUMES

Using the stabilization ratios discussed above, the mass balance and disposal volume generation rates for the ITTS systems were calculated for the waste composition and processing rates shown in Table II. The calculated disposal volume rates for the ITTS systems are shown in Fig. 1. The volume rates were generated using the ASPEN PLUS computer code for the primary system mass and energy balance (8).

DISPOSAL VOLUME SENSITIVITY

From Fig. 1, it is clear that disposal volumes vary considerably between the various systems. The total volume range between the systems studied is nearly a factor of four for the waste composition used. The range is attributable to both the choice of processing system and the choice of the stabilization media. For the baseline system (labeled A-1), a separate analysis (9) has been done in which process variations were selected to produce three different waste forms -- vitrified as in the baseline study, polyethylene stabilized, and cement grouted. This resulted in a waste volume generation rate for system A-1 of 13.6, 27.0, and 29.3 ft3/h for vitrified, polyethylene, and grout waste forms. The difference is attributed to the mass mixture ratios described above and the density of the final waste form.
The waste used in this study is mostly inorganic material, as shown in Table II, and only about 23% is combustible (these percentages exclude the soil used for vitrification). If the waste was higher in combustible material, the resulting disposal volumes from most of the systems would be lower.
Another assumption that affects the disposal volumes is the final disposition of melted or decontaminated metal. If the metal is separable from the slag or ash, then it can be melted into ingots and perhaps recycled. While the metal is likely to have some radioactive contamination , so that unrestricted release is not possible under DOE regulations, it probably can be used for fabricating waste storage containers. Currently, DOE is sponsoring several initiatives to investigate such metal recycle. In this study, it is assumed that the metal can be recycled and thus is not disposed. A total of about 1.3 ft3/h of ferrous metal is produced for recycle. If recycle is not viable, the waste disposal volume increases for most systems.

DISPOSAL COST

Disposal unit cost is one of the most uncertain parameters in this study. Very little data exist to estimate the unit cost of disposal on DOE sites because previous costs have been combined with various other operational activities and separating the disposal costs is difficult. Informal, undocumented estimates have suggested costs between $50 and $100/ft3. Direct inquires in FY 1994 for disposal of uranium oxide at the Nevada Test Site and Hanford, the only two sites accepting wastes other than their own, produced numbers of $10 and $58.70/ft3 for low-level waste and $36 and $168.68/ft3 for mixed waste (Reference 10). Commercial radioactive waste disposal rates can approach $300/ft3 and plans for new commercial disposal facilities often have rate projections that exceeded this amount. Consequently, for the ITTS study it was assumed that the disposal facility would be new and that it would meet Resource Conservation and Recovery Act regulations for mixed waste. Such a facility was costed at $243/ft3. The most recent waste disposal cost, which was provided by Envirocare, references the disposal cost in their contract with DOE (Reference 11). This rate was quoted as about $35/ft3.
Higher disposal unit costs provide greater incentive to minimize the disposal volume. Higher fractions of noncombustible residues increase the importance of

maximum waste residue densification. Fig. 2 shows the impact of the disposal unit cost on total life cycle cost for the baseline system producing grouted and vitrified waste forms. For this system, the grout-based waste form has a lower life cycle cost if disposal unit costs are less than $58/ft3. For disposal units costs above that amount, using a melter to vitrify the residues yields a lower life cycle cost.

For vitrification, system A-1 uses 498 lb. of contaminated soil per 1000 lb of waste to provide the proper quantity of glass formers as discussed earlier in this paper. There are large quantities of contaminated soil throughout the DOE system that are not listed in Table I. This soil equates to about 7.4 ft3/h of additional waste (at 67 lb/ft3) and produces an additional 2.7 ft3/h of glass-ceramic waste form (at 187 lb/ft3), which is included in the totals of Fig. 1. A cost credit can be claimed for the systems that treat this contaminated soil. The credit depends on the cost of treating and disposing of the soil using alternative means. An alternative treatment cost of $300/yd3 for contaminated unsolidified soil would produce a credit of $82/hr when the soil is used as a glass former in the ITTS system. Since the baseline system disposes of 13.6 ft3/h, the credit for treatment of the soil is estimated to be about $6/ft3 of vitrified waste. Thus, the break-even point for vitrified vs grouted waste disposal is reduced to about $52/ft3. If the cost of remediating the radioactively-contaminated waste is higher, the credit is proportionately higher.

CONCLUSIONS

From the material presented in this paper, it is clear that different systems for processing complex waste compositions can produce widely differing disposal volumes. Disposal volume is a function of the waste makeup and residue solidification method. The systems in this study had disposal volumes that varied by nearly a factor of four -- from 10.7 to 42.5ft3/h. The choice of a technology and final waste form can strongly affect the total life cycle cost. Disposal unit costs greater than about $58/ft3 appear to justify the cost of residue vitrification on economic grounds alone, without giving credit for the use of contaminated soil in the vitrification process. If credit for the use of contaminated soil is included, this break-even cost reduces to about $52/ft3 (using a $300/yd3 avoided cost). Vitrified wastes provide other intangible benefits that are not the subject of this paper.

ABSTRACT
A survey of radioactive sources and types of wastes arising from their usage in Thailand has been conducted, following the analogous study performed in the year 1990. The significant increase in the volume of wastes from medical application was found, while a small change occurred in the other sectors. The projection of radioactive wastes generation in the next 30 years was established including the accumulated waste volume to be disposed of at about 3500 m3 in the year of 2025. From the information obtained, the conceptual plans for treatment, conditioning, storage and disposal facilities are drawn and presented.
INTRODUCTION
Since the introduction of the nuclear energy program to Thailand in 1962, the applications of nuclear techniques has gradually increased. At present, nuclear technology is well known by most of the Thai scientists, academicians, medical doctors, industrial men, and etc. The principal usages of nuclear technology are those in the medical application i.e. therapy and nuclear medicine, research work, agriculture and industry. Currently, there are 245 licensed radioactive users(1). These licensees are a heterogenous mixture of individuals and institutions. Apart from net benefits, radioactive uses is inevitably accompanied by some negative aspects. One of them is the production of radioactive wastes.
It is a worldwide practice that radioactive wastes have to be kept under control and that their potential impact on man and his environment has to be acceptably low. Therefore, it is the policy of the Thai Atomic Energy Commission that the Office of Atomic Energy for Peace (OAEP) has to render the service of management of the radioactive wastes arising in Thailand. It is the duty of the Waste Management Division to fulfill this mission properly. All radioactive wastes generated by any user in Thailand are sent to this division for treatment and temporary storage. At present, the division is operating a waste management facility consisting of incoming waste storage tanks/rooms, a precipitation plant including ion-exchangers unit, a compactor, a small incinerator, a cement solidification unit, a crushing machine and temporary storage facility. Owing to the increasing applications of radionuclides which in turn results in the increase of the radioactive wastes generation, the present temporary storage at OAEP needs to be expanded or to be replaced by a new permanent disposal site. It is also necessary for OAEP to improve the treatment technology to serve all radioactive wastes generated in the future. In December 1989, the Thai government set a policy to establish the new Nuclear Research Center in a low population area outside Bangkok. Waste Management Facilities will also be attached to that site as a Centralized Waste Processing and Storage Facility (WPSF). At present, this Project is being processed. The new treatment technologies and interim storage facility for processed waste packages will be provided and put into operation within this decade. Additionally, the OAEP is also planning to construct the disposal facility in the near future.
To achieve in managing of radioactive waste, it is necessary to known about sources, significant portion, and characteristic of radioactive waste generated in this country. Therefore, in 1993, Chulalongkorn University in cooperation with the OAEP conducted a survey, via a mailed questionnaire and by personal contact, about sources, types, volumes, characteristics of radioactive wastes arising in Thailand. The information obtained from the survey were used and referred to for the WPSF's conceptual plan for treatment, storage and disposal facilities.
SOURCES AND TYPE OF RADIOACTIVE WASTES
The radioactive wastes generated in Thailand originate from 123 licensees at present. There are 34 medical schools, 24 hospitals, 30 academic and research institutions, and 35 industries. Type of wastes can be classified into two categories.
According to source : Data regarding the uses of radioactivity were used to categorize the wastestreams. The three resulting wastestreams were medical, academic and research, and industrial. The distribution of type of Institution by wastestream

is presented in Table I.
According to waste form : this category can be divided into
- liquid waste form
- solid waste form
The waste compositions are shown in Table II. The produced wastes were sent to the OAEP which is responsible for controlling and managing all radioactive wastes produced in Thailand.

THE PROJECTION OF WASTE FOR THE NEXT 30 YEAR

For estimating the amount of waste production in the next 30 year, the personal communication and information obtained from the survey are used along with the following assumptions.
the projection plan starts from 1995 and ends at 2025
300 m3 of treated wastes are accumulated at the OAEP before starting the plan
From 1995-2005, the average annual treated waste will be 70 m3 based on the survey data.
From 2006-2025, the average annual treated waste will increase to 100 m3 according to the trend in increasing applications of radioisotope uses after the New Nuclear Research Center to be established.
500 m3 of waste volumes from abnormal operation will be reserved.
Therefore, approximately, the total accumulated waste generation to be disposed of at the end of the year 2025 will be 3500 m3. This amount of estimated wastes excludes the LLW and ILW from Nuclear Power Plant which may be operated at about the middle of the projection plan period. The example of the estimated waste volumes for 10 years period (1995-2005) is shown in Table III.

WASTE PROCESSING AND PACKAGING TECHNOLOGIES

In order to treat for all annual generated wastes, the processing methods, treatment technologies available now and in the future at the WPSF can be categorized and summarized as follows :

Liquid Waste Treatment

Chemical precipitation process accompanied with sludge separation process and an ion-exchanger have been used for treatment aqueous liquid wastes. For organic liquid waste, the incineration or immobilization with cement may be applied. The suggested capacity of precipitation/separation process would be 5 m3/hr.

Solid Waste Treatment

There are two suggested treatment processes for solid wastes :
Incineration: combustible materials such as papers, rubber, protective clothes, plastics and others are put into an incinerator which is associated with the off-gas treatment system. The suggested capacity of the incinerator would be 20 kg/hr of dry solid waste.
Compaction: non-combustible materials but compactable such as metal cans, glasswares, etc. are pressed by hydraulic compactor. The volume reduction factors would be in the range of 5-10.

Waste Packaging

The treated wastes shall be immobilized by cementation and cement encapsulation in 200 liter steel drum.
The flow charts of conceptual plan for processing methods are shown in Fig. 1.

INTERIM STORAGE FACILITY

The processed waste packages are temporarily stored pending final disposal. The conceptual design for storage facility would be based nominally at 10 years of the expected annual waste quantity after treatment and immobilization. (The expected quantity would be about 350 drums/year in the first 10 year plan.) Stacking the drums should be limited to three high, the storage area design should be expandable in simple modules.

DISPOSAL TECHNOLOGIES

The preliminary study for site screening has been done(2). The potentially suitable areas for waste disposal (unshaded areas) are shown in Fig. 2. From the topography and climatic considerations, three types of disposal design are suggested. There are Shallow Land Burial (SLB) with concrete floor, Above Ground Vault (AGV), and Below Ground Vault (BGV). The design basis for SLB, AGV and BGV is described as follows :

Site Capacity:

The capacity of all conceptual designs considered in this study is 3,500 m3 of waste at the time of disposal according to the waste volume estimated above.

Disposal Unit Capacity:

Each disposal facility is composed of four disposal units, whose capacity vary from facility to facility. Each disposal unit is divided into several cells. Each disposal cell is sized so that it contains at least one year waste generation.

Segregation of Waste by Waste Class:

In all disposal facilities, it has been required that all waste be in a stable form. ILW will be placed at the bottom of disposal cell. Void spaces between waste containers are be backfilled with earth material in all conceptual disposal facilities.

Support Facilities:

Common support facilities are provided for all disposal technologies. These include components such as the administrative, health physics, security, waste storage and equipment storage/maintenance building, construction warehouse, holding and evaporation ponds, and truck washdown facility. Waste storage facility is provided with a capacity sufficient to accommodate deliveries of wastes for three bad weather months (the wet season) or about one-fourth of the annual waste volume to be disposed.

Buffer Zone:

For all disposal technologies, a buffer zone of 100 meters is provided between the restricted and the unrestricted land areas. The administrative facilities are outside the restricted areas, but within the buffer zone.

The layout and section drawing of BGV and AGV disposal facilities are shown in Fig. 3 and Fig. 4, respectively.

CONCLUSIONS

The relatively static population of medical institutions produce a significant fraction of the total waste volume, if the liquid wastes from research reactor is excluded. The radioactive wastes generated from academic and research institutions depend upon the research projects they received in those years.

Most of the produced radioactive waste were LLW and ILW. The main radionuclides contained in the wastes are : H-3, C-14, P-32, S-35, Ca-45, Cr-51, Tc-99m, I-125 and I-131 and the average activity was less than 109 Bq/m3.

In the year of 2025, the estimated accumulated volumes to be disposed of would be 3500 m3. The four treatment facilities : incineration, compaction, precipitation and solidification with enough capacity would be used for all wastes generated in the future.

For selecting the suitable disposal technology, a more detailed assessment on a smaller scale using more detailed topography and other maps should be studied.

In the future plan, if the final disposal site would be established near the WPSF which is located in humid region and has a low depth of ground water table (<3m), the above ground vault technology would be the most appropriate.

MANAGEMENT OF EXCESS HIGH EXPLOSIVES AT PANTEX PLANT

Patrick Phelan, Ph.D.
Mason & Hanger
Silas Mason Co., Inc.
P.O. Box 30020
Amarillo, TX 79177

ABSTRACT

The Department of Energy's (DOE) Pantex Plant demilitarizes about 45,000 kg of high explosives each year by burning them outdoors (commonly called "open burning)." Half of this material comes from nuclear weapons that have been removed from the nation's stockpile and dismantled. Pantex Plant is the only DOE site in the nation where extensive dismantlement is done.

Burning the explosives demilitarizes them and removes all classified characteristics at the same time. Doing this outdoors is the safest and most economical way. It is a method approved by the Environmental Protection Agency (EPA) because it is

considered the best demonstrated, available technology for treating explosives. Such burning is conducted at the Pantex Plant at a special site according to strict procedures that ensure safety for personnel and the environment. Even so, alternatives to burning of these explosives are being explored.

The best alternatives to open burning are to reuse the material or sell it to commercial firms. Such sales would yield considerable savings. The major problem is that the material must first be cut up to destroy its classified nature, and such processing is inherently dangerous.

The most promising non-thermal alternative is a process known as "base hydrolysis." In this process, bases such as sodium hydroxide attack heterocyclic explosives such as 1,3,5,7-tetranitro-1,3,5,7-tetrazacyclooctane (HMX) or 1,3,5-trinitro-1,3,5-triazacyclohexane (RDX). The primary products are nitrogen oxides and sodium formate, a salt.

INTRODUCTION

The U.S. military and the Department of Energy burn, detonate, or incinerate thousands of tons of explosives each year. The military's munitions are destroyed when it is determined that they are no longer necessary for the nation's stockpile. The DOE, as part of its international commitment to remove nuclear weapons from the stockpile and dismantle them, demilitarizes and removes classified information from explosives and explosive-contaminated parts, as well as treats explosive waste by burning. Most of the dismantlement work for the DOE is done at the Pantex Plant near Amarillo, Texas. The Plant is operated for the DOE by Mason & Hanger - Silas Mason Co., Inc. Three categories of materials are burned there: 1) explosives that were the main charges in the weapons, 2) small components that contain only a few grams of explosives, and 3) wastes consisting of explosive-contaminated waste materials and explosive waste.

OUTDOOR BURNING

Background

The Pantex Plant processes about 45,000 kg of explosives and associated material each year by burning outdoors (also called "open burning.") Of the material that is strictly high explosives, half is main-charges from nuclear weapons and half is scrap from manufacturing activities on the plant site. The amounts of explosive components, explosive-contaminated parts and explosive-contaminated waste are highly variable.

Most of the bulk explosives are plastic-bonded materials made from either HMX or RDX and a plastic like Viton. The molecular structures of these compounds are depicted in Fig. 1.

Burning these explosives out-of-doors is the safest way to treat them. Open burning is a method that has been approved by the EPA for treating explosive wastes, because it is considered the best demonstrated, available technology. For the explosive components or explosive-contaminated components, such burning renders them unsuitable for military use and removes all classified characteristics at the same time. Moreover, it is economical.

Special Handling

The remainder of this section on open burning deals with the treatment of main-charges and scrap explosives. Explosive components and wastes are handled separately by a different procedure, and are not discussed.

Before the high explosives leave the weapon-disassembly buildings, they are packed in special protective containers and transported by truck to special buildings for temporary storage. The buildings are bunkers like the one depicted in Fig. 2. The bunkers' walls are made of reinforced concrete, and the buildings are flanked by hills of dirt that would deflect upwards the force of a blast in the unlikely event that the explosives stored there were to detonate.

From storage, the explosives are reloaded aboard specially-designed trucks and carefully transported to the "burning ground" for final treatment.

At each step in the process, the explosives are handled according to strict, written procedures by trained personnel who work in pairs under the guidance of a supervisor. Such care ensures the safety of the workers and guarantees that the facility remains in compliance with all rules and regulations.

The "Burning Ground"

Burning is done at a remote, 0.24-km2 site on the Pantex Plant reservation. The reservation itself is in an agricultural, sparsely-populated area. It occupies about 64 km2 of prairie in the Panhandle of Texas. The nearest town has a population of

2,300 and is 16 km to the east. The nearest major city is Amarillo (population 165,000) about 27 km to the southwest.
Access to the reservation is restricted, of course, but the burning ground is further secured against entry by unauthorized personnel with a gate and an orange barrier across the road leading to it. Warning signs are posted at the entrance.
Nine "burning trays" are regularly used. As shown in Fig. 3, the trays are steel tables measuring about 1.2 m by 6.1 m, having low walls lined with firebrick. A layer of sand covers the steel tray and insulates it against the heat. The roof-like structure on wheels at the end of the tray is a cover that is rolled over the tray at the end of the day to protect the trays and the ashes from rain.
The trays are widely separated from one another, and they are surrounded by a strip of plowed earth that guards against fire spreading beyond the immediate area should burning materials fall off them.
Strict Procedures
Once at the burning ground, the containers of explosives are unloaded from the truck either by hand or by means of a forklift truck, depending on the size of the containers. The containers are placed beside the burning trays; then the containers are opened one at a time, and the explosives are carefully removed by hand. They are placed on the trays and arranged over the surface. A paper napkin is wet with diesel fuel and taped to a piece of explosive. A squib is then placed in the napkin.
The workers ignite the fire from the safety of a bunker by electrically actuating the squib. The flame propagates from one piece of explosive to the next without causing any to detonate.
The fire burns for only 100 to 300 seconds, but the workers wait 30 minutes before going to visually inspect the tray for any unburned explosives. Up to 680 kg of explosives can be safely burned at a time.
Air Emissions
The burning ground currently operates under a written grant of authority from the Texas Natural Resources Conservation Commission (TNRCC). For the thermal treatment of waste, it operates under Resource Conservation and Recovery Act (RCRA) Interim Status. A permit modification for the burning ground is pending.
Although high explosives burn rapidly and cleanly, some explosives contain fluorine because some of the plastic binders contain fluorine. As shown in Table I, the allowable concentration of hydrogen fluoride is the most restrictive of the pollutants that might be found in the smoke. For this reason, the amount of fluorine-containing explosive that is burned at any time is carefully regulated.
The combustion products from a typical fluorine-containing explosive are listed in Table II. Although carbon monoxide and oxides of nitrogen are largely absent, the amount of hydrogen fluoride is 2% of the total. Because the allowable concentration of hydrogen fluoride is only 4.9 mg/m3 (per Table I), this is the limiting factor when such explosives are burned. Accordingly, fluorine-containing explosives are burned only once every three hours, and the amounts that are burned are carefully limited. By contrast, the explosives that contain no fluorine can be burned in almost any amount, subject only to the self-imposed limitations that have been established because of safety considerations.
Planned Improvements
Because no acceptable alternatives to open burning are yet available, the present facility is to be modified and improved. For example, the "burning trays" on which bulk explosives are burned will be equipped with natural-gas burners and will have a new, remote control system for ignition. Other improvements being considered include a gas-fired chamber to treat equipment that has been contaminated with explosives. Although open to the atmosphere, the chamber would have a way for gaseous emissions to be sampled, and rainwater runoff would be controlled. The improvements, costing about $1 million, are provided for and subject to the requirements of the proposed Hazardous and Solid Waste Permit modification to be issued by the TNRCC.
ALTERNATIVES TO OUTDOOR BURNING
Introduction
Although open burning is the best demonstrated, available technology for treating explosives, Mason & Hanger's researchers are seeking alternative methods of dealing with these materials. No single technology will serve all needs, because there are several, diverse process streams involved. Not only must main-charge explosives be treated, but there are numerous mechanical components that contain small amounts of energetic material that must be demilitarized and sanitized, too. Explosive waste

and explosive-contaminated wastes must also be treated. In general, a different technique is required for each kind of component or waste material.

Recycle

The best alternative to burning the main-charge explosives is to recycle by grinding the explosive to powder, then pressing it to form new charges. This option is especially attractive for the newer, insensitive explosives such as 1,3,5-triamino-2,4,6-trinitrobenzene, known as "TATB." (TATB is one of the best high explosives for making weapon components, because it is so insensitive that it is very safe to handle.) If TATB could be recycled, the current inventory of this material would be extended indefinitely. Recycling the old types of explosives is not desirable, because they are no longer being used much in new weapons.

Although grinding TATB to powder and then pressing it into a new part is easy to do, it is not known whether some important property will be adversely affected. Experiments completed so far show that, after three cycles of grinding it to powder and then pressing the powder to shape, the density of the charge has been satisfactory; and no defects, such as cracks, have been observed. Particle size measurements show the particles are becoming smaller, which is desirable.

Reprocess, then Sell Commercially

The second best alternative to open burning is to sell the excess material to commercial firms. Such sales would yield considerable savings in the costs associated with warehousing and with outdoor burning. However, many potential customers want pure explosives, not material containing plastic binders.

To purify the material requires that the plastic-bonded explosive be dissolved in a solvent, and the purified HMX or RDX be recovered by recrystallization. However, only a few solvents are suitable for this. Reprocessing is more complicated than simply recycling the material, because the particle morphology may be changed, yielding a much more sensitive, and more hazardous, material. Then, too, the plastic binders and dyes found in many of the explosives present problems and they must be cleanly removed. Fortunately, a Mason & Hanger researcher has developed a recovery process and is seeking a patent for it.

Even when the explosives from weapons can be sold without removing the binders, the main-charges must be processed to remove classified information. Such handling is inherently dangerous. As an alternative to cutting the explosives, Mason & Hanger researchers are investigating the feasibility of pulverizing the explosives by first freezing them in liquid nitrogen, then crushing them while they are still brittle.

New, Non-Thermal Methods

It is unlikely that all explosive material can be recycled or sold, so some will have to be managed in some other manner. As a means of demilitarizing and sanitizing large pieces of explosives, workers at the Pantex Plant have collaborated with those at Los Alamos National Laboratory to develop a process known as "base hydrolysis." In this process, a base attacks the heterocyclic compounds to produce, primarily, nitrogen oxides, nitrite, and formate. Acetate and other minor products are also formed. Mason & Hanger has perfected this base hydrolysis process and is seeking patent protection for the improvements.

Small Components That Contain Explosives

Besides main-charge explosives, the Pantex Plant has components and other items that contain small amounts of explosives. Detonating fuses are especially troublesome items. As depicted in Fig. 4, these fuses are sheaths or tubes of lead filled with an explosive. These fuses cannot be treated by open detonation, because lead particles would be thrown about. To solve this problem, a special chamber has been designed at the Pantex Plant in which the lead is melted and recovered, while the explosive burns harmlessly away.

Other small components from dismantled weapons can be rendered harmless by discharging them inside a chamber, but this process is very labor-intensive. Another approach being investigated is to pyrolyze the explosive in a plasma torch. Such torches are commercially available and, when operated under reducing conditions, they have not been defined as incinerators by the EPA and several state agencies. Preliminary tests by Plasma Energy Applied Technology in Huntsville, Alabama, show that although the components may occasionally explode, such explosions are small enough that the equipment is not damaged, nor are fugitive emissions released to the atmosphere.

CONCLUSION

Mason & Hanger is in the forefront of managing excess high explosives. Although open

burning is still the best method for treating such explosives, base hydrolysis and other alternatives are being developed for use with some of the explosive materials.

SECONDARY WASTES AND HIGH EXPLOSIVE RESIDUES GENERATED DURING PRODUCTION OF MAIN HIGH EXPLOSIVE CHARGES FOR NUCLEAR WEAPONS

L.J. Jardine
J.T. McGee
Lawrence Livermore National Laboratory
7000 East Avenue
Livermore, CA 94550

ABSTRACT
This study identifies the sources of high-explosive (HE) residues and hazardous and nonhazardous wastes generated during the production of the main HE charges for nuclear weapons, and estimates their quantities and characteristics. The results can be used as a basis for design of future handling and treatment systems for solid and liquid HE residues and wastes at any proposed new HE production facilities.
This paper outlines a general methodology for documenting and estimating the volumes and characteristics of the solid and liquid HE residues and hazardous and nonhazardous wastes. We prepared volume estimates by applying this method to actual past Pantex plant HE production operations. To facilitate the estimating, we separated the HE main-charge production process into ten discrete unit operations and four support operations, and identified the corresponding solid and liquid HE residues and waste quantities. Four different annual HE main-charge production rates of 100, 500, 1000, and 2000 HE units/yr were assumed to develop the volume estimates and to establish the sensitivity of the estimates to HE production rates.
The total solids (HE residues and hazardous and nonhazardous wastes) estimated range from 800 to 2800 ft3/yr and vary uniformly with the assumed HE production rate. The total liquids estimated range from 73,000 to 1,448,000 gal/yr and also vary uniformly with the assumed production rate.
Of the estimated solids, the hazardous wastes (e.g., electrical vehicle batteries and light tubes) were about 2% of the total volumes. The nonhazardous solid wastes were not very sensitive to the HE production rates because the air filter change-outs from the building air handling units did not depend on HE throughputs. The generation of solid HE residues varied uniformly with the HE production rates and ranged from about 20% of the total solids volume for the 100 HE units/yr case to about 60% for the 2000 units/yr case. The HE matching operations generated 60 to 80% of the total solid HE residues, depending on the assumed production rate, and were also the sources of the most concentrated HE residues.
Of the total estimated liquids, the nonhazardous wastes were dominant, with 99% of the total liquid volume being generated from the use of a once-through (i.e., no-recycle) HE machining cooling-water system. Future plants will most certainly use recycle systems and, therefore, not generate such large nonhazardous waste quantities. Thus, more meaningful comparisons of these volume estimates can be derived for design purposes by removing the once-through machining cooling water quantities and then making a new set of comparisons. The volumes of hazardous liquids are relatively small, ranging from 30 to 600 gal/yr depending on the HE production rates. The hazardous liquids are generated by x-ray film processing and analytical chemistry laboratory operations, with the former accounting for about 80% of the total hazardous liquid wastes. The liquid HE residues are generated primarily from the wet mopping of floors and contain low concentrations of HE residues. The maintenance of the wet scrubber system in the HE pressing area generates the same quantity of HE residues for all HE production rates and is only 10 to 30% of the total liquid HE residues.
We conclude that the total quantities of solid and liquid HE residues and hazardous and nonhazardous wastes generated from the production of main HE charges are not very large compared with those generated by many other types of production processes. Nevertheless, these solids and liquids must be addressed in the design and operation of future plants. This conclusion is particularly valid if future production plants eliminate the use of once-through machining cooling water systems, which generate large quantities of nonhazardous aqueous liquids.
Additional analyses of these results and the information developed in this study can provide insights into the specific HE production process operations for which wastes

and HE residues can be minimized, eliminated, or collected for recycle. The methodology can be extended to other parts of the HE production processes (synthesis, formulation, and nonmain-charge HE components) and nuclear-weapons dismantlement operations.

INTRODUCTION

As a participant in the DOE Weapons Complex Reconfiguration Project - Complex 21, Lawrence Livermore National Laboratory has been assigned the lead laboratory role for the HE production operations. This assignment includes preparing design criteria for use by DOE and the architect engineer (AE) in developing new high-explosive production facility conceptual designs for the next-generation weapons complex. A key part of developing new facility designs is providing the necessary waste-treatment facilities and equipment for processing all solid, liquid, and gaseous wastes and HE residues resulting from high-explosive production operations. Design of waste-treatment facilities and equipment requires that estimates of the amounts of HE residues and wastes and their characteristics be available.

This study identified the major sources of solid, liquid, and gaseous secondary wastes and HE residues generated during actual past production of HE main charges at the Pantex facility. We estimated the amounts and characteristics of these wastes and residues on the basis of the currently constructed Pantex facility. These estimates were developed by establishing a reference HE production flowsheet, by interviewing Pantex staff experienced in actual HE production operations, by walking through the Pantex facility production lines, and by using engineering judgment. To facilitate the systematic development of these estimates, we defined and used a three-step estimating methodology.

This report summarizes the results of the study and provides the methodology and major assumptions used to estimate the secondary wastes and HE residues. The estimates can be used both to prepare design criteria and identify candidate process areas for waste minimization. In addition, since a primary goal of the lead laboratory effort is to treat all HE residual materials as an asset, assessments must be made to consider recycle and reuse of HE residues, even though some residues must be destroyed. With this information, the design bases for a new HE main-charge production facility can be prepared.

METHODOLOGY FOR DEVELOPING ESTIMATES OF WASTES AND HE RESIDUES

We used a three-step approach to prepare the estimates. In step one, a reference process flowsheet and facility layout were defined on the basis of the Pantex facility HE main-charge production processes. We then divided the production process and facility layout into ten discrete, major, unit-operations areas. Figure 1 summarizes these ten areas. In addition, we defined four areas for support or ancillary operations, which are shown at the bottom of Fig. 1. Each area was established on the basis of past HE production process operations or current Pantex facility layouts. All areas were selected so as to be correlated with discrete groups of process operations known to create major quantities of secondary wastes and HE residues.

In step two, we studied each area in sufficient detail to identify the major equipment and operations required to carry out the functional operations. We used this information to develop process flow diagrams that show the detailed subactivities for each of the blocks in Fig 2. Figure 2 shows an example of these diagrams. We used these levels for greater detail to estimate the actual secondary wastes and HE residues that required collection and treatment in all facility designs.

In step three, we examined all activities or operations individually in order to develop estimates of solid, liquid, or gaseous waste characteristics and quantities. Where insufficient Pantex production staff experience existed, or where Pantex production records of waste and HE generation were incomplete, we used engineering judgment to develop the estimates. We then estimated the total volumes resulting from the HE main-charge production processes by tabulating the results from each of the ten discrete areas and four support areas for each waste and HE residue type.

Reference HE Production Facility and Operations

The Pantex production site is located about 18 miles northeast of Amarillo in the panhandle region of northwest Texas. The site is located on U.S. DOE property and has rail and truck access. The feed materials required for the HE production process are received and stored in storage igloos at the on-site receiving and storage area.

The main-charge HE production facilities at the Pantex site are housed in four buildings. All of these facilities are assessed in this study. They are 1) the HE and materials staging facility, 2) the main He pressing areas, 3) the radiography/x-ray facility, and 4) the HE machining areas. The building that houses the main HE pressing areas also contains the isostatic press control room, the rotoclone ventilation scrubber system, and the isostatic press fluid equipment room. The major activities performed in the building that houses the HE and materials staging facility include the receipt and staging of HE process feed materials from the storage igloos and from other staging operations, the staging of intermediate products, and the staging of HE residues from the production processes. HE process feed materials are stored in one of seven magazines until required by the production process. Intermediate HE production process products are also stored in sealed cans containing a desiccant and are staged during various phases of the HE production process. Production wastes, HE residues, and other materials are placed in cans until final disposition is determined.

In examining the HE main-charge pressing operations, we looked at both the pressing operations and associated materials-handling operations. The HE main-charge pressing operations are conduced as follows. HE materials are prepared and then sent to undergo heat treatment and subsequent materials loading into the HE mandrels/liners. The main HE charges are then isostatically pressed. The pressed HE mold breakout and initial shadowgraph product inspections are then carried out. HE products passing the shadowgraph inspections are sent in sealed cans to the radiography/x-ray building to be x-rayed or to the HE and materials staging facility for staging prior to x-ray. Any shadowgraph rejects are sent in cans to the HE and materials staging facility.

HE specimens that pass the x-ray inspections are sent to the building that houses the main HE pressing area. The specimens then undergo the lathe machining operations that are required for fabricating the rough outer, final inner, and final outer HE shapes. Although the specific order varies for different weapons components, it is assumed that the HE products from the rough outer shaping are then transported elsewhere in the building in sealed cans for density measurement and dye penetrant crack measurements. After these measurements, they are transported back to the machining area for the final inner and outer shaping operations.

The shaped HE products are then transported in sealed cans to an area where the milling machine operations required to fabricate all special shape features into the primary HE charges are performed. The machined HE products are then transported in sealed cans for dedicated gauging measurements or for gauging with a coordinated measuring machine. HE products meeting specifications are transported in sealed cans to the HE and materials staging facility for staging before being sent to subassembly. Any HE products not meeting the inspection requirements are transported in sealed cans to the HE and materials staging facility for interim product storage.

To develop the waste estimates, we assumed the specific process flow associated with the activities described above, including all the necessary HE main-charge production operations that can generate wastes and HE residues. The specific process flow of the inspection operations, gauging operations, lathe operations, and milling operations can very depending on a specific HE charge component design. In addition to the parts of the building housing the HE machining areas, we examined two associated support equipment facilities in other buildings, required by these operations for generation of waste and HE residues. One facility houses a waste-water treatment system and the other houses a central vacuum system required by the HE machining operations.

The radiography/x-ray operations generate wastes during the setting up and taking down of HE main charges from the film racks. However, the development and processing of the film generates the most significant waste quantities. These wastes, many of which are hazardous, include developer and fixer liquid solutions, drying solid materials from film processing, film processing rollers, lead cassettes, and lead film filters.

In addition to the main production process operations, there are four ancillary support operations (Fig. 1). These include 1) preventative maintenance, 2) analytical laboratory, 3) mechanical tests (mechanical and physical HE testing) and 4) HE test firing. The analytical and test facilities provide support services for HE lot acceptance, determinations from suppliers, and HE product certifications processes. Preventative maintenance includes major maintenance operations and

buildings (e.g., ventilation systems and lighting), and equipment used for the main HE production processes (e.g., forklifts and carts).
The mechanical and physical testing of HE is conducted in the same building as the one used for radiography. The operations include conducting tensile (dog bone) tests, compression (nonfailure) tests, thermal (grain growth) tests, and test specimen gauging measurements. Specimens requiring testing are received in sealed cans from either the HE and materials staging facility or the radiography/x-ray facility. The tests do not produce significant fracture particulates from the HE specimen. In fact, all specimen pieces are placed after testing in sealed cans as HE residues and are returned to the building housing the HE and materials staging facility for final disposition. Small quantities of trash (wipes and gloves) are generated during the testing.
The HE test firing operations are conducted near the on-site receiving and storage area. The preparation and setup for the test firings, as well as the actual test firings, generate wastes and HE residues. These test firing operations include measurements of HE hydrodynamics, detonation velocities, gap sensitivities, divergence, and snowball/onion skin tests. These operations generate wastes that include test cables, plastic tubes, styrofoam, wood, glass mirrors, and metals. During the test firings, the HE is consumed; however, the test remnants are currently classified as containing HE residues. The test setup operations generate primarily nonhazardous trash.
The analytical chemistry laboratory measurements are conducted in a separate building. These operations include both wet and dry sieving particle size measurements, numerous sample weighings, bulk density measurements, gelchromatograph analyses, solid (TATB and KEL-F) digestions, titrations, volatility measurements, infrared spectroscopy, gas chromatograph analyses, and burned ash content determinations. Many tests generate wastes classified as hazardous because of the organic contents. Typical wastes include gloves, wipes, reagent bottles, glassware, analytical residues, and spent test solvents.
The preventative maintenance operations that generate wastes and apply to multiple HE production process steps include maintenance for electric forklifts, electric carts, building lighting, and building ventilation filters. Other major preventative maintenance operations are discussed in the specific HE production process steps. Hazardous wastes generated consist of spent lead-acid batteries and mercury-contaminated, crushed light tubes/bulbs. The routine scheduled change-outs of the 2 X 2 ft X 2 in. filters in the numerous building air handling units generate a large quantity of wastes readily amendable to volume reduction processes.
ASSUMPTIONS AND QUALIFICATIONS
We developed flow diagrams for the blocks shown in Fig. 1 in order to identify and quantify the major process operations and equipment that generate the residues and wastes. The ten major areas are:
1. Receipt and storage on-site of HE feed materials.
2. Staging of HE feed materials and production products.
3. Inspection and weighing of feed materials.
4. Heating and HE mold preparation.
5. Isostatic HE pressing.
6. HE mold breakout and inspections.
7. HE x-ray inspections.
8. HE shape machining.
9. HE product gauging.
10. Inspection of final HE products.
The four ancillary support areas are:
11. Preventative maintenance facilities.
12. Analytical laboratory.
13. Mechanical tests.
14. Test firing.
The ten discrete areas and four support areas can be correlated directly with the reference facility and process operations described above. We examined each area one at a time by interviewing Pantex production staff experienced in the actual HE production processes to identify specific activities and equipment associated with the process operations. The activities were systematically reviewed and all major secondary HE residues and waste streams identified, estimated, and recorded. Note that no estimates for general support facilities are provided in this initial study.

To facilitate the estimating process, all activities were assigned to one of four waste categories: 1) normal operations 2) housekeeping operations, 3) preventative maintenance operations, and 4) decontamination operations.
Normal operations are defined as daily activities performed to operate the HE production processes. Normal operations include HE materials process feed preparations, HE pressing, HE product inspections, HE machining, HE materials transfers, and HE material storage or staging.
Housekeeping operations are defined as routine activities performed to keep the HE production facilities free of trash and dirt. The solid-trash floor sweepings and mop water generated in areas that contain HE materials are generally assigned to this category. In some cases, wastes in this category were assigned to the normal operation category. If these wastes were generated in an area with HE materials present, they would require special handling because they potentially contain HE residues.
Preventative maintenance activities are defined as activities performed to keep and maintain the equipment operating at the assumed production rates. These activities include liquid-system filter replacements, building ventilation filter replacements, and routine maintenance of process equipment scheduled at regular intervals.
Decontamination activities are defined as those in which HE materials are specifically removed from equipment, molds, and machine tools.
Using these four waste categories and the process flow diagrams that we developed for the blocks in Fig. 1, we tabulated the solid and liquid HE residues and waste streams for each subactivity. Only solid and liquid wastes were identified. Gaseous wastes were assumed to be insignificant and were not tabulated.
We estimated rates of waste generation by either quantity per HE unit produced or by time interval (e.g., per shift, per month). For filter changouts and scheduled maintenance events, waste quantities were tabulated per unit of time. In most cases, Pantex staff provided rates during the interviews based on past production experience. Otherwise, estimates were based on engineering judgments. For each of the ten areas and corresponding process flow diagrams, a summary datasheet was developed and totaled. Datasheets were also developed for the four ancillary support operations.
The annual secondary waste quantities generally depend on the number of HE main charge units produced per year and the number of shifts per year. Therefore, we examined four different HE production annual rates of 100, 500, 1000, and 2000 units to evaluate the sensitivity of the wastes generated for various production rates. For all production rates, we assumed only one shift of 250 working days/yr, and a production rate of 10 HE units/day. The sensitivity of waste generation to multiple shifts per day was therefore not examined. Estimates of wastes generated when no HE production takes place in a year because of excess HE production capacity were also developed.
We assumed that all HE formulation and synthesis operations were performed by an off-site supplier. Those associated secondary wastes were not in the scope of this initial study. Such required HE production operations will need a similar quantification of associated secondary wastes for a new facility design basis. It is assumed that the previously formulated and synthesized HE process feed materials from off-site suppliers were received by truck shipments. HE materials production lot sizes of 30,000 lb and single truck shipments of 10,000 lb in separate 50-lb boxes were assumed.
To develop the waste stream characterizations, we classified the solid and liquid wastes as one of three types: 1) HE residues, 2) hazardous wastes, or 3) nonhazardous wastes. HE residues are process streams containing HE materials that must be collected, handled, and treated separately from other types of wastes because of the HE content. Hazardous wastes are used to identify waste streams currently subject to the requirements of the Resource Conservation and Recovery Act (RCRA). Nonhazardous wastes are used to identify wastes not subject to RCRA requirements and which are therefore treatable as conventional industrial or nonregulated wastes.
The content of HE residues varies widely among the specific waste streams. The use of two grades, to denote either relatively high concentrations or low levels of process streams contaminated with HE materials, could be developed in the next iteration of estimating the HE residue wastes. The process streams with the relatively higher concentrations would be the HE residues most likely to merit

further processing or treatment to recover HE materials in recycle.

RESULTS OF ESTIMATES

Solid Wastes and HE Residues

Solid wastes can be either compatible or noncompactible. Compatible wastes are materials that can be treated with a mechanical process to increase packaging density for disposal or storage. Noncompactible wastes are those at or near their maximum packaging density prior to any waste treatment. Typically, compatible wastes include plastics (packing material, bags, containers, boots, gloves, tubing, bottles, hoses), paper (box liners, packing material, wipes, coveralls, absorbent paper, wrappings, boxes, cartons), cloth (filters, coveralls, lab coats, rags, mops, gloves), rubber (mold liners, hoses, gloves, pads), metal (empty cans, clamps), filters (prefilters, ventilation filters, respirator canisters) and miscellaneous items. Noncompactible wastes include wood (mold tampers, packing), filters (cartridge type), wood or metal filter frames, discarded tools (hand, power-driven), dirt (dust, floor sweepings), glass (bottles, lab glassware, mirrors, instrument tubing), conduit (tubing, cable, wire, electrical fittings), pipe/valves (pipe, tubing, valves, fittings), failed equipment, and other miscellaneous items.

Using the methodology, assumptions, waste categories, and reference HE main-charge production facility described above, we developed estimates of the solid wastes and HE residues for each of the four assumed HE production rates. These estimates are summarized in Table I and Fig. 3.

For the total estimated solids, the hazardous solid wastes (e.g., electrical vehicle batteries and light tubes) were about 2% of the total solid volumes. The nonhazardous solid wastes were not very sensitive to HE throughputs. The solid HE residues varied uniformly with HE production rate and ranged from about 20% of the total solids volume for the 100 HE units/yr case to about 60% for the 2000 HE units/yr case. The HE machining operations generated 60 to 80% of the total solid HE residues, depending on the assumed production rate, and these were also the most concentrated form of HE residues.

Liquid Wastes and HE Residues

Liquid wastes are generated during the HE production operations. The HE machining operations are a major generator of liquid wastes containing HE residues. Any oils contain trace amounts that are too low to be explicitly considered. The liquids discharged from these machines are filtered within the machining bays to recover most of the HE residues before being discharged and routed to a second water cleanup system prior to final off-site discharge.

The wet rotoclone scrubber system used to collect HE production process dust generates liquid wastes containing HE residues during its routine maintenance cycles. The maintenance and periodic replacement of the isostatic press mobilnet fluid generates nonhazardous liquid wastes containing no HE residues. The development of films as part of the x-ray inspections generates both hazardous wastes containing silver ions and nonhazardous liquid wastes.

Liquid wastes containing varying concentrations of insoluble solids (dust and dirt), detergents, chemicals and dye penetrants are collected from various laboratory drains used for inspections, mechanical testing, chemical analyses, and film processing. Some liquids generated must be collected during special HE material decontamination of equipment. Additional liquids are generated infrequently when HE lots are changed and equipment is cleaned of HE residues from a previous lot. Wet mopping of the HE production bays generates liquids containing HE residues.

To determine the types and volumes of liquid wastes, we employed the same methodology, assumptions, and reference process used for estimating solid wastes. The estimates of liquid waste volumes are shown in Table II and Fig. 4 for each of the four assumed HE production rates.

For the total estimated liquids, the nonhazardous liquids dominated the total liquid volume, with 99% of this volume being generated from the use of a once-through (e.g., no-recycle) HE machining cooling-water system. Future plants will most certainly use recycle systems and, therefore, not generate such large nonhazardous waste quantities. Thus, more meaningful comparisons of these total liquid volume estimates can be derived for design purposes by removing the once-through HE machining cooling-water quantities, and then making a new set of comparisons.

Hazardous liquid wastes are generated by x-ray film processing and analytical chemistry laboratory operations, with the former accounting for about 80% of the total hazardous liquid wastes. The liquid HE residues are generated primarily from

the wet mopping of floors and contain low concentrations of HE. The maintenance of the wet scrubber system in the HE pressing area generates the same quantity of HE residues for all HE production rates and is only 10 to 30% of the total liquid HE residues.

SUMMARY

This study identifies the source of HE residues and hazardous and nonhazardous wastes generated during the production of the main HE charges for nuclear weapons, and estimates their quantities and characteristics. The results can be used as a basis for design of future handling and treatment systems for solid and liquid HE residues and wastes at any new HE production facilities.

Because of the uncertainty of future design bases, we assumed four different annual HE main-charge production rates (100, 500, 1000, 2000 HE units) to develop volume estimates and to establish the sensitivity of the HE residue and waste quantities to production rates. The total solids (HE residues and hazardous and nonhazardous wastes) estimated range from 800 to 2800 ft3/yr and vary uniformly with the assumed HE production rate. The total liquids estimated range from 73,000 to 1,448,000 gal/yr and also vary uniformly with the assumed production rate.

We conclude that the quantities of solid and liquid wastes and HE residues generated in producing main HE charges are not very large compared with those generated by many other types of production processes. However, the solids and liquids must be addressed in the design and operation of future plants. This conclusion is particularly valid if future production plants eliminate the use of once-through machining cooling water systems, which generate large quantities of nonhazardous aqueous liquid. Further analyses of these results and the information developed in this study can provide insights into the specific HE production process operations for which wastes can be further minimized or eliminated, and for which HE residues can be most efficiently collected for reuse or eliminated.

We recognize that a new HE production facility will use facility layouts and handling operations different from those of the current Pantex general facility. A new facility will thus not necessarily generate the wastes and HE residues summarized in Table I and II. For example, the use of simple water collection and treatment systems will allow full recycling of the HE machining water rather than a once-through treat and discharge system as is currently used. This single process modification would significantly reduce liquid wastes. Nevertheless, the study provides a tabulation of the functional requirements in the HE main-charge production process and the potential waste-generating activities. Facility designers can use the information developed in this study and the results of this study, which are based on actual HE production facility staff experience, to design a new production facility that minimizes the cost among the various engineering trade-offs between waste generation, waste treatment, and waste disposal.

Grand Junction Projects Office

ABSTRACT

In 1981, the U.S. Department of Energy Grand Junction Projects Office (DOE-GJPO) was assigned responsibility for the Uranium Mill Tailings Remedial Action (UMTRA) Grand Junction Vicinity Properties Project. This project required planning, characterization, design, and remediation of more than 4,000 properties in the vicinity of Grand Junction, Colorado.

The 4,000 properties were contaminated with radioactive uranium mill tailings as a result of milling operations conducted for the U.S. Government during the 1950s and 1960s. These mill tailings were used by the community as backfill in construction projects, as a sand mixture in concrete and mortar, and as a sandy loam admixture in

the native soils to enhance the growth of gardens and lawns. Congress passed the Uranium Mill Tailings Radiation Control Act (UMTRCA) in 1978 to authorize DOE to remediate and to permanently dispose of the radioactive mill tailings that were spread throughout the southwestern United States.

DOE-GJPO and its contractor, Rust Geotech, were given the task of planning and performing the remedial action of more than 4,000 residences and businesses, the largest remedial action project of its kind. These properties included heavy and light commercial businesses, some of which contained hazardous waste that had become mixed with the mill tailings (referred to as commingled waste). Rapid resolution of the commingled waste posed a unique problem to project managers because the material was regulated by both UMTRCA and the Resource Conservation and Recovery Act (RCRA). DOE-GJPO found that resolving commingled waste problems required a cooperative effort with the Colorado Department of Public Health and Environment, which is the authorized agency to manage RCRA within Colorado.

URANIUM MILL TAILINGS HISTORICAL PERSPECTIVE

From the early 1940s through the 1960s, approximately one-half of the uranium ore mined in the United States was processed by private companies under contract to the Federal government. The uranium ore was used in national defense research, weapons development, and in the commercial nuclear energy industry.

The uranium mills were shut down as government contracts terminated, leaving large uranium tailings piles on many of the millsites. Uranium mill tailings are a sand-like waste product from the milling process that contain approximately 85 percent of the radioactivity that was present in the unprocessed uranium ore. The long-term health hazards from exposure to radioactive elements in the tailings were not known at the time the millsites were abandoned. As a result, most piles were left unstabilized, exposed to the environment, and subject to other uses.

In Grand Junction, Colorado, the Climax mill was one of these abandoned uranium ore processing sites, located adjacent to the downtown area. To minimize the growing tailings stockpile, the mill operators allowed free public access to the stockpile for private use of the sandy material. The operation of the Climax mill coincided with a large building boom in the Grand Junction area, and more than 4,000 properties in the vicinity of the mill (referred to as vicinity properties) became contaminated with the tailings. The tailings were used extensively in the construction of residences, schools, churches, public buildings, and commercial structures. These uses included, but were not limited to,

- Sand substitute in concrete and mortar mixes
- Bedding sand for utility lines and concrete structures
- Backfill around foundations
- Soil amendment for lawns and gardens
- Fill material to level properties with uneven ground

In the 1960s, medical research identified potential health hazards associated with uranium mill tailings, primarily from the inhalation of radon, a decay product of the radium present in the tailings. In 1978, Congress passed Public Law 95-604 (1) establishing the Uranium Mill Tailings Radiation Control Act (UMTRCA) to authorize the U.S. Department of Energy (DOE) to remediate 24 inactive millsites and the surrounding vicinity properties in various locations throughout the United States, including Grand Junction.

The U.S. Environmental Protection Agency (EPA) subsequently published the final rule in 1983 to establish the standards for the cleanup of inactive uranium processing sites (2). The final rule incorporates the results from evaluations of Grand Junction vicinity properties to determine the hazards associated with radon. EPA estimated that for each 0.01 working level (WL) increase in radon decay-product concentration inside a residence, there is an associated risk of lung cancer for inhabitants of "something like one-half to one in a hundred for an assumed lifetime of residency." Therefore, EPA established the objective of reducing radon to below 0.02 WL in structures, where practical, and not to exceed 0.03 WL. Since 1983, awareness of health hazards from naturally occurring radon has increased, and EPA has suggested similar standards for houses nationwide. EPA also established a radium cleanup standard of 5 picocuries per gram (pCi/g) above background in the top 15 centimeters of soil and 15 pCi/g above background on the subsurface because "soil extensively contaminated at a level of 5 pCi/g of radium can lead to indoor levels of radon decay products of 0.02 WL." Although the EPA standard addressed wastes related to the milling process, the standard did not address hazardous wastes mixed

with uranium mill tailings on vicinity properties.
In 1981, DOE assigned the Grand Junction Projects Office (GJPO) with the responsibility for remediating more than 4,000 properties in the vicinity of Grand Junction. The properties were placed in the following four principal categories to manage the large volume of properties under the project: simple residential (exterior portions of a residential vicinity property), major residential (interior portions of residential properties), simple commercial (small businesses such as gas stations), and complex commercial (large businesses or a group of properties typically worth more than $500,000). To date, 3,974 properties have been remediated, many of which involved commingled waste problems.

DISCOVERY OF HAZARDOUS WASTES

In the initial stages of the program, most of the remediated Grand Junction properties were simple residential properties with no history of hazardous wastes. In 1988, during the remediation of uranium mill tailings, a material subsequently identified as Resource Conservation Recovery Act (RCRA) hazardous waste (specifically, Toxicity Characteristic Leaching Procedure [TCLP] arsenic and lead) was excavated and inadvertently transported from two commercial properties to the State-owned Temporary Mill Tailings Repository located in Grand Junction. The hazardous waste had been improperly disposed on the two commercial properties after the mill tailings had been placed there. The GJPO confirmed that the volume and concentration of TCLP arsenic and lead were not naturally occurring in tailings nor were they related to the uranium milling process.
Because there was no clear guidance on how to manage or remediate commingled waste, GJPO established a commingled waste investigation project to evaluate Grand Junction vicinity properties for the presence of RCRA hazardous waste and TSCA substances. Currently, 20 Grand Junction vicinity properties have been identified as containing levels of hazardous waste which required special management. The most common constituents of concern are TCLP lead from improperly disposed automobile batteries and waste oil tanks, polychlorinated biphenyls (PCBs) from electrical transformers, RCRA-listed and TCLP organics from dry-cleaning operations and automotive paint shops, and miscellaneous organic constituents from a 55-gallon-drum recycling operation.

VICINITY PROPERTY CHARACTERIZATION ACTIVITIES

An evaluation of Grand Junction vicinity properties for the presence of hazardous waste was conducted in a manner similar to Phase 1 real estate assessments for environmental hazards and also closely followed EPA's guidance on preliminary assessments. Typically, this process involved historical research to evaluate current and previous operations that had been conducted on vicinity properties. Site investigations were sometimes conducted to visually evaluate the property and to use direct-reading, hand-held instruments. Site-specific sampling and analysis plans were used to perform soil and groundwater sampling when the investigation identified a need for these data. Hazardous waste problems were not expected on residential properties; therefore, primarily historical research was conducted to confirm that these properties had always been residential in nature.
Most commercial properties, especially those located in or near an industrial area, were fully assessed for commingled waste. These assessments were typically site specific because each property provided unique challenges. After a few of the initial site assessments were completed, GJPO recognized the need to establish criteria for conducting site assessments and for determining the acceptability of data.
GJPO also developed a field call-out process for use during site remediation. When anomalies such as soil discoloration, odors, or debris are discovered, all work is stopped and trained personnel are called to the field to investigate. Typically, the GJPO petrology laboratory is used to conduct x-ray diffraction for evaluation of minerals found during excavations.
Approximately 100 of the 4,000-plus vicinity properties required formal site characterization and documentation to assess RCRA hazardous waste and TSCA substances. Some of the sites identified during these assessments include a drum recycling operation, underground storage tanks (USTs), a machine shop contaminated with cyanide, and landfills. These sites are discussed in more detail below.

DRUM RECYCLING OPERATION

One of the complex commercial vicinity properties assessed under the UMTRA Project was a commercial operation that recycled and refurbished 55-gallon metal drums. At

the beginning of the investigation, the property contained more than 27,000 drums, most of which were empty. During the radiological assessment, workers discovered drums labeled as hazardous waste, uranium concentrate, and hydrofluoride acid. A commingled waste investigation was subsequently conducted, and 63 locations were sampled on the property. The results of this investigation confirmed the presence of organic and inorganic RCRA hazardous waste on the property.

EPA's Emergency Response Branch took control of the vicinity property to remove the identified hazardous waste. During fiscal year 1993, EPA removed roughly 27,000 drums from the property, 125 of which contained improperly stored hazardous waste. After further assessment, EPA demonstrated to the Colorado Department of Public Health and Environment (CDPHE) that, due to insufficient process knowledge, waste materials from this vicinity property should be managed as a RCRA-characteristic waste rather than as a listed waste. In 1994, EPA used solidification and stabilization technology to treat 12,000 tons of soil and debris on the property that was contaminated with elevated concentrations of TCLP lead. However, the treated material still contained uranium mill tailings which required proper disposal under the UMTRA Project.

GJPO obtained approval from CDPHE and the U.S. Nuclear Regulatory Commission (NRC) to dispose treated RRM at the UMTRA Cheney Disposal Site. An amendment to Mesa County's conditional-use permit for the Cheney site was also required to allow for disposal of treated hazardous waste. The approval process took approximately one year from the initial meeting where the feasibility of cleaning the property was discussed by GJPO, CDPHE, and EPA. As a result of the cooperation between agencies and stakeholders, the DOE avoided the $3.1 million cost to treat the hazardous waste.

This property also had several unusual characteristics. During the removal of the 55-gallon drums, EPA discovered that ethyl mercaptan had leaked onto the ground. This material, used to create the odor in natural gas, remained even after the soil was treated. Although the odor could not be detected by instruments and no Occupational Safety and Health Administration permissible exposure limits were exceeded, the odor was strong enough that complaints were occasionally received from neighboring property owners.

Spots of yellow pigment were also discovered during excavation of uranium mill tailings. These paint chips were tested and identified as containing elevated concentrations of TCLP lead. EPA returned to the site, evaluated the material, and has made the preliminary determination that the overall waste stream does not exceed the regulatory level for TCLP lead.

UNDERGROUND STORAGE TANKS

To date, the GJPO has removed 88 USTs that were found embedded in uranium mill tailings on vicinity properties. Most of these USTs had been leaking, resulting in uranium mill tailings mixed with fuel products and waste oils that required proper management.

Working with the CDPHE, the GJPO developed a technical position that any petroleum products identified leaking from an UST (except for waste oil tanks) could be windrowed until the uranium mill tailings passed the Penske-Marten test for ignitability. GJPO also performs a test for flammability to ensure materials are properly managed.

Underground waste oil tanks proved to be a more difficult management problem. At two sites, waste oil tanks contained concentrations of TCLP lead in excess of the regulatory threshold. Although disposing of the contents of these tanks was the responsibility of the owner, not all of the waste oil sludge was removed, leaving small quantities that exceeded a de minimis volume. At both sites, uranium mill tailings were inadvertently mixed with small quantities of the sludge while the waste oil tanks were being removed. At least one of the sites will require treatment and stabilization of the TCLP lead before the commingled material can be disposed.

CYANIDE MIXED WITH RRM AT A MACHINE SHOP

One of the vicinity properties contains a machine shop that operated for more than 40 years using a high-temperature (899 to 954C) cyanide-type carburizing bath. Principal shop operations consisted of manufacturing, repairing and distributing drilling and other types of heavy equipment, and case-hardening of steel parts. A significant portion of the machine shop was contaminated with uranium mill tailings, including the area where the case-hardening process was performed.

The case-hardening process used a liquid-cyaniding (carbonitriding) bath that became

commingled with indigenous soils and uranium mill tailings in the area surrounding the bath. GJPO performed a site assessment, collected soil samples from around the carbonitriding bath, and evaluated the case-hardening process. The information collected from the site assessment was compiled into a Technical Discussion Document and presented to CDPHE. The Technical Discussion Document detailed the materials and activities associated with the case-hardening process, and assessed regulatory issues associated with the potential cyanide-based waste streams by examining the classification of the wastes with regard to RCRA. CDPHE reviewed the Technical Discussion Document and recommended performing additional site characterization activities. GJPO subsequently completed additional soil sampling and then conducted a joint facility inspection with CDPHE to evaluate the case-hardening process on a step-by-step basis.

After reviewing the case-hardening process, CDPHE concurred with the GJPO that listed hazardous waste was not an issue at the machine shop, greatly reducing the potential treatment and disposal costs for the property. CDPHE also accepted GJPO's position that characteristic reactive cyanide was below the EPA's regulatory threshold of 250 parts per million and, therefore, did not require management as a hazardous waste. Because of these successful negotiations, GJPO remediated this property at a savings to the Government of at least $50,000.

LANDFILLS

Two large vicinity properties scheduled for remediation were at one time operated as unregulated municipal landfills. Both properties are located within the 100-year floodplain of the Colorado River and both have some form of soil cover.

The GJPO is currently planning to remediate only the top 2 feet of one of the landfills to reduce the risk of the public receiving an elevated level of gamma radiation. In accordance with the requirements of EPA standards, an application of supplemental standards for this partial remediation has been submitted to the NRC and CDPHE. If both agencies concur with this application, the remaining radiologically-contaminated landfill materials will remain in place. To justify the use of supplemental standards, the GJPO has demonstrated there is a high cost of remediation, low health risk to the public, and low likelihood of buildings being erected on the site. The likelihood of building on this site is low because of its proximity to a sewage treatment plant and because it is covered partially with wetlands.

The second landfill, located adjacent to downtown Grand Junction, is scheduled for full remediation rather than the application of supplemental standards because of the anticipated change in land use by the owner. The property was also operated as an auto salvage yard, requiring the GJPO to negotiate the removal of almost 5,000 salvage vehicles to facilitate radiological assessment. A commingled waste investigation was also performed to evaluate surface soils and groundwater directly beneath the landfill. Although these studies revealed trace concentrations of various constituents, no hazardous wastes have been identified.

GJPO is planning to remediate the radiologically-contaminated landfill materials only after establishing an agreement with CDPHE to allow treatment of RCRA-characteristic inorganic wastes, if discovered. This agreement will be used in lieu of a RCRA Part B permit. CDPHE has agreed with the DOE approach to excavating the landfill as long as the necessary precautions are taken to identify hazardous waste if it is encountered. The State has also agreed that management is not necessary for undisturbed landfill materials that are not contaminated. Only a cover, comparable to the existing one, needs to be placed over these remaining landfill materials.

GJPO found that many properties adjacent to the Colorado River, while not landfills, contained large areas of subsurface debris, junk, and household trash. In locations where broken battery cases were found, elevated concentrations of TCLP lead have been identified. The lead problem will be treated with solidification and stabilization technologies if the agreement for treating hazardous wastes with CDPHE is reached.

LESSONS LEARNED AND CONCLUSIONS

In the course of remediating the Grand Junction vicinity properties, GJPO identified a number of steps that should be established in the planning of future projects to address commingled waste issues. Specifically,

Initial planning should allow for the possibility of hazardous waste being commingled with RRM. Because the uranium mill tailings were uncontrolled, it should

be assumed that other substances could have been introduced over the years.

Project participants and regulators should establish and agree upon a hazardous waste management plan that identifies how various types of hazardous wastes would be managed (e.g., RCRA-listed waste as opposed to TSCA substances).

Applicable regulatory guidance for site characterization and hazardous waste determination should be agreed upon in the up-front planning process to determine what constitutes an adequate site assessment and representative samples, and the manner in which a constituent of concern should be evaluated (e.g., how to determine constituent concentrations and appropriate confidence intervals).

Potential hazardous waste treatments should be addressed. Certain types of hazardous waste can be remediated with established and simple treatment technologies such as solidification and stabilization.

Planning for disposal of successfully treated commingled waste at an UMTRA disposal cell should be conducted early in the project to expedite the timely completion of site remediation.

Field criteria should be established during the initial planning stages to facilitate the evaluation of objects and wastes that are uncovered in the field during remediation.

Technical contacts, written procedures, and lines of authority should be clearly delineated.

In conclusion, hazardous waste issues have been successfully resolved by the GJPO through working with EPA and CDPHE. Technical Discussion Documents, outlining process knowledge and analytical results, have been instrumental in communicating with regulators to obtain their concurrence.

DECOMMISSIONING OF THE CHORNOBYL NPP: REGULATORY AND MANAGEMENT PROBLEMS

H. Mikolaitchouk
L. Bogdan
N. Steinberg
Ukrainian State Committee for
Nuclear and Radiation Safety

ABSTRACT

According to the former USSR regulations a NPP decommissioning plan should be submitted to the regulatory body in five years before an expiration of the design-based service life of NPP unit. But the Chornobyl accident of April 26 1986 caused changes in many routine procedures and approaches, particularly concerning the Chornobyl NPP decommissioning. There is a number of particular features which needs a special consideration, as for the Chornobyl NPP decommissioning, including the 30-km exclusion zone around the Chornobyl NPP, the destroyed Unit 4 and the SHELTER object (well-known as "Sarcophagus"), a relatively high level of dose exposure rate at the Chornobyl NPP site, etc. Along with both domestic and external socioeconomic and political factors it complicates a decision-making process very much and creates many problems both for regulators and operators. The ultimate decommissioning strategy for the Chornobyl NPP is not clear yet, nevertheless certain preliminary conclusions and suggestions can be made.

LIFE HISTORY OF THE CHORNOBYL NPP

The construction of Chornobyl NPP was started in March 1970. The NPP was supposed to consist of six RBMK boiling water pressure tube, graphite moderated reactor units of 1000 MWt rated power each. Units 1-4 were commissioned in 1977, 1978, 1981 and 1983, respectively. Commissioning of Units 5 and 6 was planned for 1987-1988, but after the Chornobyl accident the plan was abandoned. After beyond the design basis accident of April 26 1986 the Unit 4 has been destroyed and received a shelter building which is not consider enough by some specialists and options of overpacking by a new shelter, fully or partly dismantling etc. are under consideration. After a major fire in the turbine hall of October 11 1991 Unit 2 is out of service and will probably never be restarted. The NPP history is summarized in Table I below.

After the accident of April 26 1986 operation of all the Units was halted. During the first post-accident months accident recovery work was done along with implementation of measures intended for the NPP safety upgrading including revision of operational manuals, personnel reexamination, technological modifications. As a result Unit 1 and 2 were put into operation by November 1986, Unit 3 - by December 1987.

In spite of all the measures implemented a proper safety upgrading of the Chornobyl NPP was considered unattainable and by the Ordinance of February 17 1990 "About environmental conditions and radical improvement measures in the Ukrainian Republic" the Verkhovna Rada (Parliament) of Ukrainian Republic made the decision about withdrawal from service three units of Chornobyl NPP by 1995. The major fire at the fourth turbogenerator of Unit 2 of October 11 1991 resulted in revision of the shutdown deadline. According to the ordinance of Ukrainian Parliament of October 29 1991 the decommissioning of Unit 2 was to be started immediately and operation of Unit 1 and 3 was to be halted by the end of 1993. According to the above-mentioned Ordinances the Concept of Chornobyl NPP Units Decommissioning was developed. The Concept considered five options for unit decommissioning. The Commission on decommissioning of Chornobyl NPP Units chose the option which consisted in safe enclosure of reactor and highly contaminated equipment for 25-30 years while dismantling the other equipment with conservation of constructions and operation of life support systems. It provides for a further dismantling of all the equipment and structures till so-called "green lawn".

But the decision was not approved by the national regulatory body on account of a poor substantiation. It was noted that before selecting a decommissioning option we should have more information about a physical and radiological status of each unit, a radionuclide inventory etc. and a decommissioning option can be selected only on the basis of a complex engineering review of status of each unit taking into account all possible effects of the destroyed Unit 4 and related structures.

Nevertheless regardless of the selected decommissioning option certain preparatory actions were to be taken including evaluation of radionuclide inventory, development of supplementary heating and electricity systems etc. But nothing was done.

On October 21 1993 in the light of the crucial situation in the national economy and power generation the Ukrainian Parliament canceled its own decision on shutting down the Chornobyl NPP. Thus the shutdown date for the Chornobyl NPP became no more a political but technological issue. But it does not mean that a deadline for all Units was postponed very much.

The Unit 1 and 2 of Chornobyl NPP had been designed before nuclear safety regulations were put in force in the former USSR. These Units belong to so-called first generation units and do not have full-scope safety systems, for example, a localization system (like other first generation RBMK units situated in Russia, the Leningrad NPP Unit 1 and 2, the Kursk NPP Unit 1 and 2). Upgrading these units to acceptable safety levels is a very complicated and expensive task and appears to be unfounded and unrealistic. Thus a decommissioning seems to be a near future task, at least for these units.

REGULATORY FRAMEWORK FOR DECOMMISSIONING IN UKRAINE

During the lengthy period of nuclear energy development in the former USSR a NPP decommissioning was left out of proper consideration. It affected both a NPP designing and regulations. Decommissioning issues began to be considered in the eighties alone.

Basic requirements for decommissioning were set forth in item 5.6 of the General Provisions on Ensuring Safety at Nuclear Plants (PB-88) as follows:

"5.6. Decommissioning of Nuclear Plants

5.6.1. Decommissioning of Nuclear Plant (Unit) is to be considered during designing, operation, maintenance and repair of Nuclear Plant (NPP).

5.6.2. At least 5 years before the design-based unit lifetime expiration the Operator has to provide for development of a decommissioning plan and its approval by State Surveillance and Control Authorities.

5.6.3. Decommissioning should be preceded by a complex review of the unit by a Commission appointed by the Operator. Decision on the unit decommissioning is to be made on the basis of complex review results.

5.6.4. By order of State Surveillance and Control Authorities a NPP Unit can be decommissioned before the design-based lifetime expiration, if the status of safety systems or the unit status as a whole does not ensure NPP safety."

More detailed requirements were set forth in the Part 15 of the Sanitary Rules for Designing and Operation of Nuclear Plants (CP AC-88) and in the Part 11 of the Radioprotection Rules for Operation of Nuclear Plants (PP AC-89). The requirements consider issues to be taken into account in selecting a decommissioning plan, organizational issues of radioprotection during decommissioning, decommissioning stages, safety considerations for dismantling and waste managing etc.

The main shortages of the system of regulations in force consist in:

- an uncertainty of a licensing procedure for decommissioning;
- a full absence of provision of funds for decommissioning;
- an absence of established quantitative criteria for recycling within the nuclear field or a free release of decommissioning materials.

It should be mentioned that the Chornobyl NPP case could not be considered in a routine way in any case due to specific on-site conditions resulted from beyond the design basis accident of April 1986. In addition insufficiency of regulatory framework for decommissioning is typical for many countries and can be overcome not until a broad decommissioning experience gained (1).

During the last two years two new regulations on decommissioning are being worked out as a part of a national programme of radioactive waste regulatory framework development, namely the General Safety Provisions for Nuclear Power Plant Decommissioning and the Basic Provisions on SHELTER Safety Assurance. The continued development of the international regulatory framework including the RADWASS Safety Standard on Decommissioning of Nuclear Facilities and the International Basic Safety Standards for Protection against Ionizing Radiation and for the Safety Radiation Sources enables development specific regulations for decommissioning which may render regulatory decisions easier, more expeditions and foreseeable on the basis of the other countries' experience, but it seems to take a lot of time.

In the Chornobyl NPP case all kinds of contingencies might arise, changing the previous regulatory strategy and requiring a new approach. So the regulatory process will develop simultaneously with the decommissioning process but certain regulatory decisions should be made in the nearest future.

The first one concerns establishment of decommissioning stages needing separate licenses. For the Chornobyl NPP unrestricted release of the site is hardly attainable in a near future regardless of a decommissioning strategy. So the final goal of the first phase of decommissioning to be licensed should be determined.

The second one concerns financial provisions. In the former USSR financial issues were out of the scope of permitting process and provisions of funds for decommissioning were not established. As a result there is no accumulated reserves for the Chornobyl NPP decommissioning yet. It can affect not only timing but the safety of decommissioning operations and has to be considered in a licensing process.

The third one concerns establishment of "clearance" level for both the site and decommissioning materials which can affect decommissioning costs as well. It appears to be the most solvable problem taking into account an availability of a set of international regulations and recommendations (2-4).

The one more problem which needs a special regulatory decision concerns a long-term storage and final disposal of radioactive waste originated from the decommissioning and the lifetime operational waste stored on-site. The enormous volumes of such waste suppose on-site or nearby siting of waste treatment and disposal facilities to be a preferable option, but under an emerging regulatory regime in waste management field in Ukraine the related decision-making process needs a special concern.

TECHNOLOGICAL BASIS FOR THE CHORNOBYL NPP DECOMMISSIONING

By now we have no experience in decommissioning of NPP Units with RBMK type reactors, so do of NPP Units after a severe accident like the Chornobyl one. Thus we can consider the Chornobyl NPP case as a pilot project and many technological problems should be solved on the case-by-case basis.

Main technological problems for NPP decommissioning are usually as follows:

- reactor defuelling, fuel storage on site, spent fuel disposal or reprocessing;
- dismantling and decontamination of equipment;
- liquid and solid waste treatment, waste storage and disposal;
- dismantling or stabilization of constructions, on-site clean-up activities.

As for a spent fuel problem, it should be mentioned that Ukraine has not established a national strategy for spent fuel management yet. In the former USSR the RBMK spent fuel used to be stored in the spent fuel storage ponds on-site because of an absence

of a reprocessing facility although the fuel reprocessing was presupposed. Taking into account the socioeconomic and political conditions in Ukraine the reprocessing option is hardly feasible in a near future. Under the emerging waste management system a deep geological repository will be available in Ukraine in fifty years at best. For such a long term the existing fuel ponds seem not to be a proper option taking into consideration problems of degradation, corrosion and weather-dependence. Moreover the available capacity is not enough for the expected amount of fuel elements. Thus an additional spent fuel storage capacity should be provided beforehand, a dry-type storage being preferable.

As already mentioned above a further decommissioning was not adequately considered in the RBMK designing. So measures to facilitate equipment and structures dismantlement like optimum geometrical layout were not taken. But the design of reactors allows relatively easy dismantling, for example the pressurized tubes and the graphite moderator blocks could be removed quite well with remote-control equipment.

The other feature which can complicate the choice and implementation of dismantling technologies arises from the accident of April 26 1986 and accident recovery work. In some cases decontamination of structures or equipment to acceptable levels was not attainable due to non-favorable geometrical layout, low effectiveness of decontamination techniques or other reasons. Then in order to minimize a occupational exposure and avoid a spread of contamination the contaminated surfaces were covered by oil, plasticate etc. Thus in addition to relatively high contamination levels, large contaminated areas and relatively high percentage of actinides among contaminating radionuclides there is a covered in-depth contamination. All these features should be considered and examined during a preliminary radiological review before selecting dismantlement and waste management strategy.

The same feature is characteristic of the Chornobyl NPP site. For example, in the nearby area of the Unit 3 and 4 where surface contamination level was extremely high all debris including fuel particles and graphite were not removed but covered by a ground and concrete layers without taking account of possible in-depth contamination of ground and groundwater. And in selecting a decommissioning option all these distinctive features should be carefully examined and considered, taking into account the destroyed Unit 4 and further recovery and stabilization work at it as well.

The concept laid down at the design stage for the management of wastes at RBMK type reactors was to store the wastes on site and to postpone decisions on conditioning and disposal until the decommissioning stage. By this means wastes from operation and dismantling suppose to be handled together. Waste collection and storage systems were developed to accommodate ten years arisings of treated operational wastes with possible extension of storage capacities. The only exceptions were for the very low level solid wastes, where on-site disposal was proposed.

In the Chornobyl NPP case no modifications of design-based waste management flow-sheet were done and the lifetime unprocessed liquid and solid wastes are stored on-site. As of the end of 1993 25940 cub.m liquid wastes were stored with the total salt content of 2986 tones and the total activity of 2474 Ci. The data for solid wastes are shown in Table II.

It should be noted that after the Chornobyl accident all dry low- and intermediate-level wastes, including routine operational ones, were transported to the BURYAKOVKA disposal site operated by the Research and Industrial Association PRYPIAT in 10 km from the Chornobyl NPP. But after issuing by the Ukrainian regulatory body the license to the RIA PRYPIAT to operate the BURYAKOVKA shallow ground disposal facility the practice was halted in accordance with license conditions outlawing disposal of wastes other than considered in the facility design. So the solid waste volume will be increased rapidly.

In addition we have to take into account waste flows from the destroyed Unit 4. Contaminated water accumulated in the destroyed Unit 4 premises creates a problem already now. For example, volume of water is estimated as 2500 cub.m with activity of 3.10-6 - 10-5 Ci for Cs-134, 10-7 Ci for Sr-90, 10-8 Ci for Pu-239 and U-235 concentration estimated about 5-20 mkg/l. In so doing a water pumping-out is complicated by both high specific activity and a presence of fissionable nuclides, which needs a special pre-treatment considering nuclear safety issues. An anticipated recovery and stabilization work at the Unit 4 including a possible

shelter replacement is expected to generate a wide range of wastes and effluents which should be considered in development waste treatment and storage capacities on-site as well.
Thus in decommissioning the Chornobyl NPP liquid and solid waste treatment plants and waste storage and disposal capacities should be provided to manage both a lifetime operational waste and decommissioning waste considering waste generated at the destroyed Unit 4 as well, only for the operational waste volumes being predictable for certain. In addition due to specific contamination features conventional waste treatment and conditioning technologies should be revised and adapted.

CONCLUSION

Due to consequences of beyond the design-basis accident and influence of the destroyed Unit 4 the Chornobyl NPP decommissioning can not be accomplished by routine procedures. Key decisions on the timing and extent of decommissioning activities should be based on a thorough knowledge of a physical and radiological status of each unit, radionuclide inventory, site characteristics etc, which needs a preliminary complex radiological and engineering examination and a continuous review of the NPP Units and site.
Case-by-case decisions and a parallel development of both regulatory and management environment will enable the best practical environmental options at a reasonable timescale.

REMOVAL OF LOW LEVEL ACTIVITY FROM THE WASTE STORAGE TANKS OF TR-2 RESEARCH REACTOR

Alper Kahraman
Mehmet Altunkaya
ekmece Nuclear Research and Training Center (NAEM)
P.K.1 Havaalan 34831 Istanbul Trkiye

ABSTRACT

TR-2 is a 5 MWt swimming pool type research reactor located at ekmece Nuclear Research and Training Center (NAEM). It has been operating since 1982. The aqueous wastes collected from this reactor used to be treated by decay storage and then discharged according to the safety regulations established by Turkish Atomic Energy Authority.
The periodical checks of storage tank liquids have usually given a radioactivity level of 50-100 Bq/L for 60Co which is the most important isotope to be considered. An unusual high contamination level has been detected in the storage tanks at March 1993. The specific activities observed were higher than discharge limits. Since 60Co has a very long life time, another method of processing other than decay was needed to reduce the activity levels.
Chemical precipitation was applied in the original storage tanks. Satisfactory decontamination factors were achieved and 60Co activity decreased to about 100 Bq/L. Cleared liquid was discharged and residual sludge was cemented.

INTRODUCTION

The aqueous wastes generated by the operation of a low power research reactor are discharged after being usually treated by decay storage or ion exchange.
TR-2 has two liquid waste storage tanks located 2 m below the ground level. They are cylindrical with a radius of 1.4 m and height of 5.7 m, and each of them has a 35 m3 storage capacity. Tanks are used sequentially and liquid wastes from different parts of reactor systems are collected and retained in these two tanks as long as possible in order to discharge after the activity being decreased below certain limits. Analyses of liquid samples taken from storage tanks have been carried out periodically. Almost same levels of activities for the contained isotopes were

observed. For example, maximum values of 60Co activities were in between 50 and 100 Bq/L (1.4x10-6 - 2.7x10-6 Ci/m3).
Other frequently faced radionuclides and their typical activity concentrations were; 124Sb=1000 Bq/L, 58Co=200 Bq/L, 137Cs=25 Bq/L. The target radionuclide was 60Co in this procedure. Therefore the other 4-5 nuclides were not considered due to their small contributions or short half life compared with the 60Co. Two of them, however, are listed for only south tank in Table I.
Higher activities are not expected normally and these very low level specific activities of 60Co are managed without any difficulty.
But, an analyses in March 1993 showed that there was an unusual radioactivity increase in the tank liquids. 60Co activity was about 18.000 Bq/L and total beta activity was up to 20.000 Bq/L. There were not significant activity increase for the other nuclides.
Possible reasons of this unexpected contamination are still being searched. Control rods of the reactor might be responsible since they include a nickel alloy. It is known that nickel always contain some cobalt impurity.
Tanks had to be emptied for the normal operations of reactor, but activity level of the liquid required a treatment before discharge. Transferring of liquid to the waste treatment plant was not possible because of the lack of equipment and pipeline connection to waste treatment plant.
A convenient treatment had to be done in the tanks, themselves. But since these tanks had been considered as only collection and retention tanks, they also did not have necessary equipments for any treatment purpose.
Chemical precipitation seemed to be the easiest process in those conditions but there were two major difficulties; one was the mixing of liquid, second was the discharge of sludge from the tank bottom.
PROCEDURE
Radioactivity Analyses
Gamma spectrometric analyses were done with 100 ml of liquid samples by Canberra Series 85 spectrometer with a HP germanium detector. 1 ml of liquid was dried on a metallic disk for total beta activity analyses which were done by Tracerlab, Low Background Counting System.
Chemical Procedure
A number of jar-tests were done in the laboratory to find out the best removal conditions of 60Co from the tank liquids. The purpose of the chemical procedure was to transform the 60Co to a sparingly soluble structure from its dissolved form in the liquid.
In alkaline medium, cobalt precipitates as its hydroxide.

$$Co^{++} + OH^- \longrightarrow Co(OH)_2 \quad (1)$$

But trace concentration of cobalt corresponding to the observed activities (i.e. 20.000 Bq/L = 4.7x10-10 g/L) does not allow to form cobalt hydroxide precipitation, because of the threshold character of solubility product value. Therefore nonradioactive cobalt was added to help the formation of Co(OH)2. Iron hydroxide precipitation was also experimented together with cobalt in order to improve the precipitation.

$$Fe^{++} + 2OH^- \longrightarrow Fe(OH)_2 \quad (2)$$

$$Fe(OH)_2 + OH^- \longrightarrow Fe(OH)_3 \quad (3)$$

Although the processes given by equations (1), (2) and (3) are simple from the chemical point of view, the removal of 60Co is not easy to explain with stoichiometric rules. As we know that, some of the free Co++ ions which may still exist in the medium are adsorbed by iron hydroxide flocks. They precipitate together. Mechanism of this co-precipitation is not clear (1), but the activity removal mainly depends on the iron hydroxide flocks which carry down the cobalt hydroxide (2).
The following steps of chemical procedure were chosen according to the results of laboratory experiments:

keep PH between 10-10.5 with NaOH in the tanks,
add 0.5 ppm CoSO4 as nonradioactive carrier,
add 0.25 g/L FeSO4.5H2O,
a continuous mixing should be carried out,
a waiting period of 10 minutes between each step.

Operational Procedure

A pipe with a jet mixer on its tip was located inside the tank and compressed air was sent through it. A homogeneous, satisfactory mixing was obtained. Degree of mixing could be arranged by air pressure. A figurative illustration of operational phases are shown in Fig.1.

1.Mixing of tank liquid with compressed air
2.Suction of clear liquid
3.Suction of sludge to waste drums

NaOH, CoSO4 and FeSO4 were used from their prepared dilute solutions. After a homogeneous mixture was obtained tanks were left to be settled for two days. After that, since the analysis of clear liquid showed a satisfactory decontamination, this part of tank contents was sucked out.

Amount of sludge and its level of height in the tanks were estimated according to the laboratory experiments (3). Suction of clear liquid was stopped at 10 cm above that level. The sludge below that level was transferred to 200 L drums. 2/3 of each drum was filled and transported to the waste treatment plant.

RESULTS AND DISCUSSION

Maximum DF values obtained in the laboratory experiments were around 120 for 60Co which were less than the DFs obtained in real tank precipitations. This may be caused by the different mixing types. But most probably the mud collected during the previous operations at the bottom of the tanks, should help the activity removal by adsorbing the metal ions and taking down them during the settling period.

All specific activities and decontamination factors are shown in Table I. Residual 60Co activities are 118 Bq/L in the south tank and 78 Bq/L in the north tank. Attained DF values for 60Co in both tanks are nearly equal between 150 and 160. That DF values are quiet satisfactory compared with the values given in Ref. 4-6, which give all DFs greater than 100.

Removal of total beta activity was less than the 60Co removal. This was expected because the other beta emitting nuclides were not the subject of the precipitation. However, two of them, 124Sb and 58Co were removed to below detection limit which were less then 10 Bq/L in our case.

63.2 m3 cleared liquid containing a total 60Co activity of 6.18x106 Bq (1.67x10-4 Ci) was discharged. This amount is about 62% of monthly allowable discharge limit of safety regulations in Turkey.

About 1.4 m3 of sludge was sucked out from the tanks and cemented in 200 lt drums. 100 kg of cement was used for every drum and 12 cemented waste drums were produced. Sludge samples were taken from each drum and analyzed. Total beta activities of each drum were found between 9x107 and 1.3x108 Bq/drum while total 60Co varied from 6x107 to 1x108 Bq/drum. Surface dose rates of the products were between 5 - 15 mR/hour.

Session 47 -- Department of Defense Waste Programs
Co-chairs: Larry McNamara, U.S. Army AMCCOM
47-1
WASTE MINIMIZATION DEPLETED URANIUM WASTE MINIMIZATION EFFORTS WITHIN THE ARMY
Tanya Palmateer Oxenberg
U.S. Army Test and Evaluation Command
Michael Los
U.S Army Production Base Modernization Activity
ABSTRACT
The Army currently utilizes depleted uranium (DU) for shielding on Abrams tanks and as a kinetic energy penetrator for a family of tank cartridges due to the metals physical properties and performance characteristics. These tank cartridges were made famous during Desert Storm and are more widely known as the "silver bullet" which were extremely effective against Iraqi armored vehicles. The use of depleted uranium by the Department of Defense has received the highest level of Congressional interest due to unsubstantiated claims that DU is responsible for Desert Storm Syndrome.
Throughout the Life Cycle of these weapon systems large quantities of Low Level Radioactive Waste (LLRW) are generated during the testing, manufacturing and demilitarization phases. With the closure of burial sites for LLRW and sky rocketing costs of disposal the Army has instituted a number of pollution prevention initiatives to minimize the generation of waste throughout the "cradle to grave" (life cycle) of these weapon systems.
The Army has successfully demonstrated and instituted three separate depleted uranium waste minimization efforts by employing both decontamination and recycle technologies. The first effort involves the recycle of depleted uranium penetrators which have been fired at various test ranges and recovered. The recovered metal was then cleaned, remelted and recycled into commercial products such as shielding vessels and counterweights.
The second effort involves recycle of demilitarized DU penetrators from obsolete cartridges and armor scrap into state of the art weapon systems. Through the recycle and reuse of Army DU resources there is no longer a need to import more depleted uranium from the Department of Energy into the Army inventory. Lastly, the Army has been successful in developing decontamination and recycle capabilities of armor plate which have been contaminated with DU at the test ranges.
The Army is closing the loop on the use of depleted uranium by minimizing waste generation to the lowest levels that can reasonably be achieved through recycle and decontamination technologies.
INTRODUCTION.
The Army has been using Depleted Uranium (DU) metal in Army weapon systems for over the past 25 years as either a penetrator in tank ammunition or as shielding in tanks. Tank ammunition containing DU was made famous during Desert Storm and is more widely known as the "silver bullet" which were extremely effective against Iraqi armored vehicles. The use of depleted uranium by the Department of Defense (DOD) has received the highest level of Congressional interest due to unsubstantiated claims that DU could be responsible for Desert Storm Syndrome.
It has been recognized that there are a large number of Low Level Radioactive (LLRW) waste streams that result from manufacturing, testing and demilitarization of DU tank ammunition. In order to maintain compliance with the Pollution Prevention Act, National Environmental Policy Act and adherence with DoD and Department of Army policy and regulations it became necessary to identify avenues to minimize these waste streams. Since numerous unsuccessful attempts were made to replace DU with tungsten alloys, focus was placed on decontamination and recycle as the primary means to minimize these waste streams. Depleted Uranium is the material of choice for Kinetic Energy penetrators (Danesi, 1990).
Three major waste streams were identified as being candidates for waste minimization: 1) recycle of depleted uranium penetrators recovered from test ranges into commercial products; 2) recycle of demilitarized DU penetrators from obsolete cartridges and DU armor scrap into state of the art weapon systems and 3) decontamination of steel rolled homogeneous armor (RHA) plate. It has been demonstrated and validated that all three waste streams have been successfully minimized by employing recycle and decontamination technologies.
RECOVERY AND REUSE OF DEPLETED URANIUM PENETRATORS TO REDUCE RADIOACTIVE WASTE

During the 1960's, the Army began to develop armor piercing munitions containing depleted uranium (DU). The DU munitions have ranged in sizes from .50 caliber to 175mm. The munitions are test fired for accuracy against plywood or cloth targets at ranges of 1000 to 4000 meters at Aberdeen Proving Ground (APG), Maryland, Jefferson Proving Ground (JPG),Indiana and Yuma Proving Ground (YPG), Arizona. As the penetrators pass through the target and impact the ground they come to rest on or beneath the surface of the ground. The penetrators may remain intact with minimal airborne particles produced, or it may fragment into pieces from striking trees or hard and rocky soil (Stoetzel, Waite, and Gilcrest 1983).

The Low Level Radioactive Waste Policy Act of 1980 and the Low Level Radioactive Waste Policy Amendment Act of 1985 require future regional compacts to manage waste disposal and allow the existing burial sites to close. Each of the test centers is located in a different compact; APG is in the Appalachian Compact, JPG is in the Midwest Compact and YPG is in the Southwest Compact. None of these com-pacts have operational burial site and as a result are required to store their waste until their compacts are operational.

U.S. Army Test and Evaluation Command (TECOM) and the test centers considered the recovered DU penetrators a marketable commodity which could be recycled into new penetrators at less cost than obtaining DU from the Department of Energy (DOE). Arrangements were made with Aerojet Ordnance of Tennessee (AOT) to accept penetrators from YPG and JPG in 1987 and 1988 at no cost to the Army. YPG had packaged the penetrators in contaminated soil for shipment. Aerojet found the cost of disposal of the soil and the cost of recycling was more expensive than the value of the DU obtained and wanted to charge the Army for processing any future shipments. In addition, the current technical data packages for large caliber only permitted in process recycle. A costly qualification and validation effort would be required prior to accepting this scrap material as feed stock for new production penetrators.

Subsequently the ammunition developer, U.S. Army Armament, Research, Development and Engineering Center at Picatinny Arsenal, New Jersey, arranged with Nuclear Metals, Inc. (NMI) in Concord, Massachusetts, to evaluate recycling the penetrators for commercial products on a trial basis at no cost to the Army. If the costs of processing the penetrators exceeded the salvage value of the DU, then the Army would be charged for any future shipments.

NMI began to accept penetrators from the test centers in 1989 and continued until 1993. The contractor later agreed to continue to accept the penetrators from the test centers, but to charge for the processing.

DEMILITARIZATION & RECYCLE OF DEPLETED URANIUM FOR CURRENT PRODUCTION TANK CARTRIDGES

Current stockpiles of antiquated kinetic energy tank ammunition have to be demilitarized, thereby generating large quantities of DU penetrators that need to be disposed. Although demilitarization procedures exist for tank ammunition, actual studies were never conducted to validate their adequacy. Improper procedures can cause serious injury, but can easily be avoided (Bishop, 1989).

The U.S. Army Production Base Modernization Activity (PBMA) entered into an agreement with NMI, AOT and APG and to determine the technical and economic feasibility of demilitarizing old ammunition. Under these small scale (45 cartridges each contractor) studies, the following was addressed; disassembly methods, contamination levels, types and quantities of waste generated, methods for decontamination and lastly, identify any potential reuse and sale of recovered components. It was determined that the penetrators were of suitable quality to be further evaluated for potential recycle into new penetrators (Laporte, 1994).

The Army currently obtains depleted uranium tetra fluoride from the DOE and through a series of processes converts it into DU metal. However, large quantities of contaminated hydrogen fluoride and magnesium fluoride are generated and much energy is expended. If the demilitarized penetrators could be recycled these waste streams would be eliminated and the Army will no longer need to bring DU into its inventory.

A follow-up demilitarization and recycle effort was conducted with both NMI and AOT on 1400 cartridges to further establish procedures and to produce recycled penetrators in accordance with current specifications which require chemical analysis, metallography and final ballistic target penetration. Three melt cast lots were produced utilizing 100% recycled penetrators. Chemical and metallographic tests were performed prior to final machining of the penetrators.

One of the contractors used input material which contained, on average 100 parts per million (ppm) of zirconium. For the three melt lots tested for mechanical properties, there was an apparent relationship between high zirconium in the melt and low compressive yield (Laporte, 1994). Due to the high levels of zirconium found in the demil stockpile, penetrators produced by NMI cannot at this time be considered for future production until additional studies can be completed. It is speculated that at the time of original alloying of the NMI M774 penetrators that zirconium coatings were used in the graphite liners. The other contractors feed material did not contain high levels of zirconium and as a result final machining resulted in delivery of 35 specification quality penetrators (Zeman and Wright, 1994) which were later ballistically fired. The program switched gears in May 1994 when it was determined that the demilitarization production line would not be in operation to support 1995 ammunition production. Depleted Uranium Armor scrap was then identified as an alternate source of material. The material chemistry of the scrap armor is well documented, therefore this was considered a low risk effort. This material had to go through similar processing and testing requirements as the M774 penetrators. Additional processing steps that were required to recycle armor that were not required for the M774 penetrators included pickling, shearing, special furnace loading procedures and alloying with titanium.

The cast ingots from three melt lots were processed in an identical fashion to standard manufacturing practices. All melt lots met required chemistry and mechanical properties. When compared to standard melt cast lots, no processing nor acceptance yield differences were noted for the armor scrap remelt lots (Laporte, 1994). Minor additional process operations were identified by AOT such as, surface corrosion on the scrap armor which may consistently require an extra pickling operation, and careful packing of the furnace with irregular shaped pieces to enhance heat yields (Zeman and Wright, 1994) From the three lots processed through heat treatment and High Energy Rate Forming, 35 blanks were machined into penetrators by each contractor and shipped to the load assemble and pack facilities for final assembly into M829A2 tank cartridges.

Forty-five cartridges were delivered to APG for final ballistic testing; 15 rounds contained AOT penetrators recycled from old penetrators, 15 rounds contained AOT penetrators recycled from armor scrap and 15 rounds contained NMI penetrators recycled from armor scrap. The high zirconium penetrators produced by NMI were not ballistically tested. All 45 rounds were fired against modern armor targets in December 1994 and January 1995. Preliminary results indicate that all have met or exceeded the current target penetration requirements.

At the time of this writing the final determination has not been officially approved as to whether or not these materials are qualified for recycle. Since all the qualification requirements have been met, approval is expected before 1995 production of M829A2 tactical tank cartridges begin.

It has been estimated that cost savings for the production of the new M829A2 penetrator will be reduced by approximately $49 utilizing recycled penetrators and $46 by utilizing armor scrap (Los, 1993). The three dollar difference is attributed to the extra processing steps (pickling, special loading and alloying).

RECYCLING STEEL ARMOR PLATE CONTAMINATED WITH DEPLETED URANIUM

The U.S. Army presently conducts research, development and testing of DU penetrators to determine penetration depths against RHA only at APG. The RHA targets are primarily composed of rolled hardened steel. As the DU penetrator impacts the plate or target, fragments and airborne particles are formed (Stoetzel, Waite and Gilcrist 1983). The target becomes contaminated with removable DU oxides, and embedded DU fragments become tightly bound or "fuzed" with the metal surface and inside the penetration site.

APG is the Army's largest generator of non-medical radioactive waste due to this type of testing. The organizations operating the test ranges at APG, TECOM, Army Research Laboratory (ARL) and the U.S. Army Combat Systems Test Activity (USACSTA), wanted to minimize the radioactive waste produced and possibly obtain beneficial reuse of the test debris. Various avenues were explored to develop methods to decontaminate the plate. A large stockpile exceeding 3000 tons of plate accumulated before a viable alternative to radioactive waste burial was adopted.

In 1982, the ARL had approximately 350 tons of armor plate in storage that had a scrap metal value of $39,200 based on the price of $.056 per pound of steel. The laboratory estimated that $100,000 could be saved in future armor procurement by

decontaminating and reusing the steel (Markland 1982). USACSTA has made only one shipment to bury the contaminated steel as radioactive waste. In 1983, 394 cubic feet of contaminated plate, consisting of 125 pieces and weighing 8 tons, were buried at Barnwell, South Carolina at a cost of $9,550. The cost was considered to be exorbitant.

Burial as radioactive waste was considered too expensive because of the costs to package, transport and bury the waste, and the loss of the scrap metal value of the steel. Cutting the plate was costly because it was labor intensive, required disposal of the contaminated section as radioactive waste, and exposed the worker to airborne radioactive material. Three potential alternatives to burial were identified, they are 1) electropolishing, 2) liquid abrasion for surface removal, and 3) reuse as high energy radiation shielding material.

Pilot electropolishing operations conducted by Quadrex Corporation and Chem Nuclear Systems, Inc. in 1980 and 1981 appeared to be very promising (Voit and Clayton 1981). Electropolishing was considered the ideal alternative because the amount of radioactive waste produced would be minimal, exposures would be reduced, and the decontaminated metal could be sold as scrap. Electropolishing is an electrochemical technique wherein the plate is immersed in an electrolyte and electrical current is used to remove the DU from the surface of the plate (Whang 1990). Quadrex Corporation decontaminated 45 tons during an eight month trial operation. Electropolishing techniques generated too much phosphoric acid, a mixed waste, and thus did not achieve reduction of waste goals and was not perused any further.

A study by Battelle Pacific Northwest Laboratory identified liquid abrasive blasting technology as the most productive method of decontaminating the plate and targets (Glissmeyer, et al. 1987). Liquid abrasive blasting uses abrasive particles in a liquid medium at high velocity to impact a surface and abrade the contamination from the surface. The spray must be contained and the abrasive separated from the water. HEPA filters and air samplers are required to protect and monitor personnel exposure from airborne radioactive materials and hazards produced.

The system was found to be effective in decontaminating the plates and targets as quickly as they are generated. Embedded fragments and bonded metal are cut from the RHA prior to abrading, but not to the extent as was required for electropolishing. The capital investment for the equipment, construction, and the labor required to operate the facility have been offset by the sales of the scrap metal and the savings normally associated with the preparation, transportation and burial of the steel as radioactive waste.

The Army Research Laboratory did not have as much success with the liquid abrasive blasting as the U.S. Army Combat Systems Test Activity and discontinued its use in 1992. The Army Research Laboratory's system was designed differently, having the plates decontaminated in an upright, vertical position, rather than horizontally. Detailed studies have not been conducted to determine the reason for the difference in effectiveness between the two systems.

Table I provides a breakdown of the cost of the liquid abrasive blasting facilities. Table II is a listing of the plate decontaminated and salvaged by the U.S. Army Combat Systems Test Activity.

In 1976, the TECOM arranged with Oak Ridge National Laboratory (ORNL) to transfer plate stockpiled at APG for melting. The Y12 plant had an estimated 600,000 tons of metal
contaminated with DU and had planned to operate a furnace by 1980 to smelt the metal, but operations never began.

ORNL and the DoE Oak Ridge Operations Office recommended the Fermi National Accelerator Laboratory (Fermilab) as a possible means of disposal. Fermilab was seeking 100,000 tons of high density material to use as shielding for accelerators. Fermilab had been previously utilizing Navy ship scrap and off-specification steel. The Army proposed to transfer the steel at no cost to the DoE. Fermilab and the DoE would only be responsible for the transportation costs from APG, Maryland to Batavia, Illinois. The federal government would save costs associated with burial of the steel as a waste, and the purchase of new steel by DOE. Fermilab determined that the plate would not be economically feasible. This was due to the additional environmental monitoring costs which exceeded the cost of steel ($140.00/ton) obtained from other sources. Monitoring was required because the laboratory planned to bury the shielding and was concerned about possible migration of the DU contamination (45 nci from surface swipes).

Los Alamos National Laboratory (LANL) approached the TECOM in March 1986 to pursue using the plate as shielding for the Los Alamos Meson Physics Facility. U.S. Army Combat Systems Test Activity had an estimated 2200 tons of plate and targets in storage and estimated that the cost to the Army to transfer the steel to LANL rather than disposal at one of the two existing burial sites at Barnwell, South Carolina and Hanford, Washington, would save at least $648,000. Table III provides the cost estimated for burial and the transfer of the steel to LANL.

Savings for the federal government actually increased by $572,000 because the DoE did not have to purchase 2200 tons of steel at $260/ton. Packaging and labor costs were reduced because the plate did not have to be packaged in Type A containers and could be shipped by rail. Prior to shipment, the fragments were removed from the plates, holes were filled with foam insulation, and the plate surfaces painted to provide a sealant. The plates were placed in rail cars and shipped to Colorado where they were then transported to LANL by truck. The cost of the armor plate shipped in 1986 exceeded the estimate of $415,000 and actually cost the Army over $500,000, but still proved to be much less expensive than burial. LANL was only able to achieve an estimated 75 percent shielding efficiency because of the holes and uneven surfaces in the plates and recommended smelting into shielding blocks by Scientific Ecology Group's (SEG). It would cost the Army $550/ton of armor to package, ship, and process the metal into shielding blocks. The DoE and LANL would be responsible for transporting the shielding blocks from Tennessee to its final destination. The total cost to the Army was the same as radioactive waste.

However, the DoE would save by not having to purchase new steel which had escalated to as much as $900/ton in 1990.

Fourteen hundred tons were transferred to SEG in 1991 as a pilot program at a cost to the Army of $732,000. SEG's furnace became operational in 1992. This pilot operation demonstrated that melting was a viable alternative to burial. LANL has obtained optimum shielding from the smooth surfaced, easily stacked blocks. The blocks are slightly radioactive, but have no removable contamination since the DU is blended in the steel. The Army has since expanded the Army's radioactive waste program to include armor plate recycling. Thirty-two hundred tons have been transferred to SEG thru 1993, eliminating the stockpile of plate and ancillary metal equipment at APG.

CONCLUSION

Recovery of the DU penetrators reduced DU concentrations in the test ranges, minimizing the opportunity for migration and reducing the ecosystems exposure to DU. The recovery of DU at the test ranges has been complicated by the terrain, weather, the presence of UXO, and personnel being prevented from entering the area due to other explosive testing near the firing ranges. A substantial number of penetrators have been removed from the test ranges near or on the surface of the ground where the potential for migration is the greatest. Recovery of DU is a viable pollution prevention program consistent with the Clean Water Act and Resource Conservation and Recovery Act.

The recovered penetrators were recycled by the manufacturers, removing them from the test centers' radioactive waste stream. Recycling DU continues to be an integral part of TECOM's radioactive waste reduction program, conserving vital space in the low-level radioactive waste depositories.

As a result of demonstrating that depleted uranium armor scrap and obsolete penetrators can be recycled into new production tank cartridges the following benefits will be realized; no additional DU will be imported into the Army inventory, contaminated magnesium fluoride and hydrogen fluoride will be eliminated, obsolete penetrators will not be buried, DU scrap armor will be reconfigured and recycled in the same step, and most importantly, the production round will cost significantly less. Follow-up studies will be conducted to determine if the structural and compressive yield failures were due to high zirconium levels.

The benefits of armor plate recycling are: 1) the practice complies with the Resource Conservation and Recovery Act and the Low Level Radioactive Waste Policy Amendments Act by recycling material and reducing the radioactive and hazardous waste produced; 2) the State of Maryland radioactive waste production and disposal is decreased; 3) the federal government's expenses for waste disposal and purchasing shielding material are reduced; and 4) less radioactive waste is stored at APG, reducing the exposure of the ecosystems to DU.

The Army Research Laboratory has decommissioned and disposed of its liquid abrasive

blast equipment and relies on recycling its armor into shielding blocks, and decontaminating less contaminated plate by cutting the contaminated metal from the surface. U.S. Army Combat Systems Test Activity has also discontinued to operate its liquid abrasive blast facility because transferring the metal for shielding is less expensive.

The Army is reducing its radioactive waste production and has eliminated the stockpile of penetrators and armor. The Army continues to explore effective methods of waste reduction with the least adverse impact to the environment.

CLEAN UP AND RELEASE OF RADIOACTIVE LYSIMETERS AT THE HANFORD SITE

David L. Stanton
U.S. Army Corps of Engineers
Richland, WA 99352

INTRODUCTION

This report is a record of the US Army Corps of Engineers (USACE) experience in the investigation and remediation of radioactive soil sites at the Department of Energy (DOE) Hanford Site in Washington State. This report by no means chronicles all of the efforts leading up to the actual site remediation. Environmental work at Hanford is unique in that there are various DOE contractors assigned different areas of responsibilities. The Hanford site is also governed by an agreement between DOE, the

Environmental Protection Agency (EPA), and the Washington State Department of Ecology (WDOE). This agreement is known as the Tri-Party agreement and makes EPA and WDOE direct participants in environmental actions at Hanford.

Purpose

The areas in question, known as lysimeter plots, had been sampled previously by Pacific Northwest Labs-Battelle (PNL) after the conclusion of the experimentation and the subsequent removal and disposal of the contaminated material. The results of this initial sampling indicated that no residual contamination remained in these areas; however the USACE was tasked to perform the follow up verification sampling for two reasons. First there was a concern raised by the Washington State Department of Health that the analytical methods used by PNL, (i.e., gross alpha and beta counting), might not adequately detect all of the types or quantity of radiation expected due to matrix effects and screening in the soil being analyzed. Secondly, it is US Department of Energy policy to conduct independent verification of clean closure especially in the case of radiological analyses that support releasing property for unrestricted public use such as this.

History

The Arid Lands Ecology (ALE) is a 311 square km (120 square miles) area, south of the Hanford site, that prior to 1942 contained a few homesteads and natural gas wells. In 1942 the US Government acquired the area as a buffer area for the Hanford site. In the early 1950's a NIKE missile site was constructed by the Army for protection of the Hanford site from air attacks. The Army remained until the early 1960s. In 1967, this area was established as the ALE, and functioned as a National Ecological Preserve. The area is currently managed by PNL for DOE. In 1993, USACE was tasked by DOE to investigate and remediate CERCLA sites on the ALE to allow DOE to release the ALE to non-DOE use.

In mid-July 1994, the US Army Corps of Engineers conducted sampling of two areas within the Arid Lands Ecology that had previously been used by PNL in radiological experiments. The samples were analyzed for a number of specific radioisotopes to verify that these areas did not contain significant radiological contamination. To adequately address these concerns, a sampling and analysis plan was devised by USACE in close consultation with WDH that sampled over 20 percent of the more than 500 individual locations that had contained lysimeters in the two plots and analyzed these samples for the specific radioisotopes associated with the individual lysimeters. In addition split samples were analyzed by the WDH state laboratory to provide additional Quality Assurance and coordination was conducted with Oak Ridge National Laboratories to provide further independent analyses for the DOE. The results from this sampling effort substantiate that clean closure was accomplished by PNL. The results from all of the project samples exhibit insignificant activities, with all but one of the samples having activities of < 1.2 pCi/g. The one caveat was a sample that had 53 pCi/g. This sample was taken from an area that had been previously identified by PNL as a place where ants had been discovered in one of the lysimeters and small amounts of contamination could have escaped the lysimeter tube with the ants. Although activities for this isotope (Pu-238) at this level and volume are associated with extremely small exposure risks, USACE in consultation with the Environmental Protection Agency excavated and properly disposed of soil from this area to further mitigate any exposure risks.

Lysimeter experiments were performed by PNL in the 1970s and 1980s on the Arid Lands Ecology. The purpose of the experiments were to calculate transmission and migration rates through soil and plant uptake of the radio nuclides. The lysimeters used contained I-131, I-129, Pu-238, Pu-239, Am-241, Cm-244, Np-237, U-232, and U-238. There were three locations where lysimeters were placed known as "lysimeter plots." Names are assigned to the plots sampled for the purpose of this report reflecting the commonly used name for the plot.

The first set of lysimeters are identified as the "Main Plot," 310 lysimeters were used at this site. The lysimeters consisted of a radioisotope mixed with soil and placed in PVC tubes 5" in diameter and 1 meter in length. The tubes were set inside a 6" diameter tube and sealed at the bottom and placed vertically in the ground, with the open top of the tubes flush with the ground surface. Isotopes used in the main plot consisted of 1-129, Pu- 238, Pu-239, Am-241, Cm-244, Np-237, U-232, and U-238 spiked at concentrations per tube up to 1.0 mCi. PNL decommissioned the main plot in 1992 by removing the lysimeter tubes and transporting them to the main Hanford site for disposal as radioactive waste PNL then performed a soil analysis

for gross alpha and beta at the surface and at 1 meter depth of every third lysimeter tube. The results from this first sampling event indicated that a clean closure of the lysimeters had been accomplished. To verify these results the US Army Corps of Engineers was tasked to perform another sampling event analyzing for the specific radioisotopes of concern. This sampling was conducted and coordinated in cooperation with the Washington State Department of Health (WDH).
The second location is identified as the "Old Plot". These lysimeters contained Pu-238, I-129, and Am-241. In 1979, after a brush fire swept the area, the lysimeter tubes were removed and placed in the main plot. There were a total of 128 lysimeters similar in the main plot. No prior sampling data was available from the decommissioning of the abandoned plot.
The third plot was identified as the "Kathy Moss" plot. This name was assigned in reference to the individual that performed the lysimeter experiments at that location in 1989 (ref PNL document #7298). This lysimeter consisted of direct injection of I-131 into Bunch Grass (Agropyron Spicatum). A glass tube, with a camera, was placed adjacent to the plant roots in order to observe the plant uptake of the I-131. A total of 18 plants were injected with the I-131. No confirmation sampling was performed at this location since I-131 has a half-life of 8 days and as a result any I-131 left in the soil would have decayed to background levels.
Sampling Rational and Description
The USACE designed and coordinated verification sampling of the Main and Abandoned plots. Verification was performed anticipating the Arid Lands Ecology land being eventually released for non-Department of Energy use. Prior to sampling, a site survey was performed by Westinghouse Hanford Co. (WHC) using the Ultra-Sonic Ranging and Data System (USRAD) and field survey instruments to verity that no contamination was present at levels hazardous to workers. The USRAD system consists of a backpack mounted radiation detection system with data links to a remote receiving station. The receiving station collects and correlates the detector data, and generates an accurate survey map of large areas.
Samples were collected by the WHC sampling group for shipment through a USACE contracted lab to TMA-NORCAL in Richmond, CA. The Washington State Department of Health radiochemistry lab volunteered to perform the QA for this project with no cost to the government. Along with saving monies, this allowed the WDH to directly participate in the site remediation process. An Independent Verification Contractor (IVC), Oak Ridge National Labs, also performed sampling. The IVC is a Department of Energy (DOE) unique requirement used for independent verification of the contractor sampling process. Although no sampling was slated for the Kathy Moss plot, radiation field surveys were performed to ensure no unanticipated contamination was present.
No formal clean-up level was set for this site, although an ongoing dialog was established between USACE, EPA, DOE, and WDH throughout the design and performance of this sampling. Current DOE clean-up levels for unrestrictive use of a site are 100 mrem total effective dose equivalent (TEDE) to any member of the public in one year. With the application of ALARA (as low as reasonably achievable) principles, this 100 mrem value is reduced to 30 mrem. With these general guidelines, and in consultation with WDH, analytical reporting limits were set that could be used to establish exposure scenarios at least two orders of magnitude lower than the 30 mrem level when evaluating the clean closure of the lysimeter plots.
Sampling and Analysis Design
The sampling and analysis plan (SAP) was designed to meet the data quality objectives for providing data usable in establishing verification of clean removal of the lysimeters. The sampling strategy developed in consultation with the WDH provided for sampling over 20 percent of the lysimeter holes at the surface and at 38 inches below surface. These sample points were reasoned to be the most likely areas of possible contamination after lysimeter removal because any surface contamination could have been brushed to the bottom of the holes or there could be a slight possibility of leakage of the PVC containers. A morgue sample was held from each of the sampled lysimeters and composite samples were made by combining equal amounts of the homogenized soil from five samples for the same analyte into a given composite sample. This provided for analyzing a large subset of the total set of lysimeters without exorbitant analytical expense. This plan allowed for analyzing each of the sub samples for any composite that exhibited appreciable activity to pin point any possible contamination area. The samples were taken from lysimeter holes that had been previously identified and marked using plot maps provided by the PNL

scientists who had been involved with the lysimeter projects.
The sampling was designed to meet the requirements outlined in the HASQAP and in DOE order 5400.1, as well as to conform with USACE guidance. The actual field work was performed by the Westinghouse Hanford Company (WHC) field crew designated to perform radiological soil sampling in accordance with established WHC standard operating procedures and protocols. WHC also provided Health Physics Technicians for site safety. All radioactive contaminated soil was packaged, transported, and disposed by Bechtel Hanford Inc. Coordination and oversight of the sampling was provided by USACE. The project lab chosen for the specific radioisotope analyses was Thermal Analytical(TMA) in Richmond California. TMA has been used extensively for radiochemical analyses for Hanford and other DOE installations. It is a participant in a proficiency evaluation program conducted by Environmental Measurements Laboratory for DOE, and was able to provide a deliverables data package in a format similar to the Environmental Protection Agency's Contract Laboratory Program (CLP) package to facilitate data validation. A summary of the SAP for the project follows.

Sampling and Analysis Synopsis
Next is a synopsis of the sampling and analysis plan provided to the sampling crew, and to the project and analytical laboratories involved with the evaluation of the lysimeter plots. It is provided in this report to aid in reviewing the validity and appropriateness of the data generated.
PROJECT DATA QUALITY OBJECTIVES
The purpose of this sampling event is to confirm that complete and clean removal of the radioisotopes contained in these lysimeters has been accomplished. The analytical reporting level requirements have been established to provide adequate sensitivity to determine if contaminant concentrations present an exposure risk. Specific radioisotope analyses have been chosen for this testing to avoid potential analytical problems associated with gross alpha and beta screening as was previously performed to confirm clean closure of these lysimeters. The sampling and analysis proposed was of limited scope to be used as a check of the previous analyses.
As an independent verification, the Washington State Department of Health analyzed split samples from this event on at least 10% of the samples sent to the project lab. Both the project and State lab are participants in the semi-annual PE program for radiological analyses conducted by Environmental Measurements Laboratory as outlined in DOE order 5400.1. In addition the project lab submitted Quality Assurance Program manuals, Statements of Qualifications, copies of current licenses, certifications, and proficiency results for the analyses to be employed to the USACE Mandatory Center for Expertise (MCX) in Omaha, Ne. for USACE validation prior to beginning the project.
It is typical for analytical data used in risk assessment to use CLP protocol analyses and RAS deliverables with level IV data validation. In an attempt to present data of similar quality USACE asked for a CLP like deliverables package such as that developed by TMA in a software package called DVD, and following EG&G's GRRASP protocol modified to meet the project detection limits.
PARAMETERS CONSIDERED FOR ANALYTICAL METHOD QC
Control parameters are anticipated to be within ~ 2 sigma data scatter in LCS running averages expressed in % recovery assuming activities of at least 10 X of RDL. LCS levels should not be > 20 X RDL. All recoveries that are outside of specified range shall be flagged. Any samples in a batch where associated LCS recoveries are outside 60-140% shall be reanalyzed for those isotopes which are out of control. LCS and LCS duplicates will be analyzed with each batch. A batch shall be no more than 20 samples. One sample duplicate shall be analyzed with each batch. Duplicate Analyses shall be within 30% RPD for all activities greater than 10 X project specified RDL. Samples from batches with duplicates outside this limit shall be flagged and impact on data shall be addressed in a case narrative. If duplicates are > 50% RPD at activities > l0X RDL, samples from the batch shall be reanalyzed at laboratory expense.
QA/QC SAMPLING
One composite sample out of each group of composite samples for a given analyte was split into 3 replicates. Each replicate was assigned an independent sample identification number that was to be logged with the sample location in the field notebook. One replicate was sent to the State lab, and 2 replicates to the project lab. This provided a blind duplicate at the project lab for each analyte. A

background sample was taken compositing samples taken at 4 points ~ 20 yards from the sampling site boundaries and roughly encompassing the sampling site. The grids below depicted sampling strategy.
TABLE Ia
TABLE Ib
TABLE Ic
TABLE II
Each cell represents an individual lysimeter. Those lysimeters sampled, ~ 20-25% of the total originally spiked) were assigned a number. A composite was made from samples taken from the lysimeters designated with the same number from the grid above. The samples were number coded on this grid for the specific radioisotope. A morgue sample of each sample point was retained in a 4 oz. jar. The specified lysimeters were sampled using a hand or power auger at the approximate center of each lysimeter. A 2 oz. portion of soil was collected from the surface to 3 inches in depth and again in another plug taken from 39 to 42 inches in depth. The soil from these two plugs were mixed then placed in a 4 oz. jar labeled for the analyte and the lysimeter. Composites made by taking one spoonful from each jar corresponding to the same lysimeter number in the above grid were submitted to the lab, i.e. if samples #1 through 5 above are from Pu-238 lysimeters, then 5 composites were made, 4 containing aliquots from 5 sample points, and one containing aliquots from 4 points. One of these composites was split into 3 replicates for QA/QC as referenced above.
A similar sampling strategy was followed for the old lysimeter plot. This plot consisted of 128 lysimeters. Individual lysimeters were formerly spiked with either I-129, Am-241, or Pu-238. Because the Information was incomplete on the number of lysimeters spiked or which of the three isotopes was used, we sampled ~ 20 % of the holes (27 total) at random throughout the plot. These samples were composited into 6 samples and 1 background that was analyzed for all three of the radioisotopes mentioned above. The sampling was consistent with the method used in the large plot. The background sample was composited from 4 sample sites taken - 20 ft. away on each of the four sides of the old lysimeter plot. The composite aliquots were taken using the same technique as employed in the main lysimeter sampling, i,e. by taking two plugs at surface and at 39-42 inches. All 4 aliquots from the sides away from the plot were composited in an 8 oz. jar and labeled as background with appropriate location references. The background sample was analyzed for each of the referenced analytes.
Sample Results
The samples sent to TMA were analyzed on an expedited turn around time to provide the results to be interpreted in time to allow for further action to be taken before the deadline of the Tri Party Agreement Milestone.
The results strongly support PNL's conclusion that clean removal of the lysimeters has been accomplished. All of the samples with one exception exhibited activities of less than one picocurie per gram (1 pCi/g) or less than the required detection limit (RDL) for the analysis. The one sample that had an activity of 53 pCi/g was submitted for reanalysis along with the 5 sub samples that represented the individual lysimeters sampled from this composite sample. Two of these sub samples had appreciable activities of 27 and 372 pCi/g respectively. The location of these lysimeters would correspond to cells K1 and G1 in the graph. One cubic meter of soil was excavated from each location, and follow-up sampling was performed. The follow-up sampling results showed a Pu-238 concentration for location K1 still at 35 pCi/g.
Follow Up Actions
In response to verifying and pinpointing the source and extent of this minor contamination (35 pCi/g), risk base analyses were conducted by USACE using a software package designed for radiological risk assessment called RESRAD (DOE order 5400.5) RESRAD is a computer code developed at Argonne National Laboratories for DOE that is used to calculate site specific RESidual RADioactive material guidelines (cleanup criteria) and radiation dose to an on-site resident, RESRAD calculates residual concentrations of radionuclides in soil; concentrations of airborne radon decay products; external gamma radiation levels; surface contamination levels; and radionuclides in air and water. The dose is calculated using external radiation exposure; internal radiation dose from inhalation (including radon); and internal radiation dose from ingestion e.g., drinking water, food, and soil.

The purpose of using the RESRAD modeling program by USACE at this point was to establish the TEDE for this site, and whether the clean-up action was complete. By using RESRAD, it is possible to find the point at which further sampling and remediation is not plausible. The RESRAD data follows.
Two possible future use scenarios for the ALE were used to create a RESRAD model. The primary pathway for Pu-238 in this scenario is inhalation and the standard inhalation rate used by RESRAD is 8400 m3/year.
1. Subsistence Farmer. This scenario assumes that the site would be utilized for a farmer living at the site with 50% of the time indoors and 25% outdoors. The farmer would consume 70% of the crops grown at the site and would also consume water from an on-site well. This is the "worst case" scenario. By applying the standard defaults of RESRAD, which are the most conservative, the calculated dose from the 35 pCi/g concentration of Pu-238 would be a TEDE to the farmer of approximately 0.52 mrem/year.
2. Recreational Use. This scenario assumes that the site would be used for recreational use. The occupancy rate at the site is based on a maximum of 192 hours/year (8 days camping) with no indoor occupancy. By adjusting the defaults of RESRAD to reflect this scenario, the TEDE is approximately 0.039 mrem/year. Based upon the current future of the ALE, the recreational use scenario is the most likely.
In general no scenarios could be established that presented any significant exposure risk to the public.
CONCLUSIONS
No further action or sampling is anticipated to be required to release these areas as clean. At this point in time, EPA has not made a final determination on the release of this site.

CHARACTERIZATION OF THE LAKE CITY ARMY AMMUNITION PLANT RANGE FOR DEPLETED URANIUM
Thomas J. O'Dou, CHP
Allied Technology Group
Fremont, CA
ABSTRACT
This paper describes a radioactive material characterization of the Lake City Army Ammunition Plant firing range. This range was used for test and disposal firing of depleted uranium rounds for many years. The projectiles fired were experimental in nature and did not have penetrator properties. The characterization was completed manually using portable instruments to identify locations of impact on the range. Data collected was evaluated with Microsoft Excel Version 5.0 and Golden Software Surfer Version 5 to provide graphical display of the relative magnitude of depleted uranium present in each area of the range. Estimates of waste volume which may be generated in remediation of each area are made based on the area contaminated and the depth of projectile penetration.
INTRODUCTION
This characterization regards evaluation of an army ammunition plant firing range for the presence of depleted uranium, DU. The primary mission of the plant is development of munitions for the U.S. Army.
The plant operated under an NRC source material license which allowed demilitarization of an estimated 40,000 rounds made from Depleted Uranium (DU) in

the form of 20 mm penetrators by firing them into sand in a bullet catcher designed to minimize scatter of the rounds as they impacted the sand. This characterization identified the approximate location of source materials on the firing range, in a bullet catcher waste collection area, the sandpile area, and in a bullet catcher. The full range is about 2300 yards, 1.3 miles.
The radionuclides of concern in DU are 238Uranium, 234Thorium, 234mProtactinium, and 234Protactinium. The Thorium and two isotopes of Protactinium are short lived daughter products from the decay of 238Uranium. In this characterization, the photon radiation given off from the decay products of 238Uranium was used as the primary radiation for detection of source material in the soil and sand. Wipes of areas were counted with an alpha/beta counter, and direct measurements with beta and alpha detectors were made to determine spreadable activity.
Estimates of waste material which will be generated by various remediation methods are presented. These estimates are based on approximations of the number of projectiles found in each area. This is because prior to this characterization, the amount of material fired into the range could not be reasonably approximated.
HISTORY OF DEPLETED URANIUM USE ON THE RANGE
The present Safety Manager, conducted an interview with the previous Radiation Protection Officer at the site in September 1988. This interview revealed that in 1960-1961, test firings of rounds manufactured at the site was done daily. He said approximately 1200 rounds were fired into the air and not necessarily into a bullet catcher. However, he also said that there is no documentation regarding the quantity. He also indicated that around 1972, 40,000 to 60,000 rounds were shot into bullet catchers and the waste (DU round fragments) was "bucketed" up and sent off-site for disposal. In 1976 or 1977 approximately 40 rounds were demilitarized by shooting into the range.
An attempt at characterization for radioactive materials on the range in 1990 was inconclusive regarding the number and depth of projectiles fired into the range. That survey was done using a large area NaI(Tl) detector mounted to a wheeled cart and driven over the ground surface, it showed the presence of only spotty indication of photon emitters on the 2188 yard impact area.
SCOPE OF CHARACTERIZATION
Characterization of the range was to be conducted with specific attention to "affected areas" and "unaffected areas." The distribution of these areas was established and completed as follows:

Affected Areas:
1. 600 yard bullet catcher.
2. Mound adjacent to 600 yard bullet catcher.
3. Sandpile.
4. 1750 yard impact area.
5. 2188 yard impact area.
6. Building 45 weapons storage areas.*
7. Building 45 firing areas.*

Unaffected Areas:
1. 2400 yard bullet catcher.
2. All open areas under flight paths to:
    a. 600 yard bullet catcher.*
    b. 2195 yard impact area.*
    c. 2200 yard bullet catcher.*
3. Impact areas and bullet catchers adjacent to affected areas.
4. The holding pond near the sandpile.

Surveys of affected areas caused collection of more than 300,000 individual direct readings of radiation by portable scintillation detector, and collection of approximately 1000 samples for analysis by gamma spectroscopy to an MDA somewhat less than 1.3 Bq/gram (35 pCi/gram). Surveys of those areas classified as unaffected were made with the same methods as affected areas but in much less detail unless radioactive materials were detected, at which time, a more detailed evaluation of the area was made to more accurately locate the material, as was done in the affected areas.
SCHEDULE AND RESOURCES

The task was completed with five survey teams of five workers per team, a site coordinator, a labor supervisor, an HP supervisor, four lead HP technicians, a project engineer, and a project manager. The project manager was responsible for overall safe progress of the job and oversight of quality assurance in the collection and handling of data.
The majority of time spent on the survey was devoted to the external radiation survey as expected. Four survey teams were assigned arrays of 10 micro-R meters each and surveys were conducted in one foot increments over each of the affected areas except the building 45 areas. This survey
provided an in depth evaluation of DU present within the affected areas of the range. The fifth team was used for gridding and sampling of the affected areas. Surveys of the unaffected areas were conducted with different arrangements of personnel in order to ensure sufficient manpower to characterize these areas.
The survey was conducted in December 1993, and January 1994. This proved to be a very good time to evaluate the range due to elimination of hazards caused by insects and reptiles. The cold affected performance of instruments only minimally, some problems were experienced with battery contacts which caused erratic response in these instruments. Because nine other instruments were present in each array, identification of abnormal response was easy. The range was shut down from December 23 to January 3, this provided the opportunity to work more intensively on the characterization than is allowed when the range is in operation. During times of range operation, the crews had to work around the firing schedule, and characterization activities were primarily conducted during weekends.

ASSESSING THE SITE STATUS

Several surveys of areas of the range had been conducted in the past and were used to provide a skeletal framework to identify the most significant areas of site contamination except for the 1750 yard impact areas and bunkers in the flight path. The survey of the 1750 yard impact area proved that area to be as significant in DU contamination as the 2188 yard impact area.
Depleted uranium was found to be the only radioactive material present on the range by gamma analysis of samples. The radionuclides of interest are therefore 238U, 234Th, 234Pa, and 234mPa. Although 234U is also in the decay chain for 238U, it is a very long lived radionuclide and as such, it's progeny will not have achieved a significant activity in the time period since refinement of the 238U.

SITE PREPARATION PRIOR TO SURVEY

Prior to conducting surveys at the site, reference points were selected for the surveys and for subsequent remediation at the 2188 yard impact area, the 1750 yard impact area, the sandpile area, and the 600 yard bullet catcher area. The reference points were based on locations of monitoring wells or other immovable objects. Survey grids were established with reference to these points.
A grid system of reference was established to coincide with reference points of permanent objects. The final grid size was 3 meters (~10 feet) on a side over most affected areas.
Due to the extreme overgrowth of the sandpile area, it was necessary to remove brush from the planned survey areas. Grassy areas of the impact zones were trimmed in July and did not grow substantially in the areas cut. Very cold temperatures were expected and as a safety measure, insulated coveralls were provided to all crew members. The coveralls were worn by all personnel working on the range for extended periods of time. Even with work in areas restricted for contamination control, no personnel contamination was detected on these coveralls.
A large trailer was moved into the site at the entrance to the range, a small dressing area was built onto the outside of the trailer. This trailer housed the counting room for smear analysis, instruments, equipment, and a break room for the crew and the project manager's office.

WORKER PROTECTION

A number of hazards not typically present during radiation work are present at the LCAAP site. In general, ATG work procedures were in effect for safety of our workers and others. However, the following points were considered:
1. The first and most important is unexploded ordinance. Over the years, many different types of experimental and production ammunition rounds have been fired into the range. These included explosive rounds typically of the 20 millimeter size although other experimental rounds were known to have been fired. As a result of this, no ATG personnel or subcontractors were authorized to do large scale

excavation at the site with hand tools. No personnel were allowed to handle ordinance in the bunkers which may have been unexploded. An ordinance specialist from ATG at Fort Myers was present for the first three weeks and last week of the project. During that time, he searched all available areas of the range for evidence of explosives and could find none in the areas to be worked.
2. It was very cold in the LCAAP area during the characterization. All personnel wore coveralls, layers of cloth clothing, long underwear, a hard hat with visor, steel toe shoes, and safety glasses.
3. Samples of air were taken with breathing zone samplers during work operations which could have caused airborne materials such as sampling and removal of sand from the catch box. No airborne 238U or short lived daughter products associated with DU activity were identified. Samples did show evidence of radon daughters as expected, however, the level observed was not important from a radiological health standpoint.

CHARACTERIZATION

Decontamination of the specified sites must reduce the residual radioactive contamination to less than 1.3 Bq/g of DU (238U). The radiation surveys with portable scintillation counters (Ludlum Model 19) and the soil sample collection and analysis proved to be adequate to provide reasonable assurance that this level would be detected and properly characterize the range.

THE 600 YARD BULLET CATCHER

This area was determined from surveys to be the most affected area in terms of projectile accumulation, spallation, and the likelihood of spreadable activity. Surveys confirmed that activity deposited in the catch box was spread from the sand in that structure to sand outside the box and adjacent to the large mound outside the catcher. The activity in this area was found to be more due to spallation and degradation of the projectiles than in other areas. This is likely to be the result of weathering action in the sand which was exposed to rain and water accumulation near the bullet catcher. Many projectile fragments and oxidized pieces were found in this area.

Sand was removed as possible from the bullet catcher to facilitate survey of the structure. The surveys done in this area indicate that most of the structure can be salvaged as clean waste and only a fraction of the structural materials will need removal for disposal as radioactive material. Surveys of the structure were done with pancake probe GM detectors, alpha scintillation detectors, and micro-R meters. The sand in this catchbox is mostly contaminated with projectiles and oxidation from projectiles. The most cost effective means to remediate this area would be disposal of the sand as radioactive waste.

Samples of sand and soil in this area showed activity concentrations of DU as high as 115 Bq/g with an average concentration of 34.5 Bq/g. A total of 46 samples were taken from the sand in the bullet catcher when it was removed for survey of the structure itself.

THE 600 YARD MOUND ADJACENT TO THE BULLET CATCHER

A large mound 15 meters by 27 meters by 4.5 meters (approximately 50 feet wide by 90 feet long by 15 feet high) is present near the 600 yard bullet catcher. It appears that portions of the mound were used for dumping of sand from the bullet catcher over the years. This material has been weathered and has caused accumulations of DU and projectiles around the base of the mound and in the low spots of drainage paths from the area. Sampling has shown that the material has stayed close to the mound and has not migrated to the stream which runs adjacent to the area at less than 60 meters to the north west of the bullet catcher. Eighty-one samples were taken from the mound and the area around the bullet catcher.

Remediation of this area should consider an approximate depth of soil containing projectiles and DU oxidation products of 60 cm. The area contaminated around the mound is estimated from surveys to be approximately 75 square meters. This relates to an approximate waste volume of 45 cubic meters (1600 cubic feet).

THE SANDPILE AREA

The sandpile area was originally considered to be only minimally contaminated with dumpings from the 600 yard bullet catcher. After surveys of this area, it is obvious that material from this bullet catcher was dumped in more than one location of the sandpile area but the dumpings appear to be localized into small groupings over most of the sandpile with some very small piles dumped immediately outside the area.

A depth study was done on the piles found to contain projectiles in different areas of the sandpile. Two methods were used in this study, a scintillation detector was

used to identify activity as a function of depth by monitoring the sampling holes. This method showed that readings stayed constant to about 60 cm to 90 cm and then decreased to background below that depth. This was reasonably consistent from hole to hole. A second method, excavation of a grid at different depths, similar to that done at the 1750 and 2188 yard impact areas, was used at the sandpile to identify depth below contaminated piles. When the small contaminated piles were collected with a front loader, no activity was identified below the piles.
In addition to the external radiation surveys, 148 samples were taken in the affected area of the sandpile. The results of those samples show activity predominately near the surface. Depth samples did not show activity above the remediation level.

IMPACT AREAS

Two large impact areas were surveyed with Ludlum Model 19 micro-R meters to establish a profile of emissions from the soil. Readings were taken one foot on center and the response was plotted over the area surveyed to identify areas of higher DU concentration.
In all, 1541, 10' by 10' grid squares on the 1750 yard impact area, and 1970 grid squares on the 2188 yard impact area were established and readings were taken every square foot.
Samples of soil were taken in all areas of the impact zone and in the creek bed. Similar to the sample results at the 2188 yard impact area, samples showed localized accumulations of activity in the immediate area of the projectiles and no accumulation with depth. Studies of the depth of projectiles in the soil were done in several sample holes and by digging up one of the grids in this area. The results showed that activity did not travel into the soil and no activity could be found at greater than 30 centimeters into the soil. Over one hundred samples of soil were taken in this area.
The 2188 yard impact area was initially considered as the most important of the impact areas for DU projectiles. A large initial grid was set in the geographical center of the impact zone. This grid proved to encompass the most significant projectile impact area but did not contain the entire area. Several grid additions were made to attempt definition of the affected area. In addition, 204 samples were taken to determine activity transfer to the soil and all wells in the area were sampled for the presence of DU.

AREAS OF SCATTERED ROUNDS

When firing into the long range areas, scattering of rounds off of the soil surface or off of subsurface rocks was possible. Foot traverses of these probable ricochet areas with a scintillation detector and count rate meter was the method recommended by the NRC. This method was enhanced using of micro-R meters to locate projectile impact zones within the firing line.
Wooded areas adjacent to the 2188 yard impact area were searched with the same instruments, accumulations of projectile fragments were found within 6 meters of the woods line on the north side of the area. The searches were conducted with 5 people each with a detector, and all surfaces not extremely hindered by trees and shrubs were surveyed. Areas where projectiles or fragments were found were identified with surveyors flags.

INTRUSIVE SAMPLING

Samples were taken in all areas of the range, affected and unaffected. Each sample was a combined depth and surface activity evaluation when this was practical. The samples were collected when practical with a California hollow point auger. In some cases, the auger was not sufficient to remove soil/sand from the hole and a planters shovel was used to collect the sample. Due to the hard, frozen clay soil found in most areas of the range, a power auger was used to reach sampling depth. All sampling tools were cleaned between each sample collection, and efforts to minimize cross contamination were used as practical. The extreme cold and windy conditions made this difficult.

SAMPLE ANALYSIS

The method for measurements of soil samples taken from the various areas of the site were evaluated by comparison counting to a 238U soil standard. The focus of the analysis was the 92.3 keV and 92.8 keV photons emitted from 234Th, the immediate daughter of 238U. These photons are emitted with a photon yield of approximately 2.73% and 2.69% respectively. A region of interest around the 92.5 keV energy range allowed quantification of the 238U in equilibrium with it's Thorium daughter. The

analysis was conducted by Scientech Laboratory.

BACKGROUND SAMPLES

Background soil samples were taken primarily in four unaffected areas of the range and also in several locations off of the range. These samples were taken, similar to the range characterization samples, at depths of 15 cm, 60 cm, and 90 cm when possible. It was intended that background sample activity would be subtracted from characterization sample activity, but background activity proved to be insignificant compared to the MDA of 0.37 Bq/gram (10 pCi/gram) for most samples.

SENSITIVITY OF ANALYSIS

The comparison of sample activity results with the limiting level of 1.3 Bq/gram is to be based on a gamma spectral analysis of each sample. The detection level, due to laboratory requirements, was established at approximately 0.37 Bq/gram, approximately 30% of the limiting concentration for DU. The limiting guidelines, established by NRC, are directly related to the risk posed by the nuclide 238U in equilibrium with it's short lived daughters through defined exposure pathways.

ESTIMATES OF WASTE VOLUME

Waste volume estimates were made based on the degree of surface area found to be above background response and the accepted depth of activity based on sampling. In anticipation that soils surrounding the primary areas of projectile accumulation, the following volume could be considered above the NRC remediation guidelines:

600 yard bullet catcher area 1020 cubic meters (36,000 cubic feet)
Sandpile area 187 cubic meters (6,600 cubic feet)
1750 yard impact area: 5240 cubic meters (185,000 cubic feet)*
2188 yard impact area: 5000 cubic meters (177,000 cubic feet)*

These numbers are based on the area of significant emissions above background. In the impact areas, there was not evidence of activity spread from the immediate impact zones. Extraction of small amounts of soil around each impact would reduce total waste volume to approximately

ABSTRACT

The Montclair/West Orange and Glen Ridge Superfund Sites are located 12 miles west of New York City in Essex County, New Jersey. The sites are contaminated with waste materials from radium-processing facilities which operated in the area during the early 1900's. The waste materials, containing radium and other radioactive isotopes were placed in three separate landfill sites. As the towns were developed, homes and streets were constructed on or near the disposal areas. Some of the contaminated materials were also used as fill around basements foundations and yards.

There are 769 residential and commercial properties, having a combined area of approximately 210 acres, included in the two Superfund Sites. The principal contaminant is radium 226, with lesser concentrations of thorium, uranium, and lead. Major public health risks are indoor radon gas build-up and indoor/outdoor gamma radiation.

In the early 1980's the United States Environmental Protection Agency, Region II (EPA) and the New Jersey Department of Environmental Protection (NJDEP) began a series of surveys, investigations, and studies to determine the boundaries of the contaminated areas.

In 1985, NJDEP began a pilot study to remediate the properties by excavation and off-site disposal of contaminated material. The study was interrupted when the disposal permit to the off-site disposal facility was revoked. Residents of four partially remediated homes were left in temporary accommodations for nearly five additional years, while a new disposal facility could be identified and utilized.

In 1989, the EPA issued a Record of Decision (ROD) which chose excavation and off-site disposal of contaminated material as the preferred alternative.

Additionally, through an Interagency Agreement, the EPA engaged the Kansas City District of the U.S. Army Corps of Engineers (USACE) to perform the remedial design. Bechtel National, Inc., (BNI) was selected by the Kansas City District Corps of Engineers to perform the extensive field investigations and provide the detailed engineering designs for the remedial work.

The purpose of this presentation is to highlight key elements of the design process for the remedial action at Montclair. Those key elements are as follows:

- Meeting community relations challenges
- Measuring radioactive contamination
- Developing plans and specifications
- Packaging of remedial action contracts
- Continually improving both the process and the designs

COMMUNITY RELATIONS CHALLENGES

Long Site History

The Montclair/West Orange and Glen Ridge Superfund Sites include three separate residential areas in Essex County, New Jersey, consisting of 769 residential and commercial properties contaminated with radioactive materials. The contamination originated from radium processing facilities which operated in the area during the early 1900's. Radium research and processing facilities were prevalent in Northern New Jersey from the early 1900's to the late 1920's. The processing facilities produced luminous paint for watch dials, surveying equipment and airplane instruments; and later extracted the radium for research and medical applications. By the early 1930's the effects of excessive exposure to radium were discovered, which subsequently caused an end to the processing facilities.

The radioactive waste materials from these facilities were disposed as landfill in what were once rural areas. As development flourished, homes and streets were constructed over the landfilled waste. In 1981 the EPA was requested by the NJDEP to conduct an aerial gamma radiation survey of the area to determine the presence of radioactive materials.

The aerial survey in Essex County identified several residential areas with elevated gamma radiation levels. Ground investigations conducted in 1983 confirmed the presence of radium contamination and identified a number of homes in the towns of Montclair and Glen Ridge with gamma radiation and/or radon decay products exceeding acceptable levels. Further contamination was discovered in the town of West Orange as the investigation continued into 1984.

The initial ground investigations at the sites focused on the identification of homes with elevated radon levels or indoor gamma radiation exposure levels. During

these initial investigations a number of homes were found to have radon levels up to 100 times the normal background for the area. At that time, the potential risks of naturally occurring radon had not been identified. Even so, these readings were considered to be extremely high.

Due to the elevated levels of gamma radiation and radon decay products, the EPA implemented mitigation actions by installing radon abatement systems to ventilate basements. These systems were designed to dilute the level of indoor radon by drawing "clean" air from the outside of the home. To reduce the gamma radiation exposure level in a home, one-eighth-inch thick lead sheets were placed in layers over areas emitting high gamma radiation until there was enough shielding to reduce the radiation exposure to acceptable levels.

Unlike most Superfund sites where residential properties are adjacent to the contaminated area, the Montclair/West Orange and Glen Ridge sites are almost entirely residential properties. The majority of the homes are one and two family residences of brick or timber-framed construction with full basements, front and back porches and detached garages.

The properties were classified into one of five categories according to their public health hazard and engineering requirements. Category I properties were core area properties which contained extensive areas of radium-contaminated soil throughout the property, including under and around the house foundation. Category II properties used a criteria of basement wall or outdoor gamma radiation levels equal to or greater than 50 micro-Roentgens per hour and extensive radium contamination. Category III properties had radon and radon decay product or gamma radiation levels above health guidelines, and with limited "hot spot" radium contamination. Category IV properties contained soil contamination above the cleanup standards of 5 picocuries per gram, but with no radon decay product or gamma radiation levels above health guidelines. Category V properties had no detectable radium-contaminated soil present in excess of soil clean-up standards.

Initial Remedial Experiences

There was a great deal of pressure on both EPA and NJDEP to initiate permanent remedial measures at the contaminated properties. In May 1984, EPA and NJDEP planned a pilot study to test the feasibility of excavation and off-site disposal of the radium contaminated soil. Twelve properties were selected for the pilot study and preliminary engineering assessments were prepared. In the fall of 1984, EPA decided to forgo the pilot study and proceed with a full Remedial Investigation/Feasibility Study (RI/FS). The sites were included on EPA's National Priorities List of Superfund Sites in a special listing in February 1985. NJDEP elected to proceed with the pilot program.

NJDEP began excavating soil in June 1985. After four properties in Glen Ridge had been completely remediated, the disposal permit was revoked. Work had begun on four different properties of the pilot study in the Town of Montclair. Excavation was halted immediately. The occupants of the homes remained in temporary housing while NJDEP attempted to secure a disposal site. A significant amount of negative publicity was generated by NJDEP's search for a disposal site and the images of drums of contaminated soil stored in the middle of a residential neighborhood. In the fall of 1987, NJDEP was able to remove the soil from Montclair. The pilot program demonstrated that excavation is technically feasible and effective. It also demonstrated that technical issues such as support of structures and building material decontamination were readily solvable. The major obstacle was finding and maintaining a permanent disposal site.

In 1985, concurrent with the pilot excavation program, the EPA completed the draft RI/FS. Because of the problems associated with the disposal of the radium-contaminated soil and the public's demands for a permanent solution to the problem, the EPA initiated a supplemental feasibility study in March 1987.

EPA Records of Decision

EPA issued a ROD for each site on June 30, 1989. The RODs called for total excavation of soil from the most severely contaminated properties. They also called for continued installation and maintenance of interim controls for radon gas and gamma radiation where public health standards were exceeded. EPA reserved a decision on the remaining contaminated properties pending further study. This remedy was expected to cost $53 million and require several years to complete.

Public comment was received until January 31, 1990, on the portions of the plan covering the properties not included in the first RODs. As a result of strong public

opinion and the recent identification of a viable disposal site, EPA issued the second set of RODs on June 1, 1990 calling for excavation and off-site disposal of contaminated material on each property where this material exceeded the cleanup criteria. The combined remedy for the sites was expected to cost over $250 million and require more than ten years to complete. EPA stated in the 1990 RODs that several factors could influence the implementation of the proposed remedy and the cleanup schedule. These factors included funding for the project and the long-term availability of a disposal site.

Overcoming Inertia

After nine years of study and unsuccessful attempts at remediation, the challenges to EPA, USACE and Bechtel were as follows:

- Regain public confidence
- Conduct detailed design investigations of 769 properties
- Address worst cases first
- Prepare individualized designs for each contaminated property
- Move quickly from study to actual remediation
- Minimize the disruption in the neighborhoods

In the spring of 1990, EPA, USACE and Bechtel began a two-phased program to jump-start the project. EPA and Bechtel began an intensive program of community relations in the three communities to inform homeowners of the overall plan for the remedial work and to obtain individual access to properties for design testing. As soon as access was received, Bechtel mobilized test crews to conduct the necessary investigations required to prepare remedial designs. By the end of the first year, investigations on almost 200 of the properties were completed. Within three years, design investigations were completed on over 740 properties.

By the fall of 1990, USACE had awarded a contract to Sevenson Environmental Services, Inc., (SES) for the removal of contaminated material from the four properties in Montclair that had remained vacant ever since the State was forced to abandon the pilot project. Due to the deteriorated condition of these properties that had occurred over five years, EPA determined that restoration would not be feasible. Therefore, the government purchased the homes and demolished them. Removal of the contaminated material on these properties was completed early in 1991. In order to maintain the momentum created by finally completing the long delayed remediation, Bechtel was able to quickly deliver final designs for cleanup of 5 more homes in the immediate area. USACE added the cleanup of these homes to the SES's scope of work.

From the fall of 1990 through the present, there has been a continuous process of design investigations, remedial actions, and final verifications underway at the Superfund sites. Remedial designs for over 200 individual properties have been completed. Four separate construction contracts have been awarded. Two of those contracts have been completed and over 100 homes have been remediated.

MEASUREMENT OF RADIOACTIVE CONTAMINATION

Early in the remedial process at these sites, EPA made a determination that it was important to provide homeowners with the most complete information possible regarding the extent of contamination on their property. For properties with extensive contamination, this information would be needed to determine whether relocation would be necessary. In other cases, the homeowner would need a sense of the inconvenience that would result from the cleanup of the property and the specifics of the restoration that would be required. Therefore, a comprehensive program for determining the extent of contamination was developed by EPA, USACE and Bechtel.

Gamma Walkovers

The first step in a property investigation is a complete indoor and outdoor gamma survey. The property is divided into 6-foot square grids. Technicians slowly move the gamma scintillator (TMA SPA-3 with 2x2 sodium iodide crystals) just over the surface in each grid. The highest and average number of counts for each grid is recorded. Inside the basement, a similar survey is conducted on a 3-foot grid. Gamma measurements are also recorded for the basement walls. Additionally, gamma exposure rates are taken using a pressurized ion chamber. The measurements are compared to normal background readings for the area. Since many building materials including some types of brick and belgian block have naturally elevated gamma radiation levels, the gamma readings may be above background in some areas. Although normal background for this area is between 8K and 10K counts per minute (cpm), a reading

above 20K cpm usually indicates that the property needs to be further investigated by taking a sample of the soil or building materials.

Exterior Radon Canisters

Recognizing that gamma radiation can be shielded by clean surface soil, Bechtel established the use of charcoal canisters to detect radon in the soil gases as a secondary diagnostic technique. Typically, twenty 3-inch charcoal canisters are distributed over the yard. They are covered with inverted 1-quart flower pots and left for 24 hours. The canisters are collected and each is analyzed for radon. Any locations with radon flux measurements exceeding 2 picocurie/square meter/second are earmarked for further soil sampling. This criterion was developed based on an analysis of flux measurements versus soil sample analyses. The use of this criterion has been 90% effective in detecting buried deposits of contaminated material.

Soil Sampling

Over the course of the project, a number of soil sampling techniques have been used. Initially, a drill rig with hollow-stem auger and split-spoons was used. The drill rig was difficult to maneuver and, at times, caused damage to lawns. Next, a portable tripod with a gasoline-powered cat-head and 140-lb. hammer driving split-spoons was employed. Setting up and moving the tripod and hammer proved to be time-consuming. It also was difficult to use this system in close proximity to houses.

A 4-inch, hand-turned, stainless steel soil auger became the method of choice. The auger is used to extract soil samples in 6-inch lift. The majority of the boreholes can be obtained using this technique. It also is advantageous while working around underground utilities, the locations of which may not be clearly known or marked. Boreholes are drilled to 5 feet or greater to insure that the vertical extent of contamination has been identified. After completion of drilling, radiological technicians perform a downhole gamma survey at 6-inch intervals. If the gamma readings are elevated at the bottom of the hole, or if they are increasing, the depth of the hole is increased. The lateral limits of the contaminated material are determined by evaluating the surface gamma readings and installing boundary boreholes having downhole gamma readings which are not elevated. For large areas of contamination, boundary holes are set at least ten feet from a contaminated borehole. In the case of a "hot spot", or small area of contamination, the boundary holes are pulled in closer to better define the extent of the contamination. Boreholes cannot fully delineate the limits of contamination on the site because the contaminated material is not homogeneous and was deposited randomly. Therefore, a borehole drilled six inches from a contaminated area may be clean. Boreholes are the best means of getting a good sense of the extent of contamination while limiting the inconvenience to the homeowner and damage to the property.

To compensate for the limits inherent in using boreholes, particular attention is paid to structures, driveways, large trees and other items of concern to homeowners. This decreases the likelihood that an item which is not scheduled to be affected by the remediation will have to be removed during the cleanup.

Field Screening of Samples

In order to better select which soil samples should be sent for full radiological analysis, Bechtel's subcontractor, TMA/Eberline uses a quick count system for preliminary screening. Radionuclides are not uniformly distributed throughout the soil, therefore, it is difficult to be sure that a selected sample is representative of the area from which it is taken. Quick-count gamma measurements are taken on undried samples using a 3-inch by 3-inch sodium iodide crystal after 24 hours. This analysis is compared to the downhole readings taken at the sample depth to ensure that the sample is representative of the area and not contaminated by material falling into the hole during the drilling. This technique is used only as an indicator in determining which samples are sent for complete analysis.

Radiological Analyses

TMA/Eberline uses standard methods for most of the measurements for the radionuclides of concern and has developed or refined techniques for the remainder. Measurements for the radiological activity of radium-226, radium-228, thorium-232, potassium-40, uranium-234 and uranium-238 use a mixed-acid digestion followed by gamma spectroscopy for detection.

Thorium-230 is not a gamma emitter, therefore, a different technique is required. TMA/Eberline has developed the PERALS (Photoelectron Rejective Alpha Liquid Scintillation) method for determining the activity of thorium-230. This procedure

calls for the selective separation of the thorium ions after acid digestion. Detection is then accomplished using alpha spectroscopy.
Measurements for both thorium ions are important for two reasons. First, the majority of the radiological measurements used on the project rely on detection of gamma radiation. Thorium-230 is not a gamma emitter. Second, measurement of thorium-230 is needed to determine the degree of radiological equilibrium of the contaminants in the soil.

Alpha Track Detectors

The final analytical step for properties that have been remediated, and for properties which do not exceed cleanup guidelines, is a 1-year radon study. Bechtel uses track etch devices for long-term radon detection. During the radiological decay of radon, alpha particles are released. The particles etch a track on a small mylar strip inside the device. These tracks are counted by microscope and can be correlated to the concentration of indoor radon. Three or four devices are installed in the basements and analyzed as follows:

- After 2 months exposure
- After 4 months exposure
- After 1 year exposure
- 10% duplicate analysis for quality control

DEVELOPMENT OF PLANS AND SPECIFICATIONS

Remedial design for a property included preparation of an excavation plan, restoration plan, sections, landscape schedule and subsurface borehole profiles. The excavation plan based on the surface walkovers and the boreholes showed areas of known radioactive materials exceeding cleanup standards. Excavation was designed to be conducted in two stages as follows:

- stage 1 - defined as primary excavation
- stage 2 - secondary excavation

The primary cut lines directed the remedial action contractor (RAC) to excavate where contamination boundaries are clearly defined. After primary excavation, the RAC was directed to conduct further gamma scans and to continue excavating until all contamination had been removed. The secondary excavation cut lines represented the anticipated limits of material removal based on "clean" boundary holes identified during the field investigations.
Cross sections through areas of excavation showed the depth of excavation in relation to the existing ground line. By design, all material removed by primary excavation was contaminated. The secondary excavation line was established to show a contractor the anticipated excavation breadth and depth. The contractor was directed to continue excavating beyond secondary cut lines if there was still evidence of contamination.
A restoration plan was developed for each property disturbed by excavation. Restoration of a property required the replacement of features such as demolished structures (garages), driveways, sidewalks, curbs, lawns, trees, shrubs, and all other disturbed features. The restoration plans required a RAC to restore the property to preconstruction conditions. In virtually all cases, the quality of the restored areas exceeded the preconstruction conditions.
With all of the above concurrent activity occurring, frequent coordination calls were made between Bechtel's Field Engineers, home office engineers, and USACE and EPA personnel. Weekly conference calls were conducted to review progress, identify potential problems, and reach decisions. Minutes of each conference call were prepared and distributed to each participant to assure that action items and relevant decisions are documented.

PACKAGING OF REMEDIAL ACTION CONTRACTS

The preparation of remedial designs was the area of greatest USACE, EPA, and Bechtel interaction. Of the 769 properties, approximately 250 have had or will require remedial action. It is not practical nor was it possible to remediate all properties simultaneously. Not all of the homeowners responded to requests for access in a timely manner. Some properties presented the far greater health risks. Finally, it was necessary politically to initiate some action in each of the communities within the first year. This resulted in a phasing of both the design and the remedial actions for specific areas or neighborhoods within the sites.
A major objective of the design plan was to minimize the impacts of remedial actions on individual residents and communities by disrupting a neighborhood only one time. In order to accomplish this, early emphasis on the investigations and designs

centered first on the worst case properties. Ideally, work would then move outward towards areas of lesser contamination. To a large degree, the phasing of work has accomplished this objective. Sporadic response from some homeowners and proverbial hardcore holdouts prevented complete designs of entire blocks.

Within individual phases, clusters of adjoining homes were selected for simultaneous remediation. The careful clustering and sequencing of work activities provided the following:

- The cluster could be isolated for safety and health considerations
- Heavy equipment could push contamination across property boundaries within the cluster
- A centralized bagging and loading point could be established
- A sense of community could be maintained (neighbors would be out of their homes and return in the same time frame)

In order to also maintain the momentum that had been established, construction packages of 25 to 50 homes were prepared as soon as test results were available.

CONTINUOUS IMPROVEMENTS IN THE PROCESS AND THE DESIGNS

Design Review

In developing the design, Bechtel initially prepared design packages at the 35, 65, 95, and 100% levels for review and approval by USACE. Design reviewers provided comments for each stage of review. Initially, these review comments were provided by letter.

Continuous improvements by both USACE and Bechtel along with the "partnering" that developed lead to substantial time savings that helped to accelerate the entire project. These improvements are as follows:

- Use of the Automated Review Management System (ARMS)
- Elimination of the 35 and 65% review cycles
- Flexibility in design submissions

Use of ARMS provided USACE a centralized and uniform mechanism of gathering comments on each design package and then transferring those comments electronically to Bechtel. ARMS also provided the mechanism to ensure that those comments were addressed.

After the first two design packages were completed, USACE felt comfortable enough with Bechtel's design performance that it was decided to progress to the 95% level as the initial review. Most of the designs were similar from property to property and the specifications required few changes.

A continuous sequencing of design reviews also allowed great flexibility in expanding or contracting individual phases of remediation. Many times, recalcitrant homeowners would be turned around when work began in their immediate area. As soon as they granted access for design, Bechtel would quickly complete testwork and prepare designs as necessary. Again based on USACE's confidence in Bechtel's designs, those properties could be added to a construction package ready for bid or in some cases added as a contract modification to an existing construction contract.

The design process was also dynamic. Since the design crews were working in one area while the RAC was remediating in another, lessons learned from the construction could be incorporated as design improvements to successive phases and clusters within phases. Many of these lessons involved discovering areas of contamination not apparent from initial test procedures. Later designs also provided greater flexibility to handle unforeseen circumstances such a radium contamination imbedded in the concrete footings and mortar mixes.

Data Management and Transmittal to Homeowners

A significant amount of data is generated during each property survey. This data is used by EPA and Bechtel to determine whether a property must be remediated and, if so, the extent of the contamination on the property. This data must also be available to anyone interfacing with a resident who may have questions regarding the status of their property.

EPA must also transmit data to the homeowner in an easily understandable format and in a timely manner. The most frequent complaints EPA received from the community during the early stages of the design process was in reference to the length of time between the data that a property was surveyed and the date that the homeowner received information regarding the status of the property. Part of the delay was a result of the time necessary to perform the radiological analysis on soil samples. In addition, Quality Assurance and Quality Control procedures required review by Bechtel's Oak Ridge office before data was released. Further complicating the matter

was keeping track of the following:
- Which of the 769 homeowners had received reports
- The status of test work on the property
- The results of the analyses

Bechtel developed a computerized database that is shared among the field site, the Oak Ridge Office and EPA's Region II office. The database contains the following types of data:
- Owner information
- Status of field testing
- Status of lab analysis
- Results of field testing
- Results of lab analysis
- Record of communications and reports to homeowners
- Schedule for current and future work on a property

Standard property reports are routinely generated from the database as soon as work is complete. In addition, the database provides a complete look at the status of work on a property.

Alternate Trench Method

The most significant concern expressed by homeowners whose homes required basement excavation was the potential damage to the structure of their home as a result of the cleanup. The classic approach to remediation under foundations and basements calls for underpinning or cribbing of the house to allow for complete removal of contamination. Once cribbing is in place, the entire foundation is demolished and any contaminated material removed. This is effective, but there are some risks. The lifting and cribbing stress the structure of the house and the process is time-consuming and costly. In addition to these risks, a number of the home in Glen Ridge are part of a National Historical District. The structure of these homes could not be damaged or altered.

Bechtel engineers suggested an alternative approach which called for the footing to be removed in altering 3-foot sections. After contaminated materials are removed, the void space is filled with concrete and the next section is removed. The house never moves and the risk of damage is greatly reduced.

ACCOMPLISHMENTS AND LESSONS LEARNED

The Montclair, West Orange, and Glen Ridge Superfund Sites have been very challenging sites to remediate. Dedicated personnel working for the government and its contractors have all contributed to the success of this project. The initial effort was to overcome the fears of the citizens living in the superfund sites. The government had to assure the citizens that we were capable of remediating their properties with minimal disruption to their lives. Previous removal action was halted by not having a disposal facility available to accept the large volumes of radium-contaminated soils.

In February 1988, this problem was alleviated when Envirocare of Utah obtained a license to dispose of Naturally Occurring Radioactive Material (NORM) from the Utah Department of Health. This facility was contracted to receive and dispose of the material from the site. All of the remaining material from the Pilot Home Project was transported to the Envirocare facility, thus ending the five year interruption in the completion of the initial project.

The coordination of the EPA and Army Corps has been considerable. EPA, being the lead agency, has had the responsibility for outreach and community relations. The EPA representatives on site are available to answer questions and concerns of the citizens. Property owners feel more secure when they see a familiar face. It was quickly realized that individual meetings accomplish more than large group meetings, especially when dealing with individual property owners.

The Army Corps' design contract with Bechtel National includes field design investigations and remedial designs. With the extensive field investigation being performed to characterize the sites, Bechtel has had personnel at the site for the past four years. These people are very helpful in explaining the technical issues to the property owners. During the individual meetings, EPA requests assistance from the field personnel to explain technical issues of the remediation. The availability of the site personnel has improved the government's responsiveness to the citizens.

Design packages were prepared using the following guidelines:
- Remediate the most contaminated properties first
- Minimize the disruption to an individual location

With the effort to have all the Category I properties investigated first and proceed on through the Category II, III, IV, and V's, property clusters were developed. These clusters were placed into biddable packages to be awarded over the course of the design. Concerned that the number of available rental properties in the area might be insufficient, the government developed remedial packages that were sensitive to the relocation issue. Award of the remedial action contracts were staggered to not have too many people out of their homes at one time. This paradigm was repeated to show continued remediation progress in the field.
The project has incorporated the team approach to remediation. All government agencies and contractors are kept well informed as to the status of activities at the sites. Meetings are formally held at least once a week to discuss site conditions.
Property owners are presented with the results of the tests as soon as possible after the testing is completed. This keeps the owners updated regarding any changes in the cleanup plan for their properties.
Each property owner's concerns are unique. The government representatives are well prepared to listen to their concerns before determining the best course of action.
The community, including local officials, citizen groups, and residents not directly affected by the cleanup are periodically updated on the status of the project. The updates are initiated at city council meetings, press releases, and via mailings.
The local officials are involved in the logistics of the cleanup on all levels including traffic control, utility work, tree selection, and building permits.
The remediation of these properties has been turned from a disaster into a success by the coordinated efforts of the EPA, USACE, and their contractors. Expectations are that the high performance efforts of all concerned will conclude this project ahead of schedule and as much as $100 million below the original $250 million estimate.

COMMUNICATIONS IN THE FIELD OF RADIOACTIVE
WASTE MANAGEMENT IN SPAIN
Valentn Gonzlez
Jos R. Armada
Mariano Molina
Communications Division
ENRESA
Madrid (Spain)
ABSTRACT
The generation of electrical energy by nuclear means began in Spain in 1968. There are currently nine nuclear groups producing approximately 38% of the country's total electricity. In addition, there are a further 1,300 installations at which radioisotopes are used for medical, industrial or research purposes and which, like the nuclear power plants, produce radioactive wastes.
In 1984, the Spanish Government set up the Empresa Nacional de Residuos Radiactivos (ENRESA) with a view to reorganizing radioactive waste management and centralizing this activity within the framework of a public company.
One of ENRESA's main tasks is to inform society of the activities it performs, since as is the case in most countries public opinion is highly sensitive to any issue relating to radioactivity, and especially to radioactive wastes. The main reason for such attitudes is a lack of knowledge of the activities and practices performed, this in turn being due mainly to a lack of information on the subject and, in certain cases, to inadequate use of the information available by certain politicians, environmentalist groups and media.
From the very beginning, ENRESA considered that there was a need for its information actions to be ordered within a Communications Plan defining continuous, long-term

interactions between the company and the public at large. This Plan, which is being applied in a series of different stages at local and national level, works well in the areas surrounding a facility for the definitive disposal of low and intermediate level wastes (El Cabril) and a disused uranium mill (AUM) which has been decommissioned and closed.
The Plan is oriented towards achieving understanding and rationalization of the tasks performed by ENRESA, establishing courses of action and projects serving to enhance conditions in the areas hosting the company's installations and to dispel whatever fantasies might exist among the population in relation to radioactive wastes and their handling.
The main activities performed in Spain in order to provide information on radioactive waste management are described in the paper, as are the most important informative efforts to be made in the future with a view to favoring the implementation of a high level waste repository. Special attention is paid to the need for widespread agreement between the main political forces, performance of an information campaign at national level and the establishment of research and demonstration centers.
RADIOACTIVE WASTE MANAGEMENT IN SPAIN
In Spain, 93% of radioactive wastes are generated at nuclear power plants. The country has nine nuclear groups at seven sites (Fig. 1) with a joint installed power level of 7,405 MWe; in 1994 these groups generated 55,314 GWh, 38.5% of the country's total electricity production (Table I). There is also a group which is now shut down, Vandells I, where dismantling operations will soon begin.
Fig. 1.
TABLE I
The nuclear program started in 1968 with start-up of the Zorita Nuclear Power Plant, and subsequently developed in three stages. Between 1968 and 1974, 1,130 MW were installed at three plants using PWR, BWR and graphite-gas technologies respectively. Between 1982 and 1985 a further five groups amounting to 4,695 MWe came on line, and in 1988 two third-generation groups with a capacity of 2,000 MWe were connected to the grid. In 1984, the Government decided to freeze the construction of 5 nuclear groups whose design and development had been initiated. The 1991 revision of the National Energy Plan ratified this decision, and the construction of new nuclear plants was put off until such time as the country's energy demand were to require them, and in no case earlier than the year 2000.
Radioactive wastes are also produced at 1,300 installations using radioisotopes for medical, industrial and research purposes.
Management of these wastes is the responsibility of the Empresa Nacional de Residuos Radiactivos (ENRESA), which carries out its work in accordance with the strategies defined in the General Radioactive Waste Plan, a document issued by the Government and periodically updated. The latest estimates on waste production consider that the current installations will produce 191,700 m3 of low and intermediate level wastes and 9,020 m3 of high level wastes in the form of spent fuel (Table II).
TABLE II
The 4th Plan, approved in 1994, defines the following activities for management of these wastes:
i. Low and intermediate level wastes
These are disposed of at El Cabril, a shallow underground facility with engineered barriers using cement as a waste immobilization matrix. The authorized capacity of this facility is for 35,000 m3 of conditioned wastes, which will allow for disposal of all the wastes produced in the country from now until the beginning of the next century.
ii. High level wastes
The Spanish strategy for the definitive disposal of high level wastes consists of emplacing them in geological formations of granite, clay or salt at great depth. In 1987, work began on determining the best suited locations for construction of a repository. It is expected that by the year 2000 sufficient information will be available for a proposal to be made to the Government regarding a site for a disposal facility.
Meanwhile, the spent fuel will be stored at the plants. In the future, as the plant pools fill up with wastes, the fuel will be stored on site in dry containers for subsequent removal to a centralized store.
iii.Dismantling

In July 1993, ENRESA concluded dismantling and decommissioning works at a disused uranium mill at Andjar (AUM) in the province of Jan. The design and performance of these works, based on projects used by the US Department of Energy (DOE) for the Uranium Milling Tailing Remedial Action (UMTRA) project, were accomplished with technical assistance from the JACOBS ENGINEERING GROUP. As regards nuclear power plants, the Spanish Plan contemplates dismantling to level on the scale defined by the International Atomic Energy Agency (IAEA) at the end of their service lifetime. ENRESA is currently working on the tasks to be completed prior to dismantling of the Vandells I plant, which was closed by Government decision in 1990.

iv.Research and development

Research and development is carried out mainly in order to increase knowledge of the technical and operational needs of the definitive high level waste disposal facility. The costs foreseen in this area, up to implementation of the facility half way through the next century, amount to some 500 million dollars.

PUBLIC PERCEPTION OF RADIOACTIVE WASTES

The various sociological surveys performed show that the attitudes and opinions of the Spanish population towards nuclear energy are mainly negative. In simplified terms, between 30 and 35% of Spaniards are radically opposed to this energy form, while those decidedly in favor amount to between 4 and 6%. Gaining insight into the underlying reasons for such attitudes is a complex problem and is addressed in Spain and in other countries from various perspectives. In general these are not clearly defined, although it is thought that in all cases three factors are implicitly involved:

Growing sensitivity in relation to protection of the environment and an ecological awareness that is becoming a majority social and cultural trend.

A lack of information regarding the nuclear issue. In spite of the interest that most people claim to have in this question, only 6% consider themselves to be sufficiently informed.

The problems posed by the nuclear installations of the Eastern European countries and the extension of these problems in the media to the rest of the world's nuclear installations.

The most important of these factors is the ecological awareness that constitutes the underlying substrate of values and beliefs supporting mainly negative attitudes towards, and opinions of nuclear issues. By way of an example, Table III shows the evolution of this trend in the opinion of Spanish people, when asked about their perceptions of the radiation risk involved in different options.

TABLE III

In Spain, radioactive wastes are considered to constitute an important drawback as regards the use of nuclear energy. In recent years, anti-nuclear groups have adopted a strategy aimed at hindering waste management actions, with the ultimate objective of forcing the closure of nuclear plants. The effect on public opinion of the Chernobyl accident has diluted with time and has not been refired by any other type of nuclear accident. Consequently, wastes have become the main source of conflict in the nuclear issue, since they are perceived as being a by-product having a major, long-lasting potential for pollution.

Radioactive wastes are considered to constitute a greater threat than nuclear energy itself, and meet with non-rational opposition regarding both their existence and the possibility of their being controlled at a disposal facility. Table IV shows the results of a survey carried out by ENRESA among several urban and rural populations, some close to waste management centers. In all cases it may be appreciated that attitudes contrary to wastes and to the location of disposal facilities exceed the negative attitudes shown towards nuclear energy. Demands for information are evident in the positive change in such attitudes that occurs when the possibility of somebody undertaking management of this particular issue is posed.

TABLE IV

CHARACTERISTICS OF THE AREAS SURROUNDING THE EL CABRIL AND AUM SITES

The El Cabril disposal facility is located in the Sierra de Albarrana in the northern part of the municipal area of Hornachuelos, in the province of Crdoba (Fig. 2). The repository is to be found in the foothills of the Sierra Morena, a mountainous area with mild winters, hot summers and scarce and irregular rainfall.

Fig. 2.

The populations of the area are small and widely disseminated, and their basic resources are agriculture, forestry and hunting (Table V).

TABLE V

The Andjar uranium mill (AUM) is located in the municipal area of the same name in the western part of the province of Jan, close to its border with Crdoba. This is the largest municipal area in the province, with an area of 957 km2 and a population of 37,000, of which approximately half live in the city of Andjar, 8 km from the site.

The city's most important economic sector is services, which represents almost half of the economy of Andjar. The industrial sector is of little importance and centers on the foodstuff and textile industries.

Until 1986, the El Cabril installations belonged to the Centre for Energy, Environmental and Technological Research (CIEMAT), which in 1961 began to store wastes in a disused uranium mine on the site and, at the beginning of the 1980's extended this practice to three buildings on the surface. When ENRESA took over this centre, the attitude of the local population was one of open rejection, since little information was available on the facility and what there was was charged with military implications or with exaggeration regarding the risks of the wastes.

In Andjar, little was known about the facility and its industrial process was not associated with the risks attributed to other nuclear cycle installations.

THE ENRESA COMMUNICATIONS AND PUBLIC INFORMATION PLAN

The Communications Plan was drawn up with the objective of informing the different sectors of the Spanish population of ENRESA's activities, such that there be knowledge of these activities and, to the extent possible, acceptance of them.

The Communications Plan was initiated shortly after approval of the First General Radioactive Waste Plan in 1986, with the activities organized in such a way that the main efforts were aimed at informing the different social sectors surrounding the El Cabril and Andjar sites, where ENRESA was to carry out specific tasks in the medium term. Complementary to the above, and with a view to facilitating longer-term tasks, the Communications Plan includes actions aimed at improving the attitudes of Spanish society towards the implementation of radioactive waste management centers.

From this perspective, the Communications Plan is articulated at local level around three objectives:

Informing all local community groups of the work to be performed, taking into account their social, economic and cultural characteristics.

Providing the authorities and opinion leaders of the areas in question with detailed knowledge of the activities involved in radioactive waste management.

Integration and interaction with the social agents in the areas in question and with the population in general.

The main actions carried out within the framework of the first of these objectives have been as follows:

Open day policy and explanation of the installations. Information Centers. This is considered to be important for modification of the opinions previously held by the population as a result of the negative connotations attributed to the nuclear issue, and specifically the secrecy surrounding it. Since 1986, when ENRESA took over the El Cabril facility, an information department manned by local people has operated at the site, the objectives being to promote knowledge of the installation and answer "on the spot" whatever questions might be posed. Similarly, a specific program of visits to the AUM was initiated in 1990. At both sites, the main target publics for visits are associations and other groups from the surrounding area capable of creating opinion regarding wastes. In 1990 an Information Center was built at El Cabril to improve the efficiency of the visits and receives 5,000 visitors every year. In the case of the AUM, the works have been explained to some 3,000 people.

A third Information Center was opened at the beginning of 1992 at the ENRESA head offices in Madrid, where information is provided on radioactive waste management.

Instruction on the basic principles of radioactivity and waste management. This has been developed as a specific part of the Communications Plan with a view to bringing about a reasonable level of knowledge of the elementary principles of waste management and the handling of radioactive materials among opinion leaders, fundamentally primary and secondary school teachers, post-graduates, students and members of local Corporations. Since October 1989, ENRESA has been organizing seminars on radioactivity, radioactive wastes and their management, in collaboration with specialists in different radioactivity-related applications.

These seminars include explanations of both the technical and scientific aspects of

waste management and of other social and economic matters referring to waste disposal and affecting the local area (Table VI).
TABLE VI
Meetings with political representatives and other opinion leaders (journalists, economic leaders, etc...).

This activity is carried out by ENRESA through three different types of meetings:
a. Periodically, and in addition to the controls established by legislation, representatives of ENRESA appear before the respective Commissions of Industry of the Congress and Senate of the National Parliament. Meetings are also held periodically with the members of Parliament and opinion leaders most closely linked to radioactive waste management, especially those representing Crdoba or Jan in the national or regional Parliaments.
b.The supply of information and contacts with local leaders are continuous efforts. In addition, there is an official meeting once a year with the Corporations of the area of influence.
c.Visits with political leaders and representatives of the media to radioactive waste management centers as a way of learning of the characteristics, design and operation of other sites and of increasing the availability of information regarding common management aspects.

Socio-economic cooperation with neighboring communities. In keeping with the needs expressed by local political leaders, attempts have been made to take advantage of ENRESA's operating requirements to promote improvement of the social and economic conditions of the areas in question. The main actions implemented with a view to achieving this objective are as follows:

a. Drawing up of a study of the socio-economic situation of the areas, with detailed information on local companies and of their capacity to act as contractors during the construction and operation of the installations.
b.Cooperation with the local political authorities in order to learn of their opinions regarding the situation of the areas and to be able to optimize the resources generated by ENRESA.
c. Training programs for potential site workers.
d. Preferential use of local resources.

By way of an example of the above, Table VII indicates the extent of contracting of local personnel, services and goods during the extension works carried out at El Cabril.
TABLE VII
Parallel to the above, in December 1989 the Ministry of Industry and Energy issued an Order which provided a certain amount of money for communities living in areas housing waste disposal facilities, this amount depending on the category and volume of the wastes in question.
Communication support resources
The different types of information described above are supported by publications, brochures and videos dealing with specific aspects of ENRESA's activities, these being adapted in each case to the target audience and to the environment in which the information is provided (information centers, round tables, debates, etc...).
Since 1986, ENRESA has been publishing the quarterly magazine ESTRATOS, a 64-page publication with a circulation of 4,500 copies which are mainly distributed among national opinion leaders. ESTRATOS is designed as a scientific and environmental journal dealing with questions related to radioactive waste management through articles on the principles and practices involved, and containing a fixed section on the situation of ENRESA's activities and projects.
The two-monthly SIERRA ALBARRANA is published in the El Cabril area; this is a local bulletin containing news on the facility and its surrounding area and has a circulation of 3,000 copies.
RESULTS
From the very date of announcement of the extension to be made to the El Cabril

facility, the local populations openly opposed the construction works, while at Andjar there was general agreement in relation to the project presented, albeit with some concern regarding the radiological risks possibly involved in moving the tailings. In Andalusia in general, and in the area surrounding El Cabril in particular, neither the population nor the opinion leaders would allow any action scheduled by ENRESA. In 1988 there was a demonstration in Hornachuelos attended by some 2,000 people. At national level, the politicians, journalists, etc... did not express overmuch confidence in the activities performed by ENRESA and the information published in the newspapers was for the most part negative. The Communications Plan was applied from the start to ENRESA activities and after a while public perception began to improve.
The current situation may be summarized as follows:

i. At regional level, the public living in the areas surrounding El Cabril and Andjar understand ENRESA's activities and believe the tasks performed to be safe.
   Most of the opinion leaders, such as politicians, school teachers, etc., have received information directly from ENRESA and have the impression that the work performed has been accomplished in a professional manner and to a high level of quality. In the case of the journalists, this conclusion is borne out by the fact that 60% of the information they publish is contrasted with an ENRESA spokesman.
ii. At national level, a fluid communications flow has been achieved with journalists and political representatives. This does not mean to say that they support whatever work is to be performed, indeed, the opposition to news regarding the location of a high level waste repository is always very severe. On the other hand, it is now very rare to find articles or news items not based on objective facts.

Attention should be brought to the support provided by the authorities of the Central Administration, and to the fact that this has led to considerable improvement as regards the efficiency of communications, as may be appreciated by comparing the results obtained with the difficulties experienced by other projects presenting similar social problems (major works of infrastructure, prisons, etc.).
THE NEED FOR INFORMATION IN RELATION TO THE MANAGEMENT OF HIGH LEVEL WASTES
ENRESA plans to initiate the characterization and construction of a high level waste repository during the second or third decade of the coming century. Meanwhile, the main tasks are oriented towards continuing research and development work and site selection studies for this facility.
In Spain, neither public nor political opinion is willing to accept the location of the repository, as is demonstrated by the fact that any geological research carried out in the field is automatically associated with ENRESA site selection plans, and soon becomes a source of strong local opposition.
The selection of a site for a high level waste repository requires a communications policy taking into account the following:

i. At political level, it is necessary to continue to stress the need for waste management and to obtain nationwide political consensus with a view to legitimizing and providing coverage for the solution adopted.
ii. A nationwide information campaign must be carried out emphasizing the benefits of an adequate radioactive waste management policy. This campaign would serve to fill in the information gaps currently detected among the members of the public and to discuss the solutions proposed in greater depth. In addition, the waste problem would be put into context, the scope of communications actions would be extended to include the most efficient media and the level of communication with society in general would be increased.
iii. The research and demonstration installations are centers at which public opinion might gain direct insight into the characteristics of the definitive management of high level wastes and the levels of quality applied in this process.
All the issues mentioned above in relation to better information for the public through well informed opinion leaders, through visits to information centers, through the availability of teaching materials for school teachers and students and through the existence of specific centers at which waste management tasks may be observed and learned of will help to facilitate decisions regarding the location of a high level waste disposal facility.

The strategy described above is backed by the experience acquired and by the results obtained locally by ENRESA at El Cabril and Andjar, where a high level of public information and appropriate understanding and consensus with the local opinion leaders and authorities have been achieved.

49-2
OPINION RESEARCH METHODOLOGY APPLIED BY NIREX TO KEY AUDIENCES IN THE UK'S DEEP DISPOSAL PROGRAM
Tom Curtin
John Mathieson
UK Nirex Ltd
ABSTRACT
Opinion research is an invaluable tool for tracking a company's position with its key audiences. However, different audiences may warrant different approaches for undertaking this research. Nirex, the UK national radioactive waste disposal company has adopted specific methods for monitoring the views of its key audiences.
Telephone interviewing is used for researching the opinions of the public of Cumbria, north-west England, where Nirex is investigating a potential deep repository site. Here the public's views are sought, rather than those of the decision makers as, in this case, it would be seen as inappropriate to attempt to interview directly members of the Cumbrian local government; in December 1994 they refused the Company's application for permission to construct an underground rock characterization facility.
For assessing the views of Members of Parliament (MPs), Nirex has chosen to participate in an existing scheme, in which a panel of 100 MPs are regularly sampled through postal questionnaires. The method also allows comparisons to be made with the rest of the nuclear industry and the "opposition". MPs and other Parliamentarians are a key audience for Nirex, particularly as the Government is currently reviewing its radioactive waste management policy. The results of the latest research indicate that Nirex has to do more to get its message across.
Face-to-face interviewing is the preferred method of research for journalists, who are seen as key influencers of other major audiences. The most recent survey was of the energy and environment journalists of the media. Twenty-five per cent. thought Nirex was already "causing damage to the environment" and, somewhat disturbingly, almost all find environmental organizations the most useful source of information on Nirex. More targeting of this group is therefore seen as a priority.
Nirex has adopted specific methods of gauging the perceptions of its key audiences through adopting appropriate methods of opinion research most applicable to each group. This is paying off and giving the Company a steer as to where it should be targeting its communication effort.
INTRODUCTION
Background
Nirex is the company, set up in 1982, financed by the UK's nuclear industry, responsible for developing new disposal facilities in line with Government policy. Nirex initially proceeded to look for a near-surface site for the disposal of short-lived wastes and a deep site for long-lived ILW disposal. However, in 1987, it was decided on grounds of public perception that all ILW should go deep, coupled with LLW for economic reasons.
In 1987 Nirex started a site selection process which eventually yielded 12 sites, of which two, Sellafield in Cumbria, north-west England, and Dounreay in Scotland were selected to be studied first. In 1991 Nirex decided to concentrate its efforts on Sellafield because of its transport advantages: 60% of the waste requiring deep disposal arises there. Detailed geological investigations have been carried out at Sellafield and the next step is to construct a 650m deep Rock Characterization Facility (RCF) to assist in deciding the suitability of the site. However, in December 1994, Cumbria County Council (the local government body) refused to give permission for the RCF, thereby forcing Nirex to appeal to Government which will, in all likelihood, lead to a public inquiry.
Interaction With Whom?
To help identify and better understand the needs of its key audiences, Nirex carried out a stakeholder analysis in 1993. This confirmed initial thoughts that the following three groups were the most important:
- the people of Cumbria and their local government;

national government; and,
Nirex's shareholders.

Having identified the principal audiences it is important to determine the level of support and seek ways to maintain that support through an effective communications campaign. Monitoring of opinion is done through a mixture of Nirex's own research and that commissioned from independents, particularly when anonymity is required. The results set baselines from which progress and success of specific communications programs can be judged and subsequently adjusted. This paper compares and contrasts the approaches taken with Cumbrian audiences, with national government and with the environmental/energy journalists of the UK press, a group having significant influence in the minds of the former audiences.

LOCAL GOVERNMENT

Cumbria County Council is the major potential force within the County, although the role of the smaller Copeland Borough Council has also to be respected - certain "zoning" decisions fall within its responsibility and its views carry weight with the County and National Government. Cumbria County Council is made up of 83 representatives, 47% are Labour, 34% are Conservative, 17% are Liberal Democrat and 2% are Independent. There is therefore no overall political majority, but it must be noted that the Council's attitude towards the Nirex project is not necessarily defined by party politics.

Since 1991 Nirex has established formal links with the Cumbria County Council which allow frank and open exchanges to take place. Nirex has also taken the step of establishing its main press office locally rather than at its Harwell headquarters some 300 miles away. The local office also supports other public relations activities such as exhibitions, local newsletters and facility visits.

The most important communications issue currently facing Nirex is the increasing public awareness of the organization, without a corresponding rise in understanding of what it does.

Opinion Research Methodology

Within Cumbria, Nirex conducts its own opinion polls, but also has access to those undertaken by both Cumbria County Council and Copeland Borough Council. Here, a gauge of public opinion is important as both local councils regard it as an important driver of their attitude; moreover, direct interviewing of Councillors would be seen as inappropriate.

In 1994, Nirex assessed attitudes and awareness in Cumbria to the disposal of radioactive waste, with particular reference to knowledge of and opinions about the proposed RCF, with results broken down by district, so that attitudes of the population nearest to Sellafield could be compared with those in other parts of the county.

Nirex asked Gallup to carry out a telephone interview poll. This methodology was adopted due to the dispersed spread of much of the population of Cumbria (which is England's second largest county by area). The questionnaire was deliberately kept short so that it would be easy to administer by telephone. When the results were analyzed, the data was weighted to account for any shortfall in the proportion of people in the social grades D and E in the sample, as availability of telephones among this group can be low.

Cumbria was divided into political constituencies for sampling purposes to ensure a representative spread of interviews proportional to population size across all areas of the county. However, the views of people living in the Copeland district are of particular interest to Nirex, as the RCF investigation site, most of the deep boreholes and BNFL's Sellafield site are located within its boundaries. The sample for this constituency was therefore boosted to achieve 150 interviews.

At the analysis stage, the results were weighted by population and size of constituency. Telephone numbers of households were listed from the telephone directories for Cumbria on an "nth" basis. Postcodes (analogous to Zipcodes, but more precise) were used to identify constituency boundaries. The survey was conducted using Gallup's telephone unit based in Oxfordshire. A total of 755 telephone interviews were conducted among adults (aged 15 plus) resident in Cumbria between 11 and 20 October 1994.

Results and Discussion

By way of background, at the end of 1993, 88% of Cumbria residents as a whole were aware of Nirex. Yet, despite this very high public awareness, 40% of residents did not know Nirex's purpose (even when prompted). In fact, 50% of respondents believed

a decision that the repository would go ahead had already been taken.
The 1994 Gallup results for the public's attitude to siting a deep repository at Sellafield are shown in Table I against a similar, but not identical, questionnaire set in 1992 and carried out by Copeland Borough Council.
TABLE I
The support is encouraging, as those who "tend to oppose" might accept if reassured on factors such as safety, but the results leave no room for complacency. Nirex has historically tended to concentrate its communication efforts in the Copeland area and this can be seen in the detailed results.
When asked about the RCF, there was much misunderstanding. Although to be built purely as a research facility, many people believe that it is an actual repository, as Table II shows:
TABLE II
Note that in the December 1994 decision by Cumbria County Council to refuse Nirex permission to build the RCF, of those who attended the meeting (74 out of 83), 54% voted in favor of refusal, 45% against refusal and 1 abstention; a motion to allow Nirex full permission was defeated by 71 votes to 3. An important theme in the debate was that whilst there was little "environmental impact" reason for refusal, there is a belief in Cumbria, despite the efforts of Nirex, that Sellafield is a foregone conclusion and the RCF is a "Trojan Horse" for a repository. The public and the local politicians want to be reassured through the public inquiry process before they will be ready to accept the RCF and deep repository.
NATIONAL GOVERNMENT
One of government's roles in the UK is to set the safety targets that Nirex must meet. Additionally, government accepted in 1989 the broad shape of the disposal solution to deliver that target - a deep facility accessed from land. In May 1994, the Government began a review (the first for over 10 years) of its radwaste management policy and related matters (including site selection principles). The outcome of this review, which involved extensive public consultation, is expected in the first half of 1995.
Of influence to the policy setters are the public's elected representatives, the Members of Parliament (MPs), members of Parliamentary Select Committees and the policy advisory bodies. Of particular relevance to Nirex under the last heading are the Government's independent Radioactive Waste Management Advisory Committee and Advisory Committee on the Safety of Nuclear Installations. Also of importance for the longer term are the European Commission and European Parliament.
Opinion Research Methodology
Nirex is particularly interested in monitoring the attitudes of the Members of Parliament and a company which maintains a Political Opinion Panel (POP) of 100 Members of Parliament were chosen to provide this service. They sample the POP regularly (every four to six weeks during the Parliamentary session) to gauge the views of politicians on a number of issues. From Nirex's point of view, it was advantageous to use an existing mechanism of opinion research rather than to instigate something new and different.
The POP is an established means of anonymously testing Parliamentary opinion towards organizations. It enables perceptions of a company to be compared with other companies or organizations, and examines Parliamentary attitudes towards issues affecting the company's business. It is also useful to test the effectiveness of different arguments in support of a company's views before putting them to Members of Parliament, and helps find the most effective means of communicating those arguments to them, establishing benchmarks and thereby identifying trends.
The panel is selected to represent the balance of the political parties in the House of Commons: Conservative, 52%; Labour 42%; and 6% Others. The panel is also selected to reflect the regional balance within the Commons, length of service, size of majority and age. Six Nirex questions were put into the postal survey in early 1994, and care was taken to ensure optimal positioning of the questions in order to safeguard unbiased responses and eliminate any "order effect".
Results and Discussion
Some of the top-line results of the MPs' research are shown in the following tables. One question concerned the Members' familiarity with the activities of Nirex and other organizations with an interest in radwaste disposal. The results are shown in Table III.
TABLE III

As can be seen, the results are not very encouraging, though they will in part reflect the high media profiles of the campaigning organizations and of BNFL in the 1992-1993 debate over authorization of BNFL's new "THORP" reprocessing plant.
Another question concerned the MPs' general impression of Nirex compared to the same organizations as in the previous question. The results are given in Table IV.
TABLE IV
Here, the Company does relatively better, but given that many of the respondents had earlier admitted they were not overly familiar with our activities, the results are still worrying.
An important question covered the effectiveness or ineffectiveness of Nirex and the other organizations in their communication with Members of Parliament. The results are presented in Table V:
TABLE V
The simple and obvious conclusion is that a strong communications program is vital if politicians are to be kept informed. If they are not informed they cannot make measured judgments on Nirex's intended program for waste disposal. The other obvious conclusion is that if information is not supplied effectively, then those who oppose the industry, in particular the "green" groups, will be able to advance their positions relatively easily. Also, by not communicating, the Company is paradoxically giving strong negative messages which could be interpreted as:

politicians are not thought to be worth communicating with;
that Nirex is secretive and refuses to communicate; and,
that those who condemn Nirex are, in fact, correct in their assertions.

JOURNALISTS
A further key group is journalists. MORI, another leading opinion research consultancy in the UK, carries out regular surveys of journalists, editors and broadcasters; from time to time, they also present the views of specialist journalists. Journalists represent an important link between organizations and the general public, politicians and other audiences, providing an important source of information.
The survey is also particularly useful because companies taking part are able to nominate other companies or industries and particular topics for inclusion in parts of the questionnaire. This means that useful data on how Nirex and its activities are perceived by a target group, in comparison with, for example, companies involved in toxic or domestic waste disposal or other companies involved in the nuclear industry, can be obtained as part of a much wider survey, at reasonable cost.
Nirex had previously participated in the survey in 1990. However, because of increased media coverage about the Company's activities (much of it negative), it was considered worthwhile taking part in the 1994 survey.
The survey is designed to give those companies taking part information on:

current and future environment issues;
ways in which these issues could be tackled;
the perceived environmental record of industry sectors, companies and organizations;
how their environmental records compare with those of other sectors and companies/organizations;
perceived environmental impact and responsibility of various companies and organizations; and,
perceived effectiveness of their media relations compared with other companies and organizations.

Opinion Research Methodology
A letter requesting an interview was sent by MORI to 54 of Britain's leading environment journalists, editors and broadcasters eligible for inclusion in the survey. Appointments were then made by telephone, and face-to-face interviews with 28 journalists were conducted in July and August 1994. This represents a response rate of 52%.
Those interviewed were from a wide range of media - daily and Sunday newspapers, regional press, relevant periodicals, radio and television broadcasting. Nine of the twenty-eight journalists interviewed were willing for their answers to be attributed to them by name in the report, the remainder preferring anonymity. Twenty-seven of the twenty-eight journalists agreed to be named as having participated in the survey.
Results and Discussion

Twenty-five per cent. of the journalists questioned in 1994 considered Nirex was causing a major amount of damage to the environment, compared with 4% in 1990. This would seem to reflect their views on the nuclear business rather than Nirex's particular involvement. Some of the comments are illuminating: "Nirex has failed, except when pressed very hard, to demonstrate an acceptable and water-tight way of storing nuclear waste underground". It should be stressed that one thing Nirex has never claimed for the repository is that it will be water-tight!
Thirty-two per cent. rate Nirex's press relations as very/fairly good, but 29% rated them as very poor/fairly poor. In fact, the number of journalists nationally who specialize in radioactive waste disposal is fairly small. They, and the local media in Cumbria, know who Nirex is, where it is located and that the Company will always help them with a comment, a photograph, an interview or a story. However, perhaps the most worrying statistic to come out of the survey is the fact that 93% find "voluntary environmental organizations" the most useful source of information on companies such as Nirex.
The clear message from this survey is that much more work needs to be done with this group for the Company to improve understanding of its mission and research programs.
CONCLUSION
For Nirex, opinion research guides its communication programs for key audiences and allows important issues to be isolated and targeted. It also permits a measurement of performance and gives an indication of which initiatives are successful and which are not.
In the local context public involvement in decision making has helped the Company maintain a support for its activities in Cumbria amounting to around 70%, but this needs to be translated into the minds of the local politicians. Monitoring and maintaining the support of national government and of important influencers such as journalists is of equal relevance.
Nirex has adopted specific methods of gauging the perceptions of its key audiences through adopting appropriate systems of opinion research most applicable to each group. This appears to be paying off and giving the Company a steer as to where it should be targeting its communication effort.

49-3
THE FRENCH NATIONAL INVENTORY OF RADIOACTIVE WASTE, ALL INFORMATION OPEN AND CLEAR
Armand Faussat
Michel Raynal
ANDRA
Agence Nationale pour la gestion des dchets radioactifs
Fontenay-aux-Roses
FRANCE
ABSTRACT
Article 13 of the December 30, 1991 Waste Act calls for Andra "to register the condition and location of all radioactive waste on national territory".
The establishment of a national inventory of radioactive waste and the broad distribution of inventory reports to ensure that it becomes a matter of public record constitute a new approach to public information and an effective means of fulfilling our responsibility to posterity. The register goes beyond the low-level radioactive waste disposal facilities to encompass "all" waste, wherever it may be, including waste in storage at generator sites. As a result, the register is multi-faceted, containing information on everything from highly radioactive waste to hospital waste collected by Andra and to repositories with very low-level radioactive material. Information must be provided about all of these widely divergent components, even though they cannot be treated alike.
ANDRA already published two inventories, demonstrating the durability of its new mission. The document now contains the inventory of radioactive waste generated by some activities connected with the defense program.
Article 6 of the December 30, 1991 Waste Act calls for Andra, before starting any preliminary works for a project of underground laboratory, to have concertation with elected people involved and with the public of the sites concerned. This concertation needs for ANDRA to be accepted as an open, reliable, fully honest and transparent partner in the discussion.
Data collection for the register therefore involves contacting the generators and working with these entities, whether nuclear industry companies, defense

organizations, non nuclear industries, or the 25 Regional Directorates of Industry, Research and Environment, the control institutions or the Environmental protection organizations.
The paper presents the management of data collection and the feed back questions and comments received after the 1994 issue of the document.
The yearly existence of this exchange of information between all the partners involved in radioactive waste management is one of the basic tools allowing ANDRA to be recognized as open and responsible, and to be more credible, fulfilling this way one of the essential criteria for acceptability.

THE NATIONAL RADIOACTIVE WASTE INVENTORY

Radioactive waste management is widely perceived to involve multiple stakes in terms of the environment and communication. Although suitable treatment methods for each category of waste must be applied, based on waste type and characteristics, waste disposal relies on a single set of principles: Straightforward information, clear-cut responsibilities, and concern for long-term environmental protection.
In this vein, ANDRA, the national radioactive waste management agency of France, was charged by the Waste Act of December 30, 1991 with developing a waste inventory which identifies the condition and location of all waste on French territory, in addition to fulfilling its other responsibilities (1).

COLLECTING, CLARIFYING AND SPREADING INFORMATION

The National Waste Register provides information on the location and condition of all known waste, including very low-level waste, whose disposal does not generally fall under the Agency's purview. However, Andra makes no claims for the completeness of the Register, for there is always the possibility that abandoned waste will be discovered in the coming decades.
Today's waste, whether defense or civilian, is generated by nuclear power plants and fuel cycle facilities, research laboratories, industry and hospitals, waste generated in the past is stored or disposed of at nuclear facilities, mines and old landfills.
The work involved in registering this data focuses on two activities: establishing a detailed picture that gives the status of all waste, including waste from ongoing site restoration, and making this information public. The underlying goal is to build collective memory about our defense and civilian radioactive waste.
The approach is to begin with existing registers and to expand from there through direct contact with those in possession of waste: Electricit de France (EDF), Cogema, the French Atomic Energy Commission (CEA) and other operators.
The presence of radioactive waste at a site is not necessarily synonymous with danger. What is most important is the manner in which the waste is managed and how the environment is monitored to ensure our long-term safety. With this in view, activities have already begun to clean up sites such as the old Bayard clock factories, which are not in satisfactory condition.

A MISSION CLEARLY DEFINED

Two editions of the Register were prepared by Andra's National Radioactive Waste Observatory. Radioactive waste did not begin with the development of nuclear power. In the first half of this century, industry used radium to make luminescent paints. Waste was not a subject of concern in that era. More recently, as nuclear power grew more widespread, new radioactive waste was generated. Radioactive products are frequently used in medicine, research and industry, although in small quantities. The use of their radioactive properties results in the creation of radioactive waste. This is a reality that must be faced by users, who must be encouraged to integrate good waste management practices early in their production process.
To produce the least amount of waste possible, to manage, process and dispose of final waste in a manner that protects our environment now and in the future: these are increasingly important requirements.
One of Andra's missions is to identify and collect existing data and to update them regularly so that the existence of this waste is not forgotten. Conveying this data to the public through publication of the Register ensures that the memory of the waste is shared by many.
By law, the scope of the register includes all radioactive waste on national territory. It therefore contains a variety of elements, from highly radioactive waste such as that stored at the La Hague nuclear fuel reprocessing plants, to waste collected by Andra from hospitals or landfills where materials that are only slightly radioactive are buried. We arbitrarily chose a total radioactivity

threshold of 0.5 Gbq, above which a descriptive data sheet must be established. This threshold makes it possible to provide representative examples of small generators in the fields of research, health, defense and non-nuclear industries without burying the report under hundreds of data sheets. Nevertheless, this is a low total radioactivity threshold equal to approximately one one-hundredth of a gram of radium.

The resolutely factual report on the Register transcribes data collected and made public by Andra without any added commentary or evaluation. In fact, it is not for Andra to take the place of government regulatory authorities with regard to safety, public health, or verification of regulatory compliance, which are the responsibility of the Division of Nuclear Facility Safety, the Industrial Environment Department, the Office of Radiation Protection, the Regional Departments of Industry, of Research, and of the Environment, and others.

We make no claims about completeness, and recent events such as the discovery of the Radiacontrle site at Pierrelatte or the story about Provaradior animal feed bags doped with radium show how important it is to be ever-watchful.

INFORMATION SOURCES

The search for data for the Register involves first and foremost direct contact with the operators and administrations that updated or approved the data sheets for the 1993 Register, or those that sent new data sheets, such as the Ministry of Defense. Andra's initial database was also expanded with the addition of documentation sent by associations such as the Commission for Independent Research and Information on Radioactivity (CRII-RAD), the Coalition of Scientists for Nuclear Energy Information (GSIEN), the Uranium Network of Action Environnement and the Western Association for Radioactive Monitoring at our request for information as part of the annual updating of our Register.

Andra therefore has multiple sources of information:

Companies in the nuclear industry (CEA research centers, Cogema, EDF, etc.);

The defense establishment;

Non-nuclear industries, i.e., small generators divided into fifteen business sectors: nuclear and non-nuclear industrial and commercial companies, research establishments, units of the National Scientific Research Center (CNRS), educational establishments, universities, university hospitals, units of INSERM, medical and paramedical-medical establishments, the Armed Forces Health Service, facilities of the defense establishment, suppliers of sealed sources, ministerial, prefectorial and municipal departments, and national public service entities

The twenty-five Regional Directorates of Industry, Research and the Environment.

In addition, the following associations were contacted: Action Environnement, Western Association for Radioactive Monitoring, Friends of the Earth, CRII-RAD, FLEPNA, FRAPNA, Greenpeace France, GSIEN, Robin Hood, and others.

1993 ACTIVITIES

The publication of the Register, as valuable a tool as it is for preserving memory and sensitizing the public, is not a replacement for managing waste properly, particularly in the clean-up of sites that stand out for mismanagement.

In this spirit, a major site clean-up operation was undertaken at the old Bayard plants in St. Nicolas d'Aliermont in the Seine Maritime Department, where luminescent radium paint was used to make alarm clocks. Contaminated soil that was potentially harmful to residents was removed and temporarily stored in an old facility of the former Bayard alarm clock plant pending selection of disposal methods. This operation mobilized numerous government departments -- the Ministry of Health, SCPRI, the Mobil Radiological Intervention Unit of the Fire Department, and Municipal Services of the commune --Andra, and the Office of Radiation Protection Assistance of the Institute for Nuclear Protection and Safety (IPSN). The Western Association for Radioactive Monitoring (ACRO) performed its own sampling and analysis. Special funding had to be secured to implement these operations, which were to cost several million francs, with Andra advancing funds for the most urgent tasks. A budget request was submitted to the Ministry of Industry, Postal and Telecommunications Services and Trade for the funds needed to complete the work as planned.

A similar but much less massive operation is also in progress under Court supervision relative to the Radiacontrle company site.

The Grande Paroisse S.A. Company commissioned a study by the Institut Garenne, IPSN and the Mining Radiation Protection Center (CRPM) on the activity of a

phosophogypsum dump site. The study showed that total combined annual exposure was 0.5 to 3% of the regulatory limit. As indicated in 1993, this data sheet is given as an example only; there are many other phosophogypsum dumps for which we have no information, and this is not a unique case.

There were two interesting stories about discoveries of radioactive materials and equipment indicative of widespread use of radium several decades ago:

a sort of urn in which a radium pellet was dipped to impart curative properties to the water, like some thermal waters; and

packages of animal feed under the Provaradior label were doped with radium as a growth stimulant (there is no record of whether they were charged with false advertising).

In both cases, the individuals who made the discoveries informed the local fire department, which retrieved the objects in question and contacted Andra.

CHANGES FROM 1993 TO 1994

The publication of Andra's first register in 1993 and its annual updating have evolved into an ethic of openness in both the defense and civil sectors. The Ministry of Defense and the French Atomic Energy Commission each established their own radioactive waste register for their defense-related activities.

The Defense Establishment

The register of the Ministry of Defense primarily includes equipment containing luminescent products and waste from the fabrication and testing of depleted uranium armor-piercing shells. Uranium was chosen for the shells due to its metallurgical properties only and not for any radioactive or nuclear reaction effect.

This register also includes waste generated by the repair of nuclear submarine reactors. Fifty-three sites are listed in the register, of which only eight exceed the arbitrary threshold of 0.5 GBQ requiring preparation of a descriptive data sheet.

The register of CEA sites and Cogema plants covers waste generated by the design, production and upkeep of nuclear weapons and nuclear submarine reactor cores. Nine sites are included, each of which is described in a data sheet.

Sealed Sources

The register of spent sealed sources, for which the French fabricator ORIS was the only company included in the 1993 edition, was expanded by the inclusion of spent sources at supplier sites and sources awaiting return to French or foreign fabricators. This register now includes seventy distributors, with nineteen of them described in data sheets.

Lightning Rods

Certain kinds of old lightning rods were made with tips containing americium or radium. Approximately 30,000 of this kind of lightning rod were produced through 1986. Since then, the use of these radioactive substances in lightning rods is prohibited. When these lightning rods are replaced, they become waste that must be returned to the suppliers, where the iron and metal are removed and the radioactive source is retrieved.

Andra collected all of the lightning rods stored at supplier locations. In addition, three large companies from the public sector -- EDF, TDF and France Telecom -- undertook the establishment of a register of their lightning rods.

DEVELOPMENT OF THE INVENTORY

While Article 13 of the December 30, 1991 Waste Act calls for Andra "to register the condition and location of all radioactive waste on national territory," the responsibility for nuclear facility safety clearly resides with the industrial companies, hospitals, research centers and others. The government is in charge of verifying regulatory compliance, particularly the Departmental Prefects and the Regional Directorates of the Ministries of Industry, Research and the Environment (DRIRE).

Data collection for the register therefore involves contacting the generators and working with these government entities.

Andra's program covers "all radioactive waste"; no limits are given for the register, nor is a minimum level of radioactivity specified.

ANDRA considers that :

The program scope includes not only waste disposal facilities, but any facility with waste in storage, even temporarily, whether it be a large nuclear facility or a medical or university research laboratory.

Non-reusable equipment and material, or equipment and material which the owner has

decided not to re-use, is included in the definition of radioactive waste. Nuclear facilities stopped, under decommissioning or under dismantling are considered as containing potential waste. The actual volume of waste will be depending of the level of decommissioning and of the date of this operation. Inversely nuclear material considered by the owner as reusable is not considered. This is the situation of fuel elements waiting before reprocessing and of depleted uranium owned by COGEMA.

Any product contaminated with man-made radioelements and any substance which has been mechanically or chemically altered in a manner which releases natural radioelements is considered to be radioactive.

Given this definition, the scope of the register encompasses a large number of sites which are widely divergent in terms of radioactivity, with differences of up to a factor of 10 to the 16th power, or a million billions. One must be careful, therefore, not to draw comparisons between what is not comparable.

USE OF THE INVENTORY

The data sheets are organized geographically in the register by region and by department to facilitate the public's understanding of them, particularly those close to a storage or disposal site.

Maps for each region are cross-referenced to the data sheets of registered sites. The geographically cross-referenced lists were also prepared alphabetically by site name, by waste category and by the name of the company holding the waste. These lists make up the register's first appendix.

Each data sheet contains administrative and technical information on the site, a summary description of the radioactive waste, an estimate of the waste's total and specific activity, and a list of the known radionuclides contained in the waste. Information sources are identified. Despite the very wide variety of situations encountered, we preferred a certain consistency of format to make the data sheets more readable.

Twelve categories of radioactive waste generators/sites were identified:

- nuclear power plants,
- uranium mines,
- Cogema reprocessing plants,
- other nuclear companies,
- CEA research centers,
- Andra storage and disposal facilities,
- decommissioned facilities,
- small waste generators,
- distributors of sealed sources
- non-nuclear industries
- waste dumps.
- the defense establishment

OPENNESS, RESPONSIBILITY, ACCEPTABILITY

By the end of 1989, fierce public opposition to the drilling program for the other three sites had developed. The Prime Minister of France declared a one year moratorium on all drilling activities and ordered a comprehensive review of the various aspects of the backend of the fuel cycle and waste management.

The Government asked advice from the College de la Prvention des Risques Technologiques (Technological Risk Prevention Board), group of 12 independent experts created in 1988. After various hearings the College published in april 1990 a first opinion. In this document the College underlines the necessity of underground disposal for some waste and considers that no waste can be buried in a non-reversible way before the potentiality of partitioning and transmutation has been studied. The College also gives some technical recommendations among which the creation of several underground laboratories to come to the best choice of one or more disposal sites.

In the same time, in accordance with the wish of the Prime Minister, the Parliament (National Assembly and Senate) addressed the Office Parlementaire d'Evaluation des Choix Scientifiques et Techniques (Parliamentary Office of Technology and Scientific Assessment). The Office, after contacts with a large number of people representing institutions, associations and electives, and after visiting several foreign facilities, and after four days of public hearings, reported to the Government on December 17, 1990.

The outcome of this review was the major new legislation on radioactive waste

management, enacted by Parliament on December 30, 1991.
The conclusion of the report insists on the fact that " Responsibility, transparency and democracy are the words that must now drive any process concerning waste disposal and more generally concerning the civilian nuclear policy.

RESPONSIBILITY, because we have to dispose our waste at home in France and banish any post-colonialist idea of foreign disposal. Furthermore we have to solve this question now and avoid transmitting to the next generation, to our children, the search of a solution.

TRANSPARENCY: The nineties must see the end of the secrecy culture in nuclear issues ; the military origins of this industry can explain this irritating persistency of the secrecy culture which is no more justified when anybody in France profits of the nuclear energy. We now need a transparent approach.

DEMOCRACY: Till today an autoritary and administrative method prevailed. It can have corresponded to a development without obstacle of nuclear energy in France. Without doubting of the potential of researchers and technicians it comported the risk of a technologic and scientist dizziness. Things are different today, the public requires information and wish to participate in decision making. As far as long-lived radioactive waste management is concerned, one can see that the conclusions of the report is similar to the initial objectives. BUT IT IS PROPOSED TO TAKE AN OTHER WAY using the resources of democracy and information. To this sophisticated form of energy production that nuclear is, must correspond an open decision making process. The future of nuclear energy in our country relies on our capacity to develop democracy."

The publication of the yearly updated and enlarged inventory is one major element in the volunteer trend of ANDRA towards responsibility, transparency and democracy as requested by the Parliamentary Office of Technology and Scientific Assessment in its report.
This publication is one of the supports for our credibility and later for the acceptability of new projects, in particular for the siting of the underground research laboratories to study the conditions of a potential geological waste disposal facility , reversible or not.
To be acceptable one must be credible, to be credible one must be transparent and responsible, to be transparent and responsible one must be independent.
But being independent, transparent, responsible and credible is not enough to be acceptable.

ABSTRACT
In this paper we describe an organizational learning paradigm we used to evaluate how well the U.S. Department of Energy's (DOE's) National Technology Information Exchange (TIE) Workshops are achieving their mission. The National TIE Workshops are described as an organizational learning process because their mission is to increase efficiency and reduce overall costs in DOE's environmental restoration programs by sharing lessons learned. We evaluated TIE's effectiveness by measuring whether lessons learned were actually being shared and applied to other problem solving experiences. This paper outlines the TIE process, defines organizational learning and performance, and characterizes the methods we used. We also present evaluation findings and provide an evaluation approach that could be applied to other DOE meetings or group events.
INTRODUCTION
The U.S. Department of Energy (DOE) hosts a wide variety of workshops, meetings, and other events in an effort to improve performance among its program offices and sites. These gatherings bring people together to increase learning on an individual and organizational level. Defining, measuring, and demonstrating this learning is vital in today's tightening fiscal climate.
DOE's 1994 strategic plan outlines a total quality management (TQM) approach to managing its national programs in a post-Cold War era: " The world has changed....Our challenge is to move away from the Cold War economy, invest in people and technology to strengthen the economy and protect the environment, and reinvent a government that is efficient, serves the American people, and provides more services with fewer resources." Part of the transformation to a TQM environment is becoming a learning organization. In fact, one of DOE's TQM success factors is assessing how information is communicated and trust is built.
In learning organizations, successes and failures are captured and made available, responsible people have access to information when they need it, and the sharing of information becomes a performance measure (14). Organizational learning is the process through which these activities occur. We suggest organizational learning includes sharing lessons learned, applying the new knowledge, and sharing lessons learned again. DOE is moving in the direction of becoming a learning organization.
TECHNOLOGY INFORMATION EXCHANGE (TIE) WORKSHOPS
Within DOE, the National Technology Information Exchange (TIE) Workshops exemplify an organizational learning tool. The National TIE Workshops were founded to provide environmental management (EM) workers an interactive forum to share information about existing environmental restoration and waste management problems, technology needs, and potential near-term technology solutions. The intended result is new and existing environmental restoration and waste management technologies will be applied more efficiently, less expensively, with better results, and in compliance with regulatory requirements. TIE's theme is "Using Today's Technologies Better."
TIE's primary participants are those who actually do the environmental management workthe engineers, geologists, chemists, etc. who implement restoration and waste management technologies. TIE's secondary audience is made up of technology developers, both within DOE and industry, and other stakeholders, such as regulators. TIE attracts DOE and contractor personnel across the complex and encourages participation from other federal agencies, regulators, and industry.
Each TIE Workshop features a variety of interactive formats designed to help peers share information about their success and failures. These formats include: panel, poster, and interactive poster sessions; spontaneous and scheduled breakout sessions; concurrent sessions; and site tours. Topics and presentations for the TIE Workshops are selected by approximately 25 volunteers from DOE sites who serve as members of the Field Area Technology Representatives Steering Committee.
The TIE Quarterly newsletter continues the information exchange begun at TIE

workshops. Distributed to approximately 3,000 people, the TIE Quarterly covers lessons learned presented at each workshop and environmental management activities and technologies at DOE sites.

The TIE Workshop as a Learning System

We view TIE in the context of a cyclic learning system. Figure 1 illustrates this system. Participants from across the DOE complex bring Lessons Learned (inputs) about implementing environmental restoration and waste management technology to a National TIE Workshop. Sharing these lessons learned with peers changes and increases the knowledge of other participants (outputs). Participants use this Shared and Changed Knowledge in the field (DOE Field Actions) on environmental restoration and waste management projects (outcomes), benefiting and improving DOE Performance in environmental restoration and waste management. In turn, participants have the opportunity to share lessons learned from applying their changed knowledge at future National TIE Workshops. However, the TIE process is not a closed system. Lessons learned are continually being fed into the process by Other Sources from within DOE, other government agencies, regulators, and industry. In summary, TIE converts inputs to outputs for an outcome to its customers: DOE environmental management workers and ultimately the DOE environmental management program as a whole. Seen as a cyclic, systemic process, the National TIE Workshop is a model of DOE organizational learning.

Fig. 1.

Organizational Learning

Garvin (6) defines a learning organization as "an organization skilled at creating, acquiring, and transferring knowledge, and at modifying its behavior to reflect new knowledge and insights" (p. 80). The process of sharing knowledge is called organizational learning. The intent of organizational learning is to improve organizational performance through the use of knowledge (4). Knowledge gained from experiences is transferred through lessons learned.

A lesson learned is a "catchall phrase describing what has been learned from experience" (8). Lessons learned are developed, stored, retrieved (distributed), and interpreted by individuals or groups of individuals in an organization as a result of problem solving (7,3,12,4,). Organizational learning includes gathering or describing data, relating the data to the current situation, and applying the data to build information and knowledge (9,14).

Figure 2 illustrates the process of organizational learning. The solid rectangles in Figure 2 represent the four functions of organizational learning. The first function, Problem-Solving Experience, occurs when an individual produces a lesson learned or organizational knowledge through applying some method or data to a situation and understanding the results. DOE Program Activities exemplify such problem-solving experiences.

The second function, Storage and Refinement of Organizational Knowledge, is the process "by which knowledge is stored for future use" (7) and organizational memory is refined or updated. Organizational Memory is refined by supporting applications or actions that met expectations and reducing or disconfirming applications or actions that didn't meet expectations. The third function is the Distribution and Retrieval of Organization Knowledge, or accessing the knowledge gathered from problem-solving experiences. The second and third functions, with organizational learning, are represented by the National TIE Workshops.

TIE is an example of a formal mechanism to refine, store, distribute, and retrieve lessons learned in DOE's environmental management program. Lessons learned gained from a problem-solving experience are stored and refined in organizational memory as knowledge. This knowledge is retrieved, distributed, and interpreted to help solve an analogous problem. For example, a team at the Lawrence Livermore National Laboratory (LLNL) was faced with the problem of chromium (Cr^{6+}) contamination in the ground water. After testing several alternatives, they developed an ion exchange resin to filter the chromium. The team brought this lesson learned to a National TIE Workshop.

The fourth function, Interpretation and Use of Lessons Learned, is applying new information to another problem-solving experience. This function represents the decisions and actions TIE participants implement after National TIE Workshops to begin a new problem-solving experience. Without a mechanism to store and retrieve lessons learned (organizational knowledge), an organization will be unable to improve decisions and actions based on experience.

Returning to the problem of chromium contamination, an individual presented the lesson learned at the National TIE Workshop and the information was also stored and distributed to a larger audience in the TIE Quarterly. An individual from Hanford retrieved this experience and applied it to the chromium contamination problem at the Hanford 100 Area. TIE provides the learning mechanism, but individual decisions and actions determine the outcome of the process.
Fig. 2.

ORGANIZATIONAL PERFORMANCE

Sink and Tuttle (13) define organizational performance in terms of seven criteria or types of measures:

- effectiveness
- efficiency
- quality
- productivity
- quality of work life
- innovation, and
- profitability/budgetability.

To evaluate TIE's performance expectations, we identified the desired outputs and outcomes described in its mission statement. TIE's mission statement discusses all seven performance criteria. In some organizations, these criteria are not found in mission statements, but rather in a statement of objectives or other document. TIE's mission is:

> to promote the sharing of information concerning the environmental restoration and waste management problems, plans, actions, successes, failures, and related technology needs and development among persons directly involved in environmental restoration, waste management, decontamination and decommissioning, and related technology development activities. The focus is on the sharing of lessons learned among "hands-on" field personnel who can benefit from a more effective utilization of their current technologies, in particular, those which can achieve a cost savings. The TIE Workshops have an ongoing "shoptalk" environment which technologically "ties" the sites together. The goal of TIE is the identification and implementation of the best available, cost-effective, and appropriate technology to address DOE environmental restoration and waste management problems today.

Because TIE is a model of organizational learning, a measure of effectiveness is constantly sharing and using lessons learned and other information. Both Sink and Tuttle (13) and TIE's mission define additional measures. TIE (and organizational learning) is concerned with quality. Better use of technologies improves efficiency and productivity. Cost savings improves budgetability. The TIE process of involving DOE workers from all DOE sites improves quality of work life. Using the most appropriate technology addresses innovation. TIE achieves its performance expectations if DOE environmental management workers increase their knowledge and reduce DOE costs as a result of attending National TIE Workshops.

To TIE's organizational learning performance, we decided to examine both the outputs and outcomes of TIEthat is, (1) whether participants learned about a technology, technique, or approach at TIE (shared and changed knowledge) [outputs) and (2) whether participants then made decisions and took actions to apply that shared and changed knowledge at their sites [outcomes], and (3) whether TIE participants anticipated cost savings or improved efficiency as a result of their decisions and actions after attending a National TIE Workshop [outcomes].

METHODOLOGY

We measured TIE's effectiveness in three phases. The first phase was gathering participant feedback on benefits they received from the National TIE Workshop. We used oral and written surveys during the first five TIE workshops. During the second phase, we compiled the survey feedback and conducted a content analysis to understand the feedback more completely. A content analysis is a process of culling meaning and categories of meanings from qualitative data. We looked for patterns in the expected and reported outputs and outcomes participants said they gained from National TIE Workshops. We then created a revised survey based on the content analysis and used it at the Sixth National TIE Workshop. The third phase was an interim survey between the sixth and seventh National TIE Workshops. (The seventh workshop will be held in April 1995.)

At the first five TIE Workshops, both the oral and written surveys predominantly focused on lessons learned, benefits, and expected performance outcomes of applying

knowledge gained at the workshop. Most participants reported they exchanged lessons learned and made valuable contacts with their peers. Some participants anticipated saving significant development and labor costs. At later workshops, some participants reported outcomes realized from applying lessons learned from a previous National TIE Workshop. Based on participants' feedback from these surveys, we concluded TIE was meeting its mission on a workshop-by-workshop basis.

But after five workshops, we wanted to understand how well the National TIE Workshops were performing as a whole. We wanted to identify and evaluate the outputs and outcomes of TIE. We recognized an inherent time lag between the outputs and outcomes of a TIE Workshop that couldn't be accounted for through surveys at a particular workshop. We wanted to document actual performance outcomes that may have been realized over the past three years.

We developed and executed a process to evaluate the outputs and outcomes of TIE:

1. Identify performance expectations by examining TIE's mission statement.
2. Conduct general surveys at the first 5 National TIE Workshops.
3. Analyze TIE survey feedback by performing a content analysis of past TIE survey results.
4. Develop a conceptual model of TIE based on the content analysis (see Fig. 3).
5. Develop and administer a structured survey based on the conceptual model to measure TIE outputs and expected outcomes.
6. Analyze the survey results.
7. Develop an interim (between workshop) survey to document additional outcomes.
8. Administer the interim survey to all past TIE Workshop participants.
9. Analyze survey results.

Conceptual Model of TIE Workshops

Figure 3 shows a conceptual model of the relationships of TIE outputs and outcomes. We developed this model based on our content analysis. According to our analysis, the National TIE Workshops produce two kinds of outputs: Knowledge and Relationships (the first part of the Fig. 3). TIE participants develop new relationships with peers across the complex. These relationships support the exchange of information and knowledge during and after the workshops. The TIE process results in shared or changed knowledge. We categorized the types of knowledge participants acquired at TIE:

1. general: suggestions, feedback, studies completed, current literature to use as a reference, benchmarking;
2. status of DOE complex: the goals and scope of the problems facing the complex;
3. specific discussions of methods/technologies: what worked, what didn't work, resources needed, alternative methods, how methods support regulatory compliance;
4. cases: examples of general approaches for program successes and failures; and
5. need: needs of other sites, mutual problems, opportunities for sharing technologies and efforts.

The next section of the figure is Individual Actions. The knowledge and relationship outputs support actions taken by individuals in the field. Participants reported they made decisions to pursue or not pursue an approach to solving their site problem as a result of the information and knowledge gained at the National TIE Workshops. They also reported following-up with other participants by calling them or establishing information exchanges.

Fig. 3.

Individual Actions lead to Program Level actions. Participants identified program level actions focusing on technology and coordination. Participants reported information shared at the workshops resulted in technology being bought, sold, borrowed, or demonstrated between sites and industry. Coordination of activities included sharing and re-using technology between sites, eliminating duplication, increasing consistency, and saving resources.

Program Actions lead to Program Performance. Participants identified the following program performance outcome measures as a result of attending TIE: compliance, time, public acceptance, dollars, efficiency, quality, and safety. Participants believed they could bring a project into compliance, meet the regulations more quickly, avoid non-compliance, and comply with regulations they didn't know about. Participants reported they would save time as measured in person days, years, and workload in development and implementation of methods learned about at TIE. The public's acceptance of DOE, confidence in DOE, and perception of DOE's credibility would increase as a result of the individual and program level actions derived from TIE.

Participants believed the Environmental Management program would operate more efficiently with greater quality and more safely. Participants believed all these benefits would result in the dollars saved (though few were able to quantify). They also identified cost reductions in marketing, equipment development, research and development, analysis, and travel cost.

Based on this conceptual model, we developed a survey to evaluate and quantify the outputs and outcomes TIE participants said they received. We used subjective measures because 1) the participants were surveyed at the workshop and 2) there is an inherent time lag between the change in knowledge and the use of the knowledge. The survey included lists of outputs and outcomes based on previous participant feedback identified in the content analysis. For example, we asked participants to tell us how many of the following outcomes they received from attending a National TIE Workshop:

- communicate more with other sites
- coordinate environmental restoration efforts with another site
- save time
- save person hours
- save other resources
- adapt existing technology methods to your site (instead of developing new ones)
- apply successful methods from another site
- adapt existing data from studies to your site
- work better with regulators
- transfer technology to another site
- share equipment with another site
- increase credibility inside DOE
- increase credibility outside DOE
- immediately impact projects
- increase consistency across the DOE complex
- reduce workload in out years
- abandon bad ideas

We gave this survey to the participants at the Sixth National TIE Workshop, hosted by Richland Operations Office.

RESULTS AND DISCUSSION

At the Sixth National TIE Workshop, the return rate was almost double the response rate of past workshops. (At most workshops we get about a 10 percent return rate; at the sixth workshop, our return rate was about 20 percent.) Ninety-four percent of the survey respondents believed TIE is achieving its mission. Ninety-six percent thought there was increased cooperation among DOE sites doing environmental restoration work because of TIE. Respondents said they gained knowledge and made contacts that would impact their work, benefiting both the Environmental Restoration program and DOE as a whole:

Workshop Outputs

88% will follow up with other participants after the workshop.

41% learned something that will prevent them from improperly implementing an environmental restoration technology.

45% will explore the option of transferring technology or equipment from another site as a result of TIE.

48% learned of an opportunity to collaborate with another site on a project.

Performance Outcomes

56% will be able to apply information gained at TIE to save costs and improve efficiency.

76% said duplication of effort among DOE sites conducting ER work will be reduced as a result of TIE.

69% said their organization will share technology and projects with other sites as a result of TIE.

64% said their organization is likely to use methods or technologies discussed at TIE.

After the Sixth National TIE Workshop, we developed an interim survey to gather information on what TIE participants did with the knowledge they gained at TIE after the workshops. This survey was mailed to all past TIE participants (about 1200 people). For the interim survey, we had a 17% return rate, an expected rate given the method we used (we mailed the surveys with no follow-up). Twenty-four percent of respondents reported they have applied technologies or methods at their site based

on information gained at TIE. The time delay for implementing a technology or method ranged from zero to three years. (However, the workshop has only been held for three years.) For example, one participant reported that Oak Ridge implemented the SAFER approach to characterization immediately after TIE. Another participant reported that his/her organization entered into a Cooperative Research and Development Agreement (CRADA) with Lawrence Livermore National Laboratory as a result of TIE, and he/she expected the resulting technology to be implemented in three years. Sixty-eight percent of respondents said they expanded their communications or peer groups as a result of TIE. Most participants built networks of contacts for specific technology applications. Many visited other sites to observe or present technologies. Some developed and improved relations with their regulators by inviting them to TIE. And, some participants even formed their own mini-TIE's. For example, as a result of TIE, the Savannah River Site and Oak Ridge National Laboratory hold quarterly meetings to exchange environmental restoration lessons learned. These examples represent TIE's primary audience, DOE environmental restoration workers in the field.

Many respondents gave specific examples of ways they have saved money, increased efficiency, and/or brought a project into compliance because of TIE.

Hanford saved $109,000 on ground water cleanup technology recommended by Lawrence Livermore National Laboratory (LLNL). Took one year to implement.

One group at Rocky Flats saved three months and $30,000 when they found another group at Rocky Flats that had completed a data study similar to one they were planning to do.

By using the six-phase heating technology developed by Pacific Northwest Laboratories, Rocky Flats will reduce the time of subsurface remediation of NAPL from 10 years to less than one by increasing the mass removal rate of subsurface contaminants.

Our demographics section of the survey revealed that many survey respondents were unable to identify specific examples of benefits because they were part of TIE's secondary audience. TIE's secondary audience, technology developers, both within DOE and industry, and other stakeholders, such as regulators, though essential to the success of TIE, are contributors of knowledge, not implementers of technology solutions. The outputs and outcomes for TIE's secondary audience differ from that of the primary audience but contribute to TIE outcomes. For example, the DOE-Oakland Operations Office invited some of its regulators from the State of California to the Sixth National TIE Workshop. The regulators learned that 1) the dense nonaqueous phase liquid contamination problem is not limited to Lawrence Livermore National Laboratory (LLNL) and the problem is much greater at other sites and 2) other sites are having success with more innovative technologies than currently outlined by LLNL's/California's regulatory agreement. The outcome of this shared and changed knowledge led to LLNL/DOE coming to agreement "with its regulatory agencies to broaden application and testing of innovative remediation technologies at LLNL's Site 300 Building 834 Operable Unit." The ultimate outcome will be bringing this project into compliance, potentially saving time, money, and resources, and forging a stronger relationship with regulators.

CONCLUSION

In evaluating the National TIE Workshops, we examined the desired performance outcomes described in its mission. We defined effectiveness in organizational learning as constantly sharing and using lessons learned and other information. We found TIE is successful in meeting its mission, and we found it to be an effective organizational learning process. In fact, survey results suggest that performance is being improved across the spectrum of performance criteria. TIE participants are sharing lessons learned and translating this shared knowledge into outputs and outcomes that improve the Environmental Management program's performance in implementing environmental restoration and waste management technologies. TIE serves as the Environmental Management program's organizational memory for this knowledge. The TIE process can be improved by 1) improving its inputs and the workshop itself through feedback from the field and 2) improving the link between its outputs and outcomes through follow-up and evaluation of decisions which lead to actions. Within DOE, the success of activities like the National TIE Workshops is related to the ability of participants to apply the knowledge they learned at the workshops. DOE promotes organizational learning and respective performance improvement by hosting TIE Workshops, sending people to the workshop, and creating avenues for individuals

to affect change after the workshop.

LESSONS LEARNED FROM OUR PROCESS

Participants at the National TIE Workshops work with knowledge and information. Their actions during and after the workshop determine the level of improvement DOE experiences as a result. Total quality management, organizational learning, and other improvement activities are based in the actions and perceptions of people. The National TIE Workshops are focused on people. Our evaluation process was based on understanding and organizing people's reported perceptions of the National TIE Workshops to evaluate the outputs and outcomes. Following are our lessons learned:

As in all TQM activities, the evaluation process is cyclic. We used data from phase 1, which at first glance appeared unimportant to the second phase evaluation, to help us construct the conceptual model and detailed survey.

The evaluation process must be linked to the desired outcomes described in a well-formed mission statement.

A mission statement may not include all possible or desirable outcomes (or the right outcomes) and may need to be revised or expanded. In some organizations, a statement of objectives will contain desired outcomes. (Although not directly related to this evaluation, the TIE mission statement is currently being revised).

Constructing a conceptual model that described TIE as a process identified previously unidentified outputs and outcomes.

Success is often evaluated based on dollars saved. Though very important, this perspective may overlook equally important but less tangible outcomes, such as saving person hours or preventing duplicate tasks. Determining organizational learning performance requires a broader definition of success than the bottom line. One way of broadening it is to use the seven performance criteria described above.

Using an organizational learning and process perspective helped identify TIE's outputs and outcomes and provided a conceptual framework for developing a survey instrument.

This process can be used to evaluate the effectiveness of any ongoing meeting/process. These are the steps to follow:

- Examine the mission and/or objectives statement to identify desired outputs and outcomes.
- Administer general surveys longitudinally (i.e., over a period of time).
- Analyze the content from these survey responses for common themes, outputs, and outcomes by performing a content analysis.
- Develop a conceptual model of the process based on the content analysis.
- Develop and administer a structured survey based on the model and content analysis to measure outputs and expected outcomes.
- Analyze the survey results.

Next Steps

This evaluation process focused primarily on TIE's primary audiences-DOE environmental management workers. A model is needed for measuring the performance of TIE with secondary audiences of technology developers, both within DOE and industry, and other stakeholders, such as regulators. In support of organizational learning and performance improvement, TIE is effective at facilitating the sharing of information at the workshops. Individuals apply this information in the field. We don't know how often they return to TIE with lessons learned from the application of changed knowledge. This could help further define the effectiveness of National TIE Workshops. Currently, the National TIE Workshop's mission is being further defined. The mission change is significant. TIE is moving from merely facilitating information sharing to more proactively promoting technology implementation. Future evaluations will address this more comprehensive mission:

> To advance the accomplishment of the DOE Environmental Management mission by helping to promote the prompt and efficient application of the best available and tested commercial technologies and, when those are lacking, by helping to promote the development and application of appropriate new or modified technologies. (Draft TIE Mission, 1/24/95)

Continued attention should be placed on documenting performance outcome improvements objectively to complement participant's perceptions of performance improvement.

ABSTRACT

This paper addresses the importance of applying public relations research techniques to develop credible and effective public involvement programs, particularly at U.S. Department of Energy (DOE) facilities. Specifically, this paper discusses the experience at the Fernald Environmental Management Project, where two major research efforts -- a community assessment and an internal communications audit -- have been completed. The assessment and audit results are being used as a benchmark for measuring the effectiveness of future program activities. In addition, the Fernald site's public involvement program has been fine-tuned, partly in response to the findings of these two studies. Public relations research is a valuable tool for planning and implementing two-way communication between an organization and its publics, because it measures changes in awareness, attitudes, opinions, and behaviors both inside and outside the organization. Measurement and evaluation are particularly helpful for gauging program effectiveness when resource constraints require management to select the most meaningful public involvement activities.

Fernald Watchers Concerned: GOP Ascendancy Could Affect Cleanup Funding

Newspaper headlines herald the new reality for environmental remediation efforts at U.S. Department of Energy (DOE) weapons complex sites: shrinking resources are requiring managers to be more selective with their programs. When budgets barely allow for the completion of mandated remediation activities, managers are finding themselves looking carefully at public involvement efforts. Gone is the luxury of being able to apply any and all types of public involvement techniques. Additionally, the DOE is requiring measurement in all areas of performance as a way to show effectiveness and prove value.

The DOE, acknowledging past weaknesses in its own and contractor performances in its report "Making Contracting Work Better and Cost Less," noted that DOE officials "are not in a position to ensure prudent expenditure of taxpayer dollars in pursuit of our principal missions. Now is the time to reform our management practices, empower our managers to effect these reforms, and measure their success." Indeed, DOE's contract reform initiative is guided by several key principles advanced by Secretary Hazel O'Leary, including developing meaningful ways to measure DOE and contractor performance with system performance criteria and measurement mechanisms. Crafting clearly stated, results-oriented performance criteria and measures is critical, according to the DOE's Contract Reform Team report.

Although measurement typically is associated with activities such as financial accounting, safety statistics, or production quotas, it is equally valid for public involvement activities. Research is recognized as being vital for planning communication programs and for determining the success of programs.

All these factors have contributed to creating an environment in which public relations research is not just desirable, but essential.

BACKGROUND

But what is public relations research, exactly? Broadly speaking, public relations research is that activity "conducted to detect problems and assess the status quo, on the one hand, and...to evaluate the planning, implementation, and impact of public relations programs on the other." (Dozier and Repper, 1992) The first type of public relations research often is used for defining problems, while the second kind of research -- evaluation research -- is designed to determine how well public relations programs work. Both types of research have value in DOE programs, although evaluation research is currently most relevant to the Fernald program.

Prior to initiating an ongoing measurement program as a routine component of the public involvement program at Fernald, there were some sporadic evaluation efforts. Employees were surveyed in 1985 and 1990, while neighbors living near the Fernald site were interviewed in a 1989 community assessment conducted prior to development of the Community Relations Plan. The Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) requires a community assessment to characterize residents' concerns about a contaminated site. At the time, the DOE did not seek to go beyond requirements and expand the scope of the assessment to support broader management objectives. These measurement efforts were not designed to support management evaluation of overall program effectiveness. Rather, the primary means of determining program effectiveness was the "gut" sense of the public relations staff working at the site.

The only other type of measurement consistently practiced at the Fernald site prior to implementation of the current measurement program was the practice of distributing questionnaires at meetings. These meeting evaluation forms, however, were not crafted to elicit a broad range of information; most simply asked if the attendee thought his or her questions were adequately answered by the presenters at the meeting.

In 1994, DOE and the Fernald Environmental Restoration Management Corporation (FERMCO), DOE's prime contractor at Fernald, recognized that a consistently-applied evaluation program was essential. Not only did the site's Community Relations Plan require revision to reflect public involvement activities during the project's remedial design and remedial action phases, but managers realized that they needed some way to determine the effectiveness of specific program activities. The community assessment and internal communications audit were designed to meet both regulatory requirements and management's needs.

METHODOLOGY

1994 Community Assessment

The DOE conducted a comprehensive community assessment in May 1994 to improve its understanding of community concerns, needs and interests. The community assessment

consisted of a series of interviews with members of the public who are impacted, or potentially impacted, by activities at the Fernald site.
The assessment involved 50 face-to-face interviews with community leaders, including business owners, government officials, educators, local news media, representatives of the Fernald Citizens Task Force, members of the Fernald Residents for Environmental Safety and Health, and others. To gain a sense of general public perceptions about Fernald, the assessment also included 365 telephone interviews with residents within a 20-mile radius of the Fernald site. The interviews were conducted by DOE and FERMCO Public Affairs personnel.
By conducting the community assessment, DOE can establish a baseline for use in monitoring changes in public interests, needs and concerns as the Fernald facility begins its transition from the remedial investigation/feasibility study phase to the remedial design and remedial action phase.
Internal Communications Audit
In addition to the community assessment, DOE and FERMCO commissioned a separate internal communications audit of Fernald employees. The audit was conducted by the University of Cincinnati (UC) Center for Environmental Communication Studies in July 1994. The audit was designed to gather information on current communication practices and provide assessment of the organizational culture at Fernald.
The UC research team used three main techniques during the audit -- senior management interviews, a survey questionnaire, and employee focus groups. Additionally, all informal contacts with Fernald employees during the study period were documented and integrated into the qualitative data where relevant.
The survey questionnaire was distributed to all FERMCO employees, 80 DOE-Fernald employees, and about 300 subcontractor employees. About 950 questionnaires were returned, representing a 36 percent response. The research team analyzed the responses and reported its findings to DOE and FERMCO management.
Feedback from both the community assessment and communications audit has been used to benchmark Fernald's effectiveness in delivering messages to employees and the community and to develop new or better approaches for informing and involving all stakeholders, including employees.
FINDINGS
1994 Community Assessment
Community concerns and issues raised during the 1994 community assessment can be linked to four core issues:
- Providing accurate information about the Fernald site and site activities
- Involving stakeholders in the decision-making process during all phases of the project
- Desire for site remediation without wasting taxpayers' money
- Public health and safety and economic impacts.

Providing accurate information: The 1994 community assessment indicates most community leaders are satisfied with the frequency, quantity and quality of information they receive from Fernald sources, though some commented on the need to present information in a more understandable form. More than half of the community leaders say their understanding of Fernald issues has changed due to information they have received. Most community leaders have established direct, personal contacts with Fernald personnel and are satisfied with them. Community leaders indicate information from Fernald is useful and say they are encouraged by recent efforts to reach and involve the public.
Findings suggest respondents in the 20-mile areas are not as informed and are less positive about Fernald, in general, than community leaders. These respondents almost exclusively rely on mass media for information about Fernald, unlike community leaders, who primarily receive their information directly from Fernald sources. Community leaders' ratings of Fernald management's efforts to inform the public are higher than those of the general public. One-third of general public respondents do not know who within the Fernald organization to contact about Fernald-related concerns, and many say they would contact elected officials.
Involving stakeholders: Half of the community leaders indicate they are receiving enough information to be involved in the decision-making process. Of the 50 percent who said they are not receiving sufficient information, some feel they can make no impact in the decision-making process and some simply do not envision themselves as part of the decision-making process.
Assessment findings indicate individuals living or working closer to Fernald are

more likely to participate in public involvement activities than people living or working farther from the site. Most community leaders say they are satisfied with their current level of involvement and do not want to be more involved. Some indicated that they would be strongly opposed to any diminishing of public involvement opportunities as the project progressed to the remedial design and remedial action phases. Findings indicate individuals farther from the Fernald facility prefer to be informed rather than actually involved.

Respondents were asked to state the most positive thing they could say about Fernald. Community leaders responded that the most positive aspect of the Fernald facility is improvement in public involvement. In comparison, general public respondents closest to the facility mention jobs and other economic benefits, and those farther from the facility either do not know or cannot say what is positive about Fernald.

Fernald remediation schedule and cost: Through the 1994 community assessment, public interest in timely, cost effective cleanup emerged as a major concern. This contrasts with past assessments which showed health and safety issues as the chief concerns.

Community leaders ranked concerns over budget and costs equally with concerns about public and worker safety and health. Some of the community leaders indicated concerns regarding the ultimate cost of remediation, and some were concerned about availability of funds to complete the project. Remediation progress was the sixth-ranked top concern among community leaders, but was tied for first among general public respondents within a 5-mile radius and second-ranked within a 20-mile radius.

Among the community leaders, opinions regarding cleanup progress were mixed. Forty-two percent said they believe progress is slow, but 30 percent perceived cleanup is progressing. Some said they believe the cleanup has been stalled or delayed or that the paper work required to prepare for remediation is burdensome. (General public respondents were not asked to respond to this question.)

Public health and safety and economic impacts: Most community leaders report no personal or family health problems which they attribute to Fernald. However, most community leaders say they know other people, outside their own families, who attribute health problems to Fernald site activities. Within a 5-mile radius, 16 percent of general public respondents attribute health problems to Fernald, compared to seven percent within a 20-mile radius.

Almost half of the community leaders believe their property or a family members' property or quality of life has been negatively impacted by the Fernald facility. In comparison, 19 percent of general public respondents within five miles of the site and eight percent within 20 miles of the site believe their property or a family members' property has been impacted by Fernald activities. Some community leaders mention groundwater contamination as an example of how Fernald has negatively impacted local property values and residents' quality and cost of living.

Internal Communications Audit

Major audit findings can be summarized in two categories:

- Information patterns
- Organizational culture

Information patterns: Several general themes are apparent in the data on information patterns. First, employees expressed a need for more information about job restructuring issues and how management makes decisions that affect their jobs and their futures. Second, employees indicated eagerness for information about Fernald policies and activities or for government information relevant to Fernald (e.g., the Federal budget process). They are also eager to provide input into Fernald policies and procedures, but they feel that they have little opportunity to do so. Third, it is apparent that employees are receiving safety information. The importance of safety has been effectively communicated to employees. Employees expressed a need for more job and situation specific safety information, indicating they have accepted the importance of safety as a goal. Fourth, employees indicated they receive a great deal of information through the informal grapevine, though they would prefer to get it from management (see Fig. 1). Finally, most employees indicated they are overloaded with written communications and electronic mail. Employees were split along job classifications on their perceptions of internal publications.

Two other key findings were revealed by the internal communications audit. Employees

said that they want face-to-face information from their bosses. The analysis of the audit also indicated a high need for employees to communicate to their supervisors on certain issues.
Fig. 1.
Organizational culture: Two sets of questions within the survey were aimed at characterizing the existing culture. The first set was designed to reflect work relationships at Fernald and the second set was focused on identifying the level of organizational commitment at Fernald.
The data indicated that employees are generally very positive about their co-workers and immediate supervisors. Employee responses indicate a less positive relationship with top management. All job classifications indicated a high degree of trust in fellow employees and supervisors, but there was a trend toward a distrust of top management. That trend however, was not as pronounced within the manager classification. The data also showed that Fernald workers are very committed to their jobs and their individual work groups. The only negative comment by many employees focused on the fact that they wanted to accomplish their work group's goals faster, but felt that they were being held back by regulatory agencies or a lack of cooperation from other work groups.
Crossover Questions
Several questions about the future of the Fernald site were included in both the community assessment and the internal communications audit to provide information on public preferences to the Fernald Citizens Task Force. Formed in 1993, the task force will develop recommendations about cleanup solutions and future courses of action at Fernald.
Cleanup Levels: Most community leaders and Fernald employees do not believe the Fernald site should be cleaned to a "pristine" condition. Conversely, more than half of all general public respondents believe the site should be cleaned to pristine levels, even if achieving that cleanup level would require spending more taxpayer money than needed to meet cleanup levels mandated by government regulations.
Waste Disposal: The most common preference for disposal of Fernald waste indicated by community leaders, general public respondents, and employees is to dispose of waste in arid western states at existing government facilities, if possible. Eighteen percent of community leaders, 23 percent of employees, and four percent of general public respondents acknowledged that some waste should be, or would have to be, stored on site.
Future Use: Regarding the future use of the Fernald facility, most community leaders and employees said they would like the Fernald facility to return to a natural setting, such as a wildlife/nature preserve. Of the general public respondents, one-third offered no specific suggestions on what should be done with the Fernald facility once remediation is completed.
PLANNING
Equipped with the results of the community assessment and internal communications audit, Fernald management applied these findings to public involvement and communications planning during Fall 1994.
Even as plans were being developed, results of the assessment and audit were communicated to employees and the public. Summaries of the research were written and distributed, and availability sessions were held for employees to meet with the UC researchers. Management recognized that simply by conducting the research, expectations of responsiveness would rise, and reporting the findings promptly provided a means of assuring respondents that their concerns had been heard. It also established a basis for management to seek public and employee involvement in solving communications problems it could not solve alone.
Data from the community assessment were used to revise Fernald's Community Relations Plan, a regulatory required document that identifies ways in which the DOE will involve the public in decisions at the Fernald site. Moreover, assessment findings were applied to evaluate individual public involvement program elements. Established program elements were examined to determine their value given the assessment results, and new or refined techniques were adopted. The following examples of planned activities are illustrative of how the assessment has shaped Fernald's public involvement program:
Continued emphasis on person-to-person communication is planned to sustain the level of satisfaction expressed by community leaders with the information received. This communication is occurring either directly between Fernald decision-makers and

community leaders or through the Fernald Envoys, a group of DOE and FERMCO employees who have volunteered to develop relationships with community opinion leaders. Reaching a broader audience with more easily understandable information is being pursued by expanding distribution of a new, summary level community newsletter, the Fernald Progress. A community access telephone line was established as an alternative to public meetings for informing citizens. To address the need to inform the general public more effectively, an information campaign emphasizing mass communication tactics is planned.

A strategy for coordinating public meetings among Fernald Operable Unit project teams and other projects is planned to avoid "stakeholder burnout." This acknowledges community leaders' level of satisfaction with the current involvement and the increasing demands for public involvement as the project's formal decision-making process nears its conclusion.

A commitment to public involvement during remedial design and remedial action was made in the revised Fernald Community Relations Plan. The plan outlines continuing public participation throughout all phases of environmental restoration of the Fernald site.

Elements of FERMCO's employee communications program were similarly examined and adjusted. Example initiatives and program enhancements taken in response include:

A series of "cascading" meetings to establish supervisors as chief communicators with employees was planned and conducted. Top management kicked off the series at an All Supervisory Meeting where information was provided on topics employees expressed a high need to receive. Supervisors were asked to hold meetings with their work groups within ten days to convey the information throughout the organization, and questionnaires were provided for employees to indicate whether the meeting met their information needs. Small group follow up sessions with supervisors were planned to share and discuss the information needs, barriers, and recommended communication processes.

Small group employee roundtables were continued weekly. In these meetings, top management meets face-to-face with employees and discuss issues affecting Fernald.

Targeting information media to the needs of various audience segments was planned, including publishing a single monthly employee publication and publishing abstracts of available information weekly on the electronic mail bulletin board.

Providing more information on human resource policies and budget and restructuring decisions was planned by continuing or establishing regular feature articles or special editions of employee publications on these topics.

NEXT STEPS

Fernald's planned public involvement and communication program activities, including the examples described above, are in various stages of implementation. Each has been designed to accomplish specific communications objectives. Project-specific communication plans now specify measurement at predetermined stages of implementation to assess whether objectives were reached. Qualitative and quantitative data will result, enabling both subjective and objective evaluation of DOE and contractor performance in meeting public involvement and communications objectives. Initially, these results will be compared to the benchmark established by the 1994 community assessment and communications audit to determine effectiveness.

To provide added value for future communications planning, current emphasis is on developing formal measurement and evaluation of the overall impact of program activities on the relationship between the Fernald organization and affected publics. Coorientation research techniques are being developed to ascertain the level of agreement and accuracy between views expressed by people both inside and outside the Fernald organization. Using this approach, gaps in one side's perceptions of the other's views and the other's actual views can be identified and factored into planning. This is particularly important in a public involvement communications environment where the ultimate objective is to bring organizational and public interests into alignment.

CLOSING THOUGHT

During times of budget constraint, public relations research gives managers the information they need to confirm the value of public involvement programs and make informed choices about where to apply resources for maximum impact. The Fernald experience is showing this to be true in the DOE communications environment.

COMMUNITY COLLEGE NETWORK (C2NET)
Robert J. Harrison
Richard D. Dayvault
Rust Geotech*
U.S. Department of Energy
Grand Junction Projects Office
Grand Junction, Colorado
ABSTRACT
In 1990, a proposal was made to the U.S. Department of Energy (DOE) that community colleges associated with DOE facilities be given the means to interact with DOE and each other to more rapidly and consistently develop programs that deal with DOE's workforce restructuring. A specific objective in the initial proposal was the development of associate degree curriculum in environmental restoration and waste management. Representatives of eight colleges attended initial meetings in Albuquerque, New Mexico, in July and December of 1991. Since then, meetings have been held each fiscal year, with two meetings each in fiscal years 1993 and 1994. The Community College Network, or C2NET, helps member colleges progress in educational programs, while remaining flexible to deal with DOE's evolving

assessment of its workforce needs. Twenty colleges currently are members. C2NET uses networking and clearinghouse methodologies to allow each college to move forward with its own program and to develop consistency among the colleges' curricula. Semiannual meetings provide DOE Headquarters workforce perspective, lessons learned by the colleges and their facilities, and a forum for joint curriculum work. Site-specific meetings foster the relationship of each college with the local DOE office and its contractors. The Grand Junction Projects Office (GJPO), as the administrator for C2NET, maintains a database of information on curricula, courses, and instructional materials of the various colleges and makes reports available to all members. Bulletins issued quarterly provide current information on DOE workforce needs, college curricula, and C2NET activities.

During the last 4 years, DOE has continually modified its appraisal of its environmental workforce. The DOE focus has evolved from supplying several hundred thousand scientists, engineers, and technicians by "filling the pipeline" with students to "retraining and retaining" displaced weapons-plant workers. Two main reasons caused the shift in focus: 1) the end of the Cold War and the reduction of the nuclear stockpile and 2) a more experienced understanding of the personnel needed for environmental cleanup.

In fiscal year 1994, C2NET sought and was granted funding from the DOE Task Force on Worker and Community Transition. Guidance for the organization is now under Section 3161 of the 1993 Defense Authorization Act with its requirements for alleviation of the impact of DOE defense mission cutbacks on workers. The current focus is on development of a condensed curriculum to retrain displaced workers to work as environmental technicians. To do this, the colleges are identifying the core competencies from the collective associate degree programs. The goal in fiscal year 1995 is to produce a retraining curriculum that can be taught in the time frames allowed under Section 3161.

BACKGROUND

In 1989 and 1990, the U.S. Department of Energy Grand Junction Projects Office (DOE-GJPO) in Grand Junction, Colorado, collaborated with Mesa State College (also in Grand Junction) to develop the curriculum for an associate of applied science degree in Environmental Restoration Technology. That effort evolved out of the GJPO need for qualified environmental technicians and technologists and the desire to retrain some of the GJPO technicians who had only high school educations. Personnel from the GJPO operating contractor, Rust Geotech, performed most of the preliminary curriculum development in support of the Civil Engineering Technology staff at Mesa State.

During the development process, we sought help from DOE and from other colleges that might have established similar programs. In doing so, several elements became apparent:

- DOE had limited knowledge about community colleges and, therefore, had little interaction with them.
- All DOE sites we identified had a nearby community college, sometimes more than one.
- A few of those community colleges already were developing similar environmental programs, many more were considering such programs.
- Almost all of the colleges were approaching curriculum development on their own with little help from other colleges or from DOE.

In fact, some colleges with environmental programs in place had success with placement of graduates with DOE contractors but still could not get acknowledgment, let alone definition, of workforce needs. It was clear to us, if a number of community colleges were going to develop programs to support DOE's environmental workforce needs, then DOE would benefit by providing those colleges with information and by helping them to work together to develop those programs more rapidly and consistently.

In 1990, a Technical Task Plan submitted to the DOE Office of Technology Integration and Environmental Education Development (EM-522) proposed providing the community colleges with an annual meeting to share curriculum information with each other and to gather current DOE information on workforce needs. We also proposed to act as a clearinghouse of information on curricula and colleges. Funding was approved late in fiscal year 1991. In July and December of 1991, meetings were held in Albuquerque, New Mexico, with DOE representatives and faculty from eight of the community colleges associated with DOE facilities. The twofold purpose of the meetings was to

provide DOE with the capabilities, roles, and needs of the community colleges and to help the colleges gather information about DOE's perception of its workforce needs. College representatives also stressed their institutions' capabilities to perform services for DOE in nondegree areas such as training and research.
Even at that early stage, the college participants in those meetings articulated several distinct needs:
- Accurate and current information on DOE workforce needs from authoritative sources.
- Better and more official communication with DOE at the facility level.
- DOE expertise, especially in the form of adjunct faculty.
- Start-up funding when DOE wants a capability developed in a hurry.
- Equipment for highly technical courses.
- Internships for faculty and students.
- Scholarships.

A spinoff of the 1991 meetings was a DOE EM-522 attempt to initiate a "community college program." A notice of program interest was published in 1992, and funds were designated. The program's concept was that colleges would compete for grants or cooperative agreements. On what basis the colleges would compete for work at a national level when their roles were local was not established. The program did not proceed.
Our national community college program really became what it is in 1992. We began to compile a database of information on the colleges and their curricula, course content, and instructional materials. We contacted additional colleges and hosted a meeting in Denver, Colorado, in August. Thirteen colleges received invitations, and most sent representatives to the meeting.
The Denver meeting set the tone for what has truly become the DOE Community College Network (C2NET). Even though rough at times, the meeting was productive in presenting a variety of viewpoints on DOE's workforce needs and its need for the services of community colleges.
Fig. 1.
It became apparent to the colleges that DOE did not speak from one mind on these matters. One issue to be overcome was terminology with respect to "workforce." One speaker stated DOE's needs for people as being for DOE Federal employees only and predicted no real hiring of technicians. Other speakers saw the need as including contractor and even subcontractor personnel with the need for community college graduates increasing accordingly. In addition, two authors of separate assessments of DOE workforce needs were featured speakers at the meeting.
The meeting was the first time we presented the DOE-related speakers in a panel format and encouraged questions from college and industry participants. Some lively discussion resulted, even among the panelists. In addition, representatives from some of the colleges with active programs were asked to speak on educational or retraining accomplishments and lessons learned, again in a panel format. This time, with the DOE and contractor attendees asking questions, the discussion again led to what the community colleges could provide for DOE and what DOE needed to do to enable the colleges to meet DOE's needs. These topics continue to be a common theme of discussion in all meetings to date.
The Denver meeting was also the first time we formally facilitated with the assistance of a facilitator and recorded the meeting discussion on a flip chart. All meeting participants received reductions of the flip chart notes of the discussion. We found this format preferable to transcribed notes as it more accurately captures the "flavor" of the discussion and evokes discussion that was not recorded. Because of the large amount of information provided and the ensuing discussion, only a limited amount of time was dedicated to work on curriculum at that meeting. In fact, it became apparent that there was too much to be accomplished in a 2-day meeting. One of the needs expressed by the college representatives to DOE was for two meetings each yearone for information sharing and one for intercollege work on curriculum development.
Subsequent meetings were held in Albuquerque, New Mexico (spring 1993); Grand Junction, Colorado (summer 1993); Oak Ridge, Tennessee (spring 1994); and Idaho Falls, Idaho (summer 1994). We have continued the format of one meeting each year for information sharing and one for curriculum development.

CURRICULUM DEVELOPMENT

At the spring meeting, a curriculum development meeting, in Albuquerque in 1993, the

college representatives agreed to seek consistency among their various and diverse curricula. The first idea on how to build that consistency was through "competencies," the smallest building block they could identify. Competencies, as used by the C2NET colleges, refers to discrete elements of learned knowledge or skill that are single teaching objectives. The consensus of the C2NET participants, at that time, was the disparity among colleges in the curriculum structure and content of courses was too great to use as starting points.

Because of the isolated way the environmental degree programs had been developed, courses with the same name had different content at different schools, courses with different names had the same content, and subject matter contained in one course at one college was distributed in several courses at another. The typical example of the latter is Environmental Law and Regulations, taught as a single course at some colleges but distributed as supporting material in several courses at other colleges.

The first attempt to extract competencies was abortive. Only two schools had really appraised their curriculum in those terms because their governing systems required development of a competency-based curriculum. In addition, the individual who was driving the competency effort resigned during the information gathering effort.

The 1993 summer meeting in Grand Junction was an information-sharing meeting. During the working portion of that meeting, participants discussed that competencies without a framework or agreed parameters were too difficult to build. The discussion also led to the idea of a "core" of technical courses. The idea of courses again was problematic because of the mismatches among colleges. However, the concept arose that a theoretical core of technical courses, containing those subject areas and competencies that were common and essential, might be determined by consensus. The time was too short to expand on those ideas, but a diagram of a common core of courses was drawn and kept as the basis for the next year's discussions.

The agendas of the two 1994 meetings were reversed to accommodate the introduction of a new funding sponsor, the DOE Task Force on Worker and Community Transition. The spring meeting in Oak Ridge had only a half-day working component. Within that time frame, we revisited the idea of technical core courses. Through much discussion, the participants approved a preliminary list of 10 courses. To satisfy some of the concern about terminology, we agreed to refer to these as "course equivalents." The colleges are interested in attaining common academic content, not common courses. They agreed to submit their lists of competencies within that framework of course equivalents.

Our new funding sponsor was interested in the curriculum development and participated actively in the working portion of the meeting. The sponsor's interest was expressed in terms of wanting the capability to retrain displaced weapons plant workers to perform environmental work. That training might have to take place within a time frame as short as 120 days.

The 1994 summer meeting in Idaho Falls, Idaho, was truly a working meeting. Minimum time was devoted to speakers and formalities. Several of the colleges submitted competencies that fit within the 10-course equivalent framework. We compiled those competencies into a combined set, unedited, with much redundancy. We used the meeting as a facilitated session to condense the list, to eliminate redundancies, and eventually to achieve consensus. The meeting was difficult, cordiality was tested, but we accomplished our goal.

Our intent is to proceed down two paths. In terms of building commonality into the associate degree programs, the speed of C2NET seems to be workable and suitable to the colleges. Their change processes could not move much faster. The commonality ostensibly will be expressed in terms of a crosswalk of competencies. The benefits are that course work will be transferable from one college to another and that one degree will be comparable to another and considered equivalent in terms of competencies. Beginning with the 1995 meetings, the idea of such a crosswalk will be introduced and developed

The other path will be a shorter term project and is in response to DOE's need for retraining of displaced weapons plant workers in as little as 120 days. Section 3161 of the 1993 Defense Authorization Act aims at mitigating the effects on workers and communities as the DOE workforce is restructured at defense nuclear facilities. Section 3161 was written because of the anticipated worker displacement that is due to the "end of the Cold War," the reduction of the nuclear stockpile, and the resulting cutbacks in DOE's weapons production program.

One of the requirements of Section 3161 is the retraining of displaced weapons plant workers to perform environmental cleanup work. DOE funded the Accelerated Retraining Curriculum (ARC) project, which will use the core competencies from C2NET to develop a 16-week retraining curriculum. Curriculum development started in January 1995, and five C2NET colleges will receive subcontracts for the ARC project this year. Developers will build the curriculum around the 10 core technical courses from C2NET with a modular structure that is suitable for a number of time formats, the shortest and worst case being 16 weeks.

WORKFORCE INFORMATION

One of the basic needs of the community colleges associated with DOE is to understand DOE's workforce needsthe need of any community college associated with any industry. Unfortunately, DOE has, in the past, not used or communicated with the community colleges to any great extent. Recently, DOE has been in a transition of its mission that has caused it to be unclear about its workforce needs. When C2NET started, DOE was on parallel missions to continue with its nuclear-weapons-related mission as well as to clean up the environment at its facilities. The best information available on workforce needs at that time indicated there would be a great shortage of technical environmental personnel for years to come. On that basis, many programs were initiated to move people into the appropriate educational "pipelines" to meet the perceived need.

Developments associated with the end of the Cold War caused DOE to plan for reconfiguration of its weapons production system and reduction of the nuclear stockpile. This change in scope meant reduction in the weapons production mission of DOE, consolidation or closure of some facilities, and associated downsizing in its workforce. Communities and congressional districts where facilities would be lost or downsized expressed great consternation about the changes.

Action by some legislators directed DOE to alleviate the impact of such moves on the existing workforce. Section 3161 of the 1993 Defense Authorization Act requires DOE to retrain displaced "Cold Warriors" for environmental cleanup work as well as other mitigation measures. The workforce picture changed from needing new people to retraining existing people. As you may imagine, this picture change has not been altogether simultaneous or unanimous within DOE.

After 2 years of struggling with the implications of Section 3161 and its retraining requirement, it is only clear that retraining is required for compliance. It is not clear what jobs will be available for the retrainees, especially at their previous salaries. At this point, the emphasis is on developing the retraining programs so they are available for those who want to be retrained under a facility restructuring plan.

As the workforce-needs picture has changed in the last 4 years, change will continue until the needs picture coincides with reality. We will retrain some people. People earning upward of $50,000 per year in weapons production are probably not going to be retrained for $25,000-per-year environmental technician jobs. Many, if not most, of the higher technical environmental positions are already filled. Most workforce projection is still done on a budget basis rather than on a technical-needs basis. As DOE gains more experience in actual cleanup, its workforce picture will become clearer. C2NET has tried to present a broad picture of DOE's perceptions of its workforce needs to the colleges and will continue to do so as long as possible, or until it is no longer necessary.

CLEARINGHOUSE

The main component of the clearinghouse is an information database on the colleges and their curricula, course content, and instructional materials. The database, or set of relational databases, is in Paradox and is maintained by Rust. Our data gathering method was, and still is, telephoning the colleges quarterly to update and gather new information. Given the schedules of the college personnel, we are on the telephone almost dailywe are very persistent. We have had many requests for information from colleges, mostly from those not associated with C2NET, that are trying to start similar programs.

One of the initial efforts was to act as a broker for communications among colleges. If one of the colleges needed some information, a representative would call us and we, in turn, would contact other colleges in search of the information. In fact, the number of times this happened was to be one of our success measurement criteria. After an early increase in such activity, it decreased, then died almost totally. In trying to determine why, we were told that once the college personnel became

acquainted, they saw no reason to include us in their conversations. We had to consider our broker endeavor a success, even though our measurement criteria indicated it was a failure.

As a clearinghouse, we also issue a quarterly bulletin to update our members and stakeholders on C2NET activities. The bulletin also includes updates on college accomplishments and programs and on other items of interest to the colleges, such as funding sources.

DOE SUPPORT

One of the services we provide for DOE is representation of the DOE-associated community college perspective and the C2NET program at DOE meetings and workshops and through information dissemination. We also try to represent the community college resource in DOE discussions on such issues as training and workforce planning. Community colleges have been so underutilized by DOE that it sometimes does not regard them as a ready and economical resource unless it is brought to its attention.

LESSONS LEARNED

Along the way some hints on how to improve the coordination of these activities have become obvious to us, sometimes painfully:

Meeting room configuration and seating arrangements are important factors. In Denver, two columns in the room that were shown as very thin on the hotel floor plan turned out to be 3-feet thick and blocked participants' views. U-shaped seating permits better discussion than classroom (parallel rows of chairs) seating.

To manage a successful database, you must aggressively update the database as well as aggressively seek to disseminate the information. If it's not used, it's just data.

Community colleges have very limited funds for travel. We have paid travel expenses for college representatives to attend our meetings.

Arriving at a product by consensus is difficult work. Longer work sessions at one meeting are just not productive. Two 4-hour work sessions, with one 4-hour information session and one field trip, is about the length of time that people can stay enthusiastic.

DOE is very interested in working with community colleges but just not experienced. A culture populated with scientists and engineers has had a natural affinity with universities and sometimes cannot envision what a community college can do that a university cannot.

Not all community colleges are equal. We have had to arrive at a working definition. We consider a community college as one that offers associate degrees and interacts directly with local industry and the community for training and other human-resource development needs. Some of our C2NET colleges have different names, such as technical college or state college. Some are 4-year colleges that also serve as community colleges because the size of the community will not support two colleges.

THE FUTURE FOR C2NET

Community colleges exist near the doorstep of each DOE facility. They are an economical and "tappable" resource for education, training, and other human-resource development needs. C2NET provides DOE with a single, convenient way to interface with that group of colleges and provides the colleges with a forum for working together to develop training and curricula to meet DOE's needs. As DOE facilities and their contractors find themselves smaller and unable to support large internal training and other human-resource development capabilities, community colleges will be there to fill the need. We see C2NET continuing to evolve to help DOE articulate its workforce needs to the colleges. We also see C2NET continuing to facilitate interaction among the colleges. The hope is that each college will eventually be a true partner, supporting its DOE facility. Until then, C2NET will have a role encouraging their interaction. Perhaps the future for C2NET will be a true consortium of colleges doing business with DOE.

DETERMINING TRAINING NEEDS FROM SUPERVISORS' ASSESSMENT OF STAFF PROFICIENCY IN TASKS AND SKILLS*

C. Young
J. Hensley
Argonne National Laboratory

Argonne, Illinois
J. Lehr
U.S. Department of Energy
Gaithersburg, Maryland
ABSTRACT
To provide the basis for establishing training opportunities, this project investigated supervisors' views of three components of staff activities. The project established the tasks that staff perform, identified staff's level of effectiveness in performing these tasks, and investigated staff's level of proficiency in performing the skills underlying these tasks. Training opportunities were then determined in those areas where knowledge and skills could be improved for staff to perform their tasks more effectively.
Staff currently perform their tasks sufficiently well. Furthermore, supervisors indicated that for the most part staff do perform the tasks they should perform. In carrying out these tasks, staff use primarily critical thinking, problem solving, and communication skills rather than discipline-specific skills. Although staff generally have working knowledge of most of these skills, additional training in critical thinking and problem solving, program and project management techniques, and communications is appropriate to further improve the organization's effectiveness.
INTRODUCTION
To successfully implement environmental restoration, federal agencies must have skilled staff to carry out the range of activities and tasks needed to achieve the agencies' missions. This project investigated the training needs of an environmental organization by examining the tasks that the staff must perform, staff effectiveness in performing these tasks, and staff proficiency in the skills and knowledge necessary to perform these tasks.
This project sought answers to the following questions:
  What tasks do staff currently perform and are these all or nearly all of the tasks they should perform?
  How well do staff perform these tasks?
  How proficient are staff in applying the knowledge and skills needed to perform these tasks?
Answers to these questions provide guidance on what training would most benefit and improve staff's knowledge and skills.
The organization examined in this project is one headquarters office within the U.S. Department of Energy (DOE), the Office of Environmental Management (EM). This office is responsible for directing and overseeing programs rather than managing and implementing specific projects. Under this mission, DOE EM is charged with carrying out tasks under the broad functional areas of award fees, budget, communications, documents, guidance, integration and coordination, operations and contractor management, quality assurance, policy and planning, and safety (1).
METHODS
This section briefly describes the procedures used to examine tasks and the associated knowledge and skills needed to accomplish them. These procedures are further discussed in a complementary study by Young and Hensley (2).
The 4 supervisors* of a headquarters organization of DOE EM completed a workbook that asked questions about the tasks their 24 staff members perform and the knowledge and skills needed for these tasks. The workbook listed 35 tasks and 57 knowledge and skill areas that staff might use to perform their daily activities. Supervisors specified the number of staff who perform each task. In addition, even though staff might not currently perform a task because of limitations such as work priority or budget constraints, supervisors specified how many staff members should perform each task. Supervisors further indicated how well staff perform each task and staff levels of expertise in relevant knowledge and skills. Responses from the supervisors were keyed into a spreadsheet and tabulated. The data were then examined to determine the following:
  Proportion of tasks that staff currently perform and should perform,
  Mean scores in staff's effectiveness in performing their tasks, and
  Staff level of knowledge and proficiency for skills associated with these tasks.
A previous study (2) provided baseline information on the knowledge and skill areas necessary for each task. Training opportunities were determined and prioritized by looking at the knowledge and skills needed for tasks performed least well.

RESULTS

This section presents the supervisors' views on the tasks that staff currently perform and those tasks that they should perform. It also describes staff levels of effectiveness in performing tasks. Finally, this section discusses the knowledge and skills needed to perform

The various tasks that staff currently perform and staff proficiency levels in performing these skills.

What Tasks do Staff Perform and are These all or Nearly all of the Tasks They Should Perform?

Environmental restoration tasks needed to carry out the mission of a headquarters EM organization are quite diverse (Table I). These tasks can be grouped into broad categories that range from communication activities, such as preparing and reviewing documents; to policy tasks, such as "advise, assist, and provide authoritative guidance"; to administrative activities, such as monitoring schedule constraints and managing files and records; to technical oversight tasks related to the National Environmental Policy Act, land use, and waste management.

TABLE I

The organization assessed in this project is functioning essentially as it should. Supervisors indicated that, for the most part, staff are performing the tasks that they should (Table I). Furthermore, these tasks are generally consistent with staff position descriptions and with the roles and responsibilities delineated for EM (1). Although a majority of staff currently perform all these tasks, a larger proportion of staff should be interfacing with other program elements both within and outside of the organization, conducting briefings and presentations, and planning for budget and personnel required to implement projects (Table I). In addition, more staff should be overseeing several aspects of headquarters operation: land use activities; decontamination and decommissioning; independently verifying that cleanup and decontamination activities are adequate; and checking surveillance, monitoring, and inspection activities.

How well do staff perform their current tasks?

For any organization to carry out its mission effectively, staff need to be proficient at the tasks they perform. Therefore, the project looked at how well staff accomplish these tasks as well as whether the tasks performed by most staff are also the tasks in which they are most effective. In general, those tasks that the largest proportion of staff perform are also those tasks that they perform most effectively (Table II). These include "coordinate document reviews"; "interface within and outside of DOE"; "prepare and review documents"; and "advise, assist, and provide authoritative guidance." However, four tasks that a relatively large percentage (75%) of staff should perform are performed between somewhat and sufficiently well (mean scores 2.95 to 2.74) (Table II): "establish cost, schedule, and technical baselines"; "provide analyses to determine effects of remediation projects"; "develop, coordinate, and disseminate program management policies and procedures"; and "formulate, define, and modify budget." Training would be appropriate for the underlying skills associated with these four tasks to improve proficiency because they are performed by a majority of staff.

TABLE II

What Knowledge and Skills do Staff Need to Perform Their Tasks?

For an organization to operate smoothly, staff should be proficient in all knowledge and skill areas needed to carry out the tasks they perform. A previous study determined the knowledge and skills needed for each task (2). Because the tasks that staff perform for environmental restoration are complex, the knowledge and skills needed to perform these tasks are also quite diverse (Tables III, IV, and V). Thirteen knowledge and skill areas applied to 12 or more of the 35 tasks that staff currently perform (Table III). These include knowledge of the DOE mission, keeping abreast of current developments, defining criteria applicable to solving problems, and being able to work within schedule constraints. As Table III illustrates, skills needed to carry out the majority of tasks are not technical or regulatory in nature, such as knowledge of the Resource Conservation and Recovery Act; rather, these skills are generally in the categories of problem solving and critical thinking. Table IV further supports the finding that communication skills, program management techniques, and process evaluation skills are needed to perform several tasks successfully. In contrast, several unique knowledge and skill areas are needed to carry out only a few tasks (Table V). These specialized skills include knowledge of

radiation effects, health physics issues, land use issues, and emergency response procedures. Tasks associated with these specialized knowledge and skill areas are performed by fewer staff members. Consequently, although training in these areas may be appropriate for selected staff members, it would not necessarily provide the greatest benefit to the whole organization.
TABLE III
TABLE IV
TABLE V
How Proficient are Staff in the Relevant Knowledge and Skills needed to Perform Environmental Restoration Tasks?
Once the relevant knowledge and skill areas associated with 35 tasks that staff perform were identified (2), supervisors rated staff proficiency levels for each of the 57 knowledge and skill areas needed to carry out these tasks.
In a smoothly operating organization, staff first should be proficient in the knowledge and skill areas that are needed for most tasks they carry out. Once staff are proficient in these widely applicable skills, they can be trained in skills that apply to only a few tasks. Staff proficiency levels for all skills are adequate, although not outstanding (mean scores 3.6 to 2.6 on a 4-point scale) (Table VI). Staff are proficient in several of the skills common to many tasks (Table VI). Skills common to many tasks in which staff are quite proficient include working under schedule constraints, keeping abreast of current developments, providing clear guidance and direction to accomplish tasks, and prioritizing based on criteria.
TABLE VIa
TABLE VIb
On the other hand, staff proficiency levels are only moderate for some knowledge and skill areas that are common to many tasks (Table VI). These include knowledge of the DOE mission, knowledge of DOE management strategies, the ability to write succinctly and clearly, and the ability to assess strengths and weaknesses of alternatives (Table VI). Furthermore, staff are quite knowledgeable about the National Environmental Policy Act process and waste treatment/disposal technologies even though these skills are not common to many tasks (Tables V and VI).
CONCLUSIONS
Supervisors in this headquarters office of DOE EM indicated that most of their staff perform the majority of their tasks quite effectively. Supervisors further indicated that, collectively, staff have working knowledge, although not expert understanding, of the subjects and skills associated with each task they perform.
Thus, training is suggested for the knowledge and skill areas associated with those tasks performed by most staff that are performed relatively least well. These knowledge and skill areas fall under the general categories of program and project management, critical thinking and problem solving, and communications. Program management skills include knowledge of EM's mission, DOE management strategies, and defining applicable criteria. Many of these skill areas are dynamic, so training is necessary to keep staff current.
Critical thinking and problem solving skills include examining trade-offs among alternatives, comparing existing conditions to preset standards, and assessing strengths and weaknesses of alternatives. Communication skills include the ability to write clearly and succinctly, interpersonal facility, and providing clear guidance and direction to accomplish tasks. Because these are the primary skills common to many tasks (Tables III, IV, and V), training in these areas is appropriate to help the organization continue to function effectively.
The knowledge and skill areas related to communications, problem solving, and project management have been further prioritized on the basis of the margin of improvement needed to achieve expert knowledge or highly proficient skill levels and how many times the skill is needed (Table VII). Training in the knowledge and skill areas identified in Table VII will strengthen this organization so it can better carry out its roles and responsibilities. This training will further benefit the organization by allowing staff to reach their potential and make their jobs more satisfying (3,4).
TABLE VII
Different types of training opportunities should be explored. Existing training activities should be continued, and new training programs should be developed to address the diverse skills that underlie the tasks that staff perform. Supervisors should look beyond traditional training courses to improve performance. For example,

supervisors may empower their staff by sharing opportunities usually performed by management, such as conducting briefings on projects with which staff have been greatly involved and delegating authority to staff members who are capable of performing new tasks. Job proficiency may also be improved by pairing experienced staff with less experienced staff, using in-house mentors, and encouraging short-term assignments in other organizations.

ABSTRACT

Radiological profiles have been developed by Argonne National Laboratory for low-level mixed wastes (LLMWs) that are under the management of the U.S. Department of Energy (DOE). These profiles have been used in the Office of Environmental Management Programmatic Environmental Impact Statement (EM PEIS) to support the analysis of environmental and health risks associated with the various waste management strategies. The radiological characterization of DOE LLMWs is generally inadequate and has made it difficult to develop a site- and waste-stream-dependent radiological profile for LLMWs. On the basis of the operational history of the DOE sites, a simple model was developed to generate site-dependent and waste-stream-independent radiological profiles for LLMWs. This paper briefly discusses the assumptions used in this model and the uncertainties in the results.

INTRODUCTION

The U.S. Department of Energy (DOE) Office of Environmental Management (EM) has undertaken a Programmatic Environmental Impact Statement (PEIS). This EM PEIS addresses the environmental and health risks associated with the management of DOE radioactive and hazardous wastes. The treatment, storage, and disposal (TSD) of radioactive low-level mixed wastes (LLMWs) represent a major effort in the EM PEIS. LLMWs are wastes that are both hazardous under the Resource Conservation and Recovery Act (RCRA) (Title 40, Part 261 of the Code of Federal Regulations (CFR)) and meet the definition of low-level waste (LLW) under DOE Order 5820.2A (1).

The major sources of LLMW under DOE management considered in the EM PEIS are 1) currently stored LLMWs awaiting treatment and projected generated wastes from future operations, that is, Waste Management (WM) LLMWs, and 2) Environmental Restoration (ER) wastes, which are obtained from site restoration and decontamination and decommissioning (D&D) of DOE facilities, and sent to WM for TSD. Approximately 430,000 m3 of WM LLMW are expected (inventory and future generation) through 2014. More than 2,000 waste streams of LLMW at 44 separate DOE sites are identified in the 1994 Mixed Waste Inventory Report (MWIR-2) (2). In the ER "semirestricted" alternative, it is projected that the volume of ER-derived LLMW needing treatment will be approximately 7.3 million m3 through 2030. The specific ER secondary waste streams that will be sent to WM have been described in the Automated Remedial Assessment Methodology (ARAM) database provided by Pacific Northwest Laboratory (PNL) (3,4).

To support the EM PEIS effort to determine environmental and health risks associated

with the TSD of DOE LLMW, Argonne National Laboratory has established a methodology for estimating radiological and chemical profiles for the more than 2,000 waste streams at 44 DOE sites. Radiological characterization of these waste streams given in the various DOE databases on LLMW is clearly inadequate for the stated task. The databases can, however, be useful in verifying and providing data to establish some simplifying assumptions.

LLMWs are classified into four separate radiological categories. The largest volume (>99%) is contact-handled (CH) waste, which has a surface activity of less than 200 mrem/h. Remote-handled (RH) waste has a surface dose greater than 200 mrem/h. CH wastes are treated separately from RH LLMW. The type of radiation emitted also determines LLMW classification and can affect environmental and health risks. The majority of LLMW (approximately 75%) is non-alpha waste (less than 10 nCi/g transuranic (TRU) radionuclide alpha activity). The remaining 25% of LLMW is alpha LLMW (between 10-100 nCi/g TRU alpha activity). Because of regulatory concerns, the handling and routing for treatment of all LLMW are performed separately for alpha and non-alpha wastes.

The following sections of this paper cover the procedures and assumptions used to estimate the radiological profiles for LLMW for each site and include a discussion of the uncertainties associated with these results. The estimated chemical profiles associated with LLMW are presented in another paper for this conference (5).

RADIOLOGICAL PROFILES FOR LLMW

Determination of radionuclide concentrations for LLMW is difficult because there is insufficient information in MWIR-2 or in the current Waste Management Information System (WMIS) databases to quantify the concentration of the various radionuclides. Given the current data, it is not possible to construct precise radiological profiles for each of the LLMW streams at all sites.

The operational mission(s) is primarily responsible for the radionuclides generated at each site. The presence or absence of RCRA contaminants in a waste stream distinguishes LLMW from LLW and is not very likely to affect the relative proportion of radionuclides in the waste. Given that the same mix of radionuclides tends to contaminate both LLW and LLMW at a site, it is assumed that radiological profiles for LLMW are site-dependent but waste-stream-independent. The LLMW radiological profiles developed in the EM PEIS are derived from information on the radiological content of LLW contained within the 1991 Integrated Data Base (IDB) (6).

The IDB has information, accumulated over many years, on the operational history of the larger DOE sites. This information on each site is subdivided into waste volumes, activity concentration (Ci/m3), and source of activity. Because the data have been accumulated over a number of years, they represent the cumulative result of the various DOE waste-generating activities over those years. Five major DOE programs generate distinct sources of radioactivity. These sources are 1) fission products, 2) induced activity, 3) uranium/thorium, 4) TRU alpha, and 5) tritium. The IDB data provide radiological profiles near the time of generation for each of these five operations that produced LLW (see Table I).

TABLE I

In estimating the radiological profiles for the LLMW in the EM PEIS, it has been assumed that at the time of waste generation, LLMW radiological profiles for each site are the same as those for LLW because the same operational mission(s) is responsible for generating both LLW and LLMW. Furthermore, it has been assumed that radiological profiles are the same for all waste streams at a given site. Treatment facilities for LLMW are not generally expected to be available for treatment until 2003, whereas many LLW treatment facilities are already in operation. Thus, the time interval between generation and treatment will be much greater for LLMW than for LLW. Therefore, it is much more important to account for radioactive decay for LLMW than for LLW. LLW is normally disposed of soon after generation; thus, its radiological profile at the time of disposal will not be much different from that at the time of generation. On the other hand, because the proposed treatment of LLMW is to begin in 2003, the age of the LLMW at the time of treatment will be much greater than that of LLW. Therefore, the radioactive profile of LLMW at the time of treatment will differ considerably from its profile at the time of generation.

To estimate the time interval between LLMW generation and treatment, the treatment date for all LLMW has been assumed to be 2008 (the midpoint of the proposed treatment period of 2003 through 2013). The average generation date estimates are different for different sites and for the three different waste groups, that is,

current inventory, waste projected to be generated over an ensuing 20-year period, and ER waste. The generation dates were arrived at by estimating the average date (given site history) of radionuclide generation, except for the uranium/thorium source term. For the uranium/thorium source term, the generation time is defined as the time of the most recent chemical or isotopic concentration/isolation of the material.

Thus, the principal assumptions on which LLMW radiological profiles were estimated are as follows:

At the time of waste generation, LLMW radiological profiles for each site are the same as those for LLW at the same site.

At the time of waste generation at a given site, activity concentrations (Ci/m3) are the same as those for LLW.

At the time of treatment, the radiological characteristics of LLMW will be different from those of LLW only because of the greater age of the waste.

The treatment date for all LLMW is 2008.

Radiological profiles are assumed to be independent of the waste stream category at a particular site.

The average generation date of LLMW depends on the site and on whether it comes from inventory, projected generation, or ER.

The information on LLW does not distinguish between alpha-contaminated (TRU content = 10 nCi/g-100 nCi/g) waste and non-alpha- contaminated (TRU < 10 nCi/g) waste. This analysis assumes a geometric mean of 33 nCi/g (TRU) for the alpha-contaminated LLMW and 33/20, approximately 1.7 nCi/g (TRU), for the non-alpha-contaminated LLMW. These values are equivalent to .082 (Ci)/m3 and .004 Ci/m3, respectively, in TRU activity (estimated density = 2,500 kg/m3 for the two types of waste).

For sites with gaseous diffusion plants (GDPs) or that store GDP waste, adjustments were made to the uranium/thorium source term by the addition of technetium-99 (Tc-99), which through carryover of gaseous technetium (Tc-99) fluoride in the GDP process, is present (in small amounts) in this specific waste type.

The proportional LLMW source term distribution by site and the site-dependent activity percentages for the CH LLMW (non-alpha) and CH LLMW (TRU alpha) are given in Tables II and III. These tables were derived from IDB data on the accumulated radioactivity (in curies) for LLW at each site. The tables list the activity percentages near the time of generation of the radionuclides. For major sites, the assumed average times of radionuclide generation/isolation are given in Table IV. The coupling of the appropriate waste ages, activity percentages, and source term radiological profiles will generate site-dependent radiological profiles and activity concentrations for LLMW. The individual site radiological profiles are reported in a technical support document (9). Table V lists the estimated radiological profiles for WM LLMW at the average time of treatment (2008) for a number of larger DOE sites. The methodology presented here predicts substantially different radiological profiles expected at the time of treatment for the different sites. Such a result is consistent with the widely varying programmatic missions of the different DOE sites.

TABLE II

TABLE III

TABLE IV

TABLE V

This procedure can be carried beyond the time of treatment of the waste to times of interest for disposed waste. Figure I illustrates the behavior of radioactive hazard with time for a typical DOE waste stream containing plutonium. This activity time plot was obtained by ordering radionuclides according to increasing half-life and plotting cumulative sums of their activity concentrations against time. The activity concentrations were multiplied by a weighing factor that represents the radiological risk to human health (10). This fig. illustrates as a function of time the ingrowth of americium-241 (Am-241) and later of neptunium-237 (Np-237). An example might be Rocky Flats Environmental Technology Site (RFETS). Here the projected radiological profile is dominated by plutonium-241 (Pu-241) near the time of treatment. Over a time scale of hundreds of years, the Pu-241 decays away, but the resultant Am-241 grows in to become the dominant radionuclide. In a time scale of thousands of years, the Am-241 decays and Np-237 becomes prominent. Such information is useful in

determining the environmental and health risks associated with disposed waste from RFETS.
Fig. 1.
The DOE sites included within Tables II and III contain more than 98% of the total LLMW. Each of the additional small DOE sites were approximated as being similar in radiological profile to one of the large DOE sites included within Tables II and III. Table VI shows the assumed similarities between the radiological profiles of the small and large DOE sites used in this analysis.
TABLE VI
The determination of radiological profiles for ER LLMW was hampered by incomplete radiological characterization of the waste in the ARAM data. Examination of ER-derived LLMW radionuclide concentrations indicated a similarity to the site-based radiological profiles used for the WM LLMW. For this study, the site-dependent ER LLMW radionuclide source terms were assumed to be identical to those used for WM LLMW with the following three differences. First, the mean time for generation of radionuclides in all ER wastes was assumed to be 1965. This produces a different adjustment to aging for the ER wastes compared with non-current-inventory WM LLMW at each site (see Table IV). Second, the longer time for radioactive decay and dilution of ER wastes by nonradioactive external materials, such as soil, old packaging, and groundwater, tends to lower the average concentration per unit volume of ER LLMW compared with similar WM LLMW. The ARAM database indicates that the average expected activity concentration (Ci/m3) for ER wastes is about 10% of the WM LLMW activity concentration estimate derived from IDB LLW information. Thus, the radionuclide concentration of ER LLMW is taken as one-tenth the activity concentration for equivalent WM LLMW at a given site. Finally, the ARAM database lists the ER waste at Sandia National Laboratories (New Mexico) (SNL-NM) as being contaminated with uranium. Thus, in Table V, the radiological composition of SNL-NM ER LLMW is similar to that of the Fernald Environmental Management Project (FEMP) and not that of the Savannah River Site (SRS) as shown for WM waste.
UNCERTAINTIES IN RADIOLOGICAL PROFILES
The major source of uncertainty in the radiological profiles is the lack of adequate quantitative radiological characterization of LLMW streams compiled in the MWIR-2 database. For the majority of the waste streams, radiological content is described only qualitatively. For example, a waste stream will be described as containing TRU radionuclides but identities and concentrations are not given. In other cases, the radionuclide quantities are given but are not appropriately aged and the waste generation date is unknown.
Because reliable data providing contaminant characterization of waste streams are not available, models were constructed for radiological profiles. The uncertainties in radiological profiles arise from the assumptions made in developing the profiles. Two assumptions in particular contribute to the uncertainties for radiological profiles: 1) radiological profiles depend only on the site and not on the particular waste stream and 2) total activity concentrations in LLMW streams at the time of generation are the same as those in the LLW streams.
The first assumption, namely that radiological profiles do not depend on the waste treatment category, is likely to introduce the largest errors. Because different radionuclides have different solubilities, their proportions in aqueous and organic liquids will be different than in solids and sludges. For example, the proportion of tritium (H-3) may be underestimated in liquid wastes and overestimated in solid wastes, thereby affecting H-3 estimates in air and water emissions. Variations in radiological profiles among the various solid waste streams are less important because such variations will have a much less significant impact on emissions source terms.
The second assumption is that at the time of waste generation, total activity concentrations in LLMW streams are the same as in LLW streams. It is reasonable to assume that LLMW streams are similar in radionuclide composition to LLW streams because the radionuclides present in both streams are generated by the same processes. However, the total initial activity concentration in LLMW is not necessarily the same as that in LLW. The uncertainty in the total initial activity concentrations will introduce uncertainties in total radioactivity content in emission source terms. However, the impact of this uncertainty on comparisons among the different WM alternatives will be less significant because the errors in total activity concentration estimates will tend to be in the same direction for all

alternatives.
Other assumptions pertain to the age of the LLMW, values assumed for the TRU content, and Tc-99 content of wastes from GDPs. Uncertainties introduced by these assumptions are expected to be of lesser importance than those arising from the two assumptions discussed above.

ABSTRACT
Los Alamos National Laboratory (LANL) and its subcontractors recently completed a program to conduct characterization of all low-level mixed waste (LLMW) materials in storage that were accepted into the inventory prior to current-day waste acceptance criteria implementation. Characterization review was directed not only toward RCRA compliance issues, but also addressed requirements for eventual treatment or disposal of the older, or legacy, waste inventory. Waste management records for legacy wastes were found to be inadequate for a thorough characterization of all LLMW items. Further requirements to identify packaging and treatability were imposed to assess waste disposition and prioritize waste management action. Over 6,000 individual LLMW items required RCRA-certifiable characterization. This was done most economically and expeditiously through Knowledge of Process (KOP) characterization of over 95 percent of the waste items.
An environment of staff reductions, inter-divisional transfers, and personal liability concerns proved to be a challenge to those charged with obtaining the generator's knowledge of the waste. KOP interviewers were required to use existing records together with their knowledge of LANL past and present programs and

generator or waste coordinator input to construct the proper understanding of the waste-generating process. After all this information had been compiled, a robust quality assurance process for completeness, correctness and consistency allowed for characterization of the waste. Characterization was sometimes made difficult where there was not always clear guidance from a regulatory authority. The paper presents methodology for knowledge of process characterization and shows how the results provide an understanding of LANL LLMW which meets both regulatory and waste management needs.

INTRODUCTION

This paper discusses the purpose and results of a program to characterize low-level mixed wastes (LLMWs) in storage at Los Alamos National Laboratory (the Laboratory). The program was conducted to maintain regulatory compliance and to support ongoing waste treatment and disposal activities. The characterization team conducted a characterization review of wastes stored at the Laboratory that contain both a low-level radioactive and a hazardous component. The team addressed only those wastes that were generated prior to January of 1993. The wastes which were reviewed, referred to as legacy wastes, had been generated before the implementation of comprehensive waste acceptance documentation procedures which assure regulatory compliance for more recently generated wastes. The review was performed to verify existing RCRA code assignments and was required as a component of the Laboratory's Federal Facility Compliance Agreement (FFCA). The review entailed identifying all legacy LLMW items in storage, collecting existing documentation, contacting and interviewing generators, and reviewing code assignments based upon information from knowledge of process (KOP) as allowed by RCRA. Project findings were entered into tracking and characterization databases.

The characterization team identified 7,546 legacy waste items in the current inventory, and determined that 4,200 required further RCRA characterization and documentation to satisfy the FFCA requirement. The remaining waste items had already been characterized by sampling or appropriately identified for treatment by existing or planned treatment methods. KOP characterization was successful for accurately assigning RCRA codes for all but 117 of the 4,200 items within the scope of work. Sampling and analysis requirements for complete characterization of the 117 remaining items were outlined in the project report. As a result of KOP interviews, 714 waste items were determined to be non-hazardous, while 276 were determined to be non-radioactive. Other wastes were found to be stored as suspect radioactive because of administrative requirements due to their generation in an area of incident isotope usage which was not likely to have contaminated them. Many of the suspect radioactive wastes were certified by the generators as non-radioactive and will eventually be removed from the mixed-waste inventory following radioactivity screening. Table I provides a breakdown of the Laboratory's legacy wastes.

THE PURPOSE AND BASIS OF CHARACTERIZATION

Characterization of the Laboratory's legacy LLMW was necessary not only to satisfy regulatory requirements, but also to provide important waste profile information for a rigorous schedule set forth in the FFCA to treat all LLMW in the inventory. The Laboratory's FFCA currently requires that it initiate the design of two new skid-mounted treatment processes each fiscal year through fiscal year 1997 and that it have full characterization and planned treatment for every waste item in its inventory by March, 1995. The required treatment designs can not be effectively performed without prior detailed knowledge of the nature of the waste streams involved, including much more information than the RCRA code for each waste would provide. Properties such as physical state, waste matrix, packaging, and radionuclide contamination are of critical importance when designing a safe and effective waste treatment. The capture of these types of data was an equally important task to the satisfaction of RCRA in successfully completing the characterization effort.

The diversity of waste streams encountered by the team reflects the Laboratory's mission of research and development. Much of the waste in storage was generated by such uncommon research activities as nuclear rocket propulsion, biological effects of radiation, and radioisotope power sources for space stations and medical applications. The matrix and nature of these waste streams are often such that available treatment technologies do not directly apply. Much of the characterization effort was focused on identifying similarities in the diverse inventory so that organized treatment could proceed, while maintaining distinction between truly

differing wastes. Prior to the characterization task, the Laboratory's more than 7,000 legacy LLMW had been segregated into only 23 broad treatment categories, based primarily on RCRA codes. Much more definition was required to accurately plan for waste treatment, for, as the characterization data now indicates, there are more than two hundred distinct waste streams which will require unique consideration for appropriate treatment. Fig. 1 depicts an example of characterization by RCRA code versus characterization for treatment.
Fig. 1.
RCRA Characterization
The RCRA regulations allow waste generators to apply knowledge of the hazardous characteristics of the materials in the waste and the waste generating process to determine whether the wastes are hazardous. In the case of the Laboratory, this waste characterization process consisted of reviewing existing Laboratory waste data and new process knowledge information gathered from the generator interviews. The comprehensive data were then evaluated to confirm that the Laboratory-assigned RCRA hazardous waste codes were appropriate. The process knowledge approach was chosen by the Laboratory as the most efficient means for characterization for several reasons, including:
the need to maintain personnel exposure that is required for sampling and analysis as low as reasonably achievable;
the need to keep characterization costs as low as possible; and
the notion that generator-supplied information about process wastes would be more effective than typical statistical sampling, especially when evaluating RCRA-listed properties. For example, sampling and analysis cannot distinguish between D021 characteristic and F002 chlorobenzene, which have differing treatment standards.
Characterization for Treatment
In addition to assigning RCRA hazardous waste codes, the characterization process included a compilation of the data necessary to satisfy treatment technology acceptance criteria. The questionnaires which were used to conduct the generator interviews were developed with the assistance of waste treatment design staff members at the Laboratory to provide details about packaging, complete chemical constituency, and radionuclide content. The recently developed DOE treatability coding scheme was used to segregate characterized wastes into standardized waste stream types. Process knowledge interviews also verified proper assignment of waste storage codes, and Department of Transportation (DOT) container codes to ensure safe waste storage and transportation. See Table II for a list of the types of DOE Treatability codes used by the characterization team.
RETRIEVAL AND MANAGEMENT OF INFORMATION
Hardcopy Records and Knowledge of Process Forms
Documentation for generated wastes at the Laboratory had been developed over a period of time as new regulatory and waste storage requirements became more relevant issues. Legacy wastes which were generated prior to the implementation of the comprehensive waste management system had little information available in the waste management records to support RCRA or treatability characterization. For many of wastes, generators were not required to document process knowledge nor did the waste acceptance criteria always identify all the hazardous properties of the waste. The characterization team was tasked to supplement any existing waste profile information with a standardized questionnaire, which included information such as:
complete description of the waste and its generating process;
a process flow diagram, where applicable;
chemical constituents and concentrations;
detailed packaging information, both at the primary container level and at the drum level;
radionuclide identification including activity level;
information about the area of waste generation;
physical properties of the waste including:
- physical state;
- flash point;
- pH;
- reactivity; and
- PCBs;

heavy metal identification and content; and
organic content with respect to listed halogenated and non-halogenated compounds.

Because legacy drums often contained many waste items of differing chemical, physical and radiological properties, interviews were conducted on an item basis rather than on a drum basis. Often many separate sets of characterization forms were required for one drum. Some of the legacy labpacks contained as many as 50 distinct waste items. Drums of identical wastes from the same generator were grouped together where possible into one data folder. All characterization forms and related Laboratory data were assembled into packages referred to by the team as folders. Each folder was a stand-alone document for a drum or drum group. LLMW Characterization folders were organized with new process knowledge and characterization segregated from existing Laboratory hardcopy data on the two sides of a double-sided binder. Material Safety Data Sheets (MSDSs) were also included in the files and often proved to be difficult to obtain, since many of the original suppliers had long since ceased to exist. Figure 2 outlines the organization of waste information into data folders.

Fig. 2.

Quality Assurance

The assurance of accurate and precise information was the most important criteria in the success of the characterization task. Quality assurance reviews were performed during each step of the program. The first QA/QC review was conducted after folder assembly was completed, before the folders were issued to the field team for the KOP interview. Each folder was evaluated to determine if the assembled data package was consistent and to its verify status as a stand-alone document for a drum or drum group of like wastes. Particular attention was directed toward ensuring that all available existing Laboratory documents associated with the identified waste items were present.

The second critical QA/QC review was conducted on a folder-by-folder basis following successful completion of the KOP interview. The interview forms were reviewed to verify that the level of detail was adequate to verify or legitimately modify existing Laboratory data, confirm RCRA characterization, and provide additional data in sufficient detail to meet waste treatment objectives. After it was established that the folder was complete with respect to Laboratory and Team-generated documentation, a review of the existing Laboratory data was made to compare information obtained during the KOP interview with the information contained on Laboratory documentation. In general, if inconsistencies were present, the QA/QC team verified that an explanation of the inconsistency was included in the folder. A related review was conducted of the a waste summary form which would later be used to modify electronic data pertaining to each waste item. Each data field of this form, which included all of the Laboratory's databased information for a particular item, was evaluated for consistency with the KOP interview forms and existing Laboratory data. A rationale sheet was then completed to document the reason for any modification to the electronic data.

A third critical QA/QC review was conducted following waste characterization. Waste items were characterized based on a review of all physical, chemical, and KOP information available; a waste characterization form was completed for each waste item or group of similar waste items. The form identified the RCRA hazardous waste code and the rationale for assigning the code, and also listed all Laboratory-assigned waste codes that were not properly assigned and provides an explanation. The waste characterization form also contained a DOE Mixed Waste Treatability Code assignment for each waste item and provided a rationale for that assignment. All information on the form was subject to a complete QA/QC to verify all responses. Due to the specialized expertise necessary to determine proper characterization of waste items, this review was performed by an independent member of the Characterization staff using the same review procedures employed by the QA/QC staff. Fig. 3 depicts the interview, quality assurance, and characterization loop.

Fig. 3.

Conducting the Interviews

The coordination and completion of accurate generator interviews was the most challenging aspect of the program. Over 1,500 separate interviews were necessary to complete characterization at a level consistent with the FFCA requirements. Interviewing activities were organized with the use of a tracking database and were conducted by a team of eight process- and RCRA-knowledgeable engineers. Most of the field team had prior experience with certain groups at the Laboratory from earlier tasks. The project tracking database included preliminary descriptions of waste

items, as well as information about the generating groups and locations. This information allowed for efficient coordination of interviews for many different wastes and many different generators in a short period of time. Interview assignments to team members were prioritized based upon familiarity with generators, understanding of waste streams, and specific interviewer backgrounds.
Throughout the interviewing phase, problems arose when generators perceived the necessary exchange of information as a potential for personal liability regardless of the fact that they had correctly adhered to waste management practices at the time of waste acceptance into storage. Other difficulties arose when generators had retired or moved to other facilities. The team relied heavily on the support and cooperation of Laboratory management in resolving these issues. As a result, the team was able to meet with individuals who were both familiar with wastes and willing to discuss generation details in all but the most difficult cases. A handful of drums still remains that will require sampling and analysis due to lack of generator process knowledge documentation. Most of the drums requiring sampling and analysis were insufficiently characterized because of complexities in the generating process that could not be resolved through KOP.

CHARACTERIZATION APPROACH

RCRA characterization was performed in accordance with the provisions of 40 CFR 261. Figure 4 details the process used to assign RCRA hazardous waste codes. After a complete review of all physical, chemical, process, and generator information, the Laboratory-specific waste characterization form was completed for each waste item, or group of similar wastes in each drum. The form identifies the RCRA hazardous waste code and the rationale for assigning the code. In addition, the form lists all Laboratory assigned hazardous waste codes that did not reflect waste characteristics and were properly assigned. Rationale were provided to explain why the codes did not apply to that particular waste item.

Fig. 4.

To complete characterization, each waste was evaluated to determine if it contained any regulated spent components or if it was an unused commercial chemical or spill residue. In addition, each waste was evaluated for ignitability, corrosivity, reactivity, and toxicity characteristics. MSDS sheets were helpful in many cases in providing property information for labpacks and unused materials. The team utilized RCRA-experienced chemists in determining the properties of mixtures, when necessary. The pH, flashpoint, and chemicals of concern were evaluated to identify any hazardous characteristics. Listed and characteristic codes were assigned to each waste as appropriate.

A conservative approach was applied while characterizing LLMW to ensure that all the potential waste codes were assigned. In situations where the Laboratory-assigned RCRA code could not be confirmed as correct or not, the code was left as assigned and a notation made. Due to the fact that RCRA characterization regulations and waste codes are somewhat ambiguous, EPA has developed and issued guidance materials over the years that clarify questions on various waste codes and waste management issues. The team subscribed to several guidance periodicals and solicited Laboratory policy guidance in many of the more difficult cases.

Approximately fifty percent of the RCRA hazardous waste codes originally assigned by the Laboratory were confirmed in the characterization process. Several waste streams were consistently assigned an incorrect waste code in the absence of detailed process knowledge. These waste streams are discussed in the paragraphs below. Some examples are listed below.

Many wastes had originally been assigned a D001 ignitable solid code. This code is easily assigned to liquids but it is more difficult call to assign this code to solid wastes because the wastes have to be spontaneously combustible, or create a fire upon exposure to moisture and burn so vigorously and persistently as to create a hazard. Often times this code is applied to wastes that can cause a dust explosion that flashes and burns out. According to EPA, this is not the intention of this hazardous waste code. Solid wastes that were assigned the D001 code were evaluated to determine if the code was applicable. In addition, the D001 code was applied to unused chemicals that had not been identified as DOT oxidizers.

Many legacy cylinders of gas were assigned a D002 corrosive waste code. These codes were changed based on the fact that the RCRA corrosivity characteristic is applicable only to liquid or aqueous wastes. Also, a D002 waste code was applied to solid wastes which is not the intention of the RCRA regulations, therefore the codes

were changed.
Several toxicity characteristic codes were deleted due to concentrations of the component in the waste or simply because the component was not in the waste. For example, several wastes were assigned a D009-mercury or D008-lead waste code and the Laboratory data and generator interview both noted that these contaminants were not in the waste. Frequently, wastes from analysis for heavy metals were coded with the analyte metal code, which was reversed based upon KOP. For example, a waste originally labeled as UV SPEC WASTES FROM LEAD ANALYSIS would be assumed to contain lead because of the description when it was actually just a dilute buffer solution. The waste codes were changed in these situations.
Spent solvents that were used for degreasing parts or cleaning oily or greasy equipment were identified as F001 if the solvent appeared on the F001 list. Although EPA's intention with this F001 category was to regulate solvents used in large scale degreasing operations (such as vapor cleaning), the Laboratory policy was to remain conservative and identify these wastes as F001 listed for degreasing. Wastes that were identified as F002 and were used for degreasing/cleaning parts were changed to F001 to remain consistent with Laboratory policy.
The F003 spent solvent code was incorrectly applied in several situations. This is a common area of confusion. The F003 code applies to those listed solvents only if one of the following is true: (1) the waste consists of solely an F003 listed component, (2) the waste consists of a mixture of F003 listed components, or (3) an F003 listed component is mixed with an F001, F002, F004 or F005 listed waste, or a combination of those listed wastes.
Wastes which were originally assigned solvent F-listings but were actually generated by a cooling process were changed to non-regulated or assigned an appropriate characteristic code. Cooling is not a solvent property according to EPA regulations.
In all cases, any changes in RCRA coding were documented and databased with an appropriate rationale. All of the routine errors in original RCRA coding were reported to the Laboratory waste acceptance managers to avoid the potential for similar instances in the future.

PROJECT RESULTS

Of the 7,546 legacy LLMW items in the inventory, 4,083 were RCRA and radiologically characterized by KOP at the conclusion of the project. These items were also assigned DOE treatability codes. 117 items could not be KOP-characterized due to insufficient information. The remaining items fall into other categories and will not require characterization. A significant fraction of the wastes which were reviewed by the team may be eliminated from the LLMW inventory after certification either as non-radioactive or non-hazardous. Many more unused, labpacked waste items may be re-evaluated after surface decontamination.
A preliminary sampling and analysis plan has been prepared to address the remaining legacy items. The majority of the items were RCRA-characterized by KOP but were not adequately radiologically profiled. The team has recommended varying degrees of radiological screening for these waste items, and interviews support the conclusion that most of them are surface contaminated only. Most of the RCRA-uncharacterized items are labpacked unused chemicals that will require a visual inspection to read container labels and screening to verify radioactivity data.

USING THE CHARACTERIZATION DATA

As mentioned above, the characterization task was only one element of a broad compliance effort set forth in the Laboratory's FFCA. Since completion of the characterization program, the Laboratory has continued to implement several programs which pertain to the FFCA and make use of characterization information. Many of the data from the characterization program have been captured in an electronic database, which is being made available to process engineers and waste treatment planning staff. The waste folders and all of the documentation they contain have been digitally imaged on CD-ROM and converted microfilm to provide a format which is shareable by many individuals.
The characterization information is currently being used for the conceptual and detailed design of several skid treatment processes. The feed handling systems in these designs rely on accurate packaging and matrix information from the folders. Characterization information has been provided to operators of existing treatment programs at the Laboratory. A few waste streams are currently being treated on-site including surface contaminated lead and scintillation vials. The volume and nature

of these streams was estimated prior to the development of treatment; whereas complete characterization data has now allowed detailed feed information and an inventory of all applicable wastes for these treatments.
The Laboratory is also using characterization data to store drums in the most compatible and efficient groupings. Several wastes for which RCRA coding changes were made were relocated to provide more consistency in the waste inventory. Similarly, future storage requirements are being evaluated based upon waste generation history and projections from the characterization program.
EVOLUTION OF LABORATORY WASTE MANAGEMENT
While most of the inventory of stored wastes has been addressed by KOP or other means, the continuation of environmental restoration and R&D activities suggests that the generation of LLMW will not decrease substantially in the near future. As a result of the characterization team's experience with waste generators and the historical waste management and documentation practices, the Laboratory has been able to make several improvements in maximizing the effectiveness of the waste acceptance process. Several measures have been implemented and continue to be developed to ensure that future wastes are fully documented as received and to minimize the need for characterization activities in the future.
Historically, the Laboratory's Waste Management groups have had to maintain responsibility as generator for large amounts of waste which the groups themselves did not produce. These groups have had important custodial responsibilities, but did not necessarily have much authority or control over the waste streams they receive. Much of the Los Alamos waste management structure was implemented prior to the promulgation of current waste regulations and was not prepared to follow the cradle-to-grave approach to waste stewardship. In addition, management of the waste was distributed amongst several different groups, making coordination of information difficult.
Efforts are now under way to provide a more centralized and complete tracking mechanism for generation-to-treatment waste documentation. More complete documentation is being required of waste generators, using concepts which were introduced in the characterization effort. The two databases which in the past have separately maintained storage and characterization data have been linked together to provide a more focused source for waste information. Most importantly, the Laboratory is pursuing a system to increase generator awareness and involvement in the management of their own wastes. Waste generator training has been revised to increase awareness of RCRA regulations and Laboratory policies regarding waste generation. Each waste-generating group now has a full-time waste coordinator who provides support to both the generator and the waste management groups. An interactive waste management system is being studied to allow waste generators or waste coordinators to log on to an intelligent database to characterize their waste for appropriate storage and treatment with a series of guidance questions.

Matthew G. Wiherle
Aberdeen Proving Ground
ABSTRACT
A study to characterize radioactive waste generated by tenant activities at the Aberdeen Proving Ground (APG) was conducted during the spring of 1994 for the installation's support Health Physics Office (HPO). The APG HPO was assigned responsibility for managing waste materials, coordinating disposition and providing interim storage while awaiting disposition. In order to ensure adequate interim storage, the HPO needed to characterize generation and evaluate the impacts of proposed minimization practices. This information is needed to gauge operations at the HPO's 670 square meter low level radioactive waste storage facility which will be used to temporarily store radioactive waste generated by APG tenants until the Appalachian Compact sites and builds a low level radioactive waste disposal facility.

The results show that the total annual volume of solid radioactive waste generated is 955 cubic meters (m3), of which sixty-six percent (2/3) is recyclable metal and thirty-three percent (1/3) incinerable and compactable. Only a small fraction of the waste could be classified as a mixed waste (3E-05). Depleted uranium usage is the largest single use of any radionuclide. This study also evaluated the impact of proposed waste minimization practices.

The results of the study were also used as a planning tool to develop procedures for packaging, storage and processing radioactive waste. Additionally, the findings were used to develop a inventory management system to manage and track radioactive waste stored or in processing at APG's low level radioactive waste storage facility.

INTRODUCTION

This study was conducted in order to characterize the types, form, components, quantities and generation rates of the low level radioactive waste from tenants in the Edgewood and Aberdeen Areas of Aberdeen Proving Ground (APG). Until 1989, tenants were responsible for arranging disposal of their own radioactive waste. In assuming overall responsibility for interim storage of radioactive waste generation at APG, the installation Health Physics Office (HPO) needed to establish a baseline generation rate, characterize the components of the radioactive waste stream and determine waste generation practices. The study included interviewing the tenants that use radioactive materials in order to determine the nature, type, subtypes, quantities and volumes of radioactive waste generated. The results of this study will be used by the APG HPO in order to plan future disposition of radioactive waste.

Aberdeen Proving Ground is a Test and Evaluation Command installation within the United States Army Materiel Command. The mission of the installation is to develop and test military materials and to train officers and enlisted personnel in the use and maintenance of Army equipment. The installation was established in 1917 as two separate military reservations, APG and Edgewood Arsenal. Both were consolidated into APG in 1971. APG is located in northeast Maryland, has 73,000 acres of land and water and has 59 tenant organizations. Figure 1 shows the Aberdeen Proving Ground.

METHOD

In order to effectively characterize the APG's radioactive waste, a standard form was developed for interviewing potential generators. The form requested basic information such as: types, quantities and usage rates for each radionuclide; type and form of radioactive waste generated and generation rates for each; mixed waste generation rates; segregation practices; waste minimization plans; anticipated mission changes affecting generation rates; typical container types; and storage locations. The radiation safety officer was contacted in each tenant organization to determine points of contact for generators. Each point of contact was then contacted, interviewed and generation practices discussed.

RESULTS AND DISCUSSION

Of the 59 tenants, only 11 use radioactive materials. Of the eleven tenants, a total of 29 different organizations within those tenants generate radioactive waste. The tenant name, generator name, and the activity conducted by the generator resulting in radioactive waste generation are listed in Table I, cont'd.

The type of generator activity is categorized as follows: depleted uranium munitions testing (8), laboratory research (8), radioactive commodities (6), radiological oversight (5), radiation detection instrument calibration (1) and nuclear weapon effects simulation (1). Of the twenty-nine generators only eighteen generate on a routine basis. These routine generators represent: 1) Army Research Laboratories (ARL), 2) Combat Systems Test Activity (CSTA), 3) Medical Research Institute for Chemical Defense (MRICD), 4) Army Environmental Hygiene Agency (AEHA), and 5) Edgewood Research, Development, and Engineering Center (ERDEC). A description of the type of activities generating radioactive waste follows.

Depleted Uranium Testing

ARL and CSTA conduct depleted uranium (DU) munitions testing. Depleted uranium is depleted of the natural isotopic distribution of U-235 typically found at 0.72%. The distribution of U-235 is 0.24% in DU. The other radioisotopes in DU are U-234 at 0.0054% and U-238 at 99.75%. DU munitions consist of DU incorporated into the penetrator of a projectile. Tests involve firing projectiles from small caliber as well as large caliber weapons. Tests are conducted in enclosed ranges that have air pollution controls to reduce the amount of airborne DU released to the environment from the impact of the projectiles on targets.

Material within DU test ranges becomes contaminated with DU when projectiles contact targets causing explosive debris to impact on items within the test range. Targets are the most contaminated as molten DU melts the target and becomes embedded. Airborne DU dust and debris eventually settles-out contaminating exposed surfaces. Airborne DU is filtered through a filter train consisting of roughing filters, prefilters and high efficiency particulate filters (HEPA). Larger ranges utilize baghouse upstream of the filter train to reduce filter loading. Contamination is spread throughout the interior of the range through subsequent movement of equipment and personnel. The vast majority of materials exiting the ranges are discarded as radioactive waste.

Typical material found in the range waste stream includes cotton protective clothing, wood pallets, wood used to frame x-ray film, brake screens, yawl indicators and target material. Plastic and rubber shoe covers and gloves also become contaminated. Periodically the roughing, pre and HEPA filters are changed out. The largest component is target material, which consists of metal and non-metal components. The metal stream includes hardened steel and small amounts of aluminum, titanium, copper and tungsten. The non-metal target components are glass, fiberglass, plastic, glass reinforced plastic and ceramics. In large caliber ranges the steel backstop, shot table and the interior range liner, become warped or too riddled and eventually require replacement. Testing also produces debris consisting of small pieces of wood, target material, metal, plastic, paper and glass which falls to the floor. These floor sweepings are picked up and are also disposed as radioactive waste. A liquid waste stream is produced from laundry of cotton coveralls and range decontamination. CSTA recycles their liquid radioactive waste, and until recently, ARL was releasing their liquid radioactive waste to the sanitary sewer per the Nuclear Regulatory Commission's requirements (1). Table II shows the annual volume of waste produced from ARL's and CSTA's DU testing.

Laboratory Research

Several of the MRICD, AEHA, and ERDEC generators are engaged in evaluating or analyzing the effects of toxic compounds and chemical agent on biological systems and tissues. These generators utilize in-vitro and in-vivo techniques to determine uptake, retention and excretion of radiolabeled materials. Effects of compounds on animal metabolism are also tested. Typical radionuclides used in research include H-3, C-14, P-32, S-35 and I-125.

An other AEHA generator analyzes environmental and biological samples for radioactivity. They use radionuclides such as H-3, C-14, Sr-90/Y-90, Ra-226, Uranium, Th-230, Am-241 and Cs-137 for standard preparation, analysis, sample spiking and instrument calibration.

The radioactive waste stream from laboratory generators consists of solid (mixed compactables and incinerables), liquid and other wastes. The liquid waste stream consists of liquid scintillation counting media (LSCM) and aqueous solutions. The LSCM consists of liquid scintillation cocktail, radiolabeled compounds and other organic material. Aqueous solutions consist of waste radiolabeled compounds and organic material. Tenants for the most part have switched to a non hazardous liquid scintillation cocktail solution, thus as long as the sample does not contain material considered hazardous under the Resource Conservation and Recovery Act (RCRA) (2), the LSCM is not regulated under RCRA.

Solid waste material consists of paper, cloth, plastic, glass, rubber, and wood. Of the total solid material, most is paper and plastic. Only a small portion of the solid waste stream is wood. The other waste stream consists of radioactive commodities and by products from tests conducted on small rodents.

The annual volume of radioactive waste from the laboratory generators are summarized in Table III.

Radioactive Commodities and Instrument Calibration

Radioactive commodities include those instruments and devices described in Ref. 5 found in equipment. Commodities include dials, gauges, sights, lenses, electron tubes, indicators, clocks, compasses, calibration sources, check sources and counterweights. They are also found in chemical agent detection equipment. There are eight generators that routinely utilize commodities containing radioactive material. Several of these generators use foreign radioactive commodities. Typical radionuclides include Ra-226, H-3, C-14, Am-241, Sr-90, DU and Pm-147. Generators are directed to turn in equipment if it is no longer serviceable, obsolete or otherwise usable. Test Measurement Diagnostic Equipment has a radioactive commodity

license to calibrate radiation detection equipment. As part of their calibration service they leak test detection instrument check sources and calibration sources. Leaking check and calibration sources would be turned in for disposal.
Although the rate at which commodities are turned in is sporadic, the impact of commodity volume to the installation volume is small. However, the specific activity of these commodities can be quite high, and their contribution to the installation's quantity of radioactive material for disposal can be significant.

Radiological Oversight

There are five independent tenant health physics organizations that provide oversight of generator operations conducted under their tenant license. These organizations collect and analyze smear, water, air, vegetation, soil samples and other media as necessary to ensure license conditions are being met. They also provide health physics services in addition to serving as a focal point for radioactive waste collection. Radioactive waste generation within the tenant Health Physics Offices occurs largely from analysis of samples. The waste stream consists of contaminated surgeon's gloves, planchets, sample holders and sample media, LSCM aqueous media and occasionally commodities. Excluding commodities, the combined health physics waste stream was 1.1 cubic meters per year (m3/y) for ARL, CSTA, ERDEC and MRICD.

Nuclear Effects Testing

CSTA operates a facility that simulates effects of neutron and gamma radiation from nuclear weapons on military systems and equipment. Test protocols and materials are reviewed to assure that low atomic number materials are used to the maximum extent possible thereby reducing the amount of neutron activation during tests. Facility construction was designed to maximize the amount of low atomic number materials used in construction. Use of these low atomic number materials minimizes neutron activation of components, support structures, enclosures, test pads, etc. Most of the induced radioactivity in exposed materials is short-lived. Therefore exposed materials can be stored on site for decay, reducing the volume of radioactive waste generated. Test materials resulting in long-lived radioactivity are generally returned to the experimenter if the experimenter has a radioactive material license, if not, CSTA retains possession. Quantities of radioactive waste generated from unlicensed experimenters remain low.
Tools and equipment that become activated/contaminated are reused in radiation areas. All paper, plastic, glass and small amounts of metal are placed in the same container, the annual generation rate (including outages and routine maintenance) is 0.32 m3/y.

CURRENT MINIMIZATION STRATEGIES

Tenants have been asked to segregate incinerable and compactable waste streams and maximize the use of incinerable items wherever possible. These actions will ultimately result in lowering the compactable volume and reduce interim storage requirements at APG.
Both ARL and CSTA have programs to reduce their radioactive waste generation. ARL has plans to replace wooden pallets with metal pallets. This should reduce the amount of wood to be incinerated and increase the volume of recyclable metal. ARL estimates a 90% reduction in the wood stream from 112 m3/y to 1.2 m3/y. To reduce the volume of radioactive metal, ARL plans to install a coring device that will cut most of the radioactive portion out of shot target plate. ARL is also investigating the use of abrasive materials to decontaminate targets. ARL anticipates the combination of coring and abrasives will reduce their metal waste volume by 1/3 to 2/3.
CSTA, at one time, operated a liquid abrasive unit to decontaminate target metal and cut contaminated metal from shot target. Funding for the program has been reduced and no longer operates. However CSTA's "Superbox" range is able to achieve a significant volume reduction over that of a similarly sized range. Superbox, which is located at Ford's Farm, surveys all materials in the controlled area to segregate contaminated material from uncontaminated material. Reusable material that is contaminated is marked and reused in the controlled area.

SUMMARY OF ALL WASTE STREAM TYPES

The total volume of radioactive waste generated by the tenants is illustrated in Fig. 2. Based on 1993 data and historical generation rates, APG generated 1409 m3 of radioactive waste last year. Almost half of the waste volume is metal. As discussed previously, the majority of the metal waste stream is generated by ARL and

CSTA. Most of the metal waste volume is recycled as shielding material for DOE projects.
Almost one-quarter of the annual volume is incinerable and compactable waste. This waste stream is also largely attributable to ARL's and CSTA's DU testing. Until recently, the incinerable and compactable waste stream was not segregated. With the waste reduction initiatives underway, the wood component is expected to be reduced as wood pallets are replaced with metal pallets, and compactable items are replaced with incinerable items.
The figure also shows that approximately one-third of the volume, 454 m3 is liquid waste. Most (99.9%) of the low level aqueous radioactive liquid waste volume is attributed to decontamination operations at ARL's Range 9 and Range 14. The ARL liquid volume consists of DU in solution with detergent soaps and water. Of the remaining liquid radioactive waste volume (0.04%), most is attributed to generation located from the Edgewood Area tenants. This non-range volume contains mostly H-3, C-14 in solution with LSCM or in solution with aqueous material such as waste animal fluids and other dilute laboratory chemicals.
Excluding the liquid radioactive waste stream volume from the total volume, leaves an annual solid waste volume of 955 m3/y. Of that total, 591 m3 is metal waste (62%), 334 m3 is incinerable and compactable (34%), and 30 m3 of other radioactive waste types. The vast majority of the metal is recyclable and at least half of the commingled compactable and incinerable stream is incinerable.
Figure 3 presents the contribution to the solid waste stream by tenant. As the figure shows, ARL's and CSTA's DU testing dominates the solid waste stream, where as the other generators contribute only a small fraction.
Place Figure 3 here.

MIXED WASTE SUMMARY

APG does not generate a significant quantity of mixed waste. However, the potential for generating a mixed waste does exist, given the types and nature of the that use hazardous and radioactive materials. At this time no mixed waste is generated on a routine or reoccurring basis.

CONCLUSIONS

This study summarizes the results from interviews of 29 generators at APG that generate radioactive waste. Of the 29, only 18 generate waste on a routine basis. The tenants that routinely generate radioactive waste are ARL (7), CSTA (4), MRICD (4), AEHA (2) and ERDEC (1). These generators produce over 1409 m3 of radioactive waste per year.
Of the annual volume routinely produced, 99.7% of the waste volume is produced by CSTA and ARL. Greater than 95% of the annual volume is produced by ARL's Range 9 and 14 and CSTA's Superbox and Bomb Throwing Device. Both of these tenants are engaged in DU penetrator testing, hence the principal radionuclides present in the waste are U-238, U-235, U-234 and progeny. The remaining 0.3% of the radioactive waste (approximately 3.7 m3/y) is produced by Edgewood tenants (MRICD, AEHA and ERDEC) which produce laboratory wastes. The principal radionuclides in these lab wastes are H-3 and C-14.
Excluding radioactive commodities, the radioactivity in the APG waste stream averages 3-4 Curies per year (approximately 100 to 150 billion Becquerels (Bq)). A relatively small fraction of the waste volume (less than the Edgewood generation rate) results from turn-in of commodities from domestic and foreign ordnance. In comparison to the average APG radioactive content, the quantity of radioactive material in a single commodity (which ranges from several million Bq to several hundred billion Bq) could exceed the average radioactivity in the combined volume of all waste streams generated at APG.

50-4
SUCCESSFUL CHARACTERIZATION OF RADIOACTIVE WASTE AT THE SAVANNAH RIVER SITE

Michael B. Hughes
Westinghouse Savannah River Company
G. Maxcine Miles
U. S. Department of Energy

ABSTRACT

Characterization of the low-level radioactive waste generated by forty five independent operating facilities at The Savannah River Site (SRS) experienced a slow start. However, the site effectively accelerated waste characterization based on findings of an independent assessment that recommended several changes to the existing process. The new approach included the development of a generic waste characterization protocol and methodology and the formation of a technical board to approve waste characterization. As a result, consistent, detailed characterization of waste streams from SRS facilities was achieved in six months.

SITE DESCRIPTION AND PROCESS OPERATIONS

Construction of SRS was begun by the United States Government in 1950. The site is owned and operated by the U. S. Department of Energy. Certain daily activities are carried out by managing and operating contractors, including the Westinghouse Savannah River Company (WSRC). Historically, the primary purpose of the SRS was to produce special nuclear materials, primarily plutonium and tritium. The process operations at SRS can be divided into three main categories. Raw materials such as uranium and lithium were processed into fuel and target assemblies in a fabrication facility. Next, fuel and targets were loaded into nuclear reactors where the fuel was used to bombard the targets with neutrons. This produced the desired products, including tritium and plutonium. Lastly, the products were separated and purified in chemical separations areas and then distributed to other areas for further processing or to end users as applicable. This process produced high-level radioactive waste products which are stored in underground tanks for future processing and subsequent shipment to a federal repository for permanent disposal. The recent change in the mission of SRS has shifted most operations to a fourth category, that of waste management and environmental restoration. Accordingly, increased emphasis on the management of this part of the mission has resulted in changes in the way SRS dispositions radioactive waste.

SRS Conversion from Shallow Land Burial to Concrete Vaults

In September 1988, DOE issued DOE Order 5820.2A, "Radioactive Waste Management"(1). This Order established new performance objectives for disposal of low-level radioactive waste. The Savannah River Site realized current practices of shallow land burial would no longer be acceptable because this practice could not meet the performance objectives. Prior to this time, guidance had been received from DOE Headquarters which suggested disposal practices move toward separation (isolation) from the land. At the time the guidance was received, SRS was planning for the expansion of its current disposal practices. SRS took the guidance from DOE Headquarters and a decision was reached that the expansion would be to build concrete strong vaults that met the performance objectives of the Order. These vaults are currently operational and are referred to as the E-Area Vaults.

Chapter III of the Order details policy and requirements for management of low-level waste and mixed waste (containing both radioactivity and RCRA hazardous constituents). In Chapter III, a hierarchy of requirements are laid out to ensure protection of public health and the environment. First, four performance objectives, that must be met by all waste management operations are listed. Then, for waste disposal facilities, a radiological performance assessment (PA) is required. The purpose of the PA is to demonstrate reasonable assurance that the performance objectives will be met over a span of 10,000 years or more. A Peer Review Panel (PRP) was established to ensure technical quality and consistency in the development of PAs (2, 3). Waste Acceptance Criteria (WAC) are required to be developed for each storage treatment and disposal facility. For disposal facilities, results of the

performance assessment are key inputs into the development of the WAC. Finally, waste characterization and certification are required to ensure that the waste accepted for disposal comply with the disposal facility WAC.

The Performance Assessment and Waste Acceptance Criteria at SRS

The SRS E-Area Vaults for the disposal of low-level waste was the first new facility in the DOE complex to be required to prepare and maintain a PA. The performance assessment primarily utilizes a geo-hydrological modeling process to estimate the long term environmental effect of radioisotopes disposed of in the vaults.

The performance assessment radioisotopes and their estimated concentrations that maintain long term compliance with the Order performance objectives are entered into the E-Area Vaults Waste Acceptance Criteria. In addition to the Order requirements there are also site safety analyses that establish radioisotope limits that cannot be exceeded during operational circumstances and are also entered into the WAC. In combination, then, these comprise the radioisotopes that must be characterized and the detail required for characterization by generators who send low level waste to the vaults for disposal.

These characterization requirements are documented in the SRS Waste Acceptance Criteria Manual (4) and proceduralize how SRS will comply with DOE Order 5820.2A. In 1993 the process to approve the certification programs for the 45 facilities at SRS that generate low-level waste commenced. Radioisotopic waste characterization proved to be an obstacle early on and resulted in only 3 of the 45 waste generators being certified in the first 15 months of the program.

INITIAL UNSUCCESSFUL CHARACTERIZATION EFFORTS AND LESSONS LEARNED

In the beginning, the E-Area Vaults Waste Acceptance Criteria were developed with an emphasis on all radioisotopes that were possibly important in the Performance Assessment for the Vaults, even though some of these isotopes could not be measured in the waste streams in any statistically defensible way. The then-existing certification process took the criteria and interpreted it to mean that all of these radioisotopes were important, so they all had to be measured. Concurrently, the term "process knowledge" was perceived by the waste generators as something the certification process deemed unreliable because of the importance of isotopes to the PA and would therefore not be accepted. The result of all of this was that a technical debate on characterization became established between the waste generators, the disposal facility and the certifying organization and became an impediment to the certification process. An assessment by senior waste management program and engineering managers determined that a fresh start was needed that incorporated the lessons learned in this protracted first phase. Specifically, focus on Order requirements, establish "technical" guidelines for characterization methodology at SRS to set the standard for assessments, develop a site model for radioisotopic characterization that waste generators could use as an example and compare the SRS program to commercial and other DOE sites.

CHANGE IN WASTE CHARACTERIZATION STRATEGY

These lessons learned were addressed at a site level by commissioning an independent task force to identify those necessary efforts needed to bring the Savannah River Site into compliance with the waste certification requirements of the DOE Order. The task force was led by senior executives with experience across several environmental, industrial and technical business areas. Members of the task force were drawn from SRS low-level waste generators, commercial technical consultants and internal assessment organizations.

The task force concluded early on that an impediment to waste certification had been the lack of an established and accepted method to characterize the radioisotopic constituents in low-level waste. Accordingly, it was decided that the task force should develop this methodology, apply it to sufficiently complex test cases and utilize the process as the preferred process for characterizing waste as a part of the certification program. The characterization plans developed by the task force would then serve as models for SRS waste generators and would establish the standard against which waste certification assessments could be performed.

The characterization plans were developed using a logic base that included consideration of the risk of exceeding the E-Area Vaults limits for specific radioisotopes. The underpinning of this characterization methodology lies in the ability to develop technical arguments that provide reasonable assurance that low-level waste is characterized with sufficient accuracy to permit proper segregation, treatment, and disposal as required by the specific Treatment, Storage

and Disposal (TSD) facility. Combining the above considerations into a rational approach, the task force developed a waste characterization strategy, which is shown in Fig. 1.
Fig. 1.
This strategy was applied to two separate waste generator situations and example characterization plans were produced over a period of two months. The process served as a high level forum to resolve complex issues associated with waste characterization and also provided comprehensively documented characterization packages that were made available to the SRS waste generators as standards. The two example facilities were chosen to represent the spectrum of SRS waste generators. One generator had extensive historical process knowledge that included criticality analyses, solubility studies, chemical partitioning of process solutions and health and physics radiometric surveys. This facility also had multiple radioisotopes and complex process chemistry. The other facility had rather straightforward process chemistry and simple radioisotopics but, due to the purity of their product, had very low amounts of radioactivity in their waste such that special characterization strategies were required. In the course of developing the two example plans, it became clear that the generators and TSD organizations would benefit from a better understanding of chemical and radiometric analysis principles that would assist in what could be expected from analytical laboratories. The task force also provided guidance in this area (5).

THE SRS WASTE CHARACTERIZATION BOARD

The institutionalization of the task force strategy is embodied in the Waste Characterization Board (WCB), which is functionally within the Waste Certification organization. The Board is composed of 10 voting members appointed by the Solid Waste Management Department (SWMD) manager and selected from various WSRC organizations such as laboratories, waste management, environmental compliance and the operating divisions. Members of the Board are senior level scientists or engineers and possess a knowledge of chemistry, radiochemistry, RCRA regulations as well as a knowledge of SRS conduct of operations and work practices. There are also two independent consultants who are voting members. The Board reviews and approves the SRS waste generator's characterization plans and associated documentation. In this way a consistency of approach and methodology is achieved for the characterization of the hundreds of waste streams at SRS.

The Board review is first step in the waste certification process. The waste characterization plan review typically consists of technical documents prepared and defended by the facilities' engineering or technical staff in conjunction with that division's regulatory programs branch. This group develops the characterization outline, the characterization plan, any sampling and analysis plans needed and the necessary documentation of the radioisotopic distribution baseline. These plans are developed in conjunction with the Solid Waste Management group who provides technical support and consultation to the waste generators on what the essential plan elements are that the Board will require. The key elements of the characterization plan are the following:

1. A brief description of the facility and the processes that generate waste.
2. The rational used to identify, separate and segregate the various waste streams.
3. A description of the physical forms, the radionuclide content and isotopic distribution in the waste.
4. Information on the content of, or methods of exclusion of, hazardous materials.
5. Details of the strategy used for routine curie calculations.
6. A description of the methods used to accurately determine, document and periodically validate the physical, chemical and radiological properties of the waste streams.

In the event a generator uses a characterization strategy that involves sampling for initial characterization or verification of process knowledge, the generator is expected to provide a sampling and analysis plan. The plan details the following:

7. The objectives of the sampling.
8. The rationale for the locations and numbers of samples.
9. The justification for the samples representative nature.
10. The methods of collection.
11. The analyses to be conducted.

The members of the Board receive the waste characterization plan from the generator facility technical staff for formal review of the plan in an open session. During

this session the facility engineering support or technical staff appear before the Board to defend the waste characterization plan elements and address any technical concerns raised by the Board. This is in effect a technical "oral board" process during which a majority of the board members must be convinced of the viability of the waste characterization. The generator's waste characterization plans can be disapproved, approved, or approved with action items which are then tracked to closure before actual certification of their program can occur.

RESULTING ENHANCEMENTS AND FUTURE PROGRAM DIRECTION

This strategy for accomplishing waste characterization has proved to be very successful at SRS. During the first six months, the Board approved 45 waste characterization plans representing over 100 individual waste streams. Most of the plans were approved during their first formal appearance before the board; some required multiple appearances before the board before the plans achieved approved status. This has had the effect of front end loading the overall waste certification process and eliminated some of the false starts that were present in previous efforts and has resulted in estimated overall cost savings to the site of $250,000. It has had the additional effect of dropping the cost of an individual waste certification assessment by 10-15 percent.

In addition to its specified role, the Board expanded as an advisory group for SRS waste management policies, due to its acquired expertise both in the function as an approval authority and as the repository of the site's collective waste characterization strategies. The Board has been asked to evaluate soil characterization strategies, facility operations designed to separate transuranic and hazardous waste and project strategies for SRS waste treatment and disposal facilities not yet operational.

Future waste characterization programs at SRS involve the disposition to the Waste Isolation Pilot Plant (WIPP) of transuranic waste currently in storage and the certification of SRS waste generations to use the Consolidated Incinerator Facility (CIF), which is scheduled to begin operations in late 1995.

ABSTRACT

Twenty-three of the 177 high-level waste storage tanks at the Hanford Site in southeastern Washington are being watched closely because of the possibility that flammable gas mixtures may be produced from the mixed wastes contained in the storage tanks. One tank in particular, Tank 241-SY-101 (Tank 101-SY), has exhibited episodic releases of flammable gas mixtures since its final filling in the late 1970's. It has been postulated that the organic compounds present in the waste may be precursors to the production of hydrogen. Six samples of core segments from Tank 101-SY, obtained during the window E core sampling, have been analyzed for organic

constituents using derivatization gas chromatography/mass spectrometry (GC/MS), liquid chromatography (LC), and LC/MS. Four of the samples were from the upper region, or convective layer, of the tank and two were from the lower, nonconvective layer. The combined techniques of derivatization GC/MS and LC have accounted for approximately 73 to 93% of the total organic carbon (TOC) depending on the sample.

INTRODUCTION

Large quantities of EDTA and HEDTA (at least 240 and 1500 tons, respectively) have been used in defense related activities at the Hanford site in southeastern Washington State (1). These chelators are now part of the complex mixed wastes found in large storage tanks at Hanford. Mixed waste is defined as waste containing both hazardous chemicals and radionuclides. The chelators form water-soluble complexes with most heavy metals, thereby enhancing the migration of heavy metals in soils. For example, studies at Oak Ridge National Laboratory demonstrated that EDTA caused the low-level migration of 60Co from intermediate-level liquid waste disposal pits and trenches (2). Another study at the Maxey Flats commercial low level waste disposal site revealed that Pu-EDTA and 60Co-EDTA migrated (3). In addition, after approximately 40 years of storage under radiolysis and favorable conditions for chemical degradation, other chelator fragments may have formed with equivalent or more complexing capability than the starting materials. Recent studies with simulated wastes indicate that chelator degradation is, in fact, quite vigorous (4,5). As a result, the presence of chelators is an important consideration when handling and storing mixed wastes.

Of the 177 high-level waste storage tanks at Hanford, approximately 23 tanks are being watched closely because of the possibility that flammable gas mixtures will be produced from the mixed waste contained in the storage tanks. One tank in particular, Tank 241-SY-101, has exhibited episodic releases of flammable gas mixtures since its initial filling in the late 1970's. Studies of simulated waste mixtures (SWM) have indicated that the gas generation and retention are influenced by chelator concentration. It was postulated that the chelators form hydrophobic surfaces on solids in the SWM. These hydrophobic surfaces are more conducive to bubble attachment, which leads to flotation of the solids and eventually crust formation (6). The presence of chelators becomes very important for the understanding of crust formation and gas release. In addition, among the degradation products of the chelators are a number of small organic acids, some of which may be linked to the production of flammable gases such as hydrogen.

There are no accepted methodologies for the analysis of chelators, chelator fragments, and low molecular weight acids (LMWAA) in radioactive mixed hazardous wastes. As a result, methods have been developed to analyze these organics in tank wastes. The chelators represent a class of compounds whose polarity and non-volatility preclude direct analysis by GC/MS; therefore, chemical derivatization is required. Toste et al. (7,8) used boron trifluoride/methanol for the analysis of organics in radioactive wastes. An LC method was developed to analyze LMWA. In addition, thermospray LC/MS was used to confirm the identification of LMWA (9). Waste from Tank 101-SY was analyzed using derivatization (boron trifluoride/methanol) gas chromatography/mass spectrometry (GC/MS), liquid chromatography (LC), and liquid chromatography/mass spectrometry (LC/MS) (10-12).

EXPERIMENTAL

Waste Sample

The waste sample represented a composite of several segments of actual waste obtained by core drilling the waste in Tank 101-SY. This material was highly radioactive, contained a high concentration of nitrate and nitrite, and the OH- concentration was 2M. A 5-g aliquot of the waste sample was weighed and then stirred with 10 mL of doubly-distilled water overnight. The aqueous phase was filtered through a 0.45 m filter. The filtrate was then passed through a cation exchange column (10 g, AG50W-X8 resin), rinsed using an additional 10 mL of water to quantitatively remove the organic carboxylates from the resin. The resulting sample volume was 20 mL. After surveying the samples for radioactivity levels, the aqueous solution containing the organics was removed from the hot cell facilities. Aliquots (2 mL) of the sample were transferred to Teflon-sealed vials, evaporated to dryness using nitrogen blow down techniques, and derivatized with 2 mL of BF3/methanol. The sample was heated to 100C for one hour. The sample was then hydrolyzed with a KH2PO4 solution and extracted with chloroform. The chloroform extract was then analyzed by GC/MS.

GC/MS Conditions

The instrument was equipped with a HP 5980 GC and a HP 5988 mass spectrometer operated in the splitless mode. A fused silica column (DB-5, 30m X 0.25 mm i.d., 0.25 mm film thickness, J & W Scientific) was used. The oven temperature was typically programmed in the following manner: 50C for 1 min, 8C/min to 300C, and hold at 300C for 5 min. The mass spectrometer was tuned daily with perfluorotributylamine (PFTBA). In these studies, the mass spectrometer was scanned from 50-500 amu and operated in the electron impact mode (70 eV). The source temperature was 200C, the injector port temperature was 250C, and the interfaces were also at 250C.

Chemical ionization was carried out with both methane and isobutane in both positive ion and negative ion chemical ionization modes. The temperature of the source for positive ion chemical ionization mass spectrometry was 200C and 120C for negative ion chemical ionization. The mass spectrometer was scanned from 100-600 amu in the negative ion mode and 70-500 in the positive ion mode.

LC

Anion exchange chromatography was performed with a model 510 solvent delivery pump, a model 712 WISP autosampler, and a model 484 variable wavelength UV absorption detector (Waters Associates, Milford, MA). The column was an Ion Pac A54A (250 mm x 4.0 mm) equipped with an Ion Pac AG4A guard column (50 mm x 4.0 mm) (Dionex, Sunnyvale, CA). The chromatographic data were collected and processed by Maxima 820, v3.02, software (Dynamic Solutions, Ventura, CA) on a model APC IV NEC computer (NEC, Foxbourough, MA). The mobile phase was 1.3 mM NaHCO3 and 1.4 mM NaCO3 at a flow rate of 2 mL/min. Detection was accomplished at 210 nm. The sample volume injected for analysis was 10 mL.

Ion exclusion chromatography was performed on a model 1090 high performance liquid chromatograph equipped with a diode array detector, and a data collection system (Hewlett-Packard, Palo Alto, CA). The column was an IC-PAK 50 , 300 x 7.8 mm, 7 mm, equipped with a guard column (Waters Associates). The mobile phase was 0.01 N H2SO4 at a flow rate of 0.6 mL/min. Detection was accomplished at 210 nm. The typical sample volume injection was 20 mL.

LC/MS

The thermospray analyses were performed using the HP 5988A LC/MS in the isocratic mode. The ion source was 275C and the stem initial temperature was 100C. Typical values for the tip and the vapor were 230C and 272C, respectively. Filament operation was in both the on-and-off modes. The multiplier voltage was 2692 V and the scan range was either 79-500 or 92-300 amu, depending on the mixtures being analyzed. The injection volume was either 10 mL or 20 mL, depending on the concentration of the sample.

The instrument was tuned with polyethylene glycol (PEG) tuning solution to give maximum abundance of ions. It should be noted that the thermospray ion source should be cleaned approximately once a week to remove nonvolatile chloride salts resulting from the use of HCl as the mobile phase. Also, since HCl possesses corrosive effects on metal surfaces, water was flushed through both the HPLC and thermospray system at the end of the day. As long as these cleaning and flushing procedures were followed, no detrimental effects of the thermospray or chromatographic equipment were observed.

Preparation of Deuterated-EDTA

Synthesis of this material was accomplished by the method of Vnylos (13), using d4-ethylenediamine purchased from Isotech (Miamisburg, Ohio) and sodium chloroacetate.

Recovery Study on 101-SY Matrix

An aliquot of 101-SY matrix was spiked with chelators and key chelator-related fragments in concentrations 3-5 fold above that found in initial analysis of the sample matrix. Additionally, a sample of the unspiked matrix was derivatized at the same time so that the contributions of these materials native to the matrix could be conveniently subtracted from the spiked samples. The design of this experiment was to determine the effect of the matrix on consumption of the derivatizing agent or other interference with the conversion of chelator acids to methyl esters.

RESULTS AND DISCUSSION

Six samples of core segments from Tank 101-SY, obtained during the window E core sampling, have been analyzed for organic constituents. Four of the samples were from the upper region, or convective layer, of the tank and two were from the lower,

nonconvective layer.
Values for total organic carbon (TOC) ranged from 1.0-1.4%; this range is consistent with TOC data obtained from other sub-samples of core segment composites. Among the samples analyzed, the bottom of the nonconvective layer has the highest TOC value. The combined techniques of derivatization GC/MS and LC have accounted for 73-93% of the TOC depending on the sample. Table I summarizes the data for LMWA, chelators, and chelator fragments. These component types constitute the majority of the carbon accounted for.
TABLE I
Chelators, chelator fragments, and several carboxylic acids have been quantitated in the current samples using derivatization GC/MS. The major components detected were EDTA, nitroso-iminodiacetic acid (NIDA), NTA, citric acid (CA), succinic acid (SA), and ethylenediaminetriacetic acid (ED3A). The chelator of highest concentration was EDTA in all six samples analyzed. The amount of organic carbon accounted for by derivatization GC/MS varies from 20-52% of the TOC depending on the sample. Preliminary results indicate the chelators and chelator fragments constitute more of the organic carbon in the convective than the nonconvective layer.
Liquid chromatography has been used to quantitate LMWA (oxalic, formic, glycolic, and acetic acids, which are present in the waste as acid salts). Approximately 23-61% of the TOC is accounted for by these acids. Oxalic acid constitutes approximately 40% of the TOC in the nonconvective layer samples. The concentration of oxalate in the nonconvective layer is approximately 3-4 times higher than the convective layer. The nonconvective layer sample from the lowest layer has the highest percentage of water-soluble organic carbon as low molecular weight acids. Previous work with 101-SY composite samples has identified normal paraffin hydrocarbons (NPH) as components of the water-insoluble portion of the 101-SY TOC. The NPH fraction was isolated by extracting the sample with methylene chloride. Analysis of the methylene chloride extracts by GC/MS indicated that this material accounts for an additional 4-13% of the TOC of the samples.
The elemental compositions of twenty-five components in the derivatization GC/MS total ion chromatogram have been determined using high resolution mass spectrometry (HRMS). Several nitroso compounds have been unambiguously identified. However, the nitroso compounds may be formed during the derivatization procedure; they have not yet been found by methods that do not involve acidic conditions of derivatization or separation. Thermospray LC/MS has been used to identify of many of the small organic acids including citric, acetic, formic, and glycolic. Several components in both the LC and LC/MS chromatograms are unidentified.
Nitroso compounds have been identified by GC/MS after derivatization of the waste extracts with boron trifluoride. The reaction of iminodiacetic acid (IDA) spiked in a dried, simulated waste sample containing nitrate, nitrite, and hydroxide with boron trifluoride/methanol produces NIDA as the major product. These results demonstrate that IDA, if present in the original waste, is probably a precursor for the production of NIDA during the boron trifluoride/ methanol derivatization. Under derivatization conditions, NIDA is stable. A probable precursor for two other nitroso compounds found in the derivatization product is ED3A. The question remains whether nitroso compounds are present in the original waste. A procedure for direct analysis of the waste samples for nitroso compounds by LC/MS under basic conditions that do not involve derivatization was developed. Using a mobile phase of NH_4CO_3 at pH approximately 10.5, a sample of real waste was analyzed. The mass spectrum of a major component and a standard of IDA were identical. The major ions observed included m/z 134 $(M + H)^+$ and m/z 151 $(M + NH_4^+)^+$. These results indicate the nitroso compounds were artifacts of the derivatization procedure and formed under the acidic analysis conditions.
Deuterated Chelator Probes
Deuterated chelators and/or chelator fragments have many distinct advantages over the introduction of other organic acid materials that might be used as yield probes. The methylation chemistry should be identical with that of the ordinary chelator found within the matrix, thus giving a direct measure of the efficiency of the methylation process for that particular chelator. If the labeled material is not subject to deuterium-exchange processes with the highly basic matrix, then the deuterated material can be used as a tracer; added at any point in the process, the probe acts as a monitor for loss of that material during any set of steps. The major criteria for use of these materials involves 1) deuterium stability, 2) well-defined

amount/response ratios in quantitation, and 3) MS resolution for analysis of particular fragment ions. Unfortunately, the deuterated compounds either co-elute or overlap the parent unlabeled material to some degree, necessitating ion selective monitoring by MS in order to utilize their benefits.
D4-succinic acid was purchased for initial trials. This material was found to withstand deuterium exchange if added directly to the highly basic Tank 101-SY matrix and derivatized immediately. Deuterium exchange on carbons alpha to carbonyl functions is expected to take place upon prolonged contact with base; thus d4-succinic acid is likely to suffer from some exchange during contact with the matrix. No apparent hydrogen/deuterium exchange was observed in our initial experiments, which was somewhat surprising.
A better probe would not possess exchangeable deuteriums, and an attempt was made to obtain labeled EDTA with the deuteriums on the N-N' bridge carbons. This material was not readily available commercially, and quotes from a manufacturer of labeled materials indicated that purchase would be prohibitively expensive. Methylation using BF3/methanol and subsequent GC/MS analysis indicated that the material was essentially free from chelator-type byproducts; a trace of the corresponding ED3A methyl ester was detected. High resolution MS performed with the JEOL High Resolution tandem mass spectrometer confirmed the expected deuterium content of this material. Fragment ions were observed at m/z 293, 192, 176, and 148. The structure of methyl ester of deuterated-EDTA is shown below.
Eq.
In general, the recovery was shown to be nearly quantitative; with the exception of HEDTA, which has been shown through prior work by Toste et al. (14) to undergo only partial conversion to a volatile derivative. Recovery data is shown in Table II. In addition, the use of smaller sample sizes resulted in higher recoveries.
TABLE II
Since derivatization GC/MS is time consuming and costly, other methods for direct analysis of waste are being evaluated, such as electrospray MS, atmospheric pressure chemical ionization MS, and capillary electrophoresis.

ABSTRACT

Temporary storage, transportation and final disposal of radioactive waste containers have to meet certain requirements of governmental regulations, one of which is the specification of the radionuclide inventory. In this respect a need emerges to thoroughly examine the containers' contents. This can either be achieved by destructive or non-destructive assay methods such as gamma scanning or tomography. Since destructive methods require reopening of the containers and also time consuming drilling within their contents the non-destructive analysis is generally the more preferred method. This paper describes an accurate gamma ray assay method allowing to identify all detectable radioisotopes present in Low-Level-Waste-drums (LLW) and to quantitatively determine their activity. The analysis is performed by applying a combined transmission and emission tomography technique. The paper gives a comprehensive insight of this tomographic assay procedure and describes the tomography assembly, which is extensively in operation at the KFA. Actual measurements on real LLW-drums are a special subject of the paper, and additionally, reconstructed images of the density and activity distribution of the drums' contents are included.

INTRODUCTION

The characterization and disposal of nuclear wastes is a problem of national and international importance. Governmental regulations have made it necessary to certify radioactive wastes in compliance with reliable assay techniques. The technique of segmented gamma scanning is currently the most important NDA-system (Non-Destructive Assay) to determine the radioactivity contained in large volume drums. In the case of a homogeneous waste matrix with densities between 0.1 and 3.0 g/cm3 the determination of the specific and total activity is fairly straight-forward. However, because the calculated activity is strongly dependent on the absorption characteristics of the waste matrix one or more correction factors must be included if inhomogeneous structures are present (1). A better estimation of the activity can be achieved by applying tomography techniques.

This paper exclusively focuses on 200 liter drums containing Low-Level-Waste with a maximum surface dose rate of 2 mSv/h. The radioactive waste in the drum is often compacted or cemented. If a cemented matrix of relatively high density is used to condition the waste, a considerable fraction of the inner radiation is absorbed in the drum itself. This has to be taken into account in an effort to obtain reliable results using the technique of emission tomography to quantitatively determine the specific and total activity of the waste drum. The analysis becomes even more difficult if the activity and the density of the material are distributed inhomogeneously within the drum, or if e.g. the drum contains canisters of unknown kind, number and size. The preliminary objective is the measurement of the density distribution of shielded structures and heterogeneous fillings inside nuclear waste

drums by using a transmission tomographic method, followed by the analysis of the activity distribution of the radionuclides contained in the drum by applying the technique of emission tomography.

TRANSMISSION TOMOGRAPHY

The aim of Transmission Computerized Tomography (TCT) is the determination of the density distribution of the waste drum by attenuation measurements. The general physics of TCT and its necessary components are quite elementary: the intensity of a gamma beam radiated by an external source and attenuated by the object (waste drum) is measured at various positions of the object. The drum is turned to various angle positions ranging from 0 to 180 and moved linearly through the gamma beam by a stepping motion. The attenuation data is taken at each single step. The source emits gamma rays from the decay of a radioactive isotope, such as 60Co. Typically, a high activity source is used to reduce the measuring time necessary for each drum position. Because of the fact, that an external source is required TCT is termed to be an active method. Knowing the count rate I0 of the detector of an unperturbed gamma beam, the waste drum's attenuation through a distance L can be deduced from the formula:

$I/I0 = \exp(-L)$

where I is the count rate measured at a particular drum position. Each detector reading represents a single data line for the waste drum. As the drum is moved these lines form a complex matrix of overlapping data. The work is then left to a computer reconstruction program which, in this case, iteratively constructs an image of the observed cross section of the drum by matching the plethora of measured data. The reconstruction technique, applied here, uses an ART-algorithm (Algebraic Reconstruction Technique) (2).

EMISSION TOMOGRAPHY

The aim of Emission Computerized Tomography (ECT) is the determination of the activity distribution of the radioisotopes contained in the waste drum by applying emission measurements. The radiation of various gamma sources located inside the drum is monitored by a detector at different drum positions. An external gamma source is, therefore, not required (passive method). The drum is moved in the same way as described in the transmission case, however, with angle positions ranging from 0 to 360. In general, the inner attenuation of the emitted radiation of the nuclides contained in the drum can not be neglected. For this reason the attenuation coefficients obtained from the transmission measurements are applied to correct the emission data. The sources inside the drum consist of a great variety of radioisotopes emitting gamma rays at numerous energy levels. The transmission analysis using the 60Co-source, however, is carried out at one of the two well-defined energy peaks of 60Co, preferably the upper peak at 1.332 MeV. Due to the fact, that the attenuation coefficients are strongly energy dependent the reconstruction software requires a well-fitted approximation of the energy-attenuation-relationship in terms of mathematical equations. The attenuation coefficients of various materials at different energies can be taken from literature tables (3). The reconstruction software uses a special density corrected ART-algorithm.

TOMOGRAPHY ASSEMBLY

The setup of the tomography assembly is of the translation-rotational type. The drum is positioned onto a turn table, which itself is mounted onto a linear moving bench. Both axes (rotational and translational) are driven by stepping motors, which are powered by two PC-controlled power drives. The stepping resolution of 1000 steps per revolution ensures exact positioning of the drum, which is necessary in TCT and ECT applications. Due to the high density of the cement filling a strong gamma source of 260 GBq 60Co (7 Ci) was installed as the external source within the tomography assembly. To keep radiation low for the operating personnel the gamma source is shielded by 82 kg of the very dense material 238U. The gamma beam can be exposed by remote control. The detector, which is used to collect the quanta passing through the drum, is a high purity coaxial Ge-detector of a relative efficiency of approx. 20 %. The gamma rays can be collimated by a variety of collimators different in diameter ranging from 6 to 40 mm. The material of all collimators is lead. Both the gamma source and the detector including the collimator can be manually moved in vertical direction in order to observe different horizontal cross-sections of the drum. A pre-amplifier, an amplifier and a Multi-Channel Analyzer (MCA) serve as nuclear electronic instrumentation. The nuclear data acquisition, the

synchronization with the mechanical movement of the drum and the tomography reconstruction are carried out by a standard PC. The visualization software enables the operator to quantitatively determine the density and the activity distribution of the drum by calibrated density and activity scales.

MEASUREMENTS ON A TEST DUMMY

To check the reconstruction software and the accuracy of the tomography assembly a test dummy was designed and manufactured. The dummy embodies 3 different materials, different in density (lead, steel and plastic material). These materials are enclosed by a matrix made of concrete. Since the size (diameter 56 cm) as well as the materials chosen for the dummy are those of a real waste drum the dummy allows to perform precise measurements under realistic conditions. Figure 1 shows a reconstructed horizontal cross-section of the test dummy including the insets of different materials. The calculated density distribution and the calibrated density scale enables to quantitatively determine the density of all parts of the dummy. The plastic material (right side of the figure) is only barely visible, because the type of plastic used had similar attenuation properties as the cement matrix. The image is set up by a 301x301 pixel matrix. It is based on the data of 156 angle positions, each consisting of 100 linear scan steps. The measuring time of each single step was set to 5 seconds. The quanta emitted by the source and traversing the object were collimated by a 6 mm collimator.

Fig. 1. Calculated density distribution of the test dummy.

The dummy also contains several holes and hollow spaces, in which radioactive samples can be inserted in order to simulate a gamma ray emitting waste drum. In nuclear waste management the key nuclides 60Co and 137Cs are of great interest. To simulate a self-emitting gamma spectra by the drum matrix with an energy range from 662 keV to 1332 keV several radioactive samples, namely 60Co and 137Cs, were inserted into the holes of the dummy. Inner shieldings and heterogeneous fillings are then simulated by the different insets enclosed by the concrete matrix. On this setup emission measurements were carried out and the activity distributions of both nuclides were calculated. Fig. 2 shows the result of the reconstruction of the 137Cs-activity distribution of five Cs-samples of 31 MBq each. The image is set up by a 127x127 pixel matrix. It is based on the data of 64 angle positions, each consisting of 50 linear scan steps. To keep statistical noise low the measuring time of each single step was set to 10 seconds. In order to collect enough quanta emitted by the sources a 15 mm collimator was necessary. The maximum count rate of approx. 770 c/s was monitored close to the Cs-sample near the edge on the left side of the dummy.

Fig. 2. Activity distribution of 5 137Cs-samples inserted into the dummy.

In nuclear waste management it is often of great importance to quantify the activity of a single source located at a particular position inside the waste drum (hot spot). Once a tomographic image is reconstructed this can easily be achieved by integrating, i.e. summing up, the pixel values of a certain region, in which the source is located. This technique then quantitatively gives the activity of the particular source. The five circles surrounding the Cs-samples in Fig. 2 indicate the regions of integration and the numbers near the circles display the calculated activities of these regions, i.e. the activities of the five sources. Keeping in mind, that each sample has approx. 31 MBq (10%) the technique yields results of appropriate accuracy.

As mentioned above the reconstruction algorithm uses attenuation correction of the emitted rays along the ray paths from the source to the detector. This correction has a great influence on the reconstruction of the activity distribution. Calculation of an activity image by using the identical algorithm and the same input data, but without applying density correction, gave only unsatisfactory results. In the case of the setup shown in Fig. 2 the calculated image permitted to localize only the very left source near the surface of the dummy, whereas the value of its activity was not calculated correctly.

MEASUREMENTS ON WASTE DRUMS

Figure 3 shows the density distribution of a 200 l waste drum of approx. 450 kg in weight (surface dose rate approx. 0.35 mSv/h). The density distribution was obtained by performing transmission tomography on the drum. The drum contains an inner canister surrounded by a thick cemented filling. The inner canister's contents is cemented material, which is distributed quite inhomogeneously showing a few, well defined cracks. A hole of 6 cm diameter caused by a preliminary destructive assay

can also be recognized. It is quite likely, that the inner canister contains radioactive material and that the outer cemented region is used for shielding purposes and will probably not contain any radioisotopes. This assumption is confirmed by the corresponding ECT-image (Fig. 4). The image shows the 60Co-activity distribution of the same drum at the same horizontal cross-section. All of the radioactivity is contained within the inner part of the drum, whereas the outer region is basically just a shielding. The ECT activity image also shows the above-mentioned hole, which obviously cannot contain any radioisotopes. This activity hole would not be visible if the reconstruction algorithm had not used density correction of the emission data. The activity scale of the image is not calibrated, but does give an impression of the relative quantity of the activity concentration within the observed cross-section.

Fig. 3. Density distribution of a LLW-drum (200 liter).

Fig. 4. 60Co-activity distribution of the drum shown in Fig. 3.

CONCLUSION

The experimental tomography assembly described in this paper revealed that the contents by density of nuclear waste drums can be determined non-destructively by the technique of TCT. In addition, all detectable radioisotopes can be localized within the drum volume by applying ECT. Furthermore, by applying density corrected ECT, i.e. combining TCT with ECT, the radioisotopes can be determined quantitatively. The knowledge obtained by operating and running experiments on the assembly was an aid in the construction of a new tomography assay system. The design of this advanced system has been recently completed at the KFA and the system is currently being manufactured. The new advanced tomography assay system will have extensive tomography capabilities (transmission and emission tomography), will perform gamma scanning and digital radiography, and is designed for fast assays of the waste drums. The assay system will be applied to inspect their contents in order to declare and certify their radionuclide inventory.

ABSTRACT

This paper describes the specification, procurement, commissioning and early operation of a solid waste drum gamma scanner. Batches of up to ten 220 litre drums are loaded by conveyor on to a turntable. Four fixed electro-cooled germanium detectors can use three alternative waste matrix correction methods for counting the gamma emitting isotopes present. The procurement, testing, operational procedures and initial results are discussed. It is expected to be fully operational by April 1995.

INTRODUCTION

Disposal of low level radioactive solid waste in the United Kingdom is subject to regulatory control. It is becoming a requirement to directly measure at least a proportion of waste arisings. This paper describes a design by AEA Technology, Harwell Instruments, for a Low Level Waste batch drum segmented gamma scanners (SGS) already installed in the United Kingdom. Early operational results are discussed,

prior to full operation in April 1995.
The scanner is located at the Winfrith site of the United Kingdom Atomic Energy Authority and will directly measure gamma emitting isotopes in waste contained in 220 litre drums. This site has arisings from irradiated fuel, power reactor decommissioning and waste from other commercial companies. The drums are counted before compaction and disposal at the Drigg waste repository operated by British Nuclear Fuels.

SPECIFICATION

A comprehensive specification was drawn up and submitted to Harwell Instruments, AEA Technology, Harwell, Oxfordshire, England. Harwell Instruments have a commercial agreement with EG & G Ortec Instruments for the supply of electronic equipment. The following criteria were included in the technical specification:

Nuclear industry safety standards and codes of practice.

Waste drum size to be 220 litre.

A minimum caesium-137 detection limit of 100 KBq in a matrix with density 0.4 g/cc using a drum cycle time of 10 minutes.

Ability to handle drums up to 1 tonne in weight.

Ability to take batches of 10 drums.

Ability to accommodate radiation levels from background up to at least 2 mSv/h contact.

Ability to run automatically with minimum operator intervention.

Ability to be largely unaffected by radiation from adjacent drums.

Ability to be flexible in matrix corrections and be able to act as a research instrument when required.

To have adequate warranty conditions.

To be delivered within nine months from time of order.

To have a capital cost that did not significantly exceed that of other available scanners.

GENERAL DESIGN FEATURES

The design opted for four vertical electro-cooled detectors. These were judged to require the least maintenance and provided the neatest detector arrangement.
The operator inputs the drum identification parameters and if required a 'fingerprint' to attribute any associated alpha and beta activities. Drums are fed automatically from a commercial input conveyor and are rotated on a turntable in front of the fixed 25% high purity germanium detectors. After counting they accumulate on an output conveyor (Fig. 1).

Fig. 1.

The data is processed by an industrial standard 486 computer. A drum analysis summary is written to a printer for immediate inspection. Full spectra and analyses details are written temporarily to the hard disk under reusable batch filenames. An abridged version of the printer data file is permanently stored, and can subsequently be down-loaded to the site waste data base system. Each batch spectra and analyses files are retained initially on the SGS for inspection by the system supervisor if required. As each drum generates about 1.5 MBytes of files, these are allowed to be overwritten by the next batch of drums to prevent excessive build-up on the hard disk. They can of course be stored permanently under a different filename if needed.
Peak identifications and analyses are carried out using an Ortec Maestro pulse analyser emulator and Ortec Omnigam peak analysis software. Harwell Instruments software is provided for instrument control and to allow drum matrix corrections, using the following three alternative methods:

a) Europium-152 transmission sources through the waste drum.
b) Intrinsic differential peak absorption from a multi-gamma isotope in the waste.
c) Bulk density from weight measurement and inbuilt correction factors.

The supervisor can select the method preferred, although the machine will default automatically from the differential peak option to weight correction in any segment where no suitable intrinsic isotopes can be found.
This is believed to be the only SGS in the UK with the capability of using these three matrix correction techniques.

MANUFACTURE COMMISSIONING AND OPERATION

Our Project Manager maintained continual close contact with the supplier throughout the stages leading up to delivery. This proved invaluable in deciding quickly upon detailed and sometimes unforeseen options. Close liaison was welcomed by Harwell

Instruments and proved crucial to the successful delivery within specification and time scale.
The machine was completely assembled at the Harwell site and made ready for a comprehensive series of mechanical, electrical and sensitivity tests. All aspects of the specification were individually verified by Harwell Instruments and the Project Manager in Works Acceptance Tests (Appendix 1).
After agreement had been reached, the SGS was dismantled and transported to Winfrith where much of this testing was repeated as a Site Acceptance Test. All details became part of the SGS Commissioning Quality Plan.

CALIBRATION

Energy and Absolute count-rates

Standard point sources in the centre of an empty drum have been used for calibration of the SGS. This was easier than making homogeneously distributed sources in as large a volume as a 220 litres. The effects of changing between the point and homogeneous distributions at different drum densities can be readily calculated.
The SGS is energy calibrated with caesium-137 and cobalt-60 sources. Efficiency calibration is by a single standard europium-152 source of 3.5% accuracy. The source is placed in the centre of an empty drum directly opposite each detector in turn. From the known energy and abundance of each peak, energy and efficiency calibrations are filed for future use.
After calibration the computer requires an immediate check by a verifier drum. This is automatically demanded again at future intervals, presently set at seven days. The drum contains four standard caesium-137 sources in the same vertical positions as used in the europium calibration. The measured caesium activities must agree within a pre-set percentage with the europium calibration or no further waste assays are allowed. Any differences are normally well within 3% and act as confirmation that the original calibrations have been carried out correctly.

Geometry and Matrix Corrections

Factors have been incorporated into the algorithms that take account of different drum densities. They also convert the calibration point source geometry into equivalent counts for a uniform distribution, which is assumed for unknown waste drums.
The differences due to activity positional errors have been investigated experimentally. Point sources have been counted in a series of tests in specially constructed drums fitted with vertical re-entrant plastic tubes. These enable sources to be introduced at varying heights across the drum that was filled with various matrices.
A single 2.97 MBq caesium-137 source is used in an empty 220 litre drum. Measurements are made at 5 cm vertical intervals in centre (Fig. 2) and edge tubes. It can be seen that whilst there is significant variation with position, there is no significant 'cross-talk' between the detectors. This has been repeated with the drum packed tightly with PVC (bulk density about 0.22 g/cc). Changes were small at the drum centre but the variations increased near the edge. Further tests are planned.
Fig. 2.
Each value shown has been already been corrected by the SGS software factors. The totals (MBq) from both experiments are shown (Fig. 3, centre source in-filled). If the compensations over a complete drum height and diameter are correct, the mean values for the sets of the 17 vertical measurements and every single point should be 2.97 MBq. The individual values are actually seen to vary in extreme cases by as much as 20% to 30% and 50% to 60% at the centres and edges respectively, depending upon the actual measurement positions chosen. However the overall mean values for all points are accurate to +/-2%.
Fig. 3.
The count rates decrease when the sources are positioned midway between the detector centres. This effect is least when the source is at the drum centre and greatest at the very edge. It is even just possible to miss the presence of a point source at the very edge of the drum, but only over a vertical height of less than one centimetre.

MATRIX CORRECTION METHODS

Transmission Sources

This is the least demanding and most generally applicable method. The drum segment counting is followed by counting with the four 60 MBq europium-152 transmission sources exposed for between 10% and 50% of the original drum count time. The

percentage may be varied as required. Corrections are made for each drum segment and take into account any europium already present in the waste.
The greatest errors occur when the waste has high density and a high intrinsic count rate. This makes the transmission source low energy peaks difficult to measure, with corresponding uncertainties in the correction factors at these energies. The problem is compounded if europium-152 is also present in the waste.
Differential Peak Absorption
This requires the waste to contain an isotope with gamma peaks ranging from low to high energy values. By assuming that other radioisotopes present are also similarly distributed, this method may be utilised to provide an elegant method for correcting matrix density effects.
Special requirements include a suitable isotope being present in sufficient quantity to be counted statistically accurately over a range of peak energies, that the detector efficiency calibrations are very accurate and the matrix density does not reach some limiting value. As with transmission corrections, problems also arise with a high waste intrinsic count rate and high densities.
Experiments so far on the SGS have suggested that these requirements are often difficult, but the method is capable of giving good agreement with transmission source work. In some cases, when conditions are right, it may be more accurate. However, in spite of the theoretical attractions, it seems less robust than transmission correction.
Bulk Density
The drums are accurately weighed during counting, allowing the bulk densities to be calculated. Factors measured from calibration drums of different densities, correct the measured values as a function of gamma energy.
For matrix corrections based on bulk densities, no concession of any kind has been made to inhomogeneity. With transmission and differential peak methods, corrections are made for each segment. Thus the method is ideal for waste drums with uniformly distributed materials.
Some waste drums may have heavy items at their bases making a bulk density correction inappropriate. This method is used as a default when the other two have been ruled out.
PRACTICAL INSTRUMENTATION AND INSTRUMENTAL PROBLEMS
Electronic Stability
SGS ambient conditions vary between 10C and 30C. Temperatures inside the control desk even exceeded this maximum value in very hot weather. A cooling unit has now been fitted and augmented by spectrum stabilisation to maintain proper energy calibrations under these widely varying conditions. The latter is achieved through the main amplifiers by automatically opening the europium transmission sources between drum movements for checking and feedback corrections.
The operation of gamma equipment in an industrial environment can cause other problems. As well as extreme temperature differences, electrical interference and environmental pollutants can cause impaired performance. It has proved essential to guard against these. If it is not possible to control the immediate environmental conditions, the equipment should at least be properly sealed and some temperature limiting introduced.
Initial difficulties associated with earth loops were also encountered, which only started after moving the equipment from the contractors premises to the Winfrith waste plant. The effect was a broadening and sometimes severe deformation of the peak shape. This was eventually minimised by isolating the flexible metal detector cooling pipes from each other. No other earth linking procedures seemed to be reliable. The insulated system now operates close to the designed resolution of 1.95 keV for all detectors.
Prior to using insulation, unpredictable changes took place in which peaks could fail to be properly identified. Single peaks occasionally appeared as doublets and sometimes the system would reject broad or misshapen peaks, giving inaccurate answers. Such occurrences might be overlooked if only the final summarised output data from unknown constituent drums are inspected. Only frequent inspection of spectra and full width half height value ensures good data.
High Count-Rates
Accurate pulse dead-time corrections at high count-rates must be assured. These can reach over one hundred kilohertz of accumulated counts in each detector, from drums with fission products at contact doses of 2 mSv/h or 5 mSv/h from cobalt dominated

waste. Both correspond to 80% dead-time.
Practical tests have been carried out using low level caesium-137 and cobalt-60 sources counted initially by themselves and then with gradually increasing count-rates from a separate europium-152 source. Experiment showed an accuracy of 0.3% on cobalt and 2% on caesium was still maintained at 100 kHz total count-rate. This only increased to 0.4% for cobalt, but to 11% for caesium at 300 kHz. These errors also include a component for peak area measurements where a very significant background is present, especially at lower energies. At these dead-times the accumulation times have become very long however and lower efficiency detectors would be preferable for such real waste material.

Sources

The present europium calibration source has a quoted accuracy of +/- 3.5%. Whilst better accuracy is available, this is probably adequate bearing in mind other errors and assumptions in the overall method. The cross check with the caesium sources in the verifier drum agrees to at least this accuracy.

Calibration

Great care has to be taken with system calibrations. It has been found essential to ensure sufficient source counting times, so as to get very good peak shapes and statistics. Discrepancies between measurements in earlier commissioning were traced to this cause. The present system collects spectra in only four thousand channels, although this is being changed to eight thousand.

The analysis software requires peaks to be within 1 keV of their library value, or the isotope is not recognised and is returned as an unidentified peak. In this way even a major isotope could go unreported.

DATA GATHERING

The SGS generates and uses much data. The deductions it makes should be at least as good as those of an experienced analyst. Only the system supervisor has access to manually inspect these spectral and analytical files. However except for unusual cases, it is only normally possible to look at data occasionally. Correct initial settings and conditions must be maintained to make this satisfactory.

Peak analysis will identify not only major and genuine isotopes but also a very large number of high uncertainty and low abundance peaks. In mixed fission and activation product waste, the process may start with as many as two hundred possible peaks present, many of which may be based on uncertain statistics. Although rejection of most peaks normally follows automatically from unacceptable shapes, resolutions, non-exact energies, or non substantiating additional peaks, operator examination is still needed in some cases.

REPORTING OF ISOTOPES

The unidentified peak energies from many initial drums of waste measured on the SGS were examined. Starting with only a basic isotope library, many unidentified peaks were reported. These were listed and sorted on a spreadsheet, which enabled more commonly occurring values to be seen and attributed to real minor gamma constituents. The isotope library was then extended to include these isotopes. If this procedure had not been not followed, then the great number of unknown peaks would have caused a time consuming evaluation problem for the system manager. There is significant time saving in only needing to examine the small number of remaining peaks.

A problem remains of how to deal with the reporting of those isotopes that cannot be accurately quantified by gamma spectroscopy and would be better measured by a different technique. The decision to eliminate some or all of these from the results, seems to depend upon the experience and common sense of an operator.

In our system this function can only be carried out by the system supervisor. The isotopes over which some doubt exists are isolated as a group in the print-outs and data files. The actual spectra from each drum segment are then examined and considered on their merits. The removal of unwanted data is accomplished on a separate computer using the DOS Editor, or more usually by reading the file into a spreadsheet. For those data sets where standard changes are required, macros are available to make these alterations quickly and accurately.

COMPARISON OF MEASUREMENT METHODS

Data from the different matrix correction methods is still being accumulated. A typical example for a drum of well-characterised waste stream of uniform waste with density 0.25 g/cc, shows quite small differences between total activities as measured by (1) SGS transmission, (2) direct assay from fingerprint and radiation

measurements and (3) SGS bulk density/weight corrections (Fig. 4).
Fig. 4.

SYSTEM SAFEGUARDS

The use of this SGS at UKAEA Winfrith is replacing alternative methods for determining activity contents, each of which also involves manually transcribing data on a keyboard with the attendant possibilities for errors.

The SGS system can only be accessed by the supervisor, preventing any tampering with the SGS system or the introduction of unauthorised software. The SGS specific software employs a tier password system. No access at all is available to unauthorised persons. The first password allows entries only those menu items for entering drum identities and for starting and stopping the system. All remaining menus governing the way the system is run, parameters used, analytical and all data files, require a second password known only to the system supervisor. These analyses options are held on disk and so are less subject to errors. They include counting times, type of matrix correction used, calibration parameters, tolerances and system management parameters.

The SGS will not allow drum assays unless the system verifies within set error limits.

FURTHER DEVELOPMENTS AND LIMITING FACTORS

Matrix Corrections

Only four drum measurement segments are measured with this SGS design due to a need to minimise throughput times. Other systems with less time priority can afford to measure more segments, with an attendant potential improvement in corrections. Although this machine cannot readily be altered in this respect, better information on waste matrices could bring further improvements in accuracy.

If the latter were possible, source and density configurations other than those assumed in the calibration could be calculated and the factors applied to the measured values. This may be a way forward to more exact analyses. X-radiography, counting using tomography or counter arrays giving spatial distributions may provide this information.

Perhaps the biggest error of all lies with a dependence upon an accurate knowledge of the non-gamma constituents. This has to be obtained from destructive analyses and may account in some cases for two thirds of the total activity.

LIMITS OF DETECTION

The original SGS specification called for a limit of detection of 100 kBq caesium-137 in a matrix of density 0.4 g/cc in a 10 minute cycle time. Subsequent experiment suggests that less than 40 kBq uniformly distributed may be detectable in a low background environment and using extended counting times, even with drums of density of 1 g/cc. This is equivalent to 0.2 Bq per gram and less than the UK Free Release limit.

Free Release of waste is the topic most likely to give the best financial return on effort invested. The cost differential between dumping at active repositories and public waste tips is very significant when disposing large volumes of demolition waste.

Our furthest advanced Free Release project has been on drums filled with used fire detectors with their americium-241 removed. Preliminary tests show that a point source of 37 kBq of americium-241 can easily be detected in the centre of a very low density alarm case matrix drum. Further special drums are being made to see if Free Release Limits can be achieved. Calculations suggest that a similar uniform distribution would give a 30% better limit of detection.

ACKNOWLEDGEMENT

The authors wish to acknowledge the help of the Department of Trade and Industry in financing this instrument.

APPENDIX 1

Items considered in Works and Site Acceptance Tests

- Accessibility to replaceable items
- Safety checks on electromechanical parts and radiological surface dose rates
- Loading and off-loading batches of drums
- Turntable operation
- Drum weighing
- Correct and safe transmission source operation
- Power failures and emergency stop situations
- Drum sequencing and verification checks

System information outputs
Effects on assay from nearby active drums
Uninterrupted power supplies operation on mains power failure
Correct close down sequences
Software tests
Matrix correction tests
Sensitivity and limits of detection
Correct use of 'fingerprint' factors for beta and alpha constituents
Activity distributions against height
Documentation checks

ABSTRACT

A portable swipe monitor (PoSM) has been developed at Los Alamos National Laboratory for bench top or field use. This rugged detector system uses Long-Range Alpha Detector (LRAD) ion transport technology, which monitors ionization created by alpha interactions with ambient air. The PoSM has been designed to be easily portable and insensitive to mechanical noise. Real-time background subtraction is built in, adding to its convenience in field use. Preliminary tests reveal that the PoSM is an inexpensive, fast device capable of monitoring a variety of samples in the field with very reliable statistics. Sensitivity to alpha contamination is on the order of a few dpm/100 cm2.

INTRODUCTION

In early 1994, Los Alamos National Laboratory (LANL) began developing a radiation sample monitor for assay of swipes or smears. The goal was to develop a device that could make fast, reliable measurements in a mechanically noisy environment. The primary design consideration was that it be insensitive to vibration and still yield reliable statistics in a short time. We used Long-Range Alpha Detection (LRAD) ion transport technology because we expected that it would perform well under these conditions. A prototype, which we call an LRAD-based Portable Swipe Monitor (PoSM), has been built and is being tested.

We believe that the system will have applications beyond the initial intent of the project. The PoSM is likely to be an improvement in terms of cost, sensitivity, and convenience over conventional swipe/smear monitoring technology. The prototype is 16.5 cm x 19 cm x 33 cm, weighs less than 5 kg, and can be easily carried with a shoulder strap. Its light weight and small size make it potentially very useful to radiological control technicians (RCTs). Currently, swipe monitors that are sensitive to low-level contamination tend to be large, stationary devices, so RCTs have to take swipes out of the field to be analyzed. The PoSM is a fieldable alternative.

Contamination collected on swipes is by definition removable. Transporting swipes before analysis introduces cross-contamination issues and the problem of diminished accuracy when contamination is lost from the swipe. If the contamination level has diminished, then 1) the contamination has spread and 2) the original object of interest has been mischaracterized. If the swipes had been assayed when they were taken, the likelihood of these two problems would have been greatly diminished. Other problems inherent with removing the swipes from the field involve the efficiency of work done in nuclear facilities. Many kinds of work at nuclear facilities are supervised by RCTs who must make decisions based on the analysis of these swipes. The ability to take these measurements quickly in the field could eliminate work delays that occur while waiting for the analyses. Having a PoSM in the field could also alleviate much of the paperwork that is required when keeping track of large numbers of swipes and free up time for overburdened technicians.

DETECTOR CONCEPT

The strong alpha signature of transuranics, uranium, radium, and many other radioactive contaminants and the relatively high energies involved in alpha decays make alpha detection an excellent method for locating and measuring radioactive contamination. Alpha particles, however, travel only very short distances in air before all of their energy is dissipated in interactions with air molecules. The alphas deposit their energy in air by separating the charge that resides on air molecules. The lifetime of the ions that are created is on the order of seconds. Researchers at LANL have found that ions generated in air can remain at over half their initial concentration for as long as 8.4 s (1). Ions can therefore be transported much further than the alpha's range, which is typically 3.5 cm.

Long-Range Alpha Detection (LRAD) is the technique of detecting alphas by means of their ion progeny. In the LRAD swipe monitor, these ambient ions are transported to a detection electrode by a high-voltage electric field and generate currents on the order of 10-15 A. Research at Los Alamos has shown that this current is linearly proportional to the alpha activity (3) and is therefore a measure of alpha contamination.

There are two types of LRAD detectors distinguished by the ion transport mechanism employed. Airflow LRADs use fans to transport all of the air, ionized, and non-ionized molecules indiscriminately, to the detection electrode. Electrostatic LRADs, such as the PoSM (Fig. 1), transport only the ionized molecules to the detection electrode by means of an electric field. Of the two types, electrostatic LRADs are capable of greater efficiencies and higher signal to noise ratios.

Because the PoSM is intended to be a conveniently fieldable device, the background is subtracted in real time to alleviate the need to recheck background each time the device is relocated. Figure 1 shows an elevation view of the PoSM. The sample is placed on the bottom of the drawer, which seals when closed. The bottom of the drawer and walls of both volumes are kept at the potential of the negative post of the battery. The signal planes are kept 300 V above this. All of the negative ions that are generated in the sample volume are collected on the lower signal grid. Only those negative ions that are generated in the background subtraction volume are collected on the upper signal grid. The two chambers have equal volumes.

Fig. 1.

The background signal can be attributed primarily to three sources: 1) leakage current, 2) penetrating radiation, and 3) radon.

Because of the very low current levels involved, care must be taken in the design to avoid leakage currents along the surface of the insulating standoffs. These currents can be of the same order of magnitude as the currents that constitute the detector signal and so are capable of swamping the detector. To avoid these currents, the standoffs in the PoSM are guarded. The guards consist of metal rings (as shown) that are kept at the same voltage as the signal planes. Because this eliminates the potential gradient along the surface of the insulator between the signal plane and the guard ring, no charge flows between them. The leakage that takes place between the guard rings and ground is not sufficient to affect the potential of the rings and so has no effect on the signal plane. In this way, leakage currents along the insulators are effectively eliminated.

The ionization in the decay volume caused by radon results from the decays of both the radon isotopes and the alpha-emitting radon daughter products. Because radon is a gas, the amount of background contributed by disintegrations of radon isotopes for a given concentration is directly proportional to the volume (4). Because the chambers have equal volumes, we can eliminate the portion of the background due to the radon disintegrations by subtracting the top chamber's signal from the bottom's. The elements created by the decay of radon are not gaseous at room temperature, so they plate out onto the walls of the chambers. Assuming that on average the radon concentrations are the same in both chambers, the amount of alpha emitting daughter products plated to the walls and electrodes of both chambers will be the same within a few percent. Subtracting out the top chamber's signal therefore eliminates this source of background as well.

Penetrating radiation deposits very little energy in the detector volume compared to what is deposited by the alpha contamination on the sample. Gammas caused by cosmic rays and terrestrial background radiation combined deposit only about 4 MeV per minute per liter of detector volume compared to the approximately 516 MeV per minute that just 100 dpm of 239Pu contamination would deposit. The two decay volumes used

in the PoSM are 3.1 L, so even without the background subtraction, background penetrating radiation is not significant.

RESULTS

Figure 2 shows a calibration set taken with National Institute of Standards and Technology (NIST) traceable 239Pu sources. As shown in the figure, this detector sees 166 fA per 1000 dpm. The average alpha energy from 239Pu is 5.16 MeV and 34 eV are required on average to ionize one air molecule. If we assume that ionization is the only mechanism for energy loss in air, we find that about 152,000 ion pairs are created by each alpha. The PoSM sees only one ion for every pair because the positively charged signal planes collect only negative ions. Because half of the alphas will have trajectories which take them back into the source, 1000 dpm of 239Pu can be expected to generate around 203x10-15 coulombs of free charge per second in the air. This charge would become 203 fA if the signal planes picked up all of the negative ions that were generated. The 166 fA response indicates that the PoSM is about 82% efficient.

Figure 3 shows the results of a proof-of-principle test intended to determine how well the detector performs in mechanically noisy environments. A rough running vacuum pump was used as a makeshift mechanical vibrator. The outputs of the two electrometers are shown as the detector is picked up and set against the pump. (The top plate signal has been shifted up 2 mV so that it can be distinguished more easily.) The plot shows 60-s averages.

Fig. 2.

Fig. 3.

This figure shows rather dramatically that the noise in the signal is not affected by the vibration. The standard deviations of the points before and after setting the detector against the pump are 0.14 mV and 0.13 mV respectively for the top and bottom plates. The standard deviations while the pump was vibrating the detector are 0.14 mV and 0.18 mV. Of course this simple test does not guarantee that the PoSM will perform well bolted to a truck with its engine running, but the results are encouraging. The opportunity for that sort of field test has not yet arisen.

COMPARISON OF LRAD SWIPE MONITOR AND ONE TRADITIONAL METHOD

The comparison data shown in Fig. 4 was taken with an LRAD-based sample monitor (y axis) and a Berthold LB770 10 Channel Low-Level Planchet Gas Proportional Counter (x axis). The LRAD-based device is a prototype that was developed primarily for looking at small soil samples. It preceded the PoSM and is very similar in design. The figure shows results from 13 swipes, taken in a known contamination area at a nuclear facility in Los Alamos. The R2 value reflects a high degree of linearity between the two technologies.

Fig. 4. Comparison of LRAD-based swipe monitor and a commercial monitor based on gas proportional technology. The square of the regression coefficient, R2=0.999.

One advantage that the gas proportional counter and other traditional swipe monitoring technologies have over the PoSM is that they provide both alpha and beta information. Future plans could include modifying the PoSM to give beta information as well. The modification would involve sandwiching a beta-sensitive scintillator between the signal planes and adding the necessary electronics. We anticipate that the heavy lead shielding required by the Berthold device (which would severely compromise the PoSM's portability) could be avoided by adding a pulse shape discriminator to the electronics. The lead shielding is necessary to exclude ambient gamma radiation, but the pulse shape that gammas produce in scintillators is distinguishable from the shapes produced by betas. The PoSM could thus retain its portability, although it would be made somewhat more bulky by a photomultiplier tube.

SUMMARY

The work on the prototype PoSM being developed at Los Alamos has demonstrated that an LRAD-based swipe monitor will work quite well, is extremely efficient, and is capable of operating in mechanically noisy environments.

The PoSM could fill an important role in the field of radiological control. A lightweight, convenient, portable swipe monitor for in situ assay could be a significant improvement on the current practice of collecting swipes and taking them to a lab to be counted. Having a PoSM in the field could have a significant effect on the efficiency of RCTs and the work that they supervise.

ABSTRACT
The Steam Generating Heavy Water Reactor (SGHWR) at the Winfrith site was a 100 MWe (330 MWth) power reactor, with a design based on the use of discrete vertical pressure tubes, with heavy water moderator and light water coolant at a sufficiently high pressure to directly drive a turbo-generator. The reactor operated as a successful prototype from 1968, until October 1990 when the decision to stop operations and to start Stage 1 decommissioning was taken. The Stage 1 program is scheduled to complete in March 1997.
Financial responsibility for the decommissioning has been accepted by the Department of Trade and Industry (DTI) and responsibility for ensuring that the program is carried out in compliance with safety, and other statutory regulations lies with the Government Division of the United Kingdom Atomic Energy Authority (UKAEA-GD). All decommissioning work is carried out within a policy agreed between UKAEA-GD and the DTI, which is to ensure that the overall plan for the facility is optimized to provide a minimum lifetime cost (discounted at 6%) and that value for money for all work undertaken is obtained, primarily by exposing as much work as is practicable to competition.
To meet the above policy a work program was devised with the primary objective of bringing the facility to a state where it can be left, for a minimum of twenty years, with the minimum of care and surveillance. This program has five main elements, namely:
The removal of all fuel and the decommissioning of the fuel handling and transport equipment.
The emptying of fuel pond water, debris and removal of pond equipment, and decontaminating or sealing the pond surfaces, as appropriate.
The removal from service of all systems not required for the resulting care and surveillance of the facility.
To clean, seal and provide ventilation as appropriate for the primary and secondary containments.
To demolish as required, all facilities external to the main containment buildings. This includes for example, the cooling towers, auxiliary boilers and emergency generators.
AEA Technology have been appointed the Managing Agency to provide the project management and to ensure that the DTI/UKAEA-GD policies are met, particularly in using competitive tendering to award implementation contracts for work undertaken. All individual tasks above 10k in value are subject to competition, unless it can be demonstrated that this is not cost-effective.
Good technical progress has been maintained over the first four years of the

project. The critical path contains the tasks associated with the fuel and pond program and early work has concentrated on these. All fuel was removed form the site ahead of schedule, and furniture and debris has been removed from the fuel ponds. Surveys to define the state of the facility have been completed and removal of plant and equipment that would result in an excessive long term maintenance burden (such as the cooling towers) is nearing completion. Most of the work to rationalize systems required in the longer term, such as power and instrumentation, is also complete. The main tasks remaining involve the decommissioning of the fuel ponds and the rationalization of the containments ventilation system.

The work described in this paper was funded by the UK Department of Trade and Industry through the DRAWMOPS Program Letter.

INTRODUCTION

The Steam Generating Heavy Water Reactor (SGHWR) grew out of studies, undertaken by the United Kingdom Atomic Energy Authority, into the possible alternatives to the gas-cooled, graphite moderated reactors on which the UK nuclear power program had been launched. The SGHWR design was based on the use of discrete, vertical pressure tubes, with light water coolant at sufficiently high pressure to provide steam directly to the turbo-generator. The moderator was unpressurized, heavy water, which also acted to control reactor power by varying its level in the calandria. The majority of the primary systems was contained in a reinforced concrete primary containment structure.

Construction of the prototype reactor of 100 MWe (330 MWth) at Winfrith started in February 1963. Synchronization to the national grid was on 24 December 1967 and the reactor was declared available for sustained generation at the design output in January 1968. The facility operated as a prototype, providing support to the evolving UK PWR program and generated power for the national grid. The decision to stop reactor operations was taken on 2 October 1990, at which point the decision to undertake Stage 1 decommissioning was taken. During its lifetime of 23 years, the reactor operated at a load factor approaching 60 per cent. A diagram of the facility is given in Fig. 1.

Responsibility for ensuring that decommissioning is carried out in compliance with safety, and other statutory regulations lies with the Government Division of the United Kingdom Atomic Energy Authority (UKAEA-GD) as owner of the Winfrith site. Financial responsibility for all work associated with decommissioning and maintaining the SGHWR has been accepted by the Department of Trade and Industry (DTI) who are funding the work through the Decommissioning and Radioactive Waste Management and Operations (DRAWMOPS) Program letter agreed with UKAEA-GD. The whole DRAWMOPS portfolio consists of well over 100 major facilities, of which SGHWR is one. All decommissioning work is undertaken within a policy agreed between UKAEA-GD and the DTI. In essence, decommissioning is to:

Ensure a safe condition which complies with statutory requirements at all times.

Ensure that value for money is obtained for all work undertaken, primarily by exposing as much as is practicable to competitive tendering.

Ensure that all work necessary for safety, environmental or planning consent reasons, or which is justified on economic grounds, is carried out.

Consistent with the above, ensure that the overall plan is optimized to provide minimum lifetime cost (discounted at 6%) within the constraints of available funding.

Fig. 1.

DECOMMISSIONING OBJECTIVES

The main technical objective of the decommissioning process is to provide overall lifetime minimum cost subject to satisfying safety and other regulatory requirements. A conventional three Stage decommissioning strategy is envisaged for the facility and early studies showed that it was economic to proceed immediately with Stage 1 in order to reduce the hazard posed by the facility in its immediate post-operational state. That is, the cost benefits obtained through the reduction in care and surveillance costs following Stage 1 decommissioning were seen to more than compensate for the costs of undertaking the Stage 1 activities. Stages 2 and 3 being more extensive in scope and not having as great an economic benefit on their completion, were not judged to be worthwhile undertaking on an early timescale. In particular there is no national repository for intermediate level wastes and waste storage facilities on-site are limited. Thus Stages 2 and 3 are likely to be delayed until the next century when disposal facilities will be available.

Following on from the general objectives for Stage 1, more specific objectives were defined as the basis for the development of a specific work program and schedule. The Stage 1 process was split into sub-Stages with objectives as follows:

Stage 1.1 (Preliminary Decommissioning)

To render the reactor inoperative under any circumstances by defuelling the core;

To reduce the hazard posed by the tritiated heavy water moderator by discharging it from the reactor circuits and removing it from the SGHWR complex.

These activities were part of the standard shutdown and refuelling operations of the facility and were completed within a few months of closure of the facility.

Stage 1.2 (Preparation for Care and Surveillance)

To remove all fuel from the Winfrith site.

To provide appropriate long term atmospheric control of the primary and secondary containments.

To remove, fix or contain all contaminated liquids, loose or readily removable contaminated materials and other hazardous substances.

To rationalize, modify or remove plant, buildings and services where justifiable on cost and dose grounds.

To provide appropriate methods for the management of generated and accumulated wastes.

To provide appropriate equipment for monitoring, surveillance and emergency response.

To secure buildings against unauthorized entry.

These activities are programmed to be undertaken over a six year period, and will be followed by a period of care and surveillance with a requirement:

To monitor and maintain the residual reactor plant, systems and buildings, and

to perform any remedial work or other activities that become necessary for either safety or economic reasons.

These activities will be ongoing over at least a twenty year period.

As well as the technical objectives given above the project has the commercial objective of reducing the overall cost of the program to the minimum, consistent with an appropriate sharing of project risk, by offering as much of the work as is practicable to competition.

DECOMMISSIONING PROGRAM

Specific Features

A number of specific features of the facility were relevant to planning and undertaking the Stage 1 decommissioning program. The most significant of these are as follows:

Being a water reactor some corrosion has occurred in the primary circuits and as a result cobalt-60, which arose from activation of circuit materials, is an extensive source of contaminant activity. Most of the more highly radioactive components are confined within the concrete primary containment and thus operations within the primary containment need to be limited as much as possible to keep personnel dose rates as low as reasonably practicable (ALARP). This, together with the relatively short half-life of cobalt-60, made it desirable to delay decommissioning operations within the primary containment.

The facility has a direct steam cycle design. This has given rise to extensive, but mostly low level, contamination within the secondary circuits.

A number of potentially hazardous materials had been used in the facility. In particular asbestos lagging had been used on the primary and secondary circuits, some of which was in poor condition and needed either removal or treatment.

Water seepage was known to be occurring from the spent fuel storage ponds, which put some urgency in removing the spent fuel from the reactor site.

The fuel pond contained an element which had been damaged during handling and could not be dealt with using the existing fuel handling equipment and flasks. This required special equipment to be developed and proven, in order to recover and straighten the element prior to its removal from the pond.

The plant and buildings had been generally well maintained throughout their life, and thus there was no overriding need to take urgent remedial action to refurbish structures.

Program

The work program to achieve the stated objectives is shown in Fig. 2. The program started in October 1990 with the removal of fuel from the reactor core and is scheduled to complete by the end of March 1997. The main critical path for the

project includes the transfer of fuel off-site and the emptying and decommissioning of the fuel ponds. The reactor closed before a detailed decommissioning plan had been developed. In accordance with early studies, reactor and project staff systematically examined a comprehensive list of all facility systems in order to determine the most likely options for dealing with each. A work breakdown structure was drawn up and an initial decommissioning plan evolved. The physical work was divided into 105 tasks in five program areas as briefly described below.
Fig. 2.
Fuel Program
This includes the transfer of all new and irradiated fuel from the Winfrith site to the British Nuclear Fuels plc (BNFL) facilities at Springfields and Windscale - At the time of shutdown the core and fuel ponds contained the equivalent of 255 irradiated fuel elements; The repacking of all oversized and non-standard elements for transport, including the recovery of the damaged element; The decommissioning of the fuel handling and transport equipment.
Pond Program
This includes the characterisation, recovery and disposal of fuel pond sludges and debris, the removal of redundant pond furniture and other equipment, and decontaminating or sealing the pond surfaces as appropriate.
Operational Systems Program
The main objective of this program is to remove from service all systems not required for the resulting care and surveillance state of the facility. Other systems required for long term surveillance (such as some power and instrumentation systems) are to be rationalized and reduced to the minimum. Together, these actions provide for a cost-optimized long term care and surveillance program.
Containment Program
The objective of this program is to leave the primary and secondary containment structures in a state suitable for long term surveillance under a minimum facility maintenance regime. This involves a strategy of sealing, cleaning, and rationalizing the ventilation systems. Prior to determining the actual strategy a detailed survey to establish the inventory of radioactive and other hazardous materials was carried out.
External Building Program
This program is to survey, and demolish as required, all facilities external to the main containment buildings. This includes, for example, the emergency diesel generator, auxiliary boilers and cooling towers.
Commercial and Financial Considerations
The DRAWMOPS Program placed the initial contract for decommissioning with AEA Technology due to their previous experience as operators of the SGHWR. A team with experience of decommissioning, project management and SGHWR maintenance and operations was assembled, which ensured that continuity of plant knowledge was brought into the decommissioning planning and operations. In November 1992 the project management was restructured into its current form, specifically to enable competition to be brought into the decommissioning tasks and thus maximizing the value for money. The value of work let competitively has steadily increased with time, and for the final three years of the project (April 1994 to March 1997) approximately 60% by value of the decommissioning task will be undertaken by contractors awarded work on a competitive basis. All individual tasks above 10k are subject to competition unless it is demonstrated that this is not cost-effective.
Costs falling to the project come from three main sources, which are approximately comparable in magnitude

Those from the actual decommissioning work, including planning, surveys, studies and record keeping to support these tasks.

Those from work to support the facility including system operations and maintenance, health physics and dosimetry, and overall project management.

Those for services provided by the Winfrith site, including waste processing and disposal, power and utilities, security and regulatory services.

The best estimate total cost to undertake Stage 1 is approximately 77M as shown in the Table I.
Actual expenditure to the end of 1994/95 is anticipated to be 59M, which compares favorably with the budgeted estimate of 62M.
PROJECT MANAGEMENT AND CONTROL
The management of the decommissioning activities of UKAEA-GD is undertaken by the

DRAWMOPS Directorate (DD), which has contracted to AEA Technology to act as the "Managing Agency" for the Stage 1 decommissioning of the SGHWR. The day-to-day responsibilities of the managing agency include:

- Project planning, management and control
- Management of safety
- Selection of contract strategy
- Selection and supervision of contractors to undertake the decommissioning tasks.

Overall direction of the project, and responsibility for ensuring that the project meets the objectives and constraints set by the Department of Trade and Industry, the ultimate customer, lies with UKAEA-GD. A simplified diagram of the project management arrangements is shown in Fig. 3.

Fig. 3.

Stage 1 decommissioning of a power reactor is a complex project made up of, several thousand individual activities. An optimum strategy for decommissioning each system, or possibly single items of equipment, needs to be developed in order to identify what work needs to be undertaken, and perhaps more importantly, what work need not be undertaken since a high level objective is to meet the Stage 1 requirements at minimum overall cost. In addition the activities need coordinating to ensure compatibility with overall program, safety and logistical constraints. The key player in the management team is the senior project manager who is responsible not only for all of the project management, but also for ensuring that decommissioning is carried out in a manner that ensures the safety of the plant and personnel at all times. The senior project manager has reporting to him project managers responsible for defined tasks within the project, as well as a facility manager (also responsible for safety), a contract services manager and a project services manager. These latter provide support services across the whole project in relation to the preparation and negotiation of contracts for work to be undertaken, and the provision of project planning, financial and progress monitoring respectively. A task coordinator is appointed to take charge of each program and to supervise the activities of the managers of the individual tasks, each of which is progressed and controlled from inception to completion within the framework of a task flow diagram as shown in Fig. 4. The most significant aspect of this process is to show that the implications of each task have been properly considered and that an appropriate range of options has been reviewed to ensure that the optimum strategy for the task is to be followed. These studies define, for example, the potential interaction with other tasks, the hazard to be removed, radiation dose expected, waste arisings expected, safety documentation requirements and include cost benefit analysis of the various possible options. The senior project manager will authorize the task to start once he is satisfied and following advice received at the relevant planning meetings. On completion of the task a completion report is prepared which, as well as being a record of all work carried out, ensures that all ancillary actions (such as amending the relevant drawings) have been completed. The plan for each task is the responsibility of the task manager; the plans for all tasks are integrated by software link to form the complete project plan from which the senior project manager derives an overall view of the project. This two tier approach to planning has proved a valuable tool in providing effective control, coordination, resource planning and reporting, and has assisted the facility manager in the duties of safety supervision and day to day coordination for which he is responsible.

Fig. 4.

PRINCIPAL ACHIEVEMENTS

After completing the initial tasks, including the removal of fuel from the core and draining of heavy water, the first major objective to be achieved was the despatch of all fuel to BNFL at Sellafield for storage prior to possible reprocessing. This included damaged elements, dismantled elements and material from post-irradiation examination much of which was prepared for despatch in the active handling facilities at Winfrith against exacting BNFL acceptance specifications. A high standard of planning, coordination and liaison with interested parties was therefore needed. The completion of the work in May 1993 removed a significant source of risk from the project.

Despatch of fuel allowed a major objective of the Operational Systems Program to be tackled, namely the ending of shift working, which had been in place since 1966, and permanent manning of the control room. This required the provision of a comprehensive fire detection and alarm system and a computer based plant monitoring

system which would relay detailed information to the Winfrith site control centre outside normal working hours. The implementation of these systems, and the changes in working which they supported, were closely monitored by the Nuclear Installations Inspectorate, liaison with which comprised an important element of the task.
While these two programs were in progress, consideration was given to the approaches to be adopted for the pond system and the reactor containments. The pond system includes a fuel pond and transfer tunnel, two containment suppression ponds, and two quench ponds all forming an integral part of the main concrete structure. Their characterisation could not be completed until all fuel had been removed. By this time, it had been decided to maximize the use of competitive tendering for selecting contractors for decommissioning tasks. A strategy was devised in which three prequalified teams of consultants undertook option studies covering both the method for decommissioning the ponds and the end condition to be achieved during the current Stage. These studies led directly to the submission of a tender from each team. This approach involved a wide range of expertise and proprietary methods, and encouraged the submission of realistic and cost effective proposals with minimal constraint. The integration of contract expertise within the project team has contributed greatly to the effectiveness of this approach as well as the rapid introduction of competition throughout the project.
The reactor has two containments, a five feet thick concrete primary and the secondary which is formed by the double skinned, steel clad reactor building enclosing the primary containment and the turbine, feed train, pond and support systems. A ventilation system has maintained the pressure within the containments slightly below atmospheric throughout the life of the facility to ensure that no contamination can leak out. This will be expensive to operate and maintain for the whole of the care and maintenance Stage. A strategy has been developed to identify the most cost effective combination of decontamination, sealing, enclosure and airborne contamination monitoring necessary to allow the ventilation system to be turned off without challenging the external environment. This strategy also provides a consistent framework for resolving containment issues in other tasks. Because of the regulatory interface, and supporting development work, this work has been managed directly, but the work to rationalize the ventilation system will be exposed to competition. The primary containment will enclose the principal hazards (radiological and asbestos) until Stage 3. The amount of work planned to be done within it is limited but was sufficient to justify the development of a "Surrogate Tour". This is based on a collection of photographs covering all accessible detail of the primary containment and stored on a video disc. The display of these photographs in the form of a tour is managed by windows-based PC software, which also allows annotation with supplementary data and updating as plant changes are made. This tour has greatly reduced the number of visits necessary to the primary when planning work and has proved both dose and cost effective.
A key requirement of the current work is to provide a comprehensive set of information for those who will maintain the facility, undertake the later Stages of decommissioning and dispose of the wastes without the benefit of staff who were involved in the design, construction or operation. As part of this, comprehensive radiological and asbestos inventories have been drawn up, requiring close integration of surveyors, engineers and database specialists. Extensive use was made of asbestos during construction, and after initial assessments it was decided to remove all asbestos from the secondary containment as it complicated many planned activities. Conversely, asbestos has been left in the primary because it is well contained, little other work is planned and removal would involve substantial dose issues.
Implementation of the decommissioning of the ponds and the modification of the ventilation system are the two most significant remaining tasks.

CONCLUSION

The project is approaching the end of the fourth year of its six year program. All fuel and moderator have left the site; a comprehensive study of the options for decommissioning the ponds has been undertaken in readiness for placing a contract; rationalization of the mechanical, fluid, electrical and instrument systems is largely complete; an economic containment strategy has been devised; a systematic approach to the buildings associated with the facility is being implemented; and planning for handover to care and maintenance has begun. Substantial economies have already been made in the manning and maintenance of the facility.

The decommissioning is now being undertaken in a fully commercial environment, with the majority of the decommissioning tasks being awarded through competitive contracts. The project has successfully kept within the original safety, cost and time parameters by the integration from the outset of reactor and project staff within a comprehensive project management culture. The systematic approach which this encourages has permitted good delegation, planning and coordination; has provided a firm base so that changes in the external environment of the project can be assimilated; and has thus permitted the SGHWR Decommissioning Project to successfully meet its objective of providing a cost effective solution for the ongoing management of the SGHWR facility.

ABSTRACT

This paper describes the radiation monitoring systems and strategies developed as part of BNFL's 'Decommissioning and Decontamination Development Program' to support the Company's current and future decommissioning operations. A number of novel monitoring systems and techniques are described covering data capture and planning phases, through to dismantling and, finally, waste disposal. Systems described include: planning and survey tools such as the computer code 'DECOM', radiation imaging systems and a modular Passive Neutron Coincidence Counting system known as 'DISPIM'; Piece and Drum Monitors for Plutonium Contaminated Materials (PCM) arising from dismantling operations and finally; a system for monitoring walls and floors of redundant buildings, targeted at segregation of materials at the Very-Low-Level Waste/ Low-Level Waste boundary. The ongoing development of all the systems described has been carried out in close collaboration with decommissioning personnel at all stages of the decommissioning process. It is concluded that such operational experience is an essential part of the process of instrumentation and strategy development.

INTRODUCTION

The Sellafield site in North West England is operated by British Nuclear Fuels plc (BNFL). As with any nuclear site which has existed over 45 years a number of facilities over time have become redundant as a result of mission change or other factors. In many cases, shutdown facilities entered a Surveillance and Maintenance (S&M) phase. In other cases, where space within certain buildings was needed for new construction, some facilities were dismantled and secured pending future decontamination, size reduction or packaging.

With a significant number of already closed facilities awaiting decommissioning and the prospect of a further large number of facilities becoming redundant at the end of Magnox reprocessing, a decommissioning program for the Sellafield site was developed in 1981. The purpose of the program was to develop plans to reduce the backlog of facilities requiring decommissioning and to develop necessary skills and expertise to access the program of work. The mid-80's also saw the creation of a dedicated decommissioning team who would carry out the upcoming decommissioning activities. Since 1985, the Decommissioning Unit (DU) at Sellafield has grown to a manning level of over 160. Initial decommissioning plans underwent progressive development culminating in 1988 in a 100 year decommissioning program for the Sellafield site. This plan covers currently redundant buildings, those still operational and those yet to be commissioned.

Decommissioning at Sellafield is now guided by a rolling 15 year plan. This plan is updated regularly and is formulated in agreement with the regulatory body. In order to ensure that the aims of the decommissioning program could be met, a

decontamination and decommissioning development program was established in 1988 with the aim of generating all the necessary expertise and technology required in areas such as plant data capture, remote handling and radioactivity assay as well as improving the accuracy of decommissioning cost estimation and developing decommissioning strategies.

This paper describes some of the strategies and techniques in the areas of radioactivity assay that have been developed as part of the decontamination and decommissioning development program.

CHALLENGES FOR DECOMMISSIONING ASSAY

Clearly, the requirements for radioactivity assay depends very much on the particular application, for example whether the plant has handled mainly alpha active material or beta/gamma activity. However, in all cases there are a number of general driving forces underpinning the need for assay, these include:

- Safety
- Dose minimization
- Disposal cost minimization (by decategorisation and volume minimization)
- Regulatory requirements

In the case of plants dealing with alpha active contamination, in particular plutonium bearing materials, the specific requirements for assay information is dominated by the need to maintain criticality safety at all stages throughout the decommissioning operations. In addition to the general practical difficulties of making measurements in such plants, the plutonium contaminated material is often of unknown and variable isotopic and chemical composition which provides a major challenge in the design of accurate assay technology.

In the case of beta-gamma contaminated plant the requirements are usually to support dose minimization and to provide inventory information to support decategorisation and disposal regulations.

The following sections provides a description of some of the methodologies and instrumentation developed to support decommissioning operations within BNFL and, in particular, on the Sellafield site.

METHODOLOGIES FOR DECOMMISSIONING ASSAY

Alpha Plants

Strategies for decommissioning alpha plants at Sellafield have been developed around a number of lead projects (1), these include:

TABLE I

In general, the monitoring strategy adopted for alpha plants at Sellafield has taken the following form:

In order to provide fissile inventory data for planning purposes and developing criticality safety cases, a modular Passive Neutron Coincidence Counting (PNCC) system known as DISPIM (Decommissioning In-situ Plutonium Inventory Monitor) has been developed. Depending on the strategy adopted for the plant being decommissioned, two courses of action in relation to subsequent monitoring may be followed:

If levels of fissile material levels are known, or expected, to be sufficiently high that criticality safety during the dismantling phase is a major issue, because of possible redistribution of material, then 'Piece Monitoring' is employed to monitor individual pieces, after size reduction, and to provide a running total of the fissile content as these pieces are deposited into a waste drum or other storage container as appropriate. The piece monitoring system has been developed utilizing a combination of Passive Neutron Coincidence Counting and High Resolution Gamma Spectrometry and is able to deal with items of unknown Plutonium Isotopics and unknown Chemical Compositions (e.g., oxide and fluoride). In order to provide verification of the total drum fissile content prior to storage a drum monitoring system has been developed utilizing similar techniques to the piece monitors.

In some cases throughput benefits can be achieved by monitoring prior to size reduction, for example when large items are expected to contain only small amounts of fissile material. As such, piece monitoring may not be an appropriate course of action and consequently, larger monitoring systems are required. Such an approach is currently being adopted in support of finishing line decommissioning.

During the course of the dismantling phase of decommissioning operations relating to alpha plants, the DISPIM system is often re-employed to re-establish the database of fissile inventory information to provide ongoing criticality safety assurance.

Beta Gamma Plants

In a similar way to alpha plants, decommissioning strategies for beta gamma plants have been developed around a number of lead projects (2), these currently include:
TABLE II
In these cases, the monitoring strategy has adopted a slightly different form to that described for alpha plant. The first phase of monitoring is generally targeted at providing initial radiation source distributions to enable selective decontamination of 'Hot Spots' to efficiently minimize the dose uptake of decommissioning personnel. Additional monitoring requirements are usually aimed at waste segregation and decategorisation (e.g., Intermediate-Level Waste (ILW) to Low-Level Waste (LLW)) and in support of providing the necessary inventory information for storage and final disposal.
Two approaches have been adopted to assist in the determination of radiation source distributions. The first is based around inverse shielding calculations, using the DECOM computer code, to derive approximate source distributions based around Health Physics dose survey data. The second approach is based on direct mapping of radiation sources in 2D and 3D using a variety of radiation imaging tools, some of which are described in the following section. In the case of storage ponds decommissioning a variety of other instruments are currently under development to assist in the mapping of submerged radiation sources.
Work in support of decategorisation and inventory measurements has so far been centered around the production of bespoke systems to meet the specific requirements of individual projects but is generally aimed at making measurements as close to the point of origin as possible, in order to minimize mixing of different waste streams. Depending on the application, such systems range in complexity from simple Low Resolution Gamma Spectrometry devices through to major multi-technique assay stations encompassing combinations of High Resolution Gamma Spectrometry, passive and active neutron techniques and radiographic measurements.
SYSTEMS FOR SUPPORTING DECOMMISSIONING OPERATIONS AT SELLAFIELD
The following sections provide information relating to a number of systems and techniques that have been developed so far to support current and future decommissioning operations within BNFL.
The DECOM Code
As stated above, decommissioning work often involves estimations of the activities of the sources in a plant which may not be known, perhaps because they have decayed over time or because accurate information characterizing them is not available. DECOM uses information on the size, position and composition of the shields and radiation sources in a plant, together with measured dose rates taken around the plant, to calculate the activities of the sources. These calculated source activities can in turn be used to evolve a decommissioning strategy, or to calculate dose rates at other positions.
DECOM utilizes a new core calculation method which is, on average, a factor of 4 times more efficient than the point kernel method commonly used by other codes. A source subdivision algorithm is implemented automatically by the code to further increase the efficiency of the code. The subdivision implementation requires no user input.
DECOM can also be used as a conventional gamma ray shielding code and has a novel graphical interface allowing the user to view/check their model; interactively calculate the dose rate at a point; calculate and display colour dose rate contour plots and interactively change their models to answer "what-if" questions, e.g. what is the change in the dose rate at this point if I remove this shield?
The graphical interface can also be used to estimate the improvement in the precision of the calculated source activities due to additional measured dose rates before actually taking those measurements. This can be used to calculate the most beneficial position to take additional dose rate measurements whilst minimizing the exposure to the person taking the reading.
Decommissioning work so far undertaken using DECOM has included a test case involving the B41 dry storage silo at Sellafield. Each of the 5 silos in B41 contains both radioactive and non-radioactive waste of many different sizes and materials, e.g. gloveboxes, reactor hold-down weights, Magnox Swarf. No information was available as to the positions of each of the waste's many components, however, the total amount of each waste component was known.
Calculating source activities in this model presented two problems since neither the source positions nor the self shielding effects of the waste were known. The problem

was approached in the following manner.
Since most of the waste components are small it is possible to "smear out" the discrete geometry of the waste and to model it as one homogeneous material whose density was equal to the average density of the waste. The average density of the waste is calculated using the relative amount and density of each of the waste components. This is a valid and widely used assumption for gamma photons since the mass attenuation of a material is mainly dictated by its density and not the material itself, i.e. concrete (density 2.32g/cm3) and aluminum (density 2.7g/cm3) have very similar mass attenuations.
Each silo was modelled as a number of discrete blocks of known position. Modelling the silos in this manner also reflects the fact that waste of different activities were placed in the silos at different times and this will tend to form layers of waste of varying activity. These discrete blocks were then treated in the usual manner to find the source strength of each block. In this manner the source strength is calculated as a function of position.
Although there are no direct means of validating the calculated source strengths, when they were used to calculate the dose rates at the measured points it was found that 207 of the 238 calculated dose rates matched the measured dose rates to within 80% and were, on average, approximately 30% different. The remaining 31 calculated dose rates were up to 2 orders of magnitude different from the measured values. Inspection of these dose positions found them to all lie on the same vertical plane. This suggested that some significant shielding feature at this particular height had not been modelled.
The calculated dose rates were considered to give a very good fit to the measured dose rates considering the assumption made in "smearing out" the waste material geometry and in the build-up factor approximation inherent in the calculation method.
Radiation Imaging Systems
From the outset the aim of the development programs in support of radiation imaging has been to generate colour radiation maps which can be super-imposed on to TV camera views of the same scene. In this way, both the energy and intensity of incoming radiation can be presented, together with features such as hot-spot identification and isotopic analysis. Such images could also be incorporated into computer models of plant layouts, both as a tool to assist in the planning of decommissioning activities and to allow operator access to plant to be optimized in order to minimize doses. Our requirements are two-fold:
Large, fixed systems for use in equipment decontamination or in waste sorting applications. These systems will need to be very sensitive, possibly working in real time, and will have some features in common with existing medical and space systems.
Lightweight, yet rugged, devices will be required for remote deployment which will include decommissioning and incident response applications. These systems will need to use innovative design to achieve a suitable balance between portability and speed of response, and will be very different from existing systems used in other industries.
In order to meet these requirements a number of distinct radiation imaging systems have been, or are being, developed and are summarized in the following table.
TABLE III
Of the systems described in Table III the 'Cyclops' device is the furthest developed and is currently being used on plant in a variety of applications. This particular system utilizes a 18mm x 18mm photodiode coupled CsI detector with tungsten collimation giving a choice of 'fields of view' ranging from 5 to 10. This is directly coupled to a camera system and the whole assembly mounted on a computer controlled 'Pan and Tilt' mechanism. The output of the device is in 'real-time' with count rate information directly overlaid on the video recorded image. Energy discrimination may be employed if maps of individual isotopes are required. Figure 1 shows a schematic of the system.
Fig. 1.
The 'Cyclops' system has so far been used in support of many decommissioning projects, including decommissioning redundant gloveboxes in the Sellafield R & D building and preliminary survey measurements on storage ponds, and is receiving considerable general attention as a useful tool in decommissioning operations.
The DISPIM System
The Decommissioning In-Situ Plutonium Inventory Monitor (DISPIM) is a modular

Passive Neutron Coincidence Counting (PNCC) system that has been developed to assist in planning and criticality safety assessments of alpha plant decommissioning projects. The system enables measurements of the Pu-240 equivalent content of, for example, gloveboxes, vessels and pipework, to be carried out prior to and during dismantling operations. This information combined with a knowledge of the associated isotopic breakdown, obtained from plant knowledge, in-situ gamma-spectrometry or sampling, enables the fissile content of the plant item to be determined.
Considerable operational experience has been gained with the system through its successful use in a number of decommissioning projects on the Sellafield site.
Figure 2. shows the system in use for an 'on plant' glovebox measurement. The performance of such a system is dependent on the conditions relating to a particular measurement, i.e. detector geometry, matrix characteristics, background radiation levels and plutonium isotopics. However, for a typical, civil grade, plutonium contaminated glovebox monitoring exercise, with a count time of the order of a few hours, a detection limit of a few grams Pu is easily achieved.
Fig. 2.
The DISPIM system is based on up to 30 polyethylene moderated 3He detector modules combined with charge amplifiers and shift register coincidence electronics. The use of neutron coincidence counting allows the time correlated neutrons from spontaneous fission events in 240Pu and other even mass number isotopes of plutonium to be recorded separately from the randomly emitted neutrons originating from (a,n) reactions on light elements. The emission of the latter is dependent on factors other than the plutonium content, in particular the chemical composition of the plutonium compounds and the waste matrix. In-situ calibration of the system is performed via the 'add a source' technique using a Cf-252 of known activity to determine the neutron detection efficiency of the particular arrangement for fissile material in a variety of locations within the item being monitored. For criticality safety measurements, worse case data is always used by the software such that the plutonium mass calculated is based on the lowest efficiency measured during the calibration exercise. Similarly statistical fluctuations are included in the error calculations so as to provide an upper limit to the actual plutonium mass.
Figure 3. shows a schematic of the hardware making up the DISPIM system. The outputs of several detector modules are combined and connected to a single amplifier. The outputs from all the amplifiers are summed to form a single input to the neutron coincidence counting unit. The operator interface is via a terminal and keyboard with data output to both screen and printer.
Fig. 3.
DISPIM has fully QAed software written to BS5750. The package is entirely menu driven and extremely user friendly. Indeed, the system has been successfully used on plant on a routine basis by operators with minimal training.
Piece and Drum Monitoring Systems (Alpha Plants)
Both the Piece and Drum Assay Monitoring Systems utilize a combination of passive neutron and gamma measurements to determine the plutonium content of PCM waste packages or 200L drums respectively.
240Pueq content is determined by Passive Neutron Coincidence Counting using a measurement system incorporating helium-3 (3He) gas filled thermal neutron proportional counters and neutron coincidence electronics. The percentage 240Pueq relative to total plutonium is determined by High Resolution Gamma Spectrometry (HRGS) using an intrinsic germanium detector and system electronics with multichannel analysis capability.
Both systems incorporate a number of features to alert operators of the presence of materials that could produce erroneous results. For example, the presence of uranium is detected by measurement of the 186 keV gamma radiation from 235U or one of the 238U gamma-rays at 766 and 1001 keV and the operator alerted if statistically significant amounts are present. Similarly, the presence of very high fluoride contents, which can cause problems with PNCC due to extremely high (a,n) emissions, is flagged by measurement of gamma-rays simultaneously emitted from such reactions, in particular at 583 keV.
In addition, considerable attention has been paid to the issue of measurement controls, so as to ensure that all measurements are reliable and not subject to system fault or external influence. For example, neutron measurements are corrected for the effects of other decommissioning and plant operations by measurement of the background radiation at regular intervals whilst the system is in use. Similarly,

standardization checks of the gamma system is carried out on a regular basis by the use of an actuator driven radionuclide source.
Figure 4 shows a photograph of one of the piece monitoring systems supplied so far to the Sellafield site, this particular one being supplied to support decommissioning the miscellaneous facilities identified in Table I
Fig. 4.
Very-Low-Level Waste (VLLW) Assay System
This system has been developed to assist in the decategorisation process for walls, floors and other large areas of similar geometry which are at the Very-Low-Level-Waste (VLLW) / Low-Level-Waste (LLW) boundary, taken as 0.4Bq/g above natural activity levels in the UK (4,5). The radiometric monitoring sub-system employs High Resolution Gamma Spectroscopy (HRGS) techniques and incorporates a high efficiency Germanium detector, associated electronics and system software which controls both the deployment system, data acquisition, data analysis and display functions. The detector is heavily shielded such that measurements of sufficient accuracy may be made at any one location over a relatively short period. At the present time, the system has been optimized for use on uranium contaminated buildings, although the system software may readily be adjusted for other types of contamination.
The computer controlled deployment system can position the detector anywhere within an x-y plane on a wall or floor. A system of special tracks are fitted to the wall or floor and electrically propelled carriages fitted to the tracks are used to position the detector assembly anywhere within the boundary defined by the tracks. The deployment system is of modular design thereby allowing coverage of areas ranging from about 6m2 to 40m2 or more. When the monitoring of one area is complete, the whole system may be dismantled and then reassembled at the next wall/floor area which is requires to be monitoring. In this way, the majority of the internal wall and floor area of a building may be monitored with each measurement position (i.e. approx. 0.1m2 area) being sentenced as either VLLW or LLW. The degree of contamination is expressed in Bq/cm2 and the mean penetration depth of the contamination in the building material is estimated by exploiting differential absorption of gamma ray peaks in the uranium spectrum. Appropriate decontamination techniques may then be applied to the areas identified as being LLW in order to re-categorize them to VLLW. Each measurement position is permanently identified using an automated paint spray system so that areas of wall which are classed as LLW may be readily identified for future decontamination treatment.
The system is currently about to undergo active trials at the BNFL Springfields site in support of decommissioning the Residue Processing Plant associated with fuel fabrication activities.
DISCUSSION
The monitoring systems and techniques described in this paper represent only a small subset of the output from the ongoing development program to support decontamination and decommissioning operations within BNFL. In all cases the development process has been guided from the outset by discussions with decommissioning project managers and future operators in order to properly define the measurement requirements at all levels. Nevertheless, the development process is a cyclic one making full use of experience gained during initial plant operations to enhance the design and capability of the particular system. As such, the development process is ongoing in support of the various 'lead' decommissioning projects identified with the aim of having a complete suite of tools to assist in all aspects of future decommissioning projects.

ABSTRACT

Controlled blasting technique is, in general, able to demolish efficiently only specific portion in the massive concrete structures. In the Japan Power Demonstration Reactor (JPDR) decommissioning program conducted in the Japan Atomic Energy Research Institute (JAERI), the controlled blasting technique had been developed and tested to be applied to dismantling the most part of the biological shield which volume is 1,400 tons. The dismantling activities using the controlled blasting started January 1992 and completed January 1994. Through the dismantling activities, various data on industrial and radiological safety were collected to verify the work procedures using the controlled blasting technique.
Based on the data obtained, the controlled blasting technique was confirmed to be useful for dismantling the massive concrete structures in reactor facilities.

INTRODUCTION

The JPDR (BWR, 90Mwt) started to generate electricity for the first time in Japan in 1963. After training of operators and some irradiation tests, the JPDR ended its service life in 1976.
In consideration of future decommissioning of commercial nuclear power reactors, the JPDR decommissioning program was initiated in 1981 by JAERI under a contract with the Science and Technology Agency (STA) of Japan to develop techniques necessary for decommissioning of nuclear power reactors and to demonstrate these techniques in the actual dismantling work.
After the development of various decommissioning techniques such as dismantling machines, estimation of radioactive inventory, decontamination, waste management and radiation control, the actual dismantling of the JPDR started in 1986 and will completed in 1996.
By the end of October 1991, the highly radioactive components such as the reactor pressure vessel (RPV), the reactor internals, the pipes connected to the RPV and the highly activated part of the biological shield were removed by newly developed dismantling techniques with remote operation.
As a result of removing protrusion of the biological shield, the maximum dose rate in the cavity of the biological shield decreased to 3 x 10-2 mSv/h or less, where workers could approach to work by hands. The controlled blasting technique having an enormous dismantling capability was therefore applied to dismantling the remaining portion of the biological shield.
In the first step of dismantling activities using the controlled blasting, the inner layer (about 40 cm in depth) of the biological shield, which had relatively low radioactivity, was dismantled during January 1992 through October 1992. All wastes generated by this work were loaded into steel containers for storage in the waste storage facility in JAERI. In the next step of dismantling activities, the outer portion of the biological shield, which had extremely low radioactivity, dismantled during April 1993 through January 1994. All wastes were loaded into the flexible polyethylene fiber containers, and these will be disposed in the test shallow land burial place in JAERI for the study on migration behavior of radioactive nuclide.

JPDR BIOLOGICAL SHIELD

Figure 1 shows the cross sectional view of the JPDR biological shield showing area classification relating to the applied techniques and the maximum radioactivity of the concrete. The JPDR biological shield was made by reinforced concrete. Steel reinforcing bars, 29 mm in diameter, were located at interval of 150 to 200 mm. The wall was 1.5 m to 3.5 m in thickness and lined with 13 mm thick steel plate. It had a cylindrical shape with a central cavity, where the RPV was located. The sizes of

the cavity was 2.7 to 3.5 m in diameter. At the mid-core level portion, it had the inner protuberant part (a height of 3.6 m, a wall thickness of 0.4 m) to prevent the neutron irradiation. The concrete had a compressive strength of about 30 MPa(300 Kg/cm2). There were various openings and the ventilation ducts on the wall surface. A number of cooling pipes (34 mm in diameter) and neutron detector guide tubes (265 mm in diameter) were embedded in the concrete structures.
Fig. 1.
CONTROLLED BLASTING TECHNIQUE
Explosives for Controlled Blasting
Generally, the controlled blasting technique is used to make cracks in concrete structures to be demolished with minimum shocks and vibrations. In addition, the damage to surrounding structures is prevented by the use of relatively mild explosives. Recently, the controlled blasting technique has been applied to construction of tunnels and destruction of buildings.
Urbanite, which was an mildly improved form of Dynamite was used in this dismantling work. As compared with Dynamite, Urbanite has low detonation velocity and high gas pressure. When Urbanite was blasted, shock waves generated by blasting made cracks in the concrete, and then the gases produced expanded the kerf of the concrete. For this reason, Urbanite was adequate to dismantling only the specific portion of the biological shield. The amount of explosives for each blast was determined using the Hauser's empirical formula:
L = C x W x D x H
 L: Weight of explosives at each blasting hole (Kg)
 C: Blasting factor
 W: Shortest distance between blasting hole and free-surface (m)
 D: Distance between adjacent blasting holes (m)
 H: Depth of blasting hole (m)
The blasting factor (C) was determined by the mock up tests, which were conducted before the actual dismantling work.
Charging Directions
The explosives were charged vertically or horizontally. The charging direction was selected on the depth of the biological shield being demolished and the working space in the cavity of the biological shield. The vertical charge was mainly employed to demolish the inner layer of the biological shield. The blasted blocks by the vertical charge were about 2 m in width, 0.4 m in thickness, and 1.8 m in height as shown in Fig. 2 (1). In the vertical charge, the blasting force was concentrated toward the center of cavity. Therefore, the damage to the outside wall was limited to the planned portion. If the outside wall of the blasting location was thin, the blasting holes were drilled in two layers instead of one layer to prevent the development of cracking on the outside wall. The horizontal charge was mainly employed to demolish the outer portion of the biological shield. The areas being blasted by the horizontal charge were all the circumferential direction, about 2 m in thickness, and 35 cm in height as sown in Fig. 2 (2). In the horizontal charge, the blasting force was concentrated above the planned blasting areas. The circumferential areas were widely blasted at a times.
Fig. 2.
Procedure of Dismantling Work
As a preparatory work, the inner layer of the biological was slitted together with the steel liner and the reinforcing bars to a depth of about 0.25 m at the boundaries of blocks being blasted by an oxyacetylene torch and a diamond cutter. Drilling, charging of explosives and mechanical crushing were performed by workers only using the jack-hammer and the mechanical breaker on the movable platform in dismantling the inner layer. However, in dismantling the outer portion of the biological shield, a drilling machine and a back-hoe shovel were introduced to forward the work of drilling and crushing as shown in Fig. 3. The procedure for vertical charge blasting and horizontal charge blasting is summarized as follows.
  Holes were drilled on the blasting location by the use of jack-hammer or drilling machine on the platform, which was lifted by a polar crane.
  Explosives were charged in each hole. The holes were then sealed with tamped sand.
  The areas being blasted was covered with mats and sheets to prevent the scattering of concrete debris and to minimize the spread of airborne dusts.
  The explosives were set off with ignition time delay intervals of 0.025 or 0.25 seconds.

The cracked concrete was fractured using a mechanical breaker and a back-hoe shovel. The undetached reinforcing bars were cut with an oxyacetylene torch.
In dismantling the inner layer of the biological shield, the dismantled concrete and metals wastes were put into two-hundred-liter drums and one-cubic-meter containers for storage in the waste storage facility. While, in dismantling the outer portion of the biological shied, a small-wheel loader was used to load the concrete waste into flexible polyethylene fiber containers for disposal in the test shallow land burial place.
In both of dismantling the inner and outer portions of the biological shield, the above procedure was repeated starting at the top and progressing to the bottom of the biological shield.
Fig. 3.
DATA OBTAINED FROM THE DISMANTLING WORK
Through the dismantling activities, various data such as manpower expenditure, collective dose, waste generation, noise and vibration, were collected to verify the usefulness and safety of the controlled blasting technique. Table I shows the data on the dismantling work.
TABLE I
Manpower and Collective Dose
The total duration and manpower expenditure required for dismantling the inner and outer portions of the biological shield were 362 days and 8,600 man-days, respectively. The breakdown of the total duration and manpower expenditure were 153 days and 3,700 man-days for 207 tons of the inner biological shield (18 man-days/tons), 209 days and 4,900 man-days for 1260 tons of the outer biological shield (4 man-days/tons). Since the heavy machine such as the drilling machine and the back-hoe shovel were introduced to forward the dismantling activities in the outer portion of the biological shield, the manpower expenditure per unit weight of dismantled concrete was less than that of dismantling the inner layer of the biological shield.
The total collective dose was limited to be 2.3 man-mSv. Most of the radiation exposure occurred while workers engaged in the work of drilling and mechanical crushing at the mid-core level portion.
Waste Generation
The total weight of concrete and metal wastes generated by the controlled blasting was 1,500 tons. In dismantling the inner layer of the biological shield, 180 tons of concrete wastes were put into 708 two-hundred-liter drums, and 30 tons of metals which consisted reinforcing bars and steel plates were put into 16 one-cubic-meter containers. In dismantling the outer portion of the biological shield, 1190 tons of concrete wastes were loaded into 1012 flexible polyethylene fiber containers, and 70 tons of metals wastes were put into 107 two-hundred-litter drums and 29 one-cubic-meter containers, respectively.
The steel containers (two-hundred-liter drums and one-cubic-meter containers) were transported to the waste storage facility in JAERI. While, the flexible polyethylene fiber containers will be disposed in the test shallow land burial place in JAERI.
Blasting Work
The total volume of blasted concrete structures was about 580 m3 and the total weight of explosives used was 170 kg. The explosives of 250 to 500 g were required to blast the volume of 1 m3. The amount of explosives tend to increase with the weight of metals in the biological shield. By analyzing the data obtained in dismantling the inner layer of the biological shield as shown in Fig. 4, it was found that approximately 260 minutes of the total working time were required to demolish the typical blasting location; 25% for drilling using a jack-hammer, 24% for making and charging of explosives, 13% for covering the protective mats and sheets, 38% for mechanical crushing using a mechanical breaker.
Fig. 4.
Noise and Vibration
In dismantling the inner and outer portion of biological shield, the blasting noise and vibration generated by the blasting were measured in the reactor enclosure and outside of the reactor enclosure.
As an example of the noise data, the blasting sound pressure level was measured at two points, third floor in the reactor enclosure and at a distance of 10 m from the blasting location outside of the reactor enclosure. The maximum sound pressure level was about 130 dB(A) in the band of 25-250 (Hz) in the reactor enclosure. It

decreased to about 100 dB(A) outside of the reactor enclosure. Generally, the critical value of the sound pressure level to the human organization is considered to be about 130 dB (A) regardless of its duration. In this dismantling work, 130 dB (A) of the sound pressure level was measured some times in the reactor enclosure. However, since the workers were evacuated from the reactor enclosure when the blasting was initiated, it had no influence on the workers.
To evaluate the effect of vibration on the surrounding components, the acceleration of the vibration was also measured at three points: 12, 17, and 27 m from the blasting portion. The acceleration varied from 20 to 400 gal (cm/s2). Generally, the acceleration range between 100 and 400 gal corresponds to a large earthquake. However, since the vibration generated by blasting had the characteristics of high frequency and short duration, there were no damage on the remaining concrete structures and no influence on the integrity of components in the reactor enclosure.

LESSONS LEARNED
In dismantling the biological shield, it was proved that the controlled blasting technique was useful for demolishing exactly the planned portion. The lessons learned are listed as follows :
  The slits cut in the boundary and the back-hoe shovel used were very effective in improving the demolition performance of the massive steel-lined reinforced concrete structures.
  The amount of airborne dusts were effectively limited by the protective mats and sheets, the sprinkling water on the concrete to be demolished.
  For dismantling the highly activated concrete structures using the controlled blasting technique, it will be necessary to develop the drilling and charging methods with remote operation to reduce the radiation exposure.
CONCLUDING REMARKS
The controlled blasting technique was successfully applied to demolishing of the low level radioactive portion. The safety of the controlled blasting was proved by the various data on industrial and radiological safety.
After dismantling the biological shield, the major activities in the JPDR decommissioning program are decontamination of the floors and walls in the buildings together with the final survey of the radioactivity. In the beginning of 1995, the radiation controlled area will be released gradually to demolish the buildings in the JPDR site.

DECOMMISSIONING OF NUCLEAR FACILITIES THAT WERE ABRUPTLY SHUTDOWN - A LOOK AT THE UNITED STATES DEPARTMENT OF ENERGY URANIUM REFINERY
AT FERNALD, OHIO
Gregory B. Cotten
Parsons Engineering Science, Inc.
ABSTRACT
The Fernald Environmental Management Project site, formerly the Feed Materials Production Center, produced purified uranium for Department of Energy enrichment plants and production reactors for more than 35 years until production was suspended in 1989 for reasons of decreasing demand for purified uranium and increasing environmental accountability. Operations were suspended without a formal and complete shutdown being performed. This resulted in large amounts of liquid and solid materials being left in process lines, furnaces, and intermediate storage areas. The site has undergone a change in management since the days of production and is presently engaged in environmental restoration and waste management as its sole mission.
There are many challenges faced by the engineering personnel in evaluating the existing systems, providing for a safe work environment, and designing environmental remediation solutions.

For many systems the first step in decommissioning is to empty the system of all internal fluids and solids. The uranyl nitrate hexahydrate (UNH) neutralization project is tasked with neutralizing, filtering, and drumming for disposal approximately 760,000 liters (200,000 gallons) of low pH UNH, essentially an uranium-bearing nitric acid solution in water. The UNH is presently stored in 18 tanks scattered across 5 different areas of the site. The UNH was an interim product of the production process and was routinely denitrated to form uranium oxide (UO3) solid. The wastewater collected from the refinery operation was treated with magnesium oxide to precipitate the uranium. The slurry material was then returned to the refinery for processing. This involved miles of stainless steel piping, numerous pumps, and a multitude of storage tanks.

In the several years since operations ceased, there has been a rapid deterioration of system integrity resulting in numerous leaks and a loss of confidence in the ability of the system to adequately contain the UNH. The decision to use the absolute minimum amount of existing equipment in the design of the new neutralization system was an effort to restore the confidence in the system and ensure the safe processing of UNH.

INTRODUCTION

The Fernald Environmental Management Project (FEMP) site, formerly the Feed Materials Production Center, produced purified uranium for Department of Energy (DOE) enrichment plants and production reactors for more than 35 years until production was suspended in 1989 for reasons of decreasing demand for purified uranium and increasing environmental accountability. Operations were suspended without a formal and complete shutdown being performed. This resulted in large amounts of liquid and solid materials being left in process lines, furnaces, and intermediate storage areas. The site has undergone a change in management since the days of production and is presently engaged in environmental restoration and waste management as its sole mission.

There are many challenges faced by the engineering personnel in evaluating the existing systems, providing for a safe work environment, and designing environmental remediation solutions.

For many systems the first step in decommissioning is to empty the system of all internal fluids and solids. The uranyl nitrate hexahydrate* (UNH) neutralization project is tasked with neutralizing, filtering, and drumming for disposal approximately 760,000 liters (200,000 gallons) of low pH UNH, essentially an uranium-bearing nitric acid solution in water. The UNH is presently stored in 18 tanks scattered across 5 different areas of the site. The UNH ranges in normality from 0.19 to 4.65, total uranium concentration from 13.2 to 341 grams per liter, and enrichment (weight percent of U235) from 0.872 to 1.290. The UNH was an interim product of the production process and was routinely denitrated to form uranium oxide (UO3) solid. The wastewater collected from the refinery operation was treated with magnesium oxide to precipitate the uranium. The slurry material was then returned to the refinery for processing. This involved miles of stainless steel piping, numerous pumps, and a multitude of storage tanks.

In the several years since operations ceased, there has been a rapid deterioration of system integrity resulting in numerous leaks and a loss of confidence in the ability of the system to adequately contain the UNH. The decision to use the absolute minimum amount of existing equipment in the design of the new neutralization system was an effort to restore the confidence in the system and ensure the safe processing of UNH.

Configuring the existing systems to be used presented a large challenge. The integrity of the existing tanks and support equipment had to be determined, and a logical interface with the new system had to be established. The UNH storage tanks have been sitting without agitation, in some cases for over 8 years, and have settled out into layers with viscosities ranging from that of water to that of castor oil, and in some cases had crystallized into a solid mass. This paper will detail the system configuration, UNH processing, and site construction and operation that must be achieved in order to decommission this nuclear facility.

SYSTEM CONFIGURATION

Existing process equipment, storage tanks and process lines were used to the extent appropriate following an engineering evaluation of the equipment. The plant's systems had been modified significantly from their original construction to meet the requirements of the process systems needs. These modifications were rarely

incorporated into system drawings and minor modifications were frequently made without a design review. This resulted in equipment that differed greatly from the design drawings, or "as-builts," if they existed at all. The process systems had been cross-connected to allow operators to move process material virtually anywhere with any piece of equipment through any piping system be it a process line, sump line, or water line.

The UNH project team set out to develop a current set of "as-builts" to allow the maintenance personnel to work from a certified drawing. This allows performance of the necessary tank isolation to ensure no material could enter or leave the tank except through designated lines and valves whose integrity had been verified to the maximum extent possible. This task required frequent walkdowns of the system components and interfacing with the construction personnel to ensure that all interference equipment and piping was identified sufficiently so that it could be safely isolated and removed if necessary.

The maintenance personnel were required to remove connecting piping and insert blanks in the lines or install blind flanges on all penetrations to the tanks above the liquid level. Lockout and Tagout procedures were followed for all penetrations below the liquid level. These storage tanks contained UNH where a severe chemical and moderate radiological hazard required extensive Environmental, Safety and Health and Radiation Protection personnel review and supervision. The piping going into and out of the storage tanks had never been flushed, and due to cross connection of the various systems, the exact contents of the pipes could not be determined by visual inspection alone. So in order to ensure safety and protection to the personnel and the environment, conservative requirements were instituted to prevent contamination or injury through inhalation or skin contact.

The Environmental, Safety and Health and Radiation Protection requirements included the use of glove bags, secondary containment, and forced air respirators for the initial opening of tanks and process lines. After inspection and sample characterization if required, the handling procedures were adjusted to fit the actual hazard involved. The buildings that housed the process equipment and several of the storage tanks also presented hazards of their own. Transite panels that were manufactured with asbestos were disintegrating and falling off of the ceilings and walls, presenting a falling object and airborne asbestos hazard. The buildings were open to birds and the threat of histoplasmosis* required frequent Environmental, Safety and Health evaluation as well.

The maintenance staff required extensive training to bring their level of knowledge to the industry standards of today, such as the use of torque wrenches and material certification. These were two specific areas that were discovered to be inadequate during the walkdowns to develop the "as-builts." Bolts were sheared off and flanges were left installed with less than the required number of fasteners. Many leaks were identified in places where material was used that was not suitable for the low pH nitric acid environment.

The final decommissioning of the UNH piping and process equipment is a follow-on activity to the UNH neutralization project. The system will be in an environmentally benign status after processing as all lines and tanks used in the process are being cleaned and rinsed after their final use. The processing system has been identified to be potentially available for future processing of other site materials should their remediation include similar processing.

UNH PROCESSING

The UNH processing flow diagram is shown in Fig. 1. The UNH is pumped from the remote storage tank to the dilution/neutralization tank that has been previously filled with a specified amount of water to reach the required dilution factor for optimum processing. Magnesium oxide is added and the tank is agitated until a neutral pH is obtained. The slurry is then pumped out of the bottom of the dilution/neutralization tank to the filter feed tank and then to the vacuum filter. Fig. 1.

The vacuum filter pulls the liquid portion through a canvas cloth coated with a diatomaceous* pre-coat. The filtrate is then characterized and either discharged to the Great Miami River, reprocessed, or treated in the biodenitrification facility until discharge limits are met. The filter cake is removed from the vacuum filter with a knife edge that allows the pre-coat to remain on the cloth, and the filter cake is loaded into 208 liter (55 gallon) drums via a discharge chute. The drummed filter cake is characterized and prepared for shipment to the Nevada Test Site for

ultimate disposal.
The UNH process system was designed with a minimum number of flanged unions and valves to maximize the length of welded pipe. This reduces the number of places where a leak can occur and also reduces the amount of secondary containment required. Due to the construction of the process areas at the FEMP, most of the pipe unions were able to be placed over existing secondary containment areas. All piping runs were sloped to aid in the cleaning and flushing of the tanks and process lines using the minimum amount of process water possible. The entire UNH processing system underwent an extensive program of hydrostatic testing and operational testing using clean water to ensure that the system performed as required.
SITE CONSTRUCTION
Construction activities started in May 1994 and were still ongoing as of January 1995 to complete minor alterations. In an effort to utilize stock on hand, all procurement items were first screened through the on-site stores system to determine if the required material was available on site. This effort resulted in frequent delays and the identification of material that was similar but not exact according to the design specifications. When material was procured, the Federal Acquisition Regulations requirements inserted additional delays as frequently the low bidder was a Small Disadvantaged Business who rarely had the material in stock. When the material arrived on site, receipt inspections often resulted in discrepancies where the supplier chose to substitute what they believed was equal but design review showed noncompliance.
Construction activities were delayed as material did not arrive as sequenced by the construction activities schedule leading to individual systems being only 90% complete when the schedule required that system to interface with another system. This resulted in modifications to test plans, fabrication of "dummy" components to be installed to allow the systems to be made up to connecting systems, and the removal of these dummy components and installation of the required component when it arrived from the supplier.
The manufacturer of the progressive cavity pumps delivered the pumps as required by the design specification with one important exception. Four of the six initially delivered pumps had cracks in the casing in the same location indicating a flawed manufacturing process. The pumps were returned to the manufacturer for replacement. Due to this serious impact on the schedule, it was decided to suspend the order for the pumps and to procure double diaphragm pumps that were available on-site from the on-site stores system. These new pumps were installed with minor modifications to the process system.
The extensive Environmental, Safety and Health and Radiation Protection requirements imposed on the maintenance staff resulted in delays of the turnover of storage tanks and process equipment to the construction organization. These delays were somewhat mitigated by the construction manager rescheduling activities out of sequence so that downstream activities were completed ahead of schedule.
OPERATIONS
The operation of the UNH neutralization process was initially attempted in April 1993 using existing equipment. This effort resulted in a minor spill of UNH and provided the impetus to reevaluate the system conditions and ultimately led to the design and modification of the hybrid system intended for initial processing on January 17, 1994.
The process was to undergo an Operation Readiness Review (ORR) conducted by DOE Headquarters personnel to ensure that personnel and equipment performed satisfactorily to prevent and/or mitigate any potential releases of UNH during the process. DOE-HQ decided to conduct this ORR in parallel with a complete FEMP site ORR as one had not been completed since the site shifted from production to environmental restoration. The site was unable to be ready for the ORR when the UNH project required evaluation, so a Readiness Assessment was performed for the UNH project. This required the UNH project team to process clean water from a storage tank to demonstrate the process systems performance as well as the overall knowledge and professionalism of the operators and supervisors.
LESSONS LEARNED
The UNH neutralization project is one of the largest and most technically challenging projects faced by the FEMP site to date, and very likely in its entire remediation process. The difficulties encountered resulted in many lessons learned; several are summarized below:

The project has had five Project Managers in little over a year. A Project Manager should be selected in the beginning who has experience in the scope and scale of the project and the leadership skills necessary to bring the job from inception to completion.

An incentive-based procurement strategy should be established that not only meets the requirements of the Federal Acquisition Regulations, but also meets the requirements of the project as well. For example: quality and timeliness should be significant factors in addition to cost.

A facility should be shut down in a controlled and planned manner to ensure that process material is in discrete known locations to mitigate the "surprises" that may be encountered when piping systems are opened for decommissioning.

Process systems should be designed to the level commensurate to the actual risk as determined by a Safety Analysis, and not to arbitrary conservative requirements that increase cost and lengthen schedule without significantly lowering the risk to human health and the environment.

CONCLUSION

In the case of decommissioning a facility where both chemical and radiological hazards exist, it is even more important to thoroughly plan the suspension and completion of operations, the short term safety and integrity of the system, and the long term final remediation. This task can be made substantially less difficult by maintaining impeccable records of process systems and performing periodic verification of the system "as-builts." All design modifications should be evaluated as to how they impact the eventual decommissioning of the system, not just how they satisfy the immediate needs of the process requirements.

For those facilities that have been thrust into the decommissioning arena and have not been fortunate enough to be prepared for this eventuality, I suggest that the technical staff not allow themselves to be forced into arbitrary remediation schedules that do not allow for the technical review required to safely and completely execute the required task. This may seem like an impossibility, but every minute spent in planning will certainly save hours in the execution.

For those facilities that are relatively new and do not face decommissioning for many years, the unique opportunity exists to plan for the eventual decommissioning on a day-to-day basis. This will make decommissioning a smoother and more cost efficient task that is friendlier to the environment and safer to human health.

AN INTEGRATED BUILDING DEMOLITION AND WASTE PLANNING MODEL FOR THE FERNALD SITE

ABSTRACT

The Fernald DOE site will begin full-scale remediation of buildings under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) during the 1995 fiscal year pursuant to a signed Record of Decision. This effort is currently estimated to cost $350 million and span a minimum duration of 8 years, if funding is not a constraint. The identification of the most viable sequence and schedule for the effort involved the development of an integrated planning model and the commissioning of a sitewide planning team. The resulting work product represents the best combination of assumptions and calculations possible at this time and provides information necessary for compliance with the CERCLA Remedial Design documentation requirements for the over 230 component structures governed by the decision.

Sequence and integrated schedule development for the decontamination and dismantlement (D&D) of Fernald structures has involved evaluation of current and future utilization of structures, availability of waste storage and staging space, the needs and impacts of other on-going Fernald projects, Resource Conservation and Recovery Act (RCRA) waste management and remediation projects, the layout of site utilities, site hydrology, and the potential sizing, location, and construction rates for an on-property disposal cell.

BACKGROUND

Under a 1994 signed Record of Decision (1), the Fernald DOE site must initiate remediation of the site buildings before October 22, 1995 and maintain a continuous remediation program within the operable unit thereafter. The site currently plans to follow the completed remediation of Plant 7 (performed under an expedited response action) with the removal of Plant 4 (the former uranium hydrofluorination plant) followed by the removal of the majority of the Plant 1 complex (a multi-purpose sampling, milling, and staging facility). These facilities were chosen due to their availability, their relatively low amount of usefulness, and the need for additional cleared space within the former production area of the site.

During the identification of the Plant 4 and Plant 1 complexes as the initial set for remediation, it became clear that a sitewide integrated project planning effort would be required to support development of optimized sequencing for D&D projects. The approach would be required to fulfill EPA requirements, while integrating the D&D project with the other major CERCLA projects to be undertaken at the site, the waste management functions currently underway, and the RCRA driven actions mandated at the site.

INTEGRATED PLANNING TEAM

In order to ensure a comprehensive understanding of the site situation and develop an integrated approach to the sequencing, a planning team, referred to as the Sequencing Design/ Engineering/Construction (DEC) Team, was commissioned with members representing all major divisions of site management and the DOE Fernald project management staff. The major drivers and constraints were initially evaluated by the Sequencing DEC Team to determine the internal and external influences on the decision-making.

Schedules from other major projects at the site were reviewed to determine all planned uses for site facilities. Where no schedules were available, best assumptions were documented and initially considered constraints to building demolition. Date constraints for each facility were documented as milestones in a scheduling software to be used in developing a conforming schedule.

In addition to D&D constraints, several major site projects (e.g., the soil remediation and on-property disposal cell projects) assume that many of the site structures will be removed prior to their initiation or completion. Assumptions from these projects were handled as drivers for the D&D. Other drivers, major assumptions, and constraints considered by the Sequencing DEC Team for a preferred sequence are provided below:

Site hydrology (above and below grade) drives the remediation to begin in the north and move southward to prevent recontamination of remediated soils and perched water zones.

Soil use within the on-property disposal cell would require a minimum 3 to 1 ratio with respect to D&D debris to maintain adequate compaction capability.

In the absence of adequate quantities of soil, debris such as concrete and steel would be bulk stored in piles until soil could be generated.

On-property disposal cell construction is anticipated to begin receiving debris for burial in August 1997 and progress at an average rate of 95,600 cubic meters per year.

Due to inclement weather, cell construction activities are assumed to cease for three months during the winter.

D&D sequencing must progress to maximize availability of large zones for soil remediation, starting with the north and generally progressing to the south over the course of the action.

Two adjacent structures of significant size cannot simultaneously undergo dismantlement, to avoid project interferences.

No more than 5 major dismantlement projects can be undertaken simultaneously, since site construction management resources would be strained with more projects undertaken.

Safe Shutdown (removal of equipment hold-up residues, utility disconnects, and gross surface decontamination) activities must be completed in each structure prior to initiation of dismantlement.

Due to its importance in the mitigation of risks to human health and the environment, the Safe Shutdown Program is assumed to take budgeting priority over dismantlement.

Defining Remediation Complexes

Using the concept of economies of scale, the expenses for a decontamination and dismantlement project can be reduced significantly by addressing multiple components in a single project instead of remediating components as individual projects. The cost and time involved in the development, review, and submittal of contracts, work plans, health and safety plans, and other supporting project documentation are relatively independent of the number and sizes of structures within a D&D project. Other expenditures, such as subcontractor training, establishing control zones, mobilization and demobilization of construction equipment and crews, and air monitoring are also relatively independent of the number and sizes of structures within a project. Therefore, the above-grade portion of 165 individual structures were combined into twenty-three groups (called complexes) to reduce remediation costs. Similarly, the at- and below-grade portions of the operable unit was divided into three complexes (i.e., north, central, and south).

The structures were assembled into complexes based on many considerations, such as relative location of the structures to minimize impacts between dismantlement activities and the daily operations of the site. If possible, complexes were confined to a distinct area, such as a city block, that could be safely partitioned into a construction zone without adversely affecting other projects.

A second consideration for grouping structures into complexes was the current and/or future use of the facility. For example, components that support the distribution of electricity across the Fernald were combined into the Electrical Station Complex, although these components are not all located together. Two advantages to grouping structures based on their related use are that they have a high probability of becoming available altogether and are likely to be constructed of the same types of materials, making design and dismantlement activities more simple and, therefore, cheaper.

Prioritization of Complexes for Remediation

The prioritization of these complexes for remediation was initially performed by the Sequencing DEC Team without consideration of funding as a constraint. Since actual funding for a longer term project is dependent on many factors, the actual schedule of the D&D project is expected to follow the prioritized sequence, but at the rate that satisfies the funding constraints. Several average annual funding level estimates were utilized to test the viability of the preferred D&D sequence. However, since possible schedules may vary from as little as 8 years, if unconstrained by funding, to up to 30 years for minimal funding levels, the D&D sequence was required to demonstrate viability at each of the assessed funding levels. Since the preferred sequence is driven primarily by external project factors and structure reusability factors, the duration of the schedule for D&D was found to have relatively little impact on the determination of an optimal sequence.

The first step in developing a remediation schedule that is not constrained by funding is to establish the earliest possible starting date that the complex will be available for remediation. There were many structure-specific scheduling constraints that had to be factored into the schedule because many facilities are necessary to either support remediation activities or required site activities (e.g., wastewater treatment, RCRA warehouses, and ongoing maintenance) and cannot be scheduled for removal until these activities are relocated, replaced, or are no longer necessary. Although the objective is to first decontaminate and dismantle the complexes that lie within the footprint of the proposed on-property disposal cell and to clear a path for at- and below-grade remediation to proceed from north to south, some of these complexes may not become available until remedial activities are well underway. If the highest priority complex is not immediately available, remediation of that complex will be deferred until it becomes available. The availability of the second highest priority complex would then be assessed, and so on.

The second step is to factor in the impacts of several logistical constraints. Reasonable limitations on the number of workers in a given area, traffic patterns, and waste handling routing must be established to prevent overcrowding and to minimize potential health and safety hazards during remedial activities while pursuing the overall goal of a timely, efficient, and cost-effective remediation. Therefore, it was assumed that no more than five construction projects would occur at the same time. Also, careful consideration was given to avoid two construction crews working on adjacent complexes at the same time.

The final step in developing a funding-unconstrained remediation schedule is to ensure that the prioritized sequence of remediation will not heavily impact the

network of required site utilities. Fernald site utilities include electricity, plant air (used for air-supplied respirators), instrument air, natural gas, propane gas, fire protection water, sanitary water, process water, steam, sanitary sewers, storm water runoff systems, cooling water, roadways, and telephones. If the utilities are not required for the safe, efficient, and cost-effective removal of a complex, the utility lines will be capped or terminated near the boundaries of each complex (for above-grade activities) or remediation area (for at- and below-grade activities) before dismantlement begins. Utility connections to the occupied areas of Fernald will be maintained by temporary or rerouted connections, as needed. Figure 1 shows the prioritized remediation of complexes that resulted from this approach. The dashed lines represent the division between the three below-grade remediation areas (i.e., north, central, and south).

Fig. 1.

A prospective project schedule using the preferred sequence and an anticipated minimal average annual project funding level was developed to support preparation of draft remedial action compliance milestones with USEPA and the Ohio EPA. The publication of the schedule as part of the Remedial Action Work Plan will represent the first use of many intended uses for the scheduling tool developed by the Sequencing DEC Team. Annual updates are expected to be prepared for submittal to the regulatory agencies and the schedule should also represent a powerful tool for projecting and evaluating annual budget scenarios for the D&D project.

A significant portion of the schedule evaluation was for determination of waste generation rates. As a means to evaluate the impacts of waste generation rates resulting from the schedule, the known and projected waste flows were compared to handling, storage, and disposition assumptions in a material balance model.

MATERIAL BALANCE MODEL

Continued management and disposition of the production products and wastes from the site, as well as D&D wastes is a significant facet of the current site mission, requiring the reutilization of many of the former production facilities to provide covered storage. The impact of the additional waste resulting from D&D projects and the net reduction of available facilities over the course of the project was evaluated to demonstrate material flows versus capacities throughout the project. Although much of the D&D waste is expected to be eligible for disposal in the proposed on-property disposal cell, the cell is not planned to be available for D&D wastes prior to late 1998. Under the most aggressive D&D schedule, 105,000 cubic meters of debris would be generated in advance of that availability, requiring the use of 44,600 square meters of existing storage space. Additionally, several facilities currently utilized for storage would be removed under the aggressive scenario to facilitate the construction of the disposal cell, thereby reducing the overall availability of covered storage facilities.

To determine the impact of the remediation schedule on Fernald's capacity to store materials, the material balance model uses a general mass balance equation. The general equation for determining mass balance for material that enters and leaves a system is as follows:

Eq.

This general mass balance can be modified as follows to apply to material at Fernald:

Eq.

This mass balance equation considers volumetric material flow on a monthly basis. The first term in the equation, Off-Property Receipts, represents the current DOE anticipation that Fernald will not receive off-property materials for on-property storage or disposition. Therefore, in the mass balance equation, the volume of material to be received from off-property sources drops out of the mass balance equation.

The Material Generation term represents the volume of generated material that may require on-property storage prior to on- or off-property disposition. The Material Generation term specifically does not include volume estimates for uncontaminated office trash and recycled materials because these materials are dispositioned off-property in a timely manner and, therefore, do not require temporary storage at Fernald. The Material Generation term represents the total material burden, current and future, that may potentially require storage facilities prior to disposal. Table I defines the types and quantities of materials to be generated and provides the information required to calculate the Material Generation term of the mass balance

equation.

TABLE I

The Off-Property Disposition and On-Property Disposal terms represent the volumes of those materials listed in Table I that are anticipated to be either shipped off-property for disposal or recycling, or buried in the on-property disposal cell. By using the estimated volumes in the mass balance equation, the difference between annual material generation and annual material disposition equals the amount of material that requires temporary storage at any point during the project. Storage is organized into three types: hazardous and mixed waste storage; covered storage of low-level radioactive materials; and uncovered storage of low-level radioactive materials. By comparing the need for these types of temporary storage on an monthly basis with the maximum on-property storage capacities, the resulting material balance determination will indicate whether or not there is a need to provide for additional temporary storage facilities during specific periods of the project.

By performing the material balance model at monthly intervals throughout the duration of the remediation, using the information available or estimated for each of the parameters, a set of waste generation/disposition and available storage space curves were generated and compared. Figure 2 provides an example waste curve that compares the amount of needed uncovered storage space with the projected available uncovered storage capacity for a 21-year project scenario.

Fig. 2.

Rates of waste generation anticipated for each of the D&D projects were provided by evaluation of an aggressive D&D project schedule, since this scenario would arguably result in the most burdensome waste storage problem. Other waste generation activities, such as daily operation and maintenance activities, removal actions, and remedial actions of the four other operable units at Fernald, were also tracked in the model, since the resulting wastes compete for the same available storage. Waste disposition rates were developed from existing planned disposition projects or estimated for waste streams with no detailed schedules for disposition. Existing stored waste quantities were known by waste type and storage footprints (floor space utilized) were also known at the start of this analysis. Waste disposition rates for materials anticipated to be destined for disposal in the proposed on-property disposal cell were reported by the cell design effort, underway as part of the remedial design in several of the CERCLA operable units at Fernald.

MODELING RESULTS

The aggressive D&D schedule used in the material balance model, derived from the work performed in the sequencing activity, that the entire D&D effort at Fernald could be performed in an 8-year period, if funding were not a limitation.

The 8-year schedule represented the highest waste generation rate prior to development of an on-property disposal cell, and also the case under which the most storage facilities would be removed most quickly, thereby resulting in a worst case for storage needs versus capacity at the site. The analysis of this worst case demonstrated that, although the site has severely limited current storage capacity, during the course of the action, sufficient storage capacity for covered, uncovered, and hazardous/mixed wastes exists to avoid construction of new facilities. The analysis also demonstrated that the preferred sequence, in combination with other existing planned and assumed activities, was viable with respect to material disposition issues.

Since the evaluation demonstrated the necessary storage capacity was available for this worst case, and since the sequence was determined to be relatively insensitive to schedule extension, no additional modeling would be required to demonstrate feasibility of any proposed D&D schedules with respect to storage, handling, and disposition capacity.

ABSTRACT
This paper discusses changes made in a demolition project at the Fernald Environmental Management Project (FEMP), a site on the National Priorities list (NPL), owned by the Department of Energy.
The project, to demolish fourteen uranium ore silos and their structure, was based on a Removal Action Work Plan, submitted and approved by the United States Environmental Protection Agency (USEPA), that integrated Comprehensive Environmental Response Compensation and Liability Act (CERCLA) requirements to remove the source of contamination and threat to public health and the environment. After the demolition contractor defaulted at 30% complete, completion of the project by the USEPA deadline was threatened. The recovery plan included re-evaluation of project documents in addition to the schedule. It was determined that re-interpretation of the removal action criteria, including design and Removal Action Work Plan, would eliminate road-blocks, and optimize resources, resulting in project completion by the original deadline even after lost-time in mobilizing another contractor.
This presentation will discuss the "lessons learned" by the project team and illustrate how simplification of construction methods resulted in enhancements to the environmental controls, improved material handing, and created a safer work environment.
INTRODUCTION
The Fernald Environmental Management Project (FEMP), owned by the Department of Energy (DOE), was used to process uranium for U.S. Defense programs. On-site production ceased in 1989 and the facility was placed on the National Priorities List (NPL) for remediation under the CERCLA process.
The former production area included the Plant 1 Ore Silos, which were constructed in 1953 and used to store cold metal oxide by-products from processing pitchblende and lower grade uranium ores, until they were "abandoned in place" in 1961. The Plant 1 Ore Silos included four forty-four feet high, and four ten feet high, glazed tile silos and six ten feet high reinforced concrete silos. The silos, built on open steel structures, were thirty-eight feet above grade. There were platforms and material conveying equipment above and below the silos. Residues remained in the silo cone bases with depths from one foot to about six feet.
Fig. 1. Overview of Plant 1 Silos looking north.
When residues leaked from the deteriorated silos in 1991, demolition of the Plant 1 Ore Silos became a CERCLA Removal Action to speed the removal of radiological and safety hazards until final remediation of the Fernald site could be completed. A Removal Action is used to abate, minimize, stabilize, mitigate, or eliminate the release or threat of release of hazardous substances. A structural evaluation determined that, due to deterioration, the silo structures were overstressed and unable to withstand high wind forces. Demolition of the entire structure was warranted.
ORIGINAL DEMOLITION DESIGN
The initial Removal Action Work Plan listed 58 detailed, sequential steps to demolish the silos, one at a time. The demolition design required that all work be done in containment to prevent emissions of radiological contamination into the air. This containment consisted of scaffolding built around the silos and covered with plastic sheeting.
The containment sheathing had two curtain walls, an inner wall from the floor slab to the bottom of the silo and an outer wall that started above the slab near the bottom of the silo and enclosed the entire scaffold.
The ventilation system for the containments operated on three 4,000 cubic foot per minute (cfm) air-filtration devices (AFDs) equipped with High Efficiency Particulate Air (HEPA) filters. The units ventilated through a common duct and stack, which was monitored for emissions. The containment was ventilated using ducts routed to each silo which directed makeup air through the silo from outside the containment. To maintain a balance and steady number of air exchanges, multiple sizes of ductwork

and configurations of air handlers were required.
The containment scaffold around the tile silos was designed to carry hoists that would suspend a large debris slide or "funnel." The funnel would fill the shipping container immediately below the cone. Only one silo was to be demolished at a time because a multiple hoisting system was to be used to suspend a waste container and debris slide inside the silo to catch dislodged tiles as they were thrown onto the debris slide. The intent was that only the filled container would be lowered to ground level to be disconnected and replaced with another container.
The proposed hoists, required to raise and lower a debris slide, would have been individually operated with little tolerance between the slide and the perimeter of the silo. There would have been no allowance for uneven movement of the slide, which could have jammed against the silo wall.
Additional scaffold height would have been needed to install the hoists over the silos. This height would have limited access to repair any mechanical problems. The designed weight of the hoists added dynamic loading to the scaffold and complicated the scaffold design and erection.

SUBCONTRACTOR DEFAULTS

In November 1993, the construction demolition subcontractor defaulted at 30 percent completion. It would have taken five months to rebid and mobilize a new contractor to complete the work. Those five months would have been lost-time and the project would not have been completed by the December 1994 USEPA deadline and could have resulted in major fines. Therefore, the site service contractor was chosen to complete the project.

CHANGE IN STRATEGY

Reevaluation of project documents revealed ways to improve the project schedule and worker safety through design changes and activity resequencing. Project limitations, imposed by the existing work plan, were also evaluated. This evaluation was outside the scope of normal construction review.
Because the Removal Action Work Plan was a USEPA approved legal document, the construction project team proposed the enhancements to CERCLA/RCRA Unit (CRU) project engineering, environmental engineering, and safety assessment team members. This project team wrote a document detailing the changes, "Plant 1 Ore Silos Removal Action Enhancements," which was presented to DOE and USEPA. Both agencies concurred, for both worker safety and environmental reasons, that the enhancements should be implemented.
The enhanced work plan outlined the criteria and Applicable or Relevant and Appropriate Requirements (ARARs) as concepts, rather than discrete steps. Work packages were written for the different types of tasks done, rather than for each step. Worker safety was enhanced by the elimination of work under a suspended load. Environmental controls were improved by fully enclosing the containment. The changes were made during the construction phase and incorporated construction supervision and worker input on work methods during the development of work packages for the field.

PROJECT ENHANCEMENTS

Many Plant 1 Ore Silo structural design assumptions and decisions were based on evaluations to determine the life expectancy of the silos during production. New structural surveys were performed based on demolition requirements. With some additional column repair, the Plant 1 Ore Silos had sufficient structural integrity for the work to be done.
The new demolition sequence made the structure and work area directly accessible to the workers, eliminating the need for manlifts while removing auxiliary platforms, decking, etc. For safety, worker access was still limited by the number of people allowed on scaffold planks.
The containment design was changed so that all sheeting went to the floor and divided the facility into three chambers of two tall and four short silos each.
Fig. 2. Scaffolding and plastic sheeting was used to construct the containment around the tile silos.
Thus the ventilation equipment would have adequate capacity to ventilate each chamber. More silos could then be demolished at a time. Make-up air was provided at the top of the containment to avoid worker exposure to airborne contamination. Additionally, bringing the sheeting to the floor provided better control of debris from demolition of the tile.
Since the previous subcontractor had not fabricated the ductwork for the tile silos,

alternative duct routing was planned, which could use the existing duct from the concrete silos containment.
Additional savings resulted because the remaining ductwork was changed from stainless steel to galvanized and corrugated flexible duct.
The ductwork was run to the containment wall, with a branch to each chamber, to provide a minimum of seven air exchanges per hour in accordance with the plan requirements, within each chamber being worked in. The extensive ductwork of various diameters routed to the base of each silo was deleted.
To prevent the containment from becoming "dusty" with air-borne contamination, additional portable HEPA air-filtration devices were used at the base of the debris chute during the demo of each tile silo. The use of portable air-filtration devices meant more filter changes on the local units, which protected the filters in the 4,000 cfm units, which were difficult to change. The chute itself had a dust cover with duct taps sized to fit over a waste container. After the waste container was positioned under the chute, plastic was used to provide cover to the waste container to seal all voids.
Fig. 3. Waste container placed under the debris chute to collect tile silo debris and minimize emmissions due to dust.
This reconfiguration of the ductwork resulted in the duct being installed once, and allowed flexibility to do the same task on all the silos versus completely demolishing one silo before going to the next.
The decision to delete the hoist completely eliminated the safety risk to workers who would have been under the suspended load of the debris slide while connecting and disconnecting the shipping container. Eliminating the hoists allowed the scaffold roof to be lowered and sloped for drainage. The installation of the temporary roof was simplified and improved to a tube and clamp type of scaffold system verses extensive beam and headers bridging the scaffolding over the silo. Eliminating the use of the hoist made the scaffold safer by eliminating a sizable weight and reduced the anchoring needed for the scaffold footings.
Finally, the new approved plan used a combination of debris chutes and conveyors on the ground floor for movement of the waste containers. Personnel would not be required to move beneath the debris as it was being collected and moved to the waste containers. The use of chutes eliminated the need for additional electrical service and decreased the potential for mechanical failure.
Since the actual weight of the tile was unknown and there was concern over controlling the impact of falling tile into the waste container, a chute with a 45 degree off-set was used. The advantage of the off-set was that the crew loading the container, and monitoring the filters, were never under the crew breaking the tile. The chutes were made of steel to withstand impact loads and designed to prevent plugging. The silo cone bottom remained in place and funneled the debris into the chute. The impact of falling tile on the cone bottom and chute reduced the tile size so that waste containers could be efficiently loaded in compliance with the shipping weight limit.
Two sets of conveyors were mounted on the ground floor to slide the waste containers in and out of the containment. Use of the conveyor provided excellent control of the waste containers through the scaffold legs. Thus, a larger opening in the frame was not required for heavy equipment and access (i.e., fork truck). An airlock and staging area was set-up at the containment wall for the wipe-down of full waste containers to prevent spread of contamination.
An equipment mounted shear was used to demolish the steel structure rather than removing it piece-by-piece, by hand, using torch and rigging. Beside the speed at which it can cut, using the shear reduced worker risk of falls from elevated heights and exposure from lead-based paint and air-borne radiological contamination.
SUCCESSES
The Removal Action was completed safely with minimum worker or environmental exposure to contamination. The debris was containerized for shipment to an approved off-site disposal facility, the structural steel was staged for future disposition, and the concrete pads were locked-down for removal later in the demolition or the remediation of the site.
Working together, with a regard for worker safety paramount in all planning steps, resulted in a hazardous job done without incident. Although requirements, such as 100 percent tie-off of personnel, made work difficult at times, the labor force willingly complied with safety directives.

Fig. 4. Workers shown dismantling tile silo.
Summer work hours were changed to night shift because of excessive heat inside the containment. When the final structure had been demolished, this intensive eight month, 49,473 man hour, effort resulted in only four minor injuries.
Implementing changes to the Removal Action Work Plan resulted in the successful demolition of the Plant 1 Ore Silos one month ahead of the USEPA commitment date.
The lessons learned during this Removal Action include:
1. Use conventional demolition techniques, such as debris chutes.
2. Keep it simple. Don't overdesign.
3. Use a detailed work plan for field implementation, that parallels the intent of the regulatory document.
4. Be flexible. Unknown field conditions frequently happen during remediation projects.
5. Involve construction in the design phase. Communicate ideas and practical field implementation methods. Design change is expensive and results in lost time for field work.
6. Keep lines of communication with regulators open. Don't be afraid to sell enhancements, especially ones that improve safety and environmental outcomes.

DECONTAMINATION IN THE MIDST OF ACTIVE RESEARCH AND ADMINISTRATIVE OPERATIONS
Scott R. Brown
Battelle Columbus Laboratory Decommissioning Project
ABSTRACT
Many decontamination projects are performed in buildings where ongoing operations have ceased and corresponding occupants have vacated the facilities. In the case of the Battelle Columbus Laboratory Decommissioning Project (BCLDP), remediation has to proceed simultaneously with, directly adjacent to, and literally in the middle of, ongoing research and administrative operations. This has resulted in some additional planning, operational, and interfacing challenges not found in more traditional decontamination projects. Keys to successfully meeting these challenges include planning properly by taking into consideration the "extra" time and resources needed, communicating openly with facility occupants during all phases of the project, and being flexible and responsive in addressing occupants' concerns as much as practical.
INTRODUCTION
The Battelle Columbus Laboratory Decommissioning Project (BCLDP) is a Department of Energy (DOE) Environmental Management (EM) project to decontaminate and decommission (D&D) 15 privately owned buildings in central Ohio. Remediation began in 1989 and, when completed, will allow use of all facilities without any radiological restrictions. Most of the buildings and equipment items became contaminated as a result of various government sponsored nuclear research activities dating back to the 1940s. The cost of the project is shared between DOE (90%) and Battelle Memorial Institute (10%).
Battelle's Building KA-4 and Building KA-A are two of the 15 facilities and are still being used for non-nuclear research and office operations. D&D work to date in the BCLDP has been performed primarily in buildings where ongoing operations have ceased and corresponding occupants have vacated the facilities. This is a common scenario in D&D and environmental remediation projects throughout the United States. Cleanup work can proceed without major concern for other operations utilizing the facilities. However, in the case of BCLDP's Building KA-4 and Building KA-A, cleanup has had to proceed simultaneously with ongoing research and administrative operations. This has resulted in some additional planning, operating, and interfacing challenges. The remainder of this paper will explore these unique challenges and the effective methods instituted to meet them.
ADDITIONAL CHALLENGES TO THE DECONTAMINATION PROCESS
First, a criterion needs to be developed to determine what really constitutes an "additional challenge" to the decontamination process. For this paper the following criterion was used:
  Additional Challenge - an item that resulted in an activity being performed that either would not have been performed at all, or would have been performed at a significantly reduced effort if the building had been vacated and not had operations ongoing during remediation.

The additional challenges can be grouped into three categories presented below, along with descriptions of the challenges themselves:

Planning Challenges

1. Using historical records, process knowledge, and available data, specific rooms are identified as being radioactively "suspect" and are included in the project. A challenge at times is to determine the internal organization responsible for these rooms so items can be removed and schedules for relocation and remediation properly coordinated.
2. Many rooms and items identified as being suspect are in use at least partially for research or administrative operations. These rooms are properly rendered completely unusable when decontamination activities are initiated. At times, this "squeezes" organizations out of money making space. It is a challenge to plan for and accommodate the many requests for accelerated room remediation and return for unrestricted use.
3. Some rooms to be remediated are located in the middle of plush, well-furnished, and highly populated facilities. A planning challenge is to mobilize remediation equipment and personnel while minimizing the impact on the surrounding operations.

Operating Challenges:

4. It is to everyone's benefit if decontamination can be performed without relocating active functions. A challenge is to identify those "low-impact" remediation activities that can be performed while laboratories and offices remain occupied.
5. A major remediation activity is the removal of contaminated drain lines from the buildings. A challenge is to remove these lines while keeping active the intersecting uncontaminated drain lines originating from ongoing research activities remaining in the building.
6. The nature of the work in Buildings KA-4 and KA-A is such that decontamination may be performed in rooms literally surrounded by occupied offices, laboratories, and hallways. A constant challenge is to effectively isolate remediation operations from these adjacent activities.
7. In many instances, it first appears that active operations will need to be moved to allow for effective remediation. A challenge is to develop and apply "in-situ" characterization and decontamination techniques to prevent expensive relocation of operating laboratories.
8. In practice, most of the time the only practical alternative is to relocate some functions to comparable facilities. A challenge is to integrate this activity into the overall operation of the BCLDP.

Interfacing Challenges:

9. As previously mentioned, many decontamination efforts are surrounded by other research and administrative operations. It is a challenge to perform remediation and implement associated safety and operational controls in areas directly adjacent to individuals who have limited knowledge of radioactivity and/or decontamination operations.
10. Another "co-location" challenge for the BCLDP is working adjacent to research operations that are not conducive to remediation and construction type work.

METHODS TO MEET ADDITIONAL DECONTAMINATION CHALLENGES

Methods instituted that were effective in meeting the additional challenges are listed below and numerically correspond to the 10 previously presented items.

Planning Methods

1. Utilizing building diagrams and other organizational information supplied by the internal facilities department is the first step in determining ownership or occupancy of specific rooms. Personal contact is then made with individuals managing and working in targeted rooms. After a period of negotiation, plans for remediation are agreed on between both parties, preventing "surprise" remediation work crews showing up in the middle of a laboratory experiment or other important task. As much as possible, remediation is planned to coincide with operational down or slow times, thus minimizing the financial burden on the impacted organizations.
2. Priorities of the research operations are accommodated as much as possible. Many of these operations can't afford significant down time. A list of critical equipment in suspect rooms is developed and survey, decontamination (if necessary), free release and relocation of these items are scheduled as a priority. Requests for schedule acceleration to return an entire room for unrestricted use must often times be denied due to factors such as planned neighboring remediation work, Independent

Verification Contractor (IVC) schedule, and restoration activities. However, plans have been implemented that allow for acceleration of specific building floors being released for unrestricted use.
3. In mobilizing decontamination personnel and equipment, a key item is communication with surrounding occupants on remediation plans. Then both parties can plan the most efficient and least impactful methods of moving equipment and personnel into the work areas. Some of these methods include moving large equipment items after normal working hours and placing protective coverings (particle board, plywood) over plush carpeted surfaces.
Operating Methods
4. The most common activity able to be performed in occupied areas is removal of contaminated drain lines. Drain diagrams are obtained or developed so the exact rooms to be impacted can be identified. Occupants are then contacted by the remediation team and the activity is discussed, including the safety measures to be used. A schedule is agreed upon, extra precautions taken to protect items in the offices, and every effort expended to complete the job as promised. Of critical importance is leaving the office as clean, or even cleaner, than before the performance of the task.
5. In Building KA-4 and Building KA-A, contaminated drain lines can not be removed without consideration for intersecting "clean" lines. These other lines are in use constantly and provisions need to be made to keep them operating. Drain line diagrams and knowledgeable facilities personnel are consulted to explore various options. In most cases, clean drain lines in use are rerouted to other clean lines, leaving the contaminated lines free to be removed. Occasionally, the active clean drain lines need to be shut down as rerouting activities are finalized. This is coordinated with building occupants and preferably performed on weekends.
6. The most effective point of isolation in the affected buildings is at the ends of hallways. During high-impact activities such as concrete wall and floor removal, soil removal, and underground drain line removal, access must be limited to only remediation workers. Communication with affected individuals concerning inaccessibility of the hallways, planning alternative passage routes, and installing barriers at the ends of hallways proved to be effective in limiting access to active areas. During certain room surface decontamination efforts, adjacent rooms and hallways were able to remain open. Room walls actually provided a sufficient isolation barrier that negated major impacts on the neighboring operations.
7. Normal procedure for Building KA-4 is to relocate operating groups that occupied suspect or contaminated rooms prior to beginning remediation. In the case of a Class 100 Clean Room occupying laboratory space above suspect underground drain lines, an alternative method was investigated because of the potential expense involved in moving this type of facility. The drain lines were internally cleaned and flushed. A snake like probe detector was then used to obtain direct survey measurements from inside the drain line in an attempt to verify the absence of contamination in the pipe and surrounding soil. In this specific instance, results from the probe indicated contamination above release limits remained at various locations along the drain line. The laboratory was then relocated and the entire drain line excavated and removed. Direct survey measurements of the drain line during removal correlated closely with the results obtained using the snake detector, instilling further credibility in this type of detection system. Under the BCLDP, a custom-made probe able to fit through many types of drain lines is currently being developed. The goal is to use this probe to free release other drain lines or to identify only specific sections for removal as opposed to the entire line.
8. Relocating active operations is treated just as any other piece of work in the project. Activity scopes, costs, and schedules were developed by individuals in the groups moving and BCLDP staff. This information was submitted to the local DOE office for approval and then added to the formal project baseline. BCLDP staff then assumed responsibility for managing facility relocation and modification tasks in addition to their remediation roles.
Interfacing Methods
9. An important step is to assume that individuals from ongoing operations will have questions and anxieties once decontamination activities are scheduled near their facilities. This is the case in Buildings KA-4 and KA-A and questions are also routinely fielded from past occupants of areas scheduled for decontamination. Personal contact is made with impacted individuals by the BCLDP Project Manager or

Field Supervisor prior to beginning remediation activities. The nature of suspect or confirmed contamination is discussed along with what to expect operationally during remediation. Industrial safety and radiological protection hazards and controls are also discussed in as much detail as needed. Continuous communication takes place between the two parties during remediation efforts and this helps prevent "alarmist" type reactions from individuals.

10. Several types of activities not naturally conducive to decontamination and construction operations are located near the remediation areas. These include sensitive engineering research, clean room optics research, and administrative work by other Battelle organizations, government agencies, and a university function leasing some space. Special efforts taken to address these activities include coordination with affected parties on use of construction equipment, heightened attention to keeping dust and dirt levels low, and use of signs, postings, and physical barriers.

CONCLUSION

For obvious reasons, decontaminating a building while the facility still houses ongoing operations is not a preferred option. However, in the case of the BCLDP and perhaps other projects, it may be the only practical option. Two customers now need to be satisfied - the client funding the project and the owner/occupants of the facility. In situations like this, keys to success include planning properly by taking into consideration the "extra" time and resources needed, communicating openly with facility occupants during all phases of the project, and being flexible and responsive in addressing occupants' concerns as much as practical.

DOE-OWNED SPENT FUEL PROGRAM STRATEGIC PLAN: ISSUES, CHALLENGES, AND OPTIONS

John J. Jicha, Jr.
Rick Baum
U.S. DOE
Jon Katz
BDM Federal, Inc.

ABSTRACT

The Department of Energy faces a significant challenge in managing and disposing of the inventory of spent nuclear fuel (SNF) generated by past production and ongoing test/research reactor operations. The Office of Spent Fuel Management was created within DOE's Environmental Management program to address issues associated with, and coordinate activities related to, the management of DOE-owned SNF. This paper discusses DOE's efforts to plan for and implement management of its inventory of SNF, which are embodied in the DOE-owned SNF Program Strategic Plan issued in December. The SNF Strategic Plan presents an overview of issues, challenges, and options for the SNF program; another purpose is to establish a context for the other papers in the conference session that present more detailed discussions of these topics. The strategic plan indicates that the planning basis for the path forward for the ultimate disposition of DOE-owned SNF is to provide new interim storage pending placement of the SNF, along with vitrified defense high-level waste, in the first repository. This new interim storage will be designed and operated to national consensus standards as embodied by NRC requirements.

INTRODUCTION

The Department of Energy (DOE) faces a significant challenge in managing and disposing of the inventory of spent nuclear fuel (SNF) generated by past production and ongoing test/research reactor operations. SNF is composed of nuclear materials or heavy metals such as plutonium, uranium, and thorium that have been withdrawn from a nuclear reactor following irradiation. The Department currently owns and stores approximately 2700 metric tons of initial heavy metal (MTIHM) at a number of locations throughout the country. Ninety-eight percent of this SNF is stored in facilities near Richland, Washington; Idaho Falls, Idaho; Aiken, South Carolina; and West Valley, New York. Figure 1 presents the location, amount, and types of SNF in the DOE-owned SNF inventory.

SNF will need to be stored for decades because a decision regarding ultimate

disposition of DOE-owned SNF has not been made and because DOE is curtailing processing of SNF to recover strategic materials (although limited processing of SNF to meet waste acceptance criteria is under consideration). However, even after a disposal solution is identified, a number of program and policy issues affecting SNF management will remain. Pursuing the option of disposing of DOE-owned SNF in a geologic repository requires that DOE resolve questions regarding a suitable disposal site, acceptable disposal forms, and methods of storing, packaging, and transporting the spent fuel.

The Office of Spent Fuel Management was created within DOE's Environmental Management (EM) program to address these issues and coordinate/consolidate activities related to the production and management of DOE-owned SNF and associated facilities. (The Office of Civilian Radioactive Waste Management [OCRWM] is charged with managing the program for safe disposal of SNF produced by civilian nuclear power reactors.) Since its creation, the SNF management program has been addressing existing SNF vulnerabilities while planning for and working to ensure safe interim/long-term storage and eventual disposal of the SNF.

This paper discusses DOE's efforts to plan for and implement management of its inventory of SNF as represented by the DOE-owned SNF Program Strategic Plan issued in December 1994. There are a number of outstanding issues that must be resolved before progress toward disposition can be made. The paper presents an overview of issues, challenges, and options for the SNF program.

Fig. 1.

PROGRAM STATUS AND ACCOMPLISHMENTS IN FY1994

NEPA Activities

DOE currently is making key policy decisions under a process established by the National Environmental Policy Act (NEPA). DOE is preparing several EISs that will provide the specific information and analyses to help decisionmakers understand the potential environmental consequences of alternative policies and management approaches. DOE is committed to a comprehensive NEPA review process in making decisions on the storage, disposition, and, if appropriate, transportation of DOE-owned SNF. In a real sense, NEPA will drive DOE-owned SNF Program strategy.

In one EIS, titled "Department of Energy Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory (INEL) Environmental Restoration and Waste Management Programs Draft Environmental Impact Statement," DOE is considering programmatic SNF management decisions on the appropriate means of managing existing and projected quantities of SNF for an interim storage period that could last until the year 2035. The EIS, which has been released in draft form, deals with the entire SNF Program, SNF at the Idaho National Engineering Laboratory, and foreign research reactor SNF. The final draft is scheduled for release in April 1995.

Several site-specific NEPA reviews will tier from this SNF EIS and be guided by, and consistent with, it. Sites currently planning or preparing EISs to analyze site-specific management activities include the Hanford site in Washington State and the Savannah River Site (SRS) in South Carolina.

Other SNF management decisions involve SNF from foreign research reactors that contain U.S.-origin enriched uranium. In April 1994, DOE issued an Environmental Assessment (EA) of Urgent-Relief Acceptance of foreign research reactor SNF after evaluating the potential environmental impacts on a number of ports of entry and transportation routes being considered for the potential receipt and shipment of small amounts of SNF from foreign research reactors to SRS. DOE reached a Finding of No Significant Impact for the proposed action. Based on the EA, DOE decided to accept a limited number of SNF elements containing uranium enriched in the U.S. from seven research reactors in Europe. A subsequent EIS, titled the "Proposed Policy for Acceptance of U.S. Foreign Research Reactor SNF EIS", will evaluate the potential environmental effects of establishing and implementing a policy to accept the return of spent fuel from foreign research reactors over the next 10 to 13 years. The Record of Decision for this EIS is scheduled to be issued in the summer of 1995.

Other site-specific analyses like the ones discussed above will be performed to address the environmental consequences related to relocating and managing SNF inventories in a range of configurations within the DOE complex. DOE will use these analyses and evaluations to implement its programmatic decisions on SNF management.

The SNF program will also be affected by activities being carried out by other DOE programs. For example, the Office of Civilian Radioactive Waste Management is planning NEPA reviews with regard to the suitability of the Yucca Mountain, Nevada,

site as a geologic repository and the utilization of a multipurpose canister development program.
The SNF Strategic Plan is closely connected to the NEPA process. However, it is not intended to prejudice decisions on programmatic alternatives under consideration in the Programmatic SNF EIS process or in follow-on NEPA reviews involving the implementation of programmatic decisions. The Strategic Plan addresses program issues and directions for the SNF program, but cannot present a specific path forward until the Programmatic SNF EIS process is completed.
Spent Nuclear Fuel Vulnerabilities
In August 1993, the Secretary requested that the Spent Nuclear Fuel Working Group -- made up of site personnel and participants from the cognizant Secretarial Offices, Operations Offices, the National Laboratories, and the Office of Environment, Safety, and Health -- assess the conditions of DOE SNF storage facilities. After studying the conditions at 66 facilities at 11 sites, the working group published the Spent Fuel Working Group Report on Inventory and Storage of the Department's Spent Nuclear Fuel and other Reactor Irradiated Nuclear Materials and their Environmental, Safety and Health Vulnerabilities (Volume I, November 1993). The Spent Nuclear Fuel Working Group found no conditions that required immediate action to prevent harm to the workers or the public, but did identify five DOE facilities and three burial grounds that warrant priority management attention to avoid unnecessary increases in worker radiation exposure and cost during clean up. The report also raised a number of issues and concerns about Department efforts to store SNF. For example, the absence of a clear path forward for the ultimate disposition of DOE-owned SNF has complicated DOE's efforts to maintain safe interim storage.
In February 1994, EM responded to the Working Group's report by publishing the first of a three-part "Plan of Action to Resolve Spent Nuclear Fuel Vulnerabilities." The Phase I Action Plan addressed 31 of the 33 high priority vulnerabilities and 48 of the lower priority issues. The Phase II Action Plan, released in April 1994, updated the Phase I Action Plan and reflected the resolution of a number of funding issues. Originally intended to address 44 (of the initial 106) vulnerabilities, the Phase II Action Plan actually covered 81 vulnerabilities. The completion of partial action plans identified in Phase II were addressed in the Phase III Action Plan released in October 1994. The Phase III plan constituted the final Headquarters report on all programmatic activities designed to respond to the vulnerabilities identified in the SNF Working Group Report, and represented the completion of the Secretary's initiative to assess the Department's SNF facilities. In keeping with EM policy, stakeholders were given the opportunity to review and comment on all of the action plans.
KEY ISSUES IN SNF MANAGEMENT
An essential element of the planning process for the SNF Program is the systematic identification and resolution of existing and potential issues. Until the NEPA process is complete, the SNF Program will work to address and resolve near-term issues and vulnerabilities, and to define requirements for interim storage with regard to design, location, and funding. This section discusses some of the major policy, management, and technical issues requiring resolution.
Should DOE-owned SNF be placed in the first geologic repository? The Federal Government is pursuing the development of deep geologic repositories for the disposal of civilian spent nuclear fuel and high-level radioactive waste. In 1985, the President accepted the Secretary of Energy's recommendation that defense nuclear wastes should be co-located with civilian nuclear waste. In 1994, the DOE General Counsel concluded in a legal opinion that the legislation empowering the first civilian geologic repository authorizes disposal of DOE-owned SNF in that repository, conditioned upon payment by DOE of a fee adequate to cover the full cost of disposal. The first repository is limited by law to 70,000 metric tons of heavy metal, and 10 percent of that has been allocated to defense materials. However, current projections of defense materials, DOE-owned SNF, and defense high-level waste show that the allocation is inadequate for all these materials. As yet, DOE has made no final decision regarding the specific strategy for the ultimate disposition of DOE-owned SNF.
Should new interim storage facilities be licensed by the NRC? Management of DOE-owned SNF until its disposal is expected to require new interim storage with a capacity to span the time period until the geologic repository is available. DOE is reviewing the technologies used by the commercial spent fuel generators to both

condition (or stabilize) fuel for storage and to design and operate storage facilities. Several of the commercial storage technologies under evaluation have been successfully licensed and regulated by the Nuclear Regulatory Commission (NRC). DOE SNF would come under jurisdiction of the NRC when it is disposed of, similar to DOE high-level waste, in a geologic repository. However, since the current statutory framework does not allow licensing by the NRC of new DOE interim storage facilities for DOE-owned SNF, a decision must be made regarding whether DOE should proceed toward satisfaction of NRC licensing requirements and reviews for these new facilities.

Should some DOE-owned SNF be regulated under RCRA? The Federal Facility Compliance Act of 1992, which addresses management of mixed wastes, raised questions concerning the applicability of Resource Conservation and Recovery Act (RCRA) waste management regulations to DOE-owned SNF, a fraction of which may potentially exhibit the characteristics of a RCRA hazardous waste. DOE-owned SNF is being evaluated in depth, following which results will be discussed with the Environmental Protection Agency and with the affected state regulatory agencies.

The SNF Program must resolve a number of other issues at various sites that will affect the path forward for ultimate disposition of SNF. One issue involves the path forward for N-Reactor fuel, the approximately 2100 metric tons of heavy metal of uranium SNF stored in the old and seismically vulnerable Hanford K-Basins facility located near the Columbia River. After consultations with stakeholders, DOE decided in November 1994 to place the SNF in overpacks and remove it from the K-Basins on an accelerated basis, stage it temporarily in a new interim storage facility, condition it into a dry form at a new conditioning facility, and return it to the new interim storage facility for dry storage pending its ultimate disposition. The packaging, transfer, and wet staging of the SNF are to be conducted under a K-Basins EIS; a Notice of Intent for this NEPA review is scheduled to be issued in February 1995. Other important issues concern the approach to conditioning DOE-owned SNF at SRS; the receipt of foreign research reactor SNF of U.S. origin for storage; and the need for new dry, passive, cost-effective storage facilities that meet current regulatory requirements to store SNF for a prudent interim period until a geologic repository becomes available.

SNF PROGRAM STRATEGY AND GOALS FOR FY1995

The SNF Program Strategic Plan captures the goals, vision, and strategies of the SNF program. The plan is divided into four sections: Mission, Vision, Situation Analysis, and Objectives. The mission statement describes the purpose of EM's SNF management program. The vision statement articulates the results of a successful SNF program; that is, how the SNF Program will look after achieving its long-term goals. The situation analysis briefly describes the current status of the program, discusses key issues and activities that will affect direction and progress, and identifies the key program stakeholders. The objectives section details the objectives that the SNF Program will strive to meet, the proposed strategies for meeting them, and success criteria that will be used to measure progress toward each objective. Figure 2 captures the broad activities that will guide the SNF program.

The mission of the EM SNF Program is to safely, reliably, and efficiently manage Department of Energy-owned SNF and to prepare it for disposal. In completing this mission, EM will protect the environment and the health and safety of workers and the public, while working with stakeholders and fully complying with applicable Federal, State, Tribal, and local laws, orders, and regulations.

The planning basis for the path forward for the ultimate disposition of DOE-owned SNF is to provide new interim storage pending placement of the SNF, along with vitrified defense high-level waste, in the first repository. This new interim storage will be designed and operated to national consensus standards as embodied by NRC requirements. DOE is committed to the responsible management of its SNF, whether under the Atomic Energy Act or RCRA regulatory regimes, based on the results of the evaluation of SNF process knowledge and negotiations with regulators. Figure 3 portrays the SNF program's vision of the path forward to ultimate disposition.

EM has established five top-level program objectives for the SNF management program, which constitute the overall program strategy for pursuing the path forward. These objectives are the broad goals the program will strive to meet on the way to achieving its mission. Attainment of these objectives will constitute the successful implementation of the SNF Program.

1. Establish an Effective Decisionmaking Process Involving Stakeholders

Because the SNF program is relatively new and is not expected to complete its mission until well into the next century, it must establish an effective decisionmaking process to ensure that program goals can be achieved safely, efficiently, cost-effectively, and in full compliance with all applicable environmental laws and regulations. An effective decisionmaking process identifies the decisions to be made, compiles and analyzes the information needed to develop a full range of alternatives, and empowers the right people to make decisions. The SNF program will utilize a systems engineering approach to determine requirements, define alternatives, and promote communication within the SNF program and between the SNF program and its stakeholders. By establishing a sound decisionmaking process now, the managers of the SNF program can define and develop program plans and directions that reflect inputs from many stakeholders but allow for timely decisions.

2. Assure Safe Existing Storage and Resolve Vulnerabilities for DOE-Owned SNF

SNF will be safely stored and managed in existing facilities, conditioned, and consolidated as necessary to alleviate environmental, safety, and health vulnerabilities. Radiation exposure to the work force and the public must be controlled to levels as low as reasonably achievable, and all SNF storage facilities must be managed to maintain environmental regulatory compliance and safety. The policy of the SNF program is to stabilize existing SNF storage facilities until the transition to interim storage is complete.

3. Achieve Safe, Secure Interim Storage of DOE-Owned SNF

EM must establish, operate, and maintain interim storage facilities to safely store SNF until it can be disposed of. This will require determining and implementing a safe, cost-effective, and technologically-appropriate approach to interim storage. DOE must address a number of issues, including the form the SNF will be stored in, planning and constructing modular facilities to lessen budgetary impacts in a given year, and the most

Fig. 2.

Fig. 3.

effective methods of packaging and transporting. EM must coordinate interim storage with known requirements for disposal to ensure that stored fuel is in an acceptable form for disposal. EM also is reviewing the potential role and extent of external regulation; oversight by the Nuclear Regulatory Commission is considered a step along the path forward to geologic disposal. In addition, EM must design, construct, and establish interim storage facilities in a manner that anticipates and facilitates the eventual decommissioning and transition to other uses of these facilities.

4. Prepare for Disposal

DOE is planning for the ultimate disposition of DOE-owned SNF in a geologic repository. However, decisions have yet to be made regarding a disposal site and the form in which the fuel will be disposed. These decisions are essential to achieving closure on the SNF program's mission. The SNF program will work with the Office of Civilian Radioactive Waste Management to establish and meet disposal requirements. Should some of the DOE-owned SNF be determined to be unacceptable for emplacement in its current form, EM will establish a program to produce an acceptable form. The SNF program will resolve all RCRA-related issues concerning DOE-owned SNF prior to disposal.

5. Transfer Surplus Storage Facilities

During and after the shipment of DOE-owned SNF from existing storage facilities to interim facilities and then to a disposal site, EM must plan and prepare for the transition of storage facilities no longer needed for SNF management to other uses.

These interrelated programmatic objectives constitute the top of the SNF program planning hierarchy. They will be used to guide and direct all SNF program planning activities, define operational or tactical objectives and project goals, set milestones and schedules, and establish indicators of performance. Managers and planners in the program will use them to develop and implement the plans and activities that will allow the SNF program to achieve its long-term goals.

The DOE SNF Program Strategic Plan goes on to discuss each of these strategic objectives in detail, briefly explaining them, setting out related strategies for meeting them, and establishing examples of success criteria for measuring program performance in implementing of the strategies. A comprehensive and more detailed discussion of strategies and success criteria is to be provided in the EM Spent

Nuclear Fuel Program Plan.
Key Goals for FY1995
During 1995, the SNF program will complete the Programmatic SNF EIS and the foreign research reactor EIS and issue Records of Decision (RODs). These ROD's will establish the program elements and provide the basis for developing the Program Plan, which is to include a master logic schedule. The Program Plan will provide the link between the policy/planning activities that occupied the early days of the program and actual implementation of the program as defined by the NEPA process in the field.
The SNF program will also finalize the licensing strategy and systems engineering approach that will help to integrate the SNF Program vertically between Headquarters and the field, and horizontally across the sites. The licensing strategy anticipates licensability reviews conducted by the NRC for new interim storage facilities. The systems engineering approach will provide a common basis for managing spent fuel across the complex as recommended by the Defense Nuclear Facilities Safety Board in Recommendation 94-1.
Planning for a dry storage demonstration project will also mature during 1995. This demonstration project will provide a test case for both the licensing strategy and the systems engineering approach. It will also enable DOE to investigate privatization and other procurement options and the applicability of commercial dry storage technology to DOE-owned SNF.
STAKEHOLDER PARTICIPATION
Key to resolution of the major issues and to ensuring the safe storage and disposal of SNF is the establishment of a sound planning process that involves internal and external stakeholders in vital programmatic decisions. The SNF Program Strategic Plan is to be used to inform stakeholders about the program and give them access to program planning and decisionmaking efforts. An effective decisionmaking process must include participation from all stakeholders.
The Environmental Management program is committed to working closely with its stakeholders at the local, state, and federal levels in planning and implementing its management efforts across the country. EM is developing the policies and methods by which stakeholders will help the SNF program develop the nature and scope of its activities, establish short- and long-term goals, strategies, and priorities, and participate in defining budget needs and allocations. By establishing an open and communicative relationship with its stakeholders, the SNF program can help ensure that its decisions and activities reflect the needs and desires of affected communities and organizations.
CONCLUSION
The SNF Strategic Plan presents a vision for the SNF Program: to safely, efficiently, and effectively manage the interim storage of DOE-owned SNF in preparation for its disposal in the geological repository. The five strategic objectives establish the broad scope of activities needed to achieve both near- and long-term success in meeting the challenge of effective and responsible SNF management. Over the coming years, EM will implement the strategies in this plan to address vulnerabilities, interim storage needs, and disposal requirements. Successful implementation of these strategies will mean that EM has accomplished the EM SNF mission and realized the EM SNF vision. DOE-owned SNF will be well on its way to safe, environmentally sound, and responsible disposal.

ABSTRACT
One of the many legacies which DOE must address in light of the Cold War's end is the management of spent fuel from its production reactors, foreign and domestic research reactors, and other sources. For decades, these fuels were reprocessed as

part of ongoing production operations. Now, though, a reassessment of the costs, risks, and options for spent fuel management is needed within DOE. As part of this reassessment, DOE should answer several fundamental questions: Who? What? Why? How? then Where?

INTRODUCTION

For decades, many of the spent nuclear fuel (SNF) management activities of the Department of Energy (DOE) were shrouded within the clouds of nuclear weapons production, which was given high priority throughout the Cold War. Fabrication, reactor operations, chemical processing, and other weapons manufacturing functions created vast volumes of radioactive and hazardous waste and environmental contamination. The costs and environmental burdens of storing and reprocessing spent fuel from research reactors and other sources were almost invisible when held next to the costs and consequences of weapons production activities.

Now that the Cold War is over, DOE is moving to create a new plan for managing SNF. First, the Department must address the lingering costs of bringing Cold War operations to an end. In some cases, conditions within the weapons complex have reached a deplorable state, and despite a halt to production activities, much work remains to be done to ensure safety. Second, DOE still has agreements to manage domestic and foreign research reactor spent fuel, naval fuel, and other materials. Without the cover of nuclear weapons production, the costs and burdens of handling this material should become more apparent. Third, DOE also has responsibilities in the realm of managing SNF from U.S. commercial power reactors.

The first two areas of responsibility affect what is broadly referred to as DOE-owned SNF. It is this class of material which we address below (though, several of our basic contentions are relevant to commercial SNF as well). DOE should reassess the costs, risks, and options for spent fuel management in a manner that reflects policies appropriate for the 21st Century. We recommend that this reassessment address several very basic questions: who, what, why, how, and where.

WHO?

Determining who is responsible for SNF management and associated costs is essential. Without Cold War production and in light of increasing federal budget pressures, costs for managing even relatively small quantities of SNF are becoming more visible than ever before. Moreover, spent fuel activities associated with operating research reactors, for example, must compete with ongoing programs necessary to pay the costs of past production activities (e.g., safely storing corroding fuel from past weapons production).

It's inadequate to approach this future planning with an assumption that DOE will continue its historic role, and DOE perhaps recognizes this at least in part. Related issues are considered in the ongoing Environmental Impact Statement (EIS) on Foreign Research Reactor SNF. For example, the EIS examines whether and when DOE will take title to the fuel, who will pay what costs, and similar policy considerations. DOE should apply this line of thinking to other aspects of its SNF management program. Also, the Department should reexamine the role of state and tribal governments, regulators, and concerned citizens in overseeing the program and formulating decisions.

Among the questions DOE should be asking are: Who should provide independent review and regulation of DOE's SNF activities? Who must concur in SNF decisions? Who should be responsible for the costs of which SNF activities? Who is responsible for long-term liability and management?

WHAT?

You don't have to look far back in history to find the time when DOE didn't have a good understanding of the condition of its SNF inventory and related facilities. While facility managers and some others may have been aware of parts of the picture, DOE did not have a clear, complex-wide image of the status of SNF at the end of the Cold War. Similarly, DOE had a poor understanding of SNF inventories and the condition of facilities in foreign countries that participate in the Reduced Enrichment for Research and Test Reactor program.

Coupled with this, DOE often failed to address problems in a timely manner - allowing some fuels to corrode, facility conditions to deteriorate, and political pressures to build. This is not to say that problems were never addressed, but it is clear that early action could have prevented many of the expensive and risky situations faced in the nuclear weapons complex today.

It wasn't until 1993 that things began to change. Through its SNF Vulnerability

Assessment, ongoing EIS's, and the development of a SNF Strategic Plan (the first in the Department's history), DOE is moving toward being able to clearly and fairly describe what comprises its SNF program. This is a vital first step, and despite other criticisms of DOE's actions regarding SNF and even weaknesses with this first step, the value of this effort should be recognized. Without the ability to clearly understand and articulate the conditions which exist, we doubt that DOE managers can effectively implement a SNF program.

In addition to completing this characterization of existing conditions, DOE needs to put in place a program to keep current its inventory and understanding of conditions within the complex. Undoubtedly this is recognized by DOE management, but we are concerned that it may prove more difficult than expected to implement. For years, DOE has struggled with poor internal communication. It often seems that each new study raises more questions than it answers. Time and again, we have seen DOE fail to consistently implement long range programs. The current confusion, for example, over the relationship between ongoing EIS's, the SNF strategic plan, and other decision making processes exemplifies DOE's continuing struggle to become focused, to give taxpayers a clear picture of its intentions, and to move forward. These types of problems continue, and - though they don't mean DOE is doomed to failure - they pose a serious challenge to the effective development and implementation of a long term SNF strategy.

WHY?

Once you understand who is responsible and what is to be managed, the next question is why or for what purpose. DOE should articulate the rationale behind its desire to do anything with spent fuel. This is a vital element in evaluating whether a proposed action is likely to accomplish the objective.

Frequently, the rationale offered is to prepare SNF for geologic disposal. This is inadequate, though. Indeed, why geologic disposal is desirable and whether it is possible should be open for discussion.

Many other questions need to be addressed as well, each targeted to a specific component(s) of DOE's SNF program. When non-proliferation concerns are asserted, DOE should explain why this is a concern, and why management options for SNF affect non-proliferation. For domestic research reactor spent fuel, why is DOE proposing transportation? Is it to alleviate safety concerns, to reduce the cost of research, or for some other purpose? Why does DOE desire to consolidate storage of all SNF of a given type at a single location within the U.S.? Does this make storage less risky, make it easier to pursue future processing activities, or accomplish some other objective? Why does DOE hold on to the notion that its SNF may not be a waste? Again, the goal of this questioning is to identify the problem which DOE is trying to resolve for the various types of SNF under consideration. During the Cold War, why was rarely asked. The driving force was weapons production, and it was often a relatively simple matter to process other SNF in step with production operations. Now, though, we need to ensure that there is an acceptable rationale for planning future SNF management activities and for evaluating the effectiveness of options selected.

HOW?

Once the problem, responsible agencies, and rationale have been established, it is possible to decide how to best manage spent fuel. Actually, we expect the decision will be a range of management options for the varied problems and rationales.

How is the problem best addressed? If spent fuel is in unsafe condition, how can its condition be stabilized? If the problem is the storage facility, rather than the fuel itself, how can storage problems be corrected? If the issue is non-proliferation, how can spent fuel management contribute to non-proliferation goals? Also, how can non-proliferation goals be balanced with community concerns about equity and local environmental, safety, and health risks? If the issue is domestic research, how should DOE's publicly funded activities relate to the needs of research facilities?

DOE is addressing some of these questions. In particular, the Department has focused substantial attention in the past year on identifying ways to stabilize SNF and improve the condition of storage facilities. Unfortunately, DOE's efforts have too often been short circuited by hasty leaps to a final solution when none is readily available or a clinging to historical practices such as reprocessing.

Indeed, the first reaction of many people in the DOE system is to continue reprocessing, with little change from the days of weapons production. This may be a

natural tendency - reprocessing is familiar to many DOE and contractor employees - but does it make sense for the 21st Century? Are there better, more cost effective options for SNF management? When we look at how to manage spent fuel, we should recognize the new opportunities provided by the Cold War's end. How can storage be improved? If some chemical processing is necessary, how can it be done without separating weapons-usable materials? How can vitrification and other technologies play a part in SNF management?

WHERE?

The location for transporting, storing, treating, and disposing spent fuel is usually the most controversial and high profile issue. It wasn't necessarily a surprise, therefore, that DOE's draft SNF Programmatic EIS seemed designed to address principally the question of where spent fuel should be managed. Perhaps the Department was inclined to attempt to resolve the most difficult question first, hoping that answers to other questions would then fall in place.

This is, however, the wrong approach. Before determining where SNF activities should occur, DOE should answer the questions posed above. The location should be selected based on its suitability for conducting the type of operation required to meet the identified needs. DOE should also be realistic in its assumption about the likelihood that SNF will be transported in the future to some "permanent" home, as well as its own ability to foresee future events.

CONCLUSIONS

DOE is taking steps to move spent fuel management into the post-Cold War era, but many of its steps appear hindered by the legacy of past actions and habits. It won't be easy to form a broad consensus, but such an effort is needed. To get there, we suggest DOE avoid the tendency to look first for a location to store SNF and instead take a deliberate approach to build the rationale for action and a plan which accomplishes the nation's needs.

We've suggested a series of fundamental questions to move us closer to that consensus. Our suggestions, though, are just a loose framework which identify many of the key issues still to be addressed. We hope that DOE is able to incorporate them into its strategic planning to produce better results.

THE DEPARTMENT OF ENERGY FOREIGN RESEARCH REACTOR SPENT NUCLEAR FUEL PROGRAM

Charles Head
USDOE
Abe Zeitoun
SAIC

ABSTRACT

This paper presents an overview of the Department of Energy's (DOE) program for the acceptance policy for foreign research reactor (FRR) spent nuclear fuel (SNF). Since 1959, the United States, as part of the "Atoms for Peace" program, has supplied research reactor fuel (highly enriched uranium [HEU]) to foreign countries which agreed to forego the development of nuclear weapons. The U.S. accepted SNF containing HEU supplied by the U.S. from FRRs until the Off-Site Fuels Policy lapsed in 1988. A key U.S. nuclear nonproliferation policy objective is to eliminate this weapons-usable material from international civil commerce. In support of U.S. nuclear weapons nonproliferation goals, DOE is engaged in three key activities: the Reduced Enrichment for Research and Test Reactor (RERTR) program, initiated in 1978 to develop high-density, low enriched uranium (LEU) fuel to replace the use of HEU fuel in research reactors; the preparation of an Environmental Impact Statement (EIS), as required by the National Environmental Policy Act (NEPA), for a proposed policy to accept (over a 10 to 15 year period) FRR SNF containing enriched uranium supplied by the U.S. for interim storage in this country; and acceptance of a small number of SNF elements from FRRs needing urgent relief while the EIS is being prepared. The status and the technical issues associated with each of these activities will be discussed in this paper.

INTRODUCTION

For more than 50 years, the United States has played a leading role in international efforts to prevent the proliferation of nuclear weapons throughout the world. Proper management of spent nuclear fuel from foreign research reactors is a crucial part of the efforts geared toward achieving this goal since much of this spent nuclear fuel contains highly enriched uranium, which can be directly used in simple nuclear

weapons. U.S. activities have focused on preventing aggressive nations and terrorist groups from acquiring the nuclear materials necessary to make nuclear weapons. With the end of the Cold War and lessening of controls on nuclear materials in the former Soviet Union, there is worldwide concern that weapons-grade nuclear materials (highly enriched uranium and plutonium) could fall into the wrong hands.

A key element of U.S. nuclear weapons nonproliferation policy is to reduce international civilian commerce in highly enriched uranium. In support of this objective, the United States hopes to adopt and implement a policy to reduce the amount of highly enriched uranium in international commerce associated with the spent nuclear fuel from foreign research reactors, and to encourage foreign research reactor operators who use highly enriched uranium fuel to convert to high density low-enriched uranium fuel. The Department of Energy (DOE), through its foreign research reactor spent nuclear fuel program, will work with the Department of State as the agencies primarily responsible for developing and implementing a policy for the management of foreign research reactor spent nuclear fuel.

Background

Since 1945, every U.S. Administration has recognized that preventing the further spread of nuclear weapons must be a fundamental national security and foreign policy objective of the United States. The initial approach to nuclear technology was to classify all nuclear activities. However, the United States soon realized that it would be impossible to prevent other nations from acquiring nuclear technology. Consequently, since the 1950's, beginning with the "Atoms for Peace" program, the United States has provided peaceful nuclear technology to foreign nations in exchange for their promise to forego development of nuclear weapons. In addition, any nuclear technology provided would be subject to international safeguards and inspections to prevent diversion of materials or technology to nuclear weapons activities.

A major element of the "Atoms for Peace" program for peaceful nuclear cooperation, particularly in the early years, was the provision of research reactor technology and highly enriched uranium for use as fuel in the research reactors. Research reactors play a vital role in important medical, agricultural, and industrial applications, and also provide a tool for fundamental scientific research. For example, research reactors are a vital tool in cancer therapy and radioimmunoassay blood testing. Research reactors also have served as major training facilities in nuclear technology. For example, the research reactor operating in Austria is used by the International Atomic Energy Agency to train personnel who conduct international inspections of nuclear facilities worldwide.

The transfer of enriched uranium from the United States to other nations was usually supported by a bilateral research agreement for each foreign research reactor. Before 1964, these agreements provided for the lease of the enriched uranium, with explicit provision for the acceptance of the spent nuclear fuel by the United States. After 1964, most agreements provided for the sale of this material to the foreign nation.

After its use (irradiation) in a research reactor, the used (spent) fuel was generally accepted in the United States where it was reprocessed to extract the remaining uranium. In this way, control was maintained over the highly enriched uranium, which otherwise could be used in the production of nuclear weapons. The United States began accepting highly enriched uranium spent nuclear fuel from foreign research reactors in 1958.

After 1964, the operative policy under which the United States accepted foreign research reactor spent nuclear fuel containing uranium enriched in the United States became known as the "Off-Site Fuels Policy." This policy was delineated in a series of Federal Register Notices issued until 1987 and was incorporated into bilateral agreements with recipient countries. The term "Off-Site Fuels Policy" was used to indicate that the spent nuclear fuel had been irradiated at facilities not owned by the DOE. Under the "Off-Site Fuels Policy", the United States accepted, temporarily stored, and reprocessed spent nuclear fuel containing U.S.-origin highly enriched uranium. The rationale for the policy was to discourage the stockpiling abroad of spent nuclear fuel containing highly enriched uranium and to recover the fuel value of the highly enriched uranium remaining in the spent nuclear fuel.

In 1978, DOE initiated the Reduced Enrichment for Research and Test Reactors (RERTR) program. This program was aimed at reducing the use of highly enriched uranium in civilian programs by promoting the conversion of foreign research reactors from

highly enriched uranium fuel to low-enriched uranium fuel. Research reactors are of particular interest in this endeavor because the major civilian use of highly enriched uranium is as fuel in nuclear research reactors. As a part of this program, the DOE developed low-enriched uranium fuel and worked with foreign research reactor operators to modify their reactors to run on such fuel. The foreign research reactor operators who converted to low-enriched uranium fuel did so in support of nonproliferation objectives, even though such conversions were expensive and generally resulted in reductions in the capabilities of the reactors and increased operating costs.

In 1988, the DOE's "Off-Site Fuels Policy" to accept highly enriched uranium spent nuclear fuel expired. At the end of 1992, the policy as it applied to the acceptance of low-enriched uranium spent nuclear fuel also expired. The "Off-Site Fuels Policy" was not immediately renewed because of the need to assess the environmental impacts of a new policy and to comply with the National Environmental Policy Act. Because the United States has not been in a position to accept highly enriched uranium spent nuclear fuel for six years (except for a recent "urgent relief" shipment of 153 spent nuclear fuel elements described later in this paper), many foreign research reactor operators will soon run out of storage capacity or face safety and regulatory issues associated with the presence of spent nuclear fuel at their sites (these facilities were not designed for long-term storage of spent nuclear fuel). The cessation of the United States' acceptance of foreign research reactor spent nuclear fuel associated with the expiration of the "Off-Site Fuels Policy" has undercut the perceived reliability of the United States as a partner in peaceful nuclear cooperation.

Program Objectives

As part of the United States objective of curbing the proliferation of nuclear weapons, DOE and the Department of State are committed to seeking a policy to reduce the amount of highly enriched uranium in international commerce associated with the spent nuclear fuel from foreign research reactors. By developing and implementing a proactive policy to manage foreign research reactor spent nuclear fuel, the United States will offer an incentive for foreign research reactors to continue in the RERTR program by using low-enriched uranium fuel instead of highly enriched uranium fuel. This proposed policy would affect only those foreign research reactors that have received fuels containing uranium enriched in the United States. The purpose of this policy would be to reduce the likelihood of diversion of U.S.-origin highly enriched uranium for use in nuclear weapons by reducing the amount of highly enriched uranium in international commerce.

By proposing a policy for management of certain foreign research reactor spent nuclear fuel, DOE and the Department of State have no intention of establishing a commitment to continue accepting such spent nuclear fuel indefinitely. Rather, the intent of the proposed new policy and the overall program is to remove U.S.-origin highly enriched uranium from international commerce while giving the foreign research reactors and their host countries time to convert to operation with low-enriched uranium fuel and make their own arrangements for disposition of their subsequent low-enriched uranium spent nuclear fuel. After the proposed spent nuclear fuel acceptance policy expires, the reactor operators and countries in which the research reactors are operating must be prepared to implement their own arrangements for disposition of their spent nuclear fuel.

PRIMARY PROGRAM COMPONENTS

Environmental Impact Statement on a Proposed Nuclear Weapons Nonproliferation Policy Concerning Foreign Research Reactor Spent Nuclear Fuel

The Foreign Research Reactor Spent Nuclear Fuel Environmental Impact Statement (FRR SNF EIS) will evaluate the potential environmental impacts that could result from the proposed action to adopt and implement a policy to reduce the amount of highly enriched uranium in international commerce associated with the spent nuclear fuel from foreign research reactors. The proposed action applies to aluminum-based and TRIGA (for Training, Research, Isotope reactors built by General Atomic) research reactor spent nuclear fuels and targets containing highly enriched uranium and low-enriched uranium of United States origin. Implementation of the proposed action would be performed under one of three management alternatives. Management Alternative 1 is to accept and manage the spent nuclear fuel in the United States. Management Alternative 2 is to adopt and implement a policy to facilitate the management of foreign research reactor spent nuclear fuel at one or more foreign

locations. Management Alternative 3 is a combination of components of Management Alternatives 1 and 2 and is referred to as the Hybrid Alternative. The Management Alternatives of the proposed action are portrayed in Fig. 1.
The foundation for the analysis presented in the FRR SNF EIS, is the evaluation of the components that comprise the basic implementation of Management Alternative 1. Since Management Alternative 2 and the No Action Alternative would not have any direct environmental impacts in the United States, they require only policy analysis in this EIS. Management Alternatives 1 and 3, however, would both have environmental impacts in the United States and the components of the basic implementation provide the parameters with which to analyze their potential environmental impacts in this EIS.
The detail of analysis provided for the basic implementation components is based on the fact that some variation of these components is utilized in each implementation alternative under Management Alternative 1, as well as in Management Alternative 3. In this way, analysis of the implementation alternatives as well as Management Alternative 3 can be tiered from the analysis of the basic implementation. In and of itself, the basic implementation of Management Alternative 1 is a viable implementation alternative for consideration under Management Alternative 1, along with the other implementation alternatives discussed below. However, the level of detail contained in the analysis of the basic implementation does not indicate any preference for this alternative. Rather, it merely eliminates the need to duplicate information later in the analysis.
A summary of components of the basic implementation of Management Alternative 1 is as follows:
a. Policy Period: The United States would accept qualifying spent nuclear fuel (U.S.-enriched low-enriched uranium and highly enriched uranium under specific circumstances) that is currently stored or generated during the ten (10) year period beginning when the policy takes effect. The policy would allow for an additional three (3) years of shipments for foreign research reactor spent nuclear fuel generated within the ten (10) year period, but which cannot be shipped in the period because of requirements for additional cooling, logistics, or unforeseen obstacles. Spent nuclear fuel would not be accepted for new research reactors starting operation after the starting date of implementation of the policy. Spent nuclear fuel would not be accepted from highly enriched uranium-fueled research reactors that could be converted to low-enriched uranium but for which the reactor operators have refused to convert.
b. Financing Arrangements: The United States would bear the full cost for transporting and managing the foreign research reactor spent nuclear fuel received from developing nations. Developing nations are those nations identified by the World Bank as other-than-high-income-economies nations. For developed nations, the United States would charge a competitive fee for all spent nuclear fuel management activities conducted.
c. Amount of Spent Nuclear Fuel to be Accepted: The United States would receive up to a fixed amount of foreign research reactor spent nuclear fuel containing uranium enriched in the United States. The amount of foreign research reactor spent nuclear fuel that would be accepted is approximately 19.2 metric tons of heavy metal, from approximately 22,700 foreign research reactor spent nuclear fuel elements and is based on estimated inventories of foreign research reactor spent nuclear fuel currently stored or to be generated in the 10-year policy period. This amount is higher than originally estimated (12 metric tons of heavy metal, representing 15,000 elements) at the time of the 1993 Notice of Intent. The increase is due to a 3-year delay in the start date for the acceptance policy, resulting in additional inventory, plus an increase in the number of foreign countries that have indicated a desire to participate in this program.
d. Location for Taking Title: The United States would take title of the foreign research reactor spent nuclear fuel at the United States Territorial Waters Limit, or continental United States borders for shipment from Canada. Where DOE takes title would not have an effect on the environment. Title location of the spent nuclear fuel is relevant to questions that include the source and extent of liability for damage in the event of an accident outside the scope of Price-Anderson coverage.
e. Marine Transport: Marine transport of the foreign research reactor spent nuclear fuel would be accomplished by either or both chartered and/or regularly scheduled commercial ships. Chartered shipments may be on purpose-built ships or general

purpose commercial cargo ships. Regularly scheduled commercial shipments would be on general purpose commercial ships carrying other cargo at the same time.
f. Ports of Entry: The potential ports of entry are being identified through use of screening criteria that include topics such as appropriate experience, safe transit capabilities, adequate facilities, and population around the ports and along the routes to potential management sites. Several candidate ports of entry will be specified in the draft FRR SNF EIS. Three high population density ports are also being analyzed for potential impacts, these are: Elizabeth, NJ; Long Beach, CA; and Philadelphia, PA, although none of these ports are expected to be proposed ports of entry. This analysis is included only to demonstrate what the impacts would be for receipt through such high density ports.
g. Ground Transport: This component involves shipping of foreign research reactor spent nuclear fuel from the ports of entry (both seaports and Canadian border crossings) to potential DOE management sites. It could also include transport of spent nuclear fuel from one site to another within the United States. This would depend upon the availability or unavailability of certain sites to accept foreign research reactor spent nuclear fuel at the beginning of the implementation period. If a site were unable to accept the spent nuclear fuel, this could necessitate temporary receipt and management of the spent nuclear fuel at an available site and subsequent transport to another site. Both rail and highway capabilities are available to all ports and sites, except the Nevada Test Site, which lacks rail capabilities.
h. Management Sites: The potential management sites identified in this FRR SNF EIS are bounded by those sites identified in the Draft Spent Nuclear Fuel & Idaho National Engineering Laboratory Environmental Impact Statement (DOE, 1994) for foreign research reactor spent nuclear fuel. These sites are: the Savannah River Site; the Idaho National Engineering Laboratory; the Hanford Site; the Oak Ridge Reservation; and the Nevada Test Site. Of these sites, only the Savannah River Site and the Idaho National Engineering Laboratory have existing facilities that could store the spent nuclear fuel beginning in late 1995. Thus, a two phase approach to management would need to be undertaken, wherein either the Savannah River Site or the Idaho National Engineering Laboratory would accept either or both aluminum-based and TRIGA fuels during Phase 1 (approximately 10 years) and then once facilities are constructed or refurbished at the other sites, the spent nuclear fuel would be transported for management (approximately 30 years) to the Phase 2 sites. If either the Savannah River Site or the Idaho National Engineering Laboratory were chosen as the management site, then the two phase approach would not apply.
i. Storage Technologies: Under this component, DOE would receive and manage foreign research reactor spent nuclear fuel for a period starting in approximately late 1995, and continuing for 40 years until ultimate disposition. During the first few years, management would take place in existing storage facilities that use both wet and dry storage technologies. Thereafter, when construction of new facilities may become necessary, the storage technology proposed is dry technology.
Utilizing the components provided above, DOE and the will evaluate seven implementation alternatives for Management Alternative 1 in addition to the basic implementation described above. Each implementation alternative is comprised of the same components as the basic implementation, however, for analysis purposes, one of the components is varied. A summary of the seven implementation alternatives is as follows:
Alternative 1: Alternate Amounts of Spent Nuclear Fuel to be Accepted:
Under this alternative, there are three subalternatives from which to select. The first is to accept highly enriched uranium and low-enriched uranium from developing nations only. This equates to approximately 1.9 metric tons of heavy metal, representing about 5,000 elements. The second subalternative is to accept only highly enriched uranium, which equates to approximately 4.6 metric tons of heavy metal, representing about 11,200 elements. The third subalternative is to accept in addition to the amounts of spent nuclear fuel identified, highly enriched uranium and low-enriched uranium target materials used in Canada, Belgium and Indonesia for production of medical isotopes. Target materials are estimated to contain 0.6 metric tons of heavy metal, representing a uranium content of 620 typical elements. Under this subalternative, highly enriched uranium target material would only be accepted under conditions that encourage foreign research reactors to convert to the use of low-enriched uranium targets.

Alternative 2: Alternate Policy Durations:

There are two subalternatives that are being evaluated for this alternative. The proposed policy duration stated in the basic implementation is ten (10) years. Subalternative One proposes a policy duration of five (5) years. A five year period covers approximately 18,800 individual elements containing 13 metric tons of heavy metal. The policy would allow shipments and receipt of spent nuclear fuel to be made for eight (8) years starting from the effective date of the acceptance policy as long as the spent nuclear fuel was generated during the five-year period. The additional years would allow for cooling of spent nuclear fuel discharged late in the five-year period, logistics in arranging for shipment of the spent nuclear fuel and delays or other unforeseeable events.

Subalternative Two would allow for indefinite acceptance of highly enriched uranium and a ten (10) year period for acceptance of low-enriched uranium. The amount of low-enriched uranium and highly enriched uranium spent nuclear fuel is the same as stated in the basic implementation, approximately 19.2 metric tons of heavy metal, from approximately 22,700 foreign research reactor spent nuclear fuel elements.

Alternative 3: Financing Arrangements:

Under the basic implementation, the United States would bear the cost for management and transport of the spent nuclear fuel from developing nations and would charge developed nations a competitive fee. Three subalternative options are being evaluated. Under the first subalternative, DOE would subsidize developed and developing nations. In the second subalternative, DOE would charge all nations the full cost of accepting and managing the foreign research reactor spent nuclear fuel. Finally, in the third subalternative, DOE would subsidize developing nations as in the basic implementation, but charge the developed nations a full-cost recovery fee. The amount of spent nuclear fuel that would be accepted under this alternative would be the same as that identified in the basic implementation (19.2 metric tons of heavy metal, 22,700 elements) unless one or more foreign research reactor operators declined to participate in the program because of a higher fee.

Alternative 4: Location for Taking Title:

The location for taking title is relevant to questions of liability and regulatory authority. Thus, if DOE takes title at the site of the foreign research reactor, additional regulatory burden may be placed onto DOE due to the laws of a particular nation being imposed upon the owner of spent nuclear fuel. Taking title prior to shipment might impose upon DOE additional legal liability for damages not associated with a nuclear incident covered by the Price-Anderson Act. For this alternative, however, three variations for taking title were reviewed: taking title to the foreign research reactor spent nuclear fuel before shipment; taking title at the port(s) of entry; and taking title at DOE management site(s).

Alternative 5: Wet Storage Technology for New Construction:

The basic implementation allows for use of either dry or wet storage facilities during Phase 1 and construction of new dry storage facilities for Phase 2. This alternative calls for investigation of wet storage technologies for Phase 2, wherein water filled pools are used to store the spent nuclear fuel. Wet storage methods have been used historically by the nuclear industry and the management sites proposed herein to store a variety of spent nuclear fuel, including the aluminum-based fuels that make up the majority of the foreign research reactor spent nuclear fuel.

Alternative 6: Near Term Chemical Separation of Foreign Research Reactor Spent Nuclear Fuel in the United States:

Under this implementation alternative, near term conventional chemical separation would be conducted at either the Savannah River Site or the Idaho National Engineering Laboratory. Near term conventional chemical separation of foreign research reactor spent nuclear fuel at the other three proposed management sites would not be considered since the Oak Ridge Reservation and the Nevada Test Site do not have facilities in which such chemical separation could be conducted, and the facilities at the Hanford Site are either not suitable for the proposed operations, or are no longer operable. To consider chemical separation at these sites, the spent nuclear fuel would need to be stored in the United States for the period while a chemical separation facility at one of these sites was designed, a project-specific National Environmental Policy Act review performed, and the facility constructed and put into operation. Thus, near term conventional chemical separation at these sites

would not be a reasonable near term alternative.

Chemical separation activities at the Savannah River Site would be limited to aluminum-based spent nuclear fuel. In this case, the TRIGA spent nuclear fuel could, based on the Draft Programmatic SNF&INEL EIS, be transported to any one of the five potential management sites for storage. Transporting TRIGA fuel to the Hanford Site, the Oak Ridge Reservation, or the Nevada Test Site, however, would require new construction or refurbishment of an old facility. DOE believes this is unreasonable for such a small amount of spent nuclear fuel (1.0 metric tons of heavy metal). One of the reasons DOE might decide to chemically separate spent nuclear fuel would be to avoid the construction of such storage facilities. Therefore, under this alternative, the TRIGA fuel would either remain at the Savannah River Site or would be transported to the Idaho National Engineering Laboratory.

In contrast, the chemical separation activities at the Idaho National Engineering Laboratory could include both aluminum-based and TRIGA spent nuclear fuel. In this case, all the spent nuclear fuel could be transported to this site.

Alternative 7: Developmental Processing Technologies:

There is a wide variety of technologies that DOE could use to prepare the foreign research reactor spent nuclear fuel for ultimate disposition. These technologies could be applied at any of the five potential management sites and most would require the construction of new facilities. Potential environmental impacts from the applications of these technologies cannot be assessed at this time since development of the technologies is incomplete and no designs exist for facilities that might implement them. Nevertheless, DOE will discuss in the FRR SNF EIS the potential for conducting a research and development program that could lead to construction of such a facility. Examples include: Chop and Dilute; Chop and Poison; Melt and Dilute; Melt and Poison; Pyrochemical Process; Chloride Volatility Process; Glass Material Oxidation and Dissolution System; Dissolve and Dilute; Enhanced Extraction; and Dissolve and Poison. These are mentioned to provide some idea of the breadth of potential technologies that would exist for preparation of spent nuclear fuel for ultimate disposition.

For Management Alternative 2, DOE would seek to encourage and facilitate the management of foreign research reactor spent nuclear fuel overseas in a manner consistent with United States nuclear weapons non-proliferation policy. Two subalternatives are evaluated as implementation options for this Management Alternative. Subalternative One is to provide assistance to foreign nations with storage. DOE would provide assistance to ensure that appropriate storage technologies, regulations and safeguards were applied. This type of support would only be provided to those countries that are able to store their spent nuclear fuel in facilities in their own countries, as a step towards final disposition of the spent nuclear fuel. Ultimate disposition of the foreign research reactor spent nuclear fuel would still have to be arranged for at the conclusion of the storage period. In the meantime, foreign research reactor spent nuclear fuel containing highly enriched uranium would be stored in up to 41 countries around the world. Subalternative Two is to provide assistance to foreign nations with reprocessing of the spent nuclear fuel. Under this subalternative, DOE would encourage and assist foreign research reactors and reprocessors in reprocessing their spent nuclear fuel overseas in facilities operated under international safeguards sufficient to satisfy United States nuclear weapons nonproliferation concerns. The wastes resulting from this reprocessing would be returned to the country in which the spent nuclear fuel was irradiated. To comply with United States policy, agreements would have to be negotiated with one or more foreign governments to ensure compliance with United States nuclear weapons nonproliferation policy goals. Discussions are currently underway via diplomatic channels to explore the feasibility of meeting these conditions.

Under Management Alternative 3, the Hybrid Alternative, DOE would encourage the reprocessing of any foreign research reactor spent nuclear fuel at Western European reprocessing facilities (i.e., Dounreay, Scotland or Marcoule, France), as in Management Alternative 2, for those foreign research reactors that could accept back the reprocessed waste and DOE would accept and manage the rest of the foreign research reactor spent nuclear fuel in the United States as in Management Alternative 1.

Implementation of Management Alternative 2 would necessitate the negotiation of clear and binding agreements with those foreign nations capable of taking back

reprocessing wastes to ensure compliance with United States nuclear weapons nonproliferation policy. Overseas reprocessing will only be considered for aluminum-based spent nuclear fuel as the technology does not currently exist at any of the overseas facilities to reprocess TRIGA spent nuclear fuel. Thus, TRIGA spent nuclear fuel would be accepted in the United States and transported to the Idaho National Engineering Laboratory for storage until its ultimate disposition. The aluminum-based spent nuclear fuel that would be accepted in the United States would be chemically processed at the Savannah River Site. For the analysis performed on this Management Alternative, the distribution of the spent nuclear fuels by fuel type is consistent with the Draft SNF&INEL EIS Regionalization by Fuel Type Alternative.

In addition to the three Management Alternatives discussed above, the Foreign Research Reactor Spent Nuclear Fuel Environmental Impact Statement is also considering a no action policy alternative, wherein the United States would neither accept foreign research reactor spent nuclear fuel containing uranium enriched in the United States, nor provide technical assistance or financial incentives for overseas storage or reprocessing. In this case, no foreign research reactor spent nuclear fuel shipments would be sent to the United States and no assistance to foreign nations for managing foreign research reactor spent nuclear fuel overseas would take place. Since the no action policy would only have environmental impacts outside the United States, these impacts are not addressed in the environmental impact statement.

Environmental Assessment of Urgent-Relief Acceptance of Foreign Research Reactor Spent Nuclear Fuel

Because DOE had not accepted any spent nuclear fuel containing U.S.-origin highly enriched uranium since 1988, several foreign research reactor operators began to run out of storage capacity and faced safety and regulatory issues associated with the presence of spent nuclear fuel at their sites. These reactor operators were faced with the decision to either shut down, or ship their spent nuclear fuel offsite for reprocessing. Neither of these options would serve the nonproliferation interests of the United States. At the urging of the Department of State, DOE prepared an environmental assessment that proposed to accept a small number of highly enriched uranium spent nuclear fuel elements at the DOE's Savannah River Site in Aiken, South Carolina. The purpose of the proposed action evaluated in this environmental assessment was to accept the minimum number of spent nuclear fuel elements necessary to maintain the status quo relative to the participation of the foreign research reactors with the Reduced Enrichment for Research and Test Reactors Program until the environmental impact statement discussed above could be completed and a decision made on whether or not to implement a new United States policy for management of foreign research reactor spent nuclear fuel.

The draft environmental assessment was made available to affected States and interested groups on October 18, 1993. Due to the numerous comments received from elected officials, private groups, and individuals, a revised draft of the assessment was released in February of 1994 for a 30-day public review and comment period. This revised draft included the results of DOE and Department of State team site visits to foreign research reactors under consideration for urgent-relief acceptance of their spent nuclear fuel. A reactor was identified as meeting the urgent-relief criteria if, because of the lack of near-term spent nuclear fuel storage space or presence of other problems, the reactor operator was likely to: 1) retreat from the conversion process to low-enriched uranium fuel, 2) reprocess spent nuclear fuel to avoid shutdown, or 3) shut down.

Public comments on the revised draft of the assessment were addressed in March of 1994 and the environmental assessment and an accompanying finding of no significant impact were released in April 1994. Subsequently, 153 spent nuclear fuel elements containing U.S.-origin highly enriched uranium were accepted from Denmark, Austria, Sweden, and The Netherlands in September of 1994. Subsequent shipments have been blocked by an adverse Court decision. This court decision is being appealed.

FY95 GOALS AND ACCOMPLISHMENTS (10/1/94 - 9/30/95)

The following goals were established for FY95 in relation to this environmental impact statement: 1) publish the Implementation Plan in October 1994; 2) issue the draft environmental impact statement shortly, hopefully by late March, 1995; 3) resolve comments stemming from the public comment period; 4) complete the final environmental impact statement by late summer; and 5) issue the Record of Decision

before the end of the year.
To date the first goal has been successfully accomplished, as the Implementation Plan was published in October 1994. At this point in time the other goals are on schedule and are anticipated to be accomplished as scheduled.

ABSTRACT
The Spent Nuclear Fuel Project's mission at Hanford is to "Provide safe, economic and environmentally sound management of Hanford spent nuclear fuel in a manner which stages it to final disposition." The inventory of spent nuclear fuel (SNF) at the Hanford Site covers a wide variety of fuel types (production reactor to space reactor) in many facilities (reactor fuel basins to hot cells) at locations all over the Site. The 2,129 metric tons of Hanford SNF represents about 80% of the total U.S. Department of Energy (DOE) inventory. About 98.5% of the Hanford SNF is 2,100 metric tons of metallic uranium production reactor fuel currently stored in the 1950's vintage K Basins in the 100 Area. This fuel has been slowly corroding, generating sludge and contaminating the basin water. This condition, coupled with aging facilities with seismic vulnerabilities, has been identified by several groups, including stakeholders, as being one of the most urgent safety and environmental concerns at the Hanford Site.
As a direct result of these concerns, the Spent Nuclear Fuel Project was recently formed to address spent fuel issues at Hanford. The Project has developed the K Basins Path Forward to remove fuel from the basins and place it in dry interim storage. A systems engineering approach of identifying requirements and the functions necessary to address those requirements was utilized. Alternatives that addressed the requirements were developed and analyzed. The result is a two-phased approach allowing the early removal of fuel from the K Basins followed by its stabilization and interim storage consistent with the national program. The DOE approved the Westinghouse Hanford Company (WHC) Recommended Path Forward for K Basins fuel on November 9, 1994. The WHC Recommended Path Forward starts fuel removal from K Basins by December 1998 and completes it two years later in December 2000 or earlier. The fuel is taken to a new Staging and Storage Facility located in the 200 Area at the Hanford Site. The fuel is staged or held in temporary storage while the stabilization process is finalized and design and construction of the facility is completed. Following stabilization, the fuel is returned to the Staging and Storage Facility for dry, interim storage (up to 40 years) until its ultimate disposition is determined at the national level. The path forward would have the K Basins fuel placed in interim dry storage by the year 2006.
In parallel with developing the path forward for the K Basins SNF, the Spent Nuclear Fuel Project also identified a path forward for management of the other Hanford SNF inventories. This planning is being integrated with the deactivation or utilization planning for each of the facilities containing SNF, as well as the national plan for placing DOE's SNF into interim storage.
HANFORD SPENT NUCLEAR FUEL PROJECT BACKGROUND
Nuclear production reactors were operated at the DOE's Hanford Site from 1944 until 1988 to produce plutonium by irradiating uranium. The fuel from these reactors was then processed at the Hanford chemical processing facilities to separate and recover the plutonium for its intended uses. Additional fuel was irradiated at the Hanford

Site for research purposes or was shipped from off-site reactor facilities for study, storage, or recovery of nuclear materials at Hanford facilities.
The July 1990 Nuclear Weapons Stockpile Memorandum signed by the President of the United States stated that recovery of nuclear materials from Hanford SNF inventories was no longer required for national defense purposes or for future breeder reactor fuel. As a result, processing operations were phased out and legacy SNF inventories were left in a variety of facilities across the Hanford Site. Fuel irradiated at the Hanford N Reactor and single-pass production reactors, the Fast Flux Test Facility, and from the second core of the Shippingport Pressurized Water Reactor currently remain in storage on the Hanford Site, in addition to miscellaneous research and development program irradiated fuel materials.
In general, current SNF storage facilities at the Hanford Site were not intended for SNF storage for an extended period of time and are not adequate for continued storage until the means for final disposition is available (i.e., 40 years). In most cases, these facilities either have other missions or are being deactivated. The inadequacy of these existing facilities for continued SNF storage necessitates that plans to improve storage conditions at the Hanford Site, and ultimately implement interim storage, be identified and implemented in an expeditious manner.
The deficient conditions at the existing Hanford Site SNF storage facilities were identified in a number of internal and external reviews, including the DOE findings documented in the November 1993 report, "DOE Spent Fuel Working Group Report on Inventory and Storage of the Department's Spent Nuclear Fuel and other Reactor Irradiated Nuclear Materials and the Environmental, Safety and Health Vulnerabilities," (1). These reviews identified degraded fuel being stored in two deteriorating basins located near the Columbia River as requiring urgent action. In 1993 and 1994, Hanford Site stakeholders, regulators, and tribal governments also emphasized their desire for the DOE to relocate the fuel from the K Basins to an alternate location as safely and quickly as possible. These actions ultimately resulted in commitments for the expedited removal of fuel and sludge from the basins.
The Hanford Site's Spent Nuclear Fuel Project was formed in early 1994 to manage Hanford's SNF and to meet those commitments. The mission of the Spent Nuclear Fuel Project is to provide safe, economic, and environmentally sound management of Hanford spent nuclear fuel in a manner which stages it to final disposition. In completing this mission, all of the Site's spent nuclear fuel will be safely stored on site or transferred to appropriate off-site storage, consistent with national plans for all DOE-owned spent nuclear fuel, and the Project facilities prepared for deactivation or alternate use. When these conditions are met, the Project will be completed and the responsibility for management of the Hanford spent nuclear fuel will be turned over to an operating program.
HANFORD SPENT NUCLEAR FUEL STORAGE LOCATIONS AND INVENTORIES
DOE-owned spent nuclear fuel is currently located at several facilities on the Hanford Site as shown in Fig. 1. The facilities, their current primary missions, their fuel storage functions and quantities of spent nuclear fuel are as follows:
K East and K West Basins
The K East and K West Basins store irradiated defense production reactor fuel, primarily N Reactor irradiated fuel. These basins contain about 3,800 cubic meters (1 million gallons) of water each and were part of the K East and K West production reactor complex constructed in the 1950's. They were used to cool discharged fuel prior to chemical processing. After the K Reactors production mission ended, the basins were used as temporary storage capacity for N Reactor fuel while the PUREX processing facility was being refurbished and restarted. When the defense production mission ended in 1990 and PUREX operations were terminated in December 1992, part of the N Reactor fuel inventory remained in the K Basins with no means for near-term removal and processing. The K East Basin contains 1,145.8 metric tons of N Reactor fuel and 0.4 metric tons of single pass reactor fuel. The K West Basin holds 953.8 metric tons of N Reactor fuel and 0.1 metric tons of single pass reactor fuel.
The fuel at the K West Basin has been stored in lidded canisters and the basin environment is relatively clean and free of corrosion products. The fuel at the K East Basin is currently stored in open canisters and some have corroded extensively, releasing fission products to the basin water and producing a substantial quantity of sludge. The basins also have a history of leaking. In the late 1970's, K East leaked about 57,000 cubic meters (15 million gallons) of basin water and again in

1993, another 340 cubic meters (90,000 gallons) escaped. The suspected location of the leak is an unreinforced construction joint between the basin and reactor structures. These conditions lead to an extreme sense of urgency for removal of the fuel, sludge, and contaminated water as quickly as possible.

PUREX Plant

The PUREX Plant was operated to recover uranium, plutonium, and other nuclear materials from irradiated fuel for defense and research purposes. It too contained a small quantity of irradiated production reactor fuel when its operation was terminated. Some single pass reactor fuel is stored in the receiving basin at the facility and a small amount of N Reactor fuel resides on the dissolver cell floor. The total amount of spent nuclear fuel at PUREX is 2.9 metric tons. The PUREX Plant is currently in a program to place the facility in a safe, environmentally sound condition prior to decontamination and decommissioning. These plans include the transfer of the spent nuclear fuel to the K Basins to be managed along with the rest of the production reactor fuel.

T Plant

The T Plant was the first fuel reprocessing facility at Hanford. The processing equipment had been removed and the plant decontaminated. It now serves as a beta-gamma decontamination facility and provides solid waste

Fig. 1.

management services. The Shippingport Pressurized Water Reactor Core II is stored in the receiving basin at T Plant and contains 15.8 metric tons of fuel.

Fast Flux Test Facility

The Fast Flux Test Facility (FFTF) is a 400 megawatt sodium-cooled fast reactor that provided materials, fuel, and component testing capability for the U.S. breeder reactor program during the 1980's. The FFTF is located in the 400 Area at the Hanford Site. When its mission ended in 1993, 11.0 metric tons of reactor fuel cores and numerous fueled experiments remained in the reactor and in storage at the facility. The reactor has been shutdown and the facility is currently being deactivated.

308 Building

The 308 Building in the 300 Area of the Hanford Site was used for the manufacture and assembly of FFTF fuel and test assemblies. The building contains a small Training Reactor, Isotopics, General Atomic (TRIGA) reactor that was used as a neutron radiography facility to inspect fueled components. The 308 Building is being deactivated and the TRIGA reactor has been shutdown. Its core contains 0.02 metric tons of fuel which is currently stored in the reactor vessel.

325 Building

The 325 Building Shielded Analytical Laboratory in the 300 Area supports process demonstration and analytical chemistry requirements for a variety of DOE programs. Over the years, a variety of small spent nuclear fuel samples were stored initially as archive material and then accumulated while awaiting processing or disposal.

324 Building

The 324 Building, located in the 300 Area, is a shielded chemical processing laboratory used for the development of chemical processes from laboratory to pilot scale and for the examination and mechanical testing of irradiated specimens. Seven light water reactor fuel assemblies are stored in the facility. These assemblies were intended for test purposes but remain in the 324 Building only because there is no other storage location.

327 Building

The 327 Building is also located in the 300 Area. It provides shielded, ventilated, and specially equipped laboratories for physical and metallurgical examination and testing of irradiated fuels and structural materials. While the facility is central to the characterization of the fuel stored in the K Basins, its long-term future is uncertain. The spent nuclear fuel stored in this facility comes from a variety of DOE fuel testing programs that used the facility for destructive testing and metallurgical examination.

The combined spent nuclear fuel inventories at the 324, 325 and 327 Buildings total 2.3 metric tons. The total spent nuclear fuel at Hanford is 2,132 metric tons and represents about 80% of the total inventory at all DOE sites. The 2,100 metric tons of metallic uranium production reactor fuel currently stored in the K Basins is about 98% of the total spent nuclear fuel at the Hanford Site.

K BASINS PATH FORWARD

The Spent Nuclear Fuel Project has focused on resolution of the K Basins issues. A recommended path for resolving the safety and environmental concerns and providing for the safe interim storage of this material was developed. The recommendation culminates five months of engineering studies and evaluations focused on accelerated removal of fuel and sludge from the K Basins and its placement in a stable, dry storage configuration until final disposition is achieved in the future.
To arrive at the recommendation, systems engineering and risk-based decision techniques were utilized, in conjunction with a variety of technical and programmatic reviews that included independent assessments by senior experts from outside Hanford. The evaluation process included analysis of cost, schedule, regulatory and stakeholder drivers, and affected tribal values to assure a comprehensive, balanced treatment of the various alternatives. Results from these reviews and analyses were used to formulate a technical and regulatory strategy which optimizes within the alternatives studied. In developing the recommended path, a broad range of alternatives were considered including:
1. Containerization of the fuel and sludge in K East Basin and storage of these materials in the K Basins until facilities are available for the transition to dry interim storage.
2. Removal of the fuel and sludge from both basins at the earliest possible date to a newly constructed temporary wet storage basin that meets modern safety and environmental requirements until facilities are available for the transition to dry interim storage.
3. Expedited transition directly to dry interim storage based on a drying and passivation process.
4. Processing the fuel at a foreign reprocessing plant and providing retrieval and disposition of the sludge at Hanford.
5. Variations within and among the above alternatives.
The Recommended Path Forward utilizes fuel containerization, drying, passivation, and vault dry storage to achieve interim storage. Construction of the proposed vault storage facility is accelerated to allow early removal from the K Basins by staging of wet packed fuel and sludge while the more complex Stabilization Facility is constructed and brought to a fully operable state. The vault storage facility also serves the 40-year dry interim storage function as fuel and sludge are processed at the Stabilization Facility by drying and passivating and returned to the storage vault. The resulting strategy removes fuel and sludge from the K Basins by the year 2000 at a cost (through the year 2012) of approximately $1,150 million (unescalated) including operation and deactivation of Project facilities (including the K Basins).
The framework for the recommendation is a workable National Environmental Policy Act (NEPA) overlay which requires division of the Recommended Path Forward into two phases: the expedited response phase and the interim storage phase. The goal of the expedited response phase is to move the fuel and sludge into a new facility for temporary storage away from the Columbia River as soon as possible. The interim storage phase is structured to implement the Record of Decision (ROD) for a Hanford Site Spent Nuclear Fuel Management Environmental Impact Statement (EIS) which is compatible with the ROD for the DOE Programmatic EIS (2). The Recommended Path Forward is described in Ref. 3. The key elements of the Recommended Path Forward are shown in Figure 2 and described below.
Expedited Response Phase This phase, which would be evaluated as the preferred alternative in an interim action EIS, rapidly improves protection of the public, the environment, and Hanford workers. Fuel and sludge would be transferred from the K Basins to a newly constructed Staging and Storage Facility away from the Columbia River. The interim action EIS is justified by the urgent need to remove fuel and sludge from the K Basins. The preferred alternative is compatible with the DOE Programmatic EIS in that all options being evaluated in the DOE Programmatic EIS for management of spent nuclear fuel remain viable. Existing and modified facilities would be managed in accordance with DOE Orders. The new Staging and Storage Facility would be constructed and operated consistent with Nuclear Regulatory Commission (NRC) technical requirements.
In the expedited response phase, fuel and sludge in K-East and K-West basins would be packaged in large multi-canister overpacks (MCO). Modifications would be constructed at the K Basins to enable minimum fuel and sludge handling to load the MCO. The MCOs would be designed to store fuel and sludge in a wet or dry condition and would enable direct monitoring of fuel, sludge, and surrounding liquid and gas

spaces during the temporary wet storage stage. A line item project would be proposed to construct a shielded vault Staging and Storage Facility to receive, store, and monitor the MCOs. Upon receipt from K Basins, the MCOs would contain wet-packed fuel and sludge and would be stored until staged into the Stabilization Facility. Design criteria for the Staging and Storage Facility would consider other Hanford spent nuclear fuel in development of functions and requirements. The wet packed MCOs would be held in the Staging and Storage Facility only until the fuel stabilization process is available.

Interim Storage Phase

The second phase develops and constructs a fuel Stabilization Facility, based on a drying and passivation process. The fuel and sludge are dried and passivated in the MCO and recycled to the vault storage facility to be stored dry for up to 40 years. This phase is dependent on a completed ROD for the DOE Programmatic EIS and would be evaluated as the reference alternative in a Hanford Spent Nuclear Fuel Management EIS. New facilities constructed during the second phase would be designed to the intent of NRC technical requirements.

During the second phase, MCOs would be transferred from the Staging and Storage Facility to the newly constructed Fuel Stabilization Facility which would be co-located with the Staging and Storage Facility. Here, the fuel and unseparated sludge are dried and passivated to reduce the potential hazards associated with dry storage of the metal fuel. The size (annual throughput) of the Stabilization Facility would be balanced against operations costs to optimize plant size and processing duration since processing is not on the critical path to K Basins deactivation. Development of design criteria for♀

Fig. 2.

The Stabilization Facility will consider other Hanford spent nuclear fuel in development of functions and requirements. The Staging and Storage Facility would be redeployed for use as an interim storage facility until final disposition capability is available.

K BASINS PATH FORWARD NEAR-TERM OBJECTIVES

Major acquisitions will be initiated to support the K Basins Path Forward. These include the Staging and Storage Facility, the Fuel Transportation System, the Multi-Canister Overpacks and the Stabilization Facility. These acquisitions, except for the Stabilization Facility, will be necessary for completion of the expedited response phase of the path forward. Other activities will also proceed in parallel with the major acquisitions to improve the near-term safety posture at the K Basins. These actions are:

Installation of cofferdams to mitigate the consequences of a seismic event by isolating the basin from the anticipated leak site;

Establishing and maintaining Formal Conduct of Operations at the K Basins;

Completing essential systems recovery actions necessary for safe operations, such as electrical, water, fire protection, and maintenance systems improvements;

Reducing personnel exposure through improved dose reduction measures, particularly through source term reductions from cesium contaminated concrete basin walls;

Removing debris from the K East Basin such as unused canisters and discarded tools;

Implementing sludge management activities consistent with the path forward for sludge;

Treating and dispositioning K East Basin water;

Providing basin modifications and readiness for fuel removal.

Fuel and sludge characterization is in progress and technology development activities will be performed as necessary to support implementation of the major acquisitions and the other identified activities.

OTHER HANFORD SPENT NUCLEAR FUELS

To resolve vulnerabilities at other Hanford SNF facilities, and to support facility deactivations, a two-step approach will be utilized to attain safe, interim storage for these fuels. The first step for each fuel involves near-term actions to attain safe, economic pre-interim storage. The second step will be to place each fuel into interim storage as defined in the DOE Programmatic EIS ROD when completed.

Near-term actions for these fuels are as follows:

Most FFTF spent nuclear fuel will be transferred to dry storage casks at the 400 Area for pre-interim storage. The planning basis for pre-interim storage of non self-protecting (Class I by the year 2030) FFTF spent nuclear fuel is transfer to

the Plutonium Finishing Plant at the 200 Area in dry storage casks.

The 308 Building TRIGA reactor spent nuclear fuel will be transferred to the 400 Area storage pad for pre-interim storage in casks that can be qualified for off-site shipment.

The 324/325/327 Building light water reactor fuel inventories will be relocated to the 400 Area storage pad in dry storage casks to correct vulnerabilities at those facilities.

The PUREX Plant spent nuclear fuel will be transferred to the K Basins for consolidated management with the K Basins spent nuclear fuel.

The Shippingport Core II will continue to be managed at T Plant until transfer to interim storage.

The other miscellaneous spent nuclear fuels will remain where they are currently located until their disposition is defined by the DOE Programmatic EIS ROD.

CONCLUSION

In response to the identification of vulnerabilities associated with the storage of spent nuclear fuel at the Hanford Site, the Spent Nuclear Fuel Project was formed. The Project's mission is to provide safe, economic, and environmentally sound management of Hanford spent nuclear fuel in a manner which stages it to final disposition. In just a few months, the Project developed and recommended to the DOE, a path forward to place 2,100 metric tons of fuel currently stored in the K Basins (80% of the DOE's spent nuclear fuel) into dry interim storage. This plan will begin fuel removal from the basins in 1998 and complete that phase over the next two years. Planning for management of other spent nuclear fuel at the Hanford Site is also completed.

BNFL APPROACH TO DOE SPENT FUEL MANAGEMENT: TAILORING TECHNOLOGICAL CAPABILITIES TO POLICY OBJECTIVES

Marilyn F. Meigs
BNFL Inc.
Washington, DC

ABSTRACT

This paper explores the BNFL process alternatives for managing certain unique inventories of DOE spent fuel and rationalizes these alternatives from the perspective of technological maturity and preference and consistency with US policy objectives.

INTRODUCTION

BNFL has been supplying fuel cycle services to the commercial utility industry worldwide for decades. These services include uranium enrichment, conversion, and fuel fabrication on the "front end", and on the "back end", spent fuel shipment, storage, and reprocessing, and conversion of waste and byproducts to forms suitable for storage, disposal, and/or re-use, including the manufacture of mixed oxide fuel. As much as BNFL would like to think that the US offers a huge potential market opportunity for BNFL's reprocessing services, the reality is quite the contrary. US policies in the 1970s ended the US domestic reprocessing industry and set forth a path for direct disposal of commercial spent fuel, despite the fact that "recycle" seems to be the politically and socially correct choice for virtually every other US resource except uranium.

It just so happens that energy-rich countries like the United States can afford to make decisions on spent fuel management that other, energy-poor countries may view entirely differently. The fact is, BNFL would be the first to admit that either option -- direct disposal or reprocessing -- is entirely acceptable for most standard spent fuel forms and therefore both options should be able to enjoy

"peaceful co-existence." Furthermore, no nation should impose its solutions for the back end of its fuel cycle on other nations.
There are, however, certain unique inventories of spent fuel under DOE guardianship that may require special treatment, and it is these "exceptional cases" that are addressed in this paper.
Before discussing the essence of this paper, it is worth noting for the record the BNFL provides services to those customers that desire these services. BNFL is not in the business of policy-making, nor does it engage in coercion to maintain or augment its customer base. BNFL merely strives to provide practical, technically-sound options for those customers who might need these services.
In the case of DOE, BNFL has examined the inventories of DOE spent fuel and identified certain unique cases where BNFL technology and experience are particularly relevant to very unusual problems now facing DOE. The key, however, is for BNFL to be able to provide these services in a manner not inconsistent with US policy objectives.

US POLICIES RELATED TO SPENT FUEL MANAGEMENT

Fuel Cycle Policies

As already stated, the United States policy decisions in the 1970s resulted in cancellation of the US commercial reprocessing program and set forth a path for direct disposal of commercial spent fuel. However, this policy did not affect the government's nuclear weapons programs, which necessarily required reprocessing of government-owned spent fuel to separate weapons-grade plutonium in order to meet weapons stockpile requirements during the cold war.
But even the government nuclear weapons program eventually changed, due to the end of the cold war. Reprocessing facilities at DOE's Hanford and Savannah River sites were suddenly rendered obsolete, and were shut down for "maintenance" in the late 80s and early 90s, and have not operated since. In 1992, the Hanford Purex plant was placed in permanent shutdown and is now undergoing decommissioning. The fate of the Savannah River reprocessing facilities is in limbo, and subject to a National Environmental Policy Act (NEPA) review still underway.
In 1982, Congress passed the Nuclear Waste Policy Act -- later amended in 1987 -- which sets for the US government responsibilities for development of a permanent disposal facility for receipt of commercial spent fuel and government High-Level Waste (HLW) from DOE's reprocessing activities.
Ironically, the Nuclear Waste Policy Act did not address receipt and disposal of DOE-owned spent fuel, because at the time, it was assumed that all DOE fuels would be reprocessed, therefore, the only government material to be disposed of would have been in the form of vitrified HLW byproducts from the reprocessing activities.
Whether due to bad timing or lack of foresight, it turns out that DOE shut down its reprocessing facilities BEFORE it had completed the reprocessing of its rather unique inventories of spent fuel. As we all know now, DOE is grappling with a decision on how to manage the remaining 2700 metric tons of spent fuel, much of which is highly damaged or unstable, and certainly not anything like the commercial spent fuel for which direct disposal is well suited.
So to summarize, US government policies on spent fuel and HLW disposal are fairly well laid out in the direction of direct disposal, except for some "orphan" categories of DOE spent fuel that were not contemplated during the formulation and codification of US fuel cycle policy.

US Nonproliferation Policies

Overlaying the specifics of US fuel cycle policy are the much bigger demands of US nonproliferation policies. While the two are not unrelated, fuel cycle policy as discussed above is an internal, domestic policy, while nonproliferation policies are necessarily broader in scope, reflecting international policies, treaties, and objectives of a global nuclear community.
For discussion purposes, this paper will address the current nonproliferation objectives of the Clinton Administration, as articulated in a September 1993 White House Fact Sheet (1). In that statement, the US expressed its intentions to discourage reprocessing and plutonium use in the nuclear power industry worldwide, while, at the same time, not interfering with the legitimate commercial reprocessing activities underway in Western Europe and Japan.
Even though Western Europe and Japan are somewhat disappointed in the negative connotations of this US nonproliferation policy, they have so far been able to function within the constraints of these policies, despite occasional overzealous US

government "interpretations" and manifestations of these overall policy objectives.
DOE-HANFORD N-REACTOR SPENT FUEL
DOE identified a number of problems associated with its inventories of spent fuel in a DOE Spent Fuel Working Group (2) issued in December of 1993. To address these vulnerabilities, DOE is now undertaking a Programmatic Environmental Impact Statement (PEIS) (3) whose Record-of-Decision (ROD) is due out in June of 1995. Following close on the heels of this PEIS will be site-specific Environmental Impact Statements (EIS's) which will address the long-term management and disposition options specific to the inventories of fuel on each DOE site. These EIS's will identify the preferred options for stabilizing and treating each category of DOE spent fuel in a manner that will render the spent fuel effectively passive against future environmental threats and interactions (4). In some cases, this will mean simply doing nothing. In other cases, however, quite a lot will have to be done.
By far the largest and certainly the most unstable inventory of DOE spent fuel is the 2100 tons of spent fuel left over from the operations of the N-reactor at the Hanford site, now currently stored at the Hanford K-basins. This fuel would have been destined for reprocessing at the Purex plant, had the plant not been shut down in 1992. This fuel is an unusual, non-"standard" form of fuel, in uranium metal form (as opposed to the standard uranium oxide form), highly damaged and corroded, and requiring extensive chemical conditioning to render it stable for permanent disposal.
Knowing of this problem, the operators of the Hanford Plant contacted the only remaining operators of reprocessing facilities -- BNFL in England and Cogema in France -- to determine whether our respective facilities could handle this type of fuel.
It turns out that BNFL has extensive and very relevant experience in handling Magnox fuel from England's first generation of gas reactors, known as Magnox. This fuel is also metallic, and BNFL's policy has always been to store it for a minimal amount of time (less than 3 years), under water, until such time as reprocessing is undertaken. The reprocessing is done as much to stabilize the chemical form of the fuel for final disposal as it is for any recycle value attached to the fuel.
BNFL examined the situation with respect to the N-reactor fuel, and came to several conclusions:
1. The fuel was much more deteriorated than most of the fuel BNFL had ever handled, except perhaps for an inventory of highly damaged fuel from an Italian reactor customer, which BNFL successfully transferred into its own shipping casks, shipped, stored, and reprocessed. This experience demonstrates that BNFL can manage and process severely damaged metal fuel.
2. The severity of the damage to the N-reactor fuel is attributed to the excessive length of time the fuel had been stored at the K-basins (as long as 17 years), the lack of water chemistry control in the basins, and ironically, the oxygen deprivation and excessive hydriding associated with the containerized fuel stored in the K-West Basin. Some experts say the fuel is more accurately described as rubble, debris, and sludge, than it is spent fuel.
3. BNFL could indeed handle the fuel as well as the basin cleanup, all the way from providing the necessary number of Magnox shipping casks, supervising the loading of these casks, arranging for shipment by rail or truck to a sea terminal, where the fuel would be transferred to one of BNFL's dedicated ships for transport to BFL's storage and reprocessing facilities at its Sellafield site. With minor front-end modifications to either BNFL's Magnox reprocessing plant or its newly-commissioned THORP plant, the fuel could be safely reprocessed to render the material suitable for permanent disposal. Meanwhile, BNFL's success in cleaning up highly contaminated, sludge-filled spent fuel storage pools at Sellafield could be directly applied to the challenges of cleaning up the K-basins.
The operators and managers at the Hanford site, as well as technical program managers at DOE-Headquarters have shown obvious interest and enthusiasm in BNFL's technical capabilities. They were particularly impressed with the fact that BNFL could have all the fuel removed from the K-basins by the year 2002, which is DOE's commitment under the Hanford Tri-Party Agreement. Furthermore, all activities would be accomplished in compliance with applicable US, International, and UK regulatory and safety standards.
Sadly, those same DOE representatives became extremely pessimistic when it came to discussing actually putting the BNFL option into practice. This pessimism derived

from the perceived incompatibility of this option with current US nonproliferation policy objectives. For despite the fact that this was an extremely unique problem requiring a unique solution, and despite the fact that the reprocessing was to be undertaken for reasons totally unrelated to separation of plutonium from the fuel, and undertaken by the United States' closest and most trusted ally, these DOE representatives predicted that BNFL option simply would not pass the Clinton Administration nonproliferation policy litmus test.

ADAPTING BNFL TECHNOLOGY TO US POLICY OBJECTIVES

With that impasse in mind, BNFL experts set out to determine what, if anything, BNFL could do to meet the requirements of US policy of not producing any more separated weapons plutonium. After all, any successful provider of services must always be sensitive to customer needs, and BNFL is certainly no exception.

After some fairly rigorous examination of technology options available to BNFL, the following options were identified and presented to DOE representatives last May:

1. The chemical separation process could be interrupted just prior to separation of the uranium from the plutonium. The still-combined stream of uranium and plutonium would then be diverted to a nearby vitrification plant where, if proven to be feasible, the entire inventory would be vitrified in HLW glass logs suitable for permanent geological disposal. The intent here was to avoid separation of plutonium from uranium.

Due to the massive proportion of uranium as compared to plutonium in the unseparated stream, the practical result of this option would have turned out to be the generation of no less than 25,000 canisters of HLW, an amount that BNFL Transport Division would be more than happy to transport back to the United States. By contract, this compares to the normal return from such a quantity of spent fuel of this type of 450 canisters of HLW. Thus, this approach was deemed impractical, precisely because the large amounts of uranium remaining in a relatively minor amount of plutonium translated into a massive waste problem.

This difficulty lead BNFL to the conclusion that separation of uranium from the plutonium would be necessary from a practical waste-management standpoint -- not to separate out the plutonium, BUT TO SEPARATE THE MASSIVE AMOUNT OF URANIUM contained in the mixture (99% by volume).

2. Once having established the practical need to separate out the uranium in the process, the next challenge was how to deal with the plutonium stream in a manner not inconsistent with US policy objectives. So, for ideas, BNFL looked at what methods were under consideration in the US for disposing of OTHER inventories of excess weapons plutonium (the additional amount of Pu from N-reactor fuel represents only 6% of the total declared excess plutonium inventories). The National Academy of Sciences report on "Management and Disposition of Excess Weapons Plutonium" (5) recommended two preferred options, namely burning the plutonium in nuclear reactors as mixed oxide (MOX) fuel, and/or vitrifying the plutonium in HLW glass logs. These two options are the frontrunners in an ongoing PEIS on Disposition of Excess Fissile Materials, expected to be completed in the summer of 1996.

With respect to the first option of burning the plutonium as MOX fuel, there is no question that BNFL could treat the N-reactor plutonium in this manner, having done so for the rest of its customers, using a proven technology. In fact, with startup of BNFL's new Sellafield MOX Plant (SMP) in 1997, the proximity of the SMP to THORP is such that plutonium will never leave the co-located buildings. In essence, BNFL will be able to receive the N-reactor fuel at one end of THORP, reprocess it, and provide MOX fuel as the finished product out the other end. The resultant MOX fuel would have the equivalent energy of 10 million tons of coal.

With respect to the second option of putting plutonium into HLW vitrified glass, there is little or no experience worldwide with this option. In theory, adding the plutonium to the HLW glass mixture is feasible, providing that it is added in limited quantities (less than 5% by concentration) to preclude any deleterious effects on the stability of the glass form. The fact is, BNFL has no experience to date putting plutonium into glass precisely because the plutonium is purposely separated out for reuse. BNFL's HLW glass has negligible quantities of plutonium, by design. This is not to say that BNFL could not perform lab-scale tests to determine the technical feasibility of incorporating plutonium into HLW glass, and would be willing to do so, if the customer so desired. If the process proved feasible, this option would result in the production of some 2000 canisters of HLW glass, an amount substantially above the nominal 450 canisters for pure HLW glass, but still a

manageable amount to ship and dispose of.
BNFL believes that its options for stabilizing the N-reactor fuel via reprocessing, and its ability to manage the plutonium byproduct in a manner consistent with DOE's plans for disposing of other inventories of excess weapons plutonium, coupled with BNFL's flawless nonproliferation credentials and experience second-to-none in handling this type of fuel make it the only practical, feasible, and cost-effective solution. Nonproliferation concerns having been satisfied, the environmental economic consequences of NOT using the BNFL option are so dire as to defy logic.
THE DOE 'PATH FORWARD' PROPOSAL FOR INTERIM MANAGEMENT OF N-REACTOR FUEL
Putting logic aside, however, it appears that DOE has announced an interim "Path Forward" proposal (6) to remove and temporarily store the fuel on-site, at an estimated cost of $1.15 billion. Approximately half that cost is associated with the cleanup and decommissioning of the K-basins, which must be accomplished in any event. But the other half -- or roughly $600 million -- will be spent on a 40-year "interim" on-site storage facility for the spent fuel. The concept involves removing the fuel to multi-canister overpacks (MCO's), which would store the fuel wet until such time as a method can be developed and a facility can be built to convert the wet-stored material to dry storage, utilizing the same MCO's.
It is important to note that DOE has committed to meeting an NRC-equivalent safety envelope for the fuel drying process and the dry storage facility, even though the exact process for drying the fuel, rubble, and debris has yet to be developed or proven feasible, and even though NRC safety standards for drying and storing metal fuels don't exist.
According to DOE cost estimates, the as-yet-to-be designed "fuel stabilization facility" for drying the fuel and debris will cost $133 million in capital costs, and another $115 millon in operating expenses. These figures should be taken for what they really are -- cost guesstimates. All this for a facility that will not move the fuel one step closer to real, chemical stabilization that must eventually be undertaken no matter what. all this to "stabilize" fuel that is already so badly deteriorated that it is much better described as rubble, debris and sludge than it is fuel. All this to put off for 40 years onto someone else's watch a final decision that could be made today, but for an unfortunate misapplication of US policy. The really unfortunate aspect of this whole "Path Forward" option is that, after the 40 years of interim storage the facilities, the institutions, and the expertise to treat this fuel for permanent disposal may no longer exist. Meanwhile $600 million will have been wasted that could have otherwise been applied to a direct, technologically proven, final disposition route.
A CRYSTAL BALL FOR THE FATE OF N-REACTOR FUEL
BNFL has demonstrated flexibility, innovation, and sensitivity in developing options for DOE to effectively treat N-reactor fuel within the confines of US nonproliferation objectives. DOE's selection of a BNFL option will depend on political developments and NEPA analyses that have yet to be completed. BNFL will continue to provide technical expertise and experience in handling metal fuels as these deliberations unfold.
BNFL CONTRIBUTIONS TO OTHER US SPENT FUEL AND FISSILE MATERIALS MANAGEMENT PROBLEMS
If one acknowledges that BNFL technological solutions can be adapted to satisfy US nonproliferation objectives, as discussed above, then there are several other pressing but unique problems in the US to which BNFL can offer solutions. These solutions only need the political will and a "common sense" approach to become reality.
Briefly, here is a sampling of some other unique US spent fuel challenges begging for relief that are potential candidates for overseas solutions:
Foreign Research Reactor Spent Fuel
Under an Urgent Relief Environmental Assessment (7) DOE recently resumed its program to take back foreign research reactor spent fuel under its Reduced Enrichment of Research Test Reactors (RERTR) program. A formal EIS is presently underway to address the return of the remaining inventories of RERTR fuel under this program. There are approximately 15,000 subassemblies to be returned over the next 10 years. The original intent of the RERTR Program was to encourage operators of these research reactors to convert from high-enrichment cores, to low-enrichment, thereby reducing any proliferation concerns attached to the continued operation of these reactors.
The governor's office in South Carolina, where the fuel is to be shipped for

storage, has objected to his state becoming a storage site for all this RERTR spent fuel, and filed a lawsuit against DOE, the final outcome of which is yet to be determined.

A very practical, proliferation-proof solution to this dilemma that would still enable DOE to meet its policy objectives under the RERTR Program is under consideration in the full EIS. That solution involves reprocessing in England (Dounreay, or, assuming modifications could be made, at Sellafield), return of the high-enriched uranium, under full-scope safeguards, to the US where it could be blended down for return to the foreign research reactors as low-enriched fuel.

North Korean Spent Fuel

The Agreed Framework between North Korea and the United States includes a cessation in operation of the Democratic Peoples Republic of Korea (DLRK) reactor, short-term interim management of the fuel onsight, and eventual removal of the fuel from North Korea. This fuel is a metal fuel not unlike K-reactor fuel or Magnox fuel, and DOE officials have already acknowledged the fact that this fuel is unstable and will eventually require reprocessing. Again, BNFL could provide the casks, the ships, the reprocessing, and the return of plutonium to the US or a US-designated destination in a form unsuitable for weapons production (i.e., as MOX fuel or in HLW vitrified glass). DOE has already contacted BNFL to discuss these services, despite the fact that it is unwilling to move that same direction yet with respect to its own N-reactor fuel.

West Valley Fuel

DOE retained title to a small inventory (125 subassemblies) of commercial fuel at West Valley in New York, largely due to the fact that the fuel was damaged and could not easily be accepted back in the fuel ponds of its original owners. DOE is in the process of decommissioning the entire West Valley site, and had planned to ship the West Valley Fuel to the Idaho National Engineering Laboratory, up until the State of Idaho filed a lawsuit objecting to any future receipt of out-of-state fuel. The DOE has an agreement with the State of New York to have that fuel removed by the end of 1995 or otherwise be subject to a $600,000 per year penalty.

At DOE's request, BNFL has briefed the department concerning BNFL's capabilities to remove the fuel for reprocessing overseas. The same tailor-made management that would be applied to N-reactor fuel would be applied here, that is, return of the plutonium to the US in a non-weapons useable form.

The DOE Obligation to Accept Commercial Spent Fuel by 1998

Even though DOE denies the fact that it has a legal obligation to accept spent fuel from commercial nuclear utilities beginning in 1998 (8), there are a handful of utilities who are running out of on-site spent fuel storage capacity and are precluded for one reason or another from building additional on-site storage or shipping to another site. Several utilities face premature shutdown if DOE cannot take their fuel by 1998.

DOE has been unsuccessful in identifying, let alone being able to provide, any facilities for interim federal storage pending completion of a permanent geologic disposal facility. Even the proposed privatized Mescalero Monitored Retrievable Storage (MRS) Facility will not be completed until 2002, if it proceeds at all. BNFL could fill the gap for this limited quantity of "orphan fuel" until such time as DOE or the Mescalero develop an MRS, so as to enable those nuclear plants with limited on-site storage capacity to avoid premature shutdown.

Excess Weapons Plutonium Disposition

Although not strictly in the category of spent fuel, excess weapons plutonium disposition is a challenge that demands immediate resolution, especially with respect to the quantities of material in the Former Soviet Union. Western Europe has available, proven technologies and facilities, and operating history, that is directly applicable to the burning of this excess weapons material as MOX fuel. Western Europe also has industrial-scale experience with vitrification of HLW which, while not quite so directly relevant to excess weapons plutonium disposition, could be adapted to that goal if the US so desired.

CONCLUSION

Policy decisions that the US Government makes with respect to its domestic spent fuel management and disposal programs are certainly legitimate and of no consequences to other countries and their own, individual fuel cycle policies. However, there are certain unique inventories of US spent fuel that require alternative approaches.

BNFL has taken into account the sensitivities of US nonproliferation policies and unique technology problems to come up with solutions tailor-made to the "customer." It is now up to the "customer", the US Government, to acknowledge the legitimacy and practicality of these solutions in meeting US policy and program objectives.

TECHNOLOGY INTEGRATION PLAN

Roger Henry
Kenneth C. Sumpter
Lockheed Idaho Technologies Company

ABSTRACT

In 1992, the Secretary of Energy directed the Assistant Secretary for Environmental Management (EM) to develop an integrated, long-term, spent nuclear fuel (SNF) management program. In response, EM created the Integrated SNF Program to assess the U. S. Department of Energy (DOE) SNF and SNF storage facilities. As shown in Fig. 1 the Integrated SNF Program is responsible for life-cycle management of DOE SNF; that is characterization, processing, interim storage and preparation for disposal. In order to implement the Program, it was recognized that technology needs must be identified. A Technology Integration Program was formed to integrate the DOE complex-wide efforts for establishing timely, cost effective and consistent technical criteria for the development of technical solutions. The program is directed toward identification of: a) what activities need to be done, b) when they need to be completed, and c) what priority should be assigned to the various activities.

Fig. 1.

SCOPE OF THE PROBLEM

The DOE is responsible for approximately 2,700 metric tons of heavy metals (MTHM) SNF. In general the SNF is divided into five principle generation sources: Materials Production Fuels, Naval Nuclear Propulsion, Research Reactor Fuels, Specialty Fuels, and Special Case Commercial Nuclear Power Reactor Fuels. There are currently over 200,000 units (rods, elements, pieces, baskets, buckets, cans, etc.) of DOE SNF in storage at 29 different DOE facilities, universities, and private institutions in the United States. By identifiable characteristics, DOE SNF can be grouped into over 150 distinct fuels. For the purposes of the TIP the DOE-owned SNF is divided into 53 categories. These categories served as the starting point to determine the program technology needs.

The diverse inventory and its multiple locations complicate the development of an optimum SNF management plan driving the need to integrate technology development. In addition to such factors as enrichment and volume the SNF diversity, its physical integrity, and ES&H vulnerabilities all have a significant influence in determining the initial scope of the technology development program. Future increases when measured in terms of total fuel mass will increase the SNF inventory by 70%.

TECHNOLOGY INTEGRATION PLAN

The technology integration effort must be continuous, staying current with accomplishments and analysis of options. A DOE Spent Fuel Nuclear Fuel Technology Plan (TIP)* has been written containing extensive, preliminary data that is useful

in supporting some present and future planning activities. To be effective the plan must maintain program flexibility to minimize not only near-term expenditures, but life-cycle cost and environmental, safety, and health risks. The initial result from this effort indicate a clear need to continue and expand the in-depth analysis of the this effort. Technology development as defined in the TIP is "the scientific and engineering investigations required to ascertain basic principles of a process or concept."

The TIP contains technical input from the various DOE laboratories which are integrated with the programmatic goals and management philosophy identified in the new technology development plan for the DOE Office of Technology Development (EM-50). This comprehensive document focuses on major cleanup obstacles and presents a balanced set of plans are being developed to integrate all EM environmental research and technology development. The TIP will be a dynamic partner in this technology development process.

SYSTEMS APPROACH

Because of the distinct characteristics of the SNF fuels, preparation for interim storage and subsequent disposal should not be expected to follow the relatively simple pathway planned for commercial reactor SNF disposition. The selection of a management option must consider specific fuel type characteristics such as physical condition, chemical reactivity, and criticality safety issues. Some of the factors that could influence the selection of an SNF disposal technology for further development are:

- Can directly
- Dilute High Enriched Uranium with depleted uranium
- Shred, mix with glass in a geometrically safe can
- Reprocess, calcine waste, convert to glass-ceramic
- Cut; package in safe geometry
- Recycle metal/waste minimization
- Preparation of single waste form
- Dissolve, glassify, pour in commercial fuel can

In some cases, the evaluation of the proper SNF option for a particular fuel may lead to the conclusion that the SNF requires repackaging, or stabilization. Policy decision, economics and public acceptance must also be factored in the selection of the disposal pathway.

Figure 2 is a summation of the cost for identified tasks (funded and unfunded) through fiscal year 1998 (in 1995$). Potential for integration of tasks exists, but requires additional, detailed review to determine if all programmatic goals at each site can be accomplished in a timely manner after integration strategy is implemented.

Fig. 2.

In any event what is done today to manage the existing conditions and stabilize the SNF for interim storage must consider what the impact of these actions will be on the final SNF disposal. If direct disposal is possible, it would seem prudent to store robust SNF e.g., naval fuel, without further processing and, for the SNF that requires processing; process only once for both interim storage and disposal.

EXISTING STORAGE

In general most of the near-term activities are directed toward a stabilized storage posture for the DOE SNF. The technology development tasks in this area include activities related to SNF corrosion control, sludge characterization, characterization of degraded fuel, and facility conditions such as storage basin liquid leakage control. Obviously, these activities must receive priority since most of the activities are responding to vulnerabilities identified by the DOE Spent Fuel Working Group Report.* While much of the work is nonroutine and challenges the capability of the DOE laboratory complex most of the technology needed to accomplish these activities is in place. Innovative applications will be needed to resolve the existing storage vulnerabilities.

INTERIM STORAGE

Typical interim storage related activities are directed toward transitioning SNF into storage conditions that are adequate until a permanent repository is in place. Because most of the current storage practices, fuel designs, and facilities are not well suited for extended storage, many of the technology development tasks are associated with transition to dry storage, and repackaging of SNF, etc. Some level of fuel characterization will be required for interim storage. If, indeed the goal

is to stabilize the SNF such that the final fuel form may go directly to the permanent repository characterization may become critical from the standpoint of final performance form.

DISPOSAL

In general, there are two basic processes for preparing SNF for disposal; direct canning and chemical processing of the SNF to achieve an acceptable waste form. The first disposal option i.e., direct canning is straight forward although some development is needed in this area. Most of the SNF, currently stored in a wet environment must be dried before disposal. It may be difficult to dry the fuel sufficiently to prevent radiolytic and chemical production of hydrogen or fuel degradation over long periods of time. Some development work, although more of an application of existing technology, must be applied to canister configuration. The multi-purpose canister (MPC), for instance would allow near-term onsite storage, transportation, interim storage, and disposal without further handling of the SNF. Fuel characterization needs, criteria, and methodologies need to be developed foe SNF direct canning.

The second major area of development addresses the technologies needed to stabilize the SNF for interim storage. Existing chemical processing, although discontinued at this time, could assist with DOE SNF disposal. Aqueous processing is generally available. Solvent extraction processes for separation of fissile uranium and plutonium from aqueous high level waste are well developed and have been used for decades.

New processing technologies that may combine stabilization for interim storage and disposal preparation offer the additional advantage of separation of non-radioactive constituents into low level waste. These new technologies; Chloride Volatility Process, Electro Chemical Treatment, Glass Material Oxidation and Dissolution System, and various enhanced extraction technologies are in various stages of development.

EVALUATION OF TECHNOLOGY NEEDS

The TIP discusses the methodology for identifying the scope of the technology development needs for the DOE SNF and its various management options. This methodology resulted in an overview matrix that scoped individual technology development activities for each of the 53 SNF categories. There are 980 potential technology needs identified. Because of the magnitude of the potential problem each site was asked to present the SNF technology development programs (funded and unfunded) that they believed were justified by these SNF management issues. Technology development tasks that had a potential interface with other related programs were noted and discussed.

To help ensure that consistency and completeness were incorporated, the 49 funded tasks were compared to the potential technology needs to independently verify its need/justification. The funded tasks were also related to SNF categories to ensure that support was focused on problem SNF categories with issues that need early resolution. This comparative review showed good correlation between the tasks identified and the needs of the overview matrix.

As expected, the majority of tasks, Fig. 3 fall under interim storage. Perusal of the information shows little duplication in efforts for the wet storage, mechanical disassembly of fuels, properties of fuel for dry storage environment, and new technologies for disposal categories. However, there appears to be potential duplication of activities in both SNF characterization for dry storage and dry storage demonstrations.

Fig. 3.

CONCLUSIONS

The technology needs and development tasks presented in the TIP reflect roles and responsibilities that cross-cut DOE's organizational structure. Inputs, recommendations, and issues identified by these organizations were considered in developing the TIP. Additionally, in identifying the technology development needs specific to DOE SNF, consideration was given to integrating those efforts managed by organizations outside of EM-37. Some of the interfacing organizations are EM-50, RW, and DOE operations offices.

An SNF TIP has only been initially scoped. Although this effort has been greatly advanced, not all tasks required for a fully integrated plan are identified. The completeness of the data set does not allow a full picture of the ongoing technology development, and the needed development to be thoroughly assembled.

An overall time line, assessing when technologies will be needed, is difficult to derive. Such a tool is highly dependent upon assumptions such as repository opening date, acceptance criteria for DOE SNF, inventories to be emplaced in the first repository, long-term nonproliferation criticality issues for fissile material, the end of life of existing storage facilities, and possible advances that would allow SNF to be stabilized in existing storage configurations.

A PATH FORWARD FOR THE GEOLOGIC DISPOSAL OF DOE-OWNED SPENT NUCLEAR FUEL

Jon H. Thompson
Geologic Disposal Program Manager
Office of Spent Fuel Management
Office of Environmental Management
USDOE
Ralph Stein
Diana H. Hirrlinger
Golder Federal Services

ABSTRACT

The Department of Energy (DOE) Office of Spent Fuel Management has undertaken a program to ensure the safety of existing storage, provide for interim storage and prepare for ultimate disposition of DOE-owned spent nuclear fuel (SNF). DOE is responsible for managing approximately 2,700 metric tons heavy metal (MTHM) of DOE-owned SNF that is currently stored at DOE facilities. In the past, most DOE-owned SNF has been chemically processed to recover plutonium or uranium for the nuclear weapons program. However, with the phaseout of chemical processing throughout the DOE Complex, DOE-owned SNF must now be managed until its ultimate disposition, rather than for the few years until reprocessing, as originally intended.

Of the options available for ultimate disposition of DOE-owned SNF, geologic disposal is the primary option under consideration. There is a long history and numerous challenges associated with the planning for geologic disposal of SNF and high level nuclear waste (HLW). DOE faces additional challenges in its qualification of DOE-owned SNF for geologic disposal. In addition, institutional issues have recently surfaced with the introduction of additional material not originally considered in the repository program planning. Public stakeholders have expressed a keen interest both in the DOE-owned SNF program and the implications of its disposal on the repository program. DOE must also meet technical challenges to develop a coherent and cost-effective program for geologic disposal of the diverse DOE-owned SNF inventory, which in some cases is quite different than civilian SNF.

A number of efforts are underway to address the challenges associated with geologic disposal of DOE-owned SNF. The DOE Office of Spent Fuel Management is developing a memorandum that evaluates various options for introducing DOE-owned SNF into the planning for all other radioactive materials slated for repository disposal, identifies key issues and sensitivities, and proposes a path forward for geologic disposal of DOE-owned SNF. Another key effort is the formation of a joint Steering Group, consisting of the DOE Offices of Civilian Radioactive Waste Management (OCRWM) and Environmental Management (EM), to coordinate efforts in the geologic disposal of DOE-owned SNF.

BACKGROUND

The Department of Energy (DOE) is in the midst of a transition in its management of spent nuclear fuel (SNF) inventories. In the past, the liquid HLW resulting from the reprocessing of DOE-owned SNF was converted into a vitrified waste form for ultimate disposal in a geologic repository. Fissile material from the reprocessing of DOE-owned SNF was recovered for use in the nuclear weapons stockpile. However, the Secretary of Energy, in April of 1992, directed a phaseout of remaining reprocessing operations in the DOE complex, leaving an inventory of SNF to be managed along with the existing inventory of liquid HLW. Essential to the success of this transition in DOE-owned SNF management will be a new strategy to achieve ultimate disposition.

During the last four decades prior to 1992, DOE and its predecessor agencies reprocessed approximately 100,000 Metric Tons of Heavy Metal (MTHM) of SNF from various sources, including: DOE production reactors; the Naval Nuclear Propulsion Program; DOE, university, and other research and test reactors; special-case commercial power reactors; and certain foreign research reactors. Approximately

2,700 MTHM of SNF is what remains of the DOE-owned SNF inventory, and about 100 MTHM of additional SNF is projected to be received by DOE in the next 40 years.
The DOE Office of Spent Fuel Management was created in 1993 to develop a program to ensure the safe existing storage, provide for interim storage and prepare for ultimate disposition of DOE-owned SNF. Also in 1993, the DOE Office of Environment, Safety and Health issued its Spent Fuel Working Group Report. In this report, a number of vulnerabilities were identified regarding the current DOE-owned SNF inventory. One generic vulnerability identified was that, unlike HLW, there was no path forward for ultimate disposition of DOE-owned SNF.
The DOE now has a wide range of options available for the ultimate disposition of its SNF, and discussions have begun to determine if DOE-owned SNF will be disposed of in a geologic repository, along with civilian SNF. It is possible that some DOE-owned SNF will be processed to ensure efficient waste management. However, this paper focuses on the ultimate disposition of the DOE-owned SNF that remains in inventory at the time a geologic repository becomes available.
There is an established program and a long history associated with the planning for disposal of SNF and vitrified HLW. In 1955, the Atomic Energy Commission, a predecessor agency to DOE, requested input from the National Academy of Sciences (NAS) on the disposal of radioactive waste. In 1957, the NAS recommended that the best method of disposal would be placement in a deep geologic repository. Numerous studies were undertaken over the next 25 years to identify suitable geologic media for a SNF and HLW repository.
In a 1980 environmental impact statement (EIS), DOE evaluated a number of methods for permanent disposal of high-level radioactive waste and concluded that deep geologic disposal was the best method among the alternatives considered. In 1982, Congress passed the Nuclear Waste Policy Act (NWPA). All efforts to establish a repository for SNF and HLW were brought together under one Federal program: DOE's Office of Civilian Radioactive Waste Management (OCRWM). In 1983, DOE selected nine locations in six states for consideration as potential sites. Based on studies completed at these potential sites, the President approved three sites for intense scientific study, or characterization. However, in 1987 Congress amended the NWPA and directed DOE to study only one of the sites - Yucca Mountain in the state of Nevada.
At the present time, site characterization and engineering activities are being conducted to determine the suitability of Yucca Mountain as a repository site. A DOE position on technical site suitability is expected in 1998, and a final EIS on the development of a geologic repository is expected to be completed in the year 2000. This will support the DOE decision on site recommendation that will accompany a Site Recommendation Report to the President, as required by the NWPA. If the Yucca Mountain site is found to be suitable, and a site recommendation is made and approved by the President and Congress, DOE will submit a license application to the Nuclear Regulatory Commission (NRC). DOE's current schedule calls for the license application for construction authorization to be submitted by DOE to the NRC in 2001, construction to begin in 2004, and waste to be emplaced starting in 2010.
ISSUES
As DOE considers ultimate disposition of DOE-owned SNF in a geologic repository, a number of issues and constraints have become apparent. These issues and constraints lie in three general areas: OCRWM programmatic issues, institutional issues and technical issues.
Program Issues
The path forward developed by DOE for geologic disposal of its SNF inventory will need to take into account the existing constraints upon the OCRWM and EM programs. For example, the success of a path forward for geologic disposal of DOE-owned SNF is directly linked to the success of OCRWM's efforts to site and construct a geologic repository. Still more uncertainty is associated with the siting and construction of a second repository making it even more questionable as a viable alternative for ultimate disposal of DOE-owned SNF.
Even if OCRWM's efforts to site and construct a repository are successful, important programmatic issues exist regarding the space limitations for the first repository. Under the provisions of the NWPA, DOE is prohibited from emplacing more than 70,000 metric tons heavy metal (MTHM) in the first repository until a second repository is in operation. It is also possible that, upon completion of site characterization for the first geologic repository, a determination could be made that the capacity of

the repository is less than 70,000 MTHM. However, projections of waste inventories for geologic disposal are greater than 70,000 MTHM. Inventories of civilian SNF alone are expected to exceed 86,000 MTHM by the year 2030 (no new orders case). The current planning basis for the first repository anticipates the allocation of 10 percent of the available repository capacity for DOE vitrified HLW, with the first quantities of such waste planned for disposal in 2015. Inventories of DOE-owned spent nuclear fuel are anticipated to be approximately 2,800 metric tons heavy metal by the year 2035. While there is currently no consensus on a method of assigning metric ton heavy metal equivalence to high-level waste, it is anticipated that the total inventory of high-level waste alone will exceed the 10% OCRWM planning allocation. Assuming that 7,000 MTHM is available for DOE-owned SNF and HLW, there would likely not be enough space to accommodate all DOE-owned SNF and HLW without an expansion of the capacity of the first repository, or the opening of another repository. The current limitation on the first repository capacity also places importance on identifying the relative priority for disposal of DOE-owned SNF and HLW. As part of this process, a change in OCRWM's planning assumption would need to be made to accommodate a DOE decision to use all, or part of the 10% allocation to emplace DOE-owned SNF.

There are also program issues concerning the current schedule for the first repository. Currently, OCRWM is only authorized to investigate one repository and is not due to report to Congress on the need for a second repository until 2007-2010. For some of the DOE-owned SNF, it would be difficult to obtain the necessary data and analysis in time to be included in the license application for the first repository, whereas some DOE-owned SNF may be immediately available for repository emplacement.

Related to the space and schedule issues for the first repository is the need for new interim storage for some DOE-owned SNF. Many existing facilities for storage of DOE-owned SNF are old, and have environmental, safety and health vulnerabilities. In addition, the condition of some DOE-owned SNF is severely degraded and some may be unstable for handling. Therefore, DOE will have to make changes to its existing SNF management infrastructure in preparation for its ultimate disposition. In addition, there are numerous stakeholder concerns regarding interim storage of DOE-owned SNF that will have an important influence on determining the path forward for geologic disposal of DOE-owned SNF.

Institutional Issues

Resolving stakeholder concerns is a key element of the institutional issues regarding the geologic disposal of DOE-owned SNF. As part of the DOE effort to establish increased responsiveness to stakeholder concerns, the Office of Spent Fuel Management has spent significant resources and time interacting with stakeholders both through participation in the development of a number of environmental documents and through other forums for participation in the DOE-owned SNF program. A chief stakeholder concern, voiced at the recent public hearings for the Programmaic Spent Fuel Management draft Environmental Impact Statement is that storage of DOE-owned SNF at DOE sites, without a plan for ultimate disposition, may become de facto disposal of this material.

There are many other potential stakeholder concerns related to considering DOE-owned SNF for inclusion in the OCRWM program. The nuclear utilities have been dissatisfied with the progress made towards disposal of civilian SNF. Geologic disposal of DOE-owned SNF should be considered in such a way as to eliminate, or minimize, any impact on the repository program and disposal of civilian SNF. As part of its general opposition to the repository program, the candidate host State could oppose a path forward for repository disposal of DOE-owned SNF. This opposition may be further fueled by the perception that some DOE-owned spent nuclear fuel is "foreign waste". However, some stakeholders may favor a proposal for geologic disposal of foreign research reactor SNF, because it can assist in the accomplishment of the U.S. nuclear non-proliferation objective of removing U.S.-origin highly-enriched uranium from international commerce. In addition, foreign research reactor SNF would be only a very small percentage of the total SNF and HLW planned for repository disposal (less than one-twentieth of one percent).

Another institutional issue raised to date centered around the statutory authority for disposal of DOE-owned SNF in a geologic repository. Section 8 of the NWPA required the President to evaluate whether a separate repository for defense high-level waste would be required, or if defense HLW should be placed into a

civilian repository along with the SNF from civilian reactors. In 1985, the President approved the recommendation of the Secretary of Energy that defense waste should be co-located with civilian waste in a geologic repository. However, this recommendation did not explicitly address the ultimate disposition for DOE-owned SNF. Until 1992, the ultimate disposition of DOE-owned SNF was not an issue, because most was reprocessed. In November 1993, the Assistant Secretary for Environmental Management requested a legal opinion regarding the statutory authority for geologic disposal of DOE-owned SNF. In March 1994, DOE's General Counsel concluded that there is discretionary authority in Section 302(b)(4) of the NWPA for disposal of SNF by the U.S. government, conditioned upon execution of an intra-agency agreement and upon payment of a fee adequate to cover the full cost of disposal.

Technical Issues

As discussed previously, technical challenges are presented by the characterization needs for the DOE-owned SNF, diversity of DOE-owned SNF types, and lack of waste acceptance infrastructure. Characterization of DOE-owned SNF is a technical challenge that must be met in the near future. All characterization must be conducted under an approved quality assurance program based on NRC and OCRWM requirements. Much DOE-owned SNF has undergone degradation, and some may be unstable in handling, making characterization difficult. In addition, characterization facilities for DOE-owned SNF are few. Also, as most DOE-owned SNF was slated for reprocessing, much of the DOE-owned SNF inventory does not have traceability comparable to that of civilian SNF.

A characterization data base would be used to evaluate each fuel type to determine the extent of conditioning, if any, necessary to meet repository waste acceptance criteria (WAC). This data base would also be used to design engineered barriers and model long-term performance to ensure that Nuclear Regulatory Commission licensing requirements could be met. Some types of fuel would likely require substantial conditioning to meet repository WAC, requiring the development of new treatment facilities, and possibly new technologies. Other types of DOE-owned spent nuclear fuel, similar to civilian SNF, would likely meet repository WAC without further conditioning.

DOE-owned SNF consists of more than 90 types, with various enrichments, cladding, and fuel matrices. The numerous DOE-owned SNF types may appear to represent a challenge that would be very difficult to meet. However, commercial-type SNF represents 6.5%, and Naval Nuclear Propulsion Program SNF represents another 2%, of the DOE-owned SNF inventory. Both these DOE-owned SNF types should qualify for geologic disposal in a manner consistent with civilian SNF. Approximately 80% of DOE-owned SNF is Hanford N-Reactor SNF, which may have to be conditioned before geologic disposal. Thus, satisfactory qualification of three fuel types for geologic disposal would qualify approximately 90% of the DOE-owned SNF inventory for geologic disposal. The balance of the DOE-owned SNF inventory contains many fuel types that may need to be extensively conditioned, or even reprocessed, to resolve safety and environmental concerns.

Lack of a waste acceptance infrastructure, i.e. the resources necessary to determine the requirements for geologic disposal of DOE-owned SNF and how these requirements will be met, is another technical challenge. At present there is no approved waste acceptance process and no set of WAC for DOE-owned SNF. Requirements to guide qualification of DOE-owned SNF for geologic disposal can be found in the Code of Federal Regulations, 10 CFR 60 and 40 CFR 191 (currently under revision), and in the OCRWM Waste Acceptance Systems Requirements Document (WASRD). However, none of these sources are useful for detailed design of waste forms and waste packages. In addition, there are only two standard waste forms in the WASRD, civilian SNF and borosilicate vitrified HLW. Finally, the human resources necessary for ensuring waste acceptance of DOE-owned SNF are not yet in place. Personnel with substantial technical expertise, similar to the Technical Review Group for the Defense Waste Processing Facility, will need to be assembled to resolve this issue.

EFFORTS TO DEFINE A PATH FORWARD FOR GEOLOGIC DISPOSAL OF DOE-OWNED SNF

There are two primary efforts underway to address the challenges associated with geologic disposal of DOE-owned SNF. The first effort is the preparation of a memorandum that evaluates various options for integrating planning for DOE-owned SNF with the planning for all other materials slated for repository disposal, identifies key sensitivities, and proposes a path forward for geologic disposal of DOE-owned SNF. The second effort is the establishment of a joint Steering Group consisting of

the DOE Offices of Civilian Radioactive Waste Management and Environmental Management. This Steering Group will scope out the challenges related to integrating DOE-owned SNF into the repository program and identify near term priorities.
Memorandum on the Path Forward for Geologic Disposal of DOE-owned SNF
As part of the first effort, three planning options are under primary consideration for the ultimate disposition of DOE-owned SNF. Each option assumes emplacement in a geologic repository as the Department's proposed strategy for disposition of any SNF remaining in its inventory when a repository becomes available. No options for the ultimate disposition of DOE-owned SNF, other than geologic disposal, are under primary consideration by DOE at this time. The three options being considered would each integrate the Department's SNF into the program being conducted by OCRWM for the disposal of civilian SNF and establish the framework within which to evaluate DOE-owned SNF against the requirements for qualifying SNF for geologic disposal. All the options being considered are based on the assumption that the OCRWM program will accomplish its current program for constructing, licensing, and operating a geologic repository and that some DOE-owned SNF could be adequately characterized in time to be included in OCRWM's license application to the NRC. All options encompass these goals: assuring safe and environmentally sound existing storage of SNF, providing robust new interim storage facilities, as necessary, that are designed, constructed and operated to national consensus standards; and preparing all DOE-owned SNF for disposal in accordance with one of the three options addressed below.
Option 1. DOE-owned SNF and vitrified HLW would be authorized for disposal in the first repository. The total quantity of DOE-owned SNF and vitrified HLW would not exceed 10 percent of the repository capacity. Disposition of remaining DOE-owned SNF and vitrified HLW would not be decided until the DOE recommendation on the need for a second repository. In addition, under this option all DOE-owned SNF would be aggressively stabilized and prepared for repository disposal.
Emplacement priority for DOE material would be based on a systems approach that considers risk, cost, preparation time, readiness, and other factors. DOE-owned SNF that can be qualified in time may be included in the initial license application if it is of sufficiently high priority. The mix of DOE-owned SNF and vitrified HLW proposed for the first repository could be changed, if appropriate, by submitting a license application amendment after a decision on the need for a second repository. At this time, additional site characterization data and licensing experience could be incorporated into a decision on the disposition of any remaining DOE-owned SNF and/or HLW.
This option would address the lack of a path forward to ultimate disposition, by preparing for the geologic disposal of DOE-owned SNF. The option would also minimize impacts on the OCRWM licensing schedule for the first repository. Concerns over the impact of DOE-owned SNF on the queue for the first repository are minimized since there would be no change in the amount of DOE material proposed for disposal in the first repository. This option also would constitute a significant step towards satisfying stakeholders' concerns over de facto disposal of DOE-owned SNF at storage sites.
However, an amendment to any license application to change the mix of DOE-owned SNF and HLW in the first repository could add complexity to the licensing process for the repository. In addition, to the extent that DOE-owned SNF would displace some vitrified HLW that would otherwise have gone to the repository, storage of such waste would have to be maintained for a longer period. Although this may cause increased concern to stakeholders at the storage sites, almost all sites that store DOE-owned SNF also store HLW. Stakeholders would participate in any process for determining the relative disposal priority between DOE-owned SNF and HLW.
Option 2. DOE would work toward disposal of all of its SNF and vitrified HLW in the first repository, assuming that a request to Congress to remove the 70,000 MTHM limit will be granted.
This option would have all the advantages associated with Option 1. In addition, the focus of the disposal effort would be directed toward the first repository. Resolution of technical, regulatory, and institutional matters would be focused on meeting the requirements for this repository. However, it now seems unlikely that the information needed to include all types of DOE-owned SNF in the initial license application for the repository could be available by the current 2001 submittal date, although the licensing schedule could be delayed. This option would depend on

Congressional action to change the Act's restriction on the repository's capacity, an action that is uncertain. Furthermore, the candidate host state would likely oppose removal of the Act's limitation on the repository's capacity.
Option 3. All DOE-owned SNF would be deferred to a second repository.
This option would allow much of the HLW inventory to be disposed of in the first repository. The DOE Spent Fuel Management program could proceed, unencumbered by concerns related to integrating the program with the first repository activities. Also, any potential licensing or stakeholder issues arising from disposal of DOE-owned SNF in the first repository would be avoided. On the other hand, the option would not resolve the lack of path forward, as effectively as Options 1 and 2. Also, stakeholders would likely regard this option as further evidence that storage of DOE-owned SNF is, in effect, de facto disposal, given the substantial uncertainties associated with the authorization, timing, and availability of a second repository.
As progress is made towards defining the path forward for geologic disposal of DOE-owned SNF, a number of factors will play an important role. The option selected as the path forward for the ultimate disposition for DOE-owned SNF will seek to minimize impacts on the OCRWM's schedule for the first repository, while still achieving disposal objectives for DOE-owned SNF. The option selected will attempt to address stakeholder concerns regarding the program for the first repository. The option selected will also attempt to consider existing constraints of the OCRWM and EM programs. While the option selected may not be able to establish definitive timing for the disposal of DOE's SNF, it will attempt to provide DOE with the most viable option for disposal of DOE-owned SNF and constitute a significant step towards addressing stakeholders' concerns over de facto disposal of DOE-owned SNF at storage sites.
DOE-owned SNF Steering Group
The second primary effort DOE has undertaken to establish a path forward for geologic disposal of DOE-owned SNF is the establishment of a joint DOE-owned SNF Steering Group, consisting of EM and OCRWM, with other DOE offices participating on a consultative basis. The Steering Group will identify and propose resolution for technical, regulatory and programmatic issues related to geologic disposal of DOE-owned SNF and identify near term priorities. This joint Steering Group will also assist in directing DOE complex-wide planning and implementation activities related to preparation of DOE-owned SNF for geologic disposal, as well as develop disposal requirements specific to DOE-owned SNF.
A key function of the Steering Group will be to facilitate integration of the DOE-owned SNF program with the OCRWM repository program. Preparation of DOE-owned SNF for geologic disposal cannot be successful without close coordination between these two organizations. Numerous technical issues will have to be resolved jointly. Waste form specifications will have to be finalized for DOE-owned SNF. Waste package designs will need to be selected and developed. The DOE-owned SNF waste form and package will need to be integrated into the facility engineering for the repository. In addition, a decision will need to be made on whether to implement the OCRWM Multi-Purpose Canister (MPC) concept for DOE-owned SNF. DOE-owned SNF will also have to be integrated into the Performance Assessment for the repository. EM will also have to coordinate with, and possibly provide extensive support, to OCRWM as an EIS, and possibly a license application, for the first repository are developed and possibly submitted in the not too distant future.
Another notable effort of the Steering Group will be the development of an intra-agency agreement between EM and OCRWM to cover the terms of disposal of DOE-owned SNF. It has yet to be determined if existing fee methodologies are appropriate for calculating the disposal fee for DOE-owned SNF. The Code of Federal Regulations, 10 CFR 961, provides the terms for a standard contract for disposal of civilian SNF. There is also a Cost Allocation Methodology established for defense HLW, found in the Federal Register, 52 FR 161. OCRWM and EM, as part of the efforts of a joint Steering Group, have recently initiated discussions regarding an intra-agency agreement.
As the Steering Group addresses technical issues regarding the geologic disposal of DOE-owned SNF, it will draw upon the work of the DOE-owned SNF Technology Development program to help resolve these issues. This Technology Development Program is conducting a preliminary Performance Assessment (PA) to provide an initial evaluation of the performance of a number of waste forms, including a number

of DOE-owned SNF types, in various geologic media. The Technology Development Program is also examining how the DOE might implement an MPC concept for DOE-owned SNF, and potential new conditioning processes for DOE-owned SNF to ensure that repository WAC could be met.

SUMMARY

DOE is making progress towards resolving important issues regarding the ultimate disposition of DOE-owned SNF. There are a number of activities that DOE will undertake as it attempts to implement a strategy for the ultimate disposition of DOE-owned SNF. One of the key activities for the DOE will be to determine its strategy for ultimate disposition of DOE-owned SNF. Regardless of which strategy option is selected, EM will make efforts to integrate its programs for disposal of DOE-owned SNF and HLW and identify the emplacement priority for these materials, in consultation with stakeholders. Mechanisms, such as the DOE-owned SNF Steering Group are in place to resolve outstanding issues regarding geologic disposal of DOE-owned SNF. In summary, EM and OCRWM will work together to ensure that ultimate disposition of DOE-owned SNF is on a clear path forward; that DOE-owned SNF is disposed of in a technically sound manner; and that the candidate host state, nuclear utilities and other interested and/or affected parties are kept informed of progress made and consulted with during each step of the path forward.

PERFORMANCE ASSESSMENT METHODOLOGY AS APPLIED TO THE GREATER CONFINEMENT DISPOSAL SITE: PRELIMINARY RESULTS OF THE THIRD PERFORMANCE ITERATION*

Theresa J. Brown

Sandia National Laboratories

Thomas A. Baer

GRAM Inc.

Albuquerque, NM

ABSTRACT

The U.S. Department of Energy has contracted Sandia National Laboratories to conduct a performance assessment of the Greater Confinement Disposal facility, Nevada. The performance assessment is an iterative process in which transport models are used to prioritize site characterization data collection. Then the data are used to refine the conceptual and performance assessment models. The results of the first two performance assessment iterations indicate that the site is likely to comply with the performance standards under the existing hydrologic conditions. The third performance iteration expands the conceptual model of the existing transport system to include possible future events and incorporates these processes in the performance assessment models. The processes included in the third performance assessment are climate change, bioturbation, plant uptake, erosion, upward advection, human intrusion and subsidence. The work completed to date incorporates the effects of bioturbation, erosion and subsidence in the performance assessment model. Preliminary analyses indicate that the development of relatively deep-rooting plant species at the site, which could occur due to climate change, irrigated farming or subsidence, poses the greatest threat to the site's performance.

SITE DESCRIPTION

The Greater Confinement Disposal (GCD) facility is located at the Nevada Test Site in the Area 5 Radioactive Waste Management site at Frenchman Flat in Nevada (Fig. 1). Frenchman Flat is an alluvium filled basin, with maximum depth to bedrock of more than 450 meters. The site consists of twelve boreholes that are approximately 36.6 meters deep with 3 to 3.6 meter diameters. The disposal procedure consisted of filling the bottom 15.2 meters of the boreholes with waste then filling the remainder of the borehole with native sediments (1). In three of the boreholes the individual waste packages were separated by layers of probertite, a mineral which contains boron, a neutron absorber. The wastes are located within the unsaturated zone in the thick alluvial deposits of the basin, approximately 200 meters above the water table (2).

Fig. 1.

PERFORMANCE ASSESSMENT METHODOLOGY

Four of the twelve GCD boreholes contain transuranic (TRU) wastes and are regulated by 40 CFR Part 191 containment (191.13), individual protection (191.15) and groundwater protection (191.16) requirements (3). The purpose of this work is to provide the Department of Energy with enough information to determine if the site complies with these regulations. The compliance measure for the containment requirements is the calculated EPA sum. Due to the long regulatory periods (10000 years) and the complexity and uncertainty in the transport system, numerical models are required to simulate the release of the radioactive elements to the accessible environment.

The statistician George Box reminds us that no model can reproduce or predict exactly how a complex physical system behaves, but there are models that can calculate the probability of a future value lying between two specified limits (4,5). With the recent interest in the validation of groundwater flow models and the impossibility of that task (6,7) , it is important to recall Box's statement and consider which models will be the most useful in assessing the potential performance of a waste disposal site. The basic premise of this research is that the exact flow and transport system for the next 10,000 years at the GCD site cannot be predicted due to the uncertainty in the existing and future conditions at the site, but that it can be simulated and the maximum release rates bounded.

The performance assessment methodology applied to the GCD site is an iterative process of modeling and data collection (Fig.2). Sensitivity analyses of the performance assessment model are used to identify the most valuable data. In this case the most valuable data are those that minimize the uncertainty in the parameter values that cause the simulated releases to exceed the containment and protection requirements. In the first iteration of the performance assessment, the significant parameters and corresponding data needs were identified (2) and data were collected (8,9,10). The new data were used to reduce the uncertainty in the recharge rate (11), plutonium solubility (9) and plutonium adsorption coefficient (10). Additional modeling was performed using the revised parameter ranges along with refined models of plant uptake and erosion (12). As a result of the second performance assessment iteration, the conceptual model of the transport system was revised to one in which diffusion toward the ground surface provides the fastest pathway to the accessible environment. Due to the changes in the conceptual model, tortuosity and rooting depth became the most significant parameters.

Fig. 2.

The third iteration of the performance assessment involves the investigation of the diffusion pathway. This investigation includes an assessment of the combined effects of subsidence, bioturbation, erosion, plant uptake, upward advection and climate change on the site's waste-containment ability. It is assumed that all of these processes will occur, consequently they are included in the base-case model. In addition to the base case processes, other potentially significant disruptive events must be considered in the performance assessment. Scenario analyses have narrowed the suite of likely, potentially disruptive events to inadvertent human intrusion into the GCD boreholes by drilling and irrigated farming at the GCD site (13).

CONTAINMENT PERFORMANCE ASSESSMENT MODEL

The performance assessment uses a 1-D model of diffusive transport. The modeling is performed in a Monte-Carlo fashion with the uncertain parameter values generated randomly, from predefined probability density functions (pdfs), for each simulation using Latin hypercube sampling. There are a total of 40 uncertain parameters in the model. Details on these parameters and the distributions used to capture the uncertainty in the parameter values can be found in the documentation for the first two performance assessments (2,12). The results of the transport model are post-processed to calculate the EPA sum for each realization and to combine the results into a single complementary cumulative distribution function (CCDF) to assess the probability that the site will exceed the release limits specified in the containment requirements.

The performance assessment model is based on the following major assumptions:

- Transport occurs by liquid phase diffusion.
- The radioactive contaminants are sorbed on sediment surfaces.
- Individual isotopes are depleted and generated by radioactive decay.
- There is no downward, advective transport.
- The concentration of each isotope, in the liquid phase at the source, is maintained at the solubility limit for that element.

The concentration of each isotope, in the liquid phase, at the ground surface, is zero.

The above-ground concentration of the contaminants in plants is a function of the amount of the isotope at the rooting depth.

Erosion, bioturbation, subsidence and climate change will occur during the regulatory period.

After the institutional control period, there is a significant probability that people will live at or near the GCD site.

The consequences of the potentially disruptive future events and processes are being evaluated to determine the best method of incorporating these events and processes into the performance assessment. The consequence models for bioturbation and subsidence along with the details on how these consequences are incorporated in the performance assessment are given below. The climate change and human intrusion consequence models are still in development and are not included in this preliminary analysis.

Bioturbation Consequence Model

The bioturbation model is based on the following assumptions:

The contaminants are transported from the subsurface to the ground surface during burrowing.

The effective burrowing depth is uncertain, but can be bounded by the known burrowing depths for the animal and insect species found or expected at the site.

The effective depth is equal to the maximum depth of bioturbation.

All the contaminants at the maximum burrowing depth are transported to the ground surface.

As a result of these assumptions, bioturbation can be treated as a reduction in the pathlength from the waste to the accessible environment. For the preliminary analyses, bioturbation is modeled by reducing the depth of burial. The uncertainty in the maximum bioturbation depth that will occur at the site is accounted for by using a pdf to represent the probability of occurrence of each possible bioturbation depth and running the simulations in a Monte-Carlo fashion.

A literature search of studies on the existing fauna in the vicinity of the NTS indicates there are 63 different species that can be classified as burrowers. The burrowing animals include 1 owl, 14 lizard, 17 snake, 3 tortoise and 28 mammal species (mostly mice, squirrels, voles, rats and shrews). The burrowing depths of these species is generally less than 1 meter and with a maximum burrowing depth of three meters. In addition to these animals, there are numerous arthropod species that are known to burrow. The possible burrowing arthropods at the site include species of spiders, scorpions, cockroaches, ants and termites. With the exception of termites, the burrowing depths recorded for arthropods are generally less than one meter with maximum burrowing depths less than 3 meters. The literature search shows that the deepest burrowing fauna may be the termite. In general the termite is found with the food supply. In this case the maximum rooting depth would provide a limit for the termite burrowing depth. The rooting depths used in the simulations for existing conditions range from one to ten meters. However, there is evidence that some African termites burrow to the water table, down to 70 meters, to obtain water (14). The burrowing depths of the termite species at the NTS are unknown and the probability of establishing the African species at the GCD site is unknown. Preliminary analyses of the effect of bioturbation on the site's performance were conducted to determine the potential impact of deep burrowing species.

Subsidence Consequence Model

The following assumptions are made regarding the effect of subsidence on the transport system:

Subsidence will occur due to the compaction of the backfill, settling and compression of the waste containers in the boreholes and trenches.

Subsidence decreases the effective depth of burial.

The unconsolidated sediments surrounding the borehole can not maintain a steep slope or fracture due to the effects of weathering.

Subsidence in the borehole is followed immediately by side wall cave in that results in a slope of 40 degrees on the side walls.

Subsidence will occur immediately after the institutional control period.

Increased runoff into the subsidence depression results in increased plant growth.

As with bioturbation, subsidence is incorporated into the performance assessment by treating it as a decrease in the depth of burial of the waste. The subsidence depth

is an uncertain parameter value. Preliminary analyses were conducted to evaluate the potential effects of subsidence and bioturbation on the site's performance. The range of potential subsidence depths was estimated by assuming that the total collapsible void space in the boreholes was between ten and fifty percent of the volume of the borehole containing the waste (the bottom 15.2 meters). This may or may not be a conservative estimate. It is an arbitrary range selected for a preliminary analysis of the effects of subsidence and the combined effects of subsidence and bioturbation on the site's performance. Increased plant growth due to subsidence was not considered in the preliminary analysis. The subsidence depth and increase in plant growth as a function of subsidence will be bounded based on natural analog data.

PRELIMINARY RESULTS

The preliminary analyses were conducted to evaluate the effects of the uncertainty in the new model parameter values on the simulation results and to aid in the development of the performance assessment model. The parameter distributions for the existing hydraulic conditions were used in these simulations. The final performance assessment model will combine all of the significant future processes and disruptive events.

The results of the preliminary simulations incorporating different consequence models of bioturbation and subsidence are summarized in Table I. The only model that results in simulated violations of the containment standard is the one with a large range for the simulated burrowing depth. This model was designed to assess the potential significance of deep burrowing species like the African termite. The distribution selected for this simulation has a maximum burrowing depth of 19.2 meters, deep enough to reach the waste packages after erosion is included. The CCDF generated by 5000 realizations of this model is shown in Fig. 3. The last model listed in Table I combines the effects of erosion, bioturbation and subsidence. This model uses a smaller range of bioturbation depths that are more representative of the existing burrowing depths in the vicinity of the GCD site. The CCDF for the combined model shows that the site is likely to meet the containment requirements when this model is used (Fig.4).

TABLE I

Fig. 3.

Fig. 4.

SUMMARY

As a result of the first two performance iterations, the performance of the GCD site is being assessed using a diffusion transport model linked to a plant uptake model. Sensitivity analyses of the second performance assessment model indicate that plant uptake is the most important process and tortuosity and rooting depth are the most significant model parameters in determining how much of the contaminant reaches the accessible environment. The addition of subsidence and bioturbation to the performance assessment model result in simulations that produce a significant number of failures only when the bioturbation depths are allowed to exceed the existing burrowing depths. Subsidence, erosion and bioturbation are modeled as additive processes that reduce the depth of burial. As a result, these processes decrease the length of plant roots required to reach significant concentrations of the radioactive contaminants. The results of this modeling and previous sensitivity analyses indicate several modeling refinements that could significantly reduce the simulated release rates. These potential refinements include reducing the uncertainty in the minimum tortuosity value and maximum burrowing depth, and separating the bioturbation model from the calculation of the depth of burial. These changes are only necessary if the consequences of climate change, drilling and irrigated farming result in higher simulated release rates or if natural analogue studies indicate a significantly greater maximum subsidence depth than the maximum value used in the preliminary simulations. The current model of the site, for the existing hydrologic conditions with bioturbation, erosion and subsidence, indicates that the site is likely to meet the containment standards.

USE OF A SCENARIO-DEVELOPMENT PROCEDURE TO IDENTIFY POTENTIALLY DISRUPTIVE SCENARIOS, GREATER CONFINEMENT DISPOSAL FACILITY, AREA 5, NEVADA TEST SITE

Robert V. Guzowski
SAIC/Sandia National Laboratories
Safety and Risk Assessment Department

ABSTRACT

The Greater Confinement Disposal (GCD) facility includes four boreholes that contain transuranic (TRU) waste. Presence of the TRU waste means that this facility must comply with the U.S. Environmental Protection Agency's Environmental Radiation Protection Standards for Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Waste--Final Rule 40 CFR Part 191. To comply with the Containment Requirements of this rule, all potentially disruptive events and processes, and by implication all potentially disruptive combinations of events and processes (scenarios), must be identified for possible inclusion in performance assessments. A scenario-development procedure was adopted that identifies individual potentially disruptive events and processes and combines these events and processes to form scenarios. This procedure consists of five steps. Step 1 either creates, adopts, or adapts an initial list of events and processes. Step 2 classifies the events and processes using any of a variety of schemes for organizational purposes. This step may already be included in an adopted list. Step 3 screens the events and processes using well-defined criteria based on regulatory guidance to identify those events and processes that can be eliminated from scenario development without affecting the performance measure. Step 4 constructs all possible combinations of the events and processes surviving the screening process through the use of a logic diagram. Step 5

screens the scenarios using well-defined criteria to identify those scenarios that can be excluded from full-scale performance assessments without affecting the performance measure.

In using this procedure to identify potentially disruptive scenarios for the GCD facility, some modifications were made to the original procedure. To address the completeness issue of the list of events and processes to be screened, lists from 11 sources were combined and consolidated by eliminating duplications. The result was an initial list of 205 features, events, and processes (FEPs). Because of the diverse nature of the FEPs, additional screening criteria were developed. Screening of the FEPs identified four events for scenario development: exploratory drilling for natural resources, drilling withdrawal wells, irrigation, and subsidence. Recent environmental-isotope analyses of the vadose zone suggest that radionuclide transport from the boreholes to the water table by infiltration is not a feasible transport mechanism within the time frame of regulatory concern. For this reason, the event of drilling withdrawal wells was merged with exploratory drilling for resources. The descriptions of the remaining three events were modified slightly to aid in estimation of event probabilities and consequence analyses. The three events are: exploratory drilling for resources penetrates a TRU borehole, irrigation occurs at the Radioactive Waste Management Site (RWMS), and subsidence occurs at the RWMS.

Use of a logic diagram with these three events resulted in the construction of eight scenarios, including base-case (undisturbed) conditions. Screening these scenarios at this stage of scenario development was beyond the scope of this task. Based on the implementation assumptions, this scenario-development procedure produced a comprehensive set of mutually exclusive scenarios that are reproducible and auditable for use in GCD performance assessments.

DISPOSAL-SYSTEM DESCRIPTION

The Greater Confinement Disposal (GCD) facility consists of 13 boreholes (including GCD Test) augured into basin-fill deposits in Area 5 of the Nevada Test Site (Fig. 1). All of the boreholes are within the boundaries of the Radioactive Waste Management Site (RWMS) (Fig. 2), which is being used for the disposal of low-level waste. Each of the GCD boreholes is approximately 37 meters deep, and all but two boreholes are 3 meters in diameter. The remaining two boreholes are 3.7 meters in diameter (1). Four of the boreholes (Nos. 1, 2, 3, 4; Fig. 2) contain waste contaminated with transuranic (TRU) radionuclides (2). The TRU waste was placed in the bottom 15.2 meters of each borehole with probertite, in which the boron acts as a neutron absorber, used as backfill for this interval. The remainder of each borehole was filled with sifted, native material that had been removed during auguring.

Fig. 1.

Fig. 2.

Basin-fill deposits at the GCD location are approximately 506 meters thick, and the depth to the water table is approximately 244 meters. Total yearly precipitation at the GCD location ranges from 10 to 13 centimeters. Recent studies of environmental tracers in the unsaturated zone suggest that recharge is negligible to nonexistent at this location (3).

REGULATORY BASIS FOR SCENARIOS

Because of the presence of the TRU waste in four of the GCD boreholes, this facility will have to comply with the U.S. Environmental Protection Agency's Environmental Radiation Protection Standards for Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Radioactive Waste--Final Rule 40 CFR Part 191 (the Standard) (4). Performance assessments (PAs) are required to address the Containment Requirements (191.13) of this regulation. By definition in the regulation (191.12(q)), a PA includes the identification of processes and events that may affect disposal-system performance and estimates these effects. By implication, combinations of processes and events also must be included in the analyses in order to assure that no important disruptions of the disposal system are omitted from the analyses. These combinations of processes and events are referred to as scenarios.

DESCRIPTION OF THE SCENARIO-DEVELOPMENT PROCEDURE

If all combinations of all events and processes that might occur at a disposal site are constructed, the result is a larger number of scenarios than can possibly be analyzed (i.e., 2n, where n equals the number of events and processes). An alternative to identifying all scenarios is to only identify those scenarios that

may have a significant impact on the release of radionuclides from the engineered facility and/or the transport of radionuclides from the engineered facility to the accessible environment (i.e., the land surface and the geologic system more than 5 km from the repository boundary). A scenario-development procedure (5) that accomplishes this goal was developed as one component of the performance-assessment methodology (6,7) adopted by the PA Task of the GCD Project. Several assumptions are made in implementing this procedure:

only postclosure conditions are considered

only events and processes compromising the performance of the engineered facility and/or affecting radionuclide transport to the accessible environment are considered

regulatory guidance limits the severity of human-intrusion events that need to be considered

regulatory guidance limits the probability of occurrence of events and processes that need to be considered

the time frame for the scenarios is 10,000 years after disposal-system closure.

events and processes within a scenario are independent or dependence can be addressed during modeling

the sum of the probabilities of the scenarios developed by the procedure is equal to 1

These assumptions are incorporated into the scenario-development procedure as screening criteria and into the method of scenario construction.

The scenario-development procedure (5) contains five steps. In the first step, a list of events and processes that potentially can affect disposal-system performance is either created, adopted, or adapted. Cranwell et al. (5) contains a generic list of 27 events and processes that were considered to be a starting point in compiling a site-specific or geologic-medium-specific list of potentially disruptive events and processes.

The second step of the procedure classifies the events and processes using any of several schemes for organizational purposes and to help assure that no important events and processes have been omitted. One of the more useful classification schemes is to distinguish between naturally occurring, human-induced, and repository/waste-induced events and processes. Subdivisions within each category also may be useful. In an adopted or an adapted list, this step may already be incorporated in the list.

The third step of the procedure screens the events and processes using specific criteria based on guidance provided to the Standard to identify those events and processes that can be eliminated from scenario development without effecting the performance measure as determined in PAs. Three screening criteria were proposed: probability of occurrence, consequence, and physical reasonableness. Guidance to the Standard states that events and processes that have a probability of less than one chance in 10,000 of occurring in 10,000 years can be eliminated from consideration no matter what the potential magnitude of the consequence may be. The rationale behind the consequence criterion is that the elimination from analyses of any event or process that does not have the potential to affect radionuclide escape or transport simplifies scenario development by producing fewer scenarios and will not affect the calculated radionuclide releases in PAs. Screening out an event or process because of a lack of physical reasonableness is essentially the same as low probability, only the decision is based on logical arguments rather than a calculated (or elicited) numerical value.

Scenarios are constructed in the fourth step of the procedure by developing all possible combinations of the events and processes that survived the screening in Step 3. Combinations are developed through the use of a logic diagram. In the logic diagram, a decision is made at each branch as to whether the corresponding event across the top of the diagram occurs or does not occur in each path through the diagram (each path is a scenario). The sequence of events and processes within a scenario is not relevant to the definition of the scenario. Temporal relationships among events and processes may be addressed during modeling. As a result, each scenario is composed of a unique combination of occurring and nonoccurring events and processes. If none of the events and processes occur (the topmost branch in the diagram), the disposal system is undisturbed (base-case scenario). An example of a logic diagram is included in the section below demonstrating the use of this procedure for the GCD facility.

The final step of the procedure uses two screening criteria to identify which

scenarios should be included in performance-assessment analyses. Probability of occurrence is one criterion, using the same numerical constraints used to screen the events and processes. The other criterion is consequence, in the form of radionuclide releases to the accessible environment.

SCENARIO DEVELOPMENT FOR THE GCD FACILITY

One of the major concerns in scenario development is the possibility that events and processes that could have a significant impact on disposal-system performance are omitted from the original list of events and processes, thereby excluding these events and processes from scenario construction. To address this concern about completeness, scenario-development for the GCD facility (8) merged 11 lists from various sources. The sources for these 11 lists can be divided into four categories: generic lists from U.S. programs, site-specific lists from U.S. programs, generic lists from international programs, and lists from other national programs. The composite list contains 761 features, events, processes, and miscellaneous other listings, which for convenience are referred to as Features, Events, and Processes (FEPs). Consolidation of this master list by eliminating duplications and redundancies produced a revised list of 205 FEPs.

The motivation in the development of the events and processes list in Cranwell et al. (5) was to identify possible disruptions to the disposal system. Several of the merged lists were compiled with other objectives in mind (e.g., listing all conceivable FEPs, identifying pathways to man, etc.). Because of the diverse nature of these FEPs when compared to the Cranwell et al. (5) list, additional screening criteria were developed (Table I) to focus scenario development on identifying potential disruptions of the disposal system in order to address the Containment Requirements in the Standard.

TABLE I

Screening of the 205 FEPs in the revised list identified three events for scenario development: exploratory drilling for resources, irrigation, and subsidence over the Low Level Waste (LLW) trenches and/or the TRU boreholes. Exploratory drilling is a concern to disposal-system performance, because this event could result in the release of radionuclides directly to the surface if the borehole penetrates the waste in the boreholes or the diffusion halo surrounding the TRU boreholes. Both irrigation through the addition of water and subsidence through ponding of runoff are possible mechanisms for increasing the soil moisture in the vicinity of the TRU boreholes, thereby increasing the rooting depth of either crops or native vegetation. Using probability of occurrence or consequence modeling to screen these three events was beyond the scope of preliminary scenario development. The definitions of these events were modified slightly to be more specific on where the events occur for later use in probability estimation and consequence analyses. The revised wording results in the following three events: exploratory drilling penetrates a TRU borehole, irrigation occurs at the RWMS, and subsidence occurs at the RWMS. An event of drilling withdrawal wells originally survived screening, but the elimination of the transport pathway of radionuclides reaching the water table (9) eliminates concerns of withdrawal wells bringing contaminated water to the surface. The potential releases of radionuclides to the surface resulting from withdrawal wells being drilled into TRU boreholes were included by considering these boreholes to be exploratory drilling for water and therefore combined with the more generic event of exploratory drilling for resources penetrates a TRU borehole. If analyses of irrigation and subsidence indicate that the increased infiltration associated with either of these events can result in radionuclide transport to the water table, the event of drilling withdrawal wells will be reconsidered as a mechanism for radionuclide transport to the accessible environment.

The three events can be combined with the use of a logic diagram to form eight scenarios (Fig. 3). In this preliminary scenario development (8), no attempt was made to screen the constructed scenarios. Both probability estimation of and consequence analyses for the individual events in the scenarios are ongoing activities. Preliminary estimation of scenario probabilities (10) suggests that from the probability point of view, disposal-system performance is dominated by the base-case scenario (i.e., undisturbed conditions) and subsidence exclusive of the occurrence of the other two events. From the consequence point of view, no single scenario or small number of scenarios has been identified at this time through consequence analyses as dominating disposal-system performance. The dominant mechanisms of radionuclide transport to the accessible environment are human

intrusion by drilling and radionuclide uptake by plants. One or both mechanisms may be present in each scenario. Although the scenarios containing more than one of these transport mechanisms may seem more likely to result in greater consequences than scenarios with single mechanisms, the duration of occurrence of each mechanism in each scenario within the time period of regulatory concern may result in different conclusions.
Fig. 3.

CONCLUSIONS

Based on certain implementing assumptions, the use of a structured scenario-development procedure has produced a comprehensive set of mutually exclusive scenarios that are reproducible and auditable for use in PAs. Comprehensive refers to the fact that all possible scenarios are constructed from those events that survived screening. Mutually exclusive means that each scenario consists of a unique combination of events, which is essential when associating scenario consequences with scenario probabilities. The scenarios are reproducible in that an identical set of events will always produce the same scenarios. These scenarios are auditable in that the steps of the procedure are well defined, and the decisions made in implementing the procedure are documented.

ABSTRACT

The Waste Isolation Pilot Plant (WIPP) in southeastern New Mexico has been constructed to be a repository for permanent geologic disposal of transuranic waste generated by the U.S. defense programs during the past 50 years. Assessment for 10,000 year performance of the repository is being carried out by Sandia National Laboratories under contract to the U.S. Department of Energy (DOE), to determine compliance with the EPA standards for long-term disposal of transuranic wastes (40 CFR 191). The assessment consists of postulation of scenarios for release of radionuclides from the repository to the environment, selection of conceptual models for movement of contaminants, collection of data for more than 300 parameters for waste and site characteristics and engineered barriers, and probabilistic consequence analysis to represent the results as Complementary Cumulative Distribution Functions (CCDFs). The compliance with the Containment Requirements of the standards shall be judged from the CCDFs. In addition, the standards contain Assurance Requirements, Individual Protection Requirements, and the Groundwater Protection Requirements. Many unresolved issues remain in every aspect of the WIPP performance assessment. To make the assessment more robust, these unresolved issues will have to be addressed.

INTRODUCTION

The Waste Isolation Pilot Plant (WIPP), located in southwestern New Mexico 40 km east of the city of Carlsbad, is planned to be a geologic repository for transuranic (TRU) radioactive waste, generated from the U.S. defense programs. The site for the project was selected in 1973 and the site characterization work began in 1974. Full-scale construction of the surface facilities and underground excavation began in 1981. By 1988, the facility was fully constructed including one out of the eight planned "waste disposal panels" of the repository.

The underground repository has been excavated at a depth of 653 meter in the lower part of a 600 meter thick geologic formation known as the Salado Formation, which as the name indicates, consists mainly of rock salt. Details of the geologic characteristics of the site can be found in Chaturvedi (1993) (1). The repository has been designed to hold contact-handled transuranic (CH-TRU) waste in 55 gallon mild carbon steel drums and steel boxes. The drums and boxes will be stacked in eight underground "panels" each consisting of seven "rooms". Each room is 91.5 meter long, 10 meter wide, and 4 meter high (300 ft x 33 ft x 13 ft) and will contain up to 6000 drums or "drum-equivalent" of CH-TRU waste. It is also planned to stack the drums and boxes in the panel drifts leading to the "rooms" and in the drifts leading to the panels. The repository has been designed to accommodate a total of approximately 850,000 "drum-equivalent" of CH-TRU waste. In addition, it is planned to emplace 7,500 canisters of remote-handled transuranic waste in horizontal boreholes in the repository rooms and drifts.

Even though the physical facility has been ready since 1988, waste shipment to WIPP has not yet begun because the decision to use WIPP as a permanent repository has not been made. This decision will be based on performance assessment, i.e. predictions of long-term behavior of the natural environment as well as the man-made waste containment systems. This paper briefly describes the performance assessment work that has been completed and outlines some significant issues that remain. Although the WIPP has to comply with the provisions of the Resource Conservation and Recovery Act (RCRA) and other regulations, this paper addresses primarily the issues related to assessing the compliance with 40 CFR 191 Subpart B (2).

The procedure for assessment of compliance with the EPA disposal Standards (2) is called "performance assessment" and is defined in the Standards itself at 40 CFR 191.12, as follows:

An analysis that:

1. Identifies the processes and events that might affect the disposal system;
2. Examines the effects of these processes and events on the performance of the disposal system, and

3. Estimates the cumulative releases of radionuclides, considering the associated uncertainties, caused by all significant processes and events.
Subpart B of the Standards were vacated by the First Circuit Court of Boston in June 1987 on grounds that they were less stringent than the Clean Water Act of 1971, and no explanation was provided by EPA for this discrepancy. The Standards were remanded to the EPA for revision and repromulgation. Shortly after this action, New Mexico entered into a modification to the Consultation and Cooperation Agreement with DOE to continue to evaluate WIPP against the vacated 1985 Standards because the technical requirements of the revised Standards were not expected to differ substantially. The EPA published the amended Standards in the Federal Register on December 20, 1993. The amendments were made only to those parts of the Standards in which the court had found faults; the bulk of the Standards remain unchanged.
The Sandia National Laboratory (SNL) published the results of the WIPP performance assessment annually from 1990 to 1992 (3, 4, 5). The EEG provided comments on these assessments (6). The DOE plans to submit an application for certification of compliance with these Standards to the EPA in December, 1996.
The EPA disposal standards (2) contains four "requirements", viz., containment requirements, assurance requirements, individual protection requirements and groundwater protection requirements. The performance assessment technique is used to assess compliance with all of these except the assurance requirements which are meant to provide additional assurance of containment of the waste within the repository.
The process of performance assessment consists of: 1) development of potential scenarios for release of radionuclides to the environment, 2) identification and selection of the most appropriate conceptual models, 3) obtaining data for each of the input parameters for the analysis, 4) selection or development of appropriate computer codes, 5) estimating the probabilities of various scenarios, 6) calculating the consequence of the scenarios, and 7) combining the results in the form of complementary cumulative distribution functions (CCDF's).
The following discussion identifies the unresolved performance assessment issues for each of these tasks.
UNANALYZED SCENARIOS
Formulation of scenarios is the bedrock of performance assessment. The WIPP performance assessment has considered only one disruptive scenario, drilling into the repository by future generations seeking minerals. In the 1992 Performance Assessment (3), two variations of this drilling scenario were analyzed. However, these analyses were incomplete because drilling was considered for only 1900 years (between 100 years after closure to 2000 years after closure) out of 10,000 year regulatory period. The following are some examples of scenarios that should be analyzed as part of the WIPP performance assessment.
Contaminated Brine Flows to the Surface
The human-initiated events scenarios analyzed by the WIPP performance assessment so far assume that the only material reaching the surface is cuttings from the drill-bits and some "cavings" from the annulus about the drill-bit in the waste disposal room. Brine flows from a brine reservoir underlying the repository to the surface should also be assumed. The consequences of this scenario could be significant.
Pressurized brine has been encountered in several boreholes surrounding the WIPP site and in the borehole WIPP-12 at the WIPP site, 225 to 250 meter below the repository horizon in the upper part of the Castile Formation (1). Varying quantities of brine was released to the surface during each of these encounters before the flow could be controlled. The performance assessment scenario should assume that any driller would face similar situation. Drilling-mud return flow would be expected to increase the effective radius of the borehole and bring waste to the surface in suspension and in solution. The DOE has agreed to analyze these additional scenarios.
Brine Slurry Release Scenario
A brine-slurry release scenario should be analyzed. A brine slurry might result from brine inflow from the Salado salt or intrusion into a Castile brine reservoir. Such a brine slurry could be under greater than hydrostatic pressure and thus have a force capable of driving some or all of the slurry to the ground surface. The possible implications of a brine-slurry filled room were first raised by Sandia National Laboratories in 1987 and were also evaluated in 1988 by EEG (7).

Subsidence

Subsidence could occur in the area overlying the WIPP some time after repository decommissioning. Subsidence can also occur from nearby potash mining. The 1992 Performance Assessment (5) identifies subsidence from mining of potash as a credible event but it has not been analyzed.

The potential for subsidence was discussed in the 1990 Preliminary Comparison (3). It was recognized that "subsidence could in turn conceivably affect the disposal system in three ways: by increasing hydraulic conductivity of the Salado Formation, by creating fractures through the Salado Formation, or by disturbing the surface drainage and groundwater flow in overlying units." The incorporation of the effects of subsidence into the performance assessment is still planned. In the 1991 Preliminary Comparison (4), an analysis of possible caving and subsidence over the waste storage areas from room closure concluded that no problems were likely to result for the waste disposal system. The maximum subsidence at the surface was calculated to be only 0.13 meter over an area of 1.54 x 106 m2. The affected area at the surface was determined by assuming an angle of draw of 35. It was further stated that if the Rustler-Salado contact residuum had (historically) lost about 400 meters due to dissolution without disrupting the confined water-producing Culebra and Magenta dolomite aquifers, subsidence should not be a problem.

No evaluation has yet been made of subsidence from potash mining. There are significant potash resources within and outside the WIPP site boundary and it is appropriate to consider subsidence effects from potash mining.

Gas Pressurization

Concerns about gas generation from the waste was the basis for the DOE's plans to conduct experiments with waste at WIPP. The performance assessment calculations, however, do not incorporate the potential fracturing of the repository leading to release of a fraction of the waste to the environment.

Climate Change

Geological effects of climate change, i.e. dissolution, subsidence, change in hydrological properties of subsurface strata, etc., should be considered in formulating release scenarios.

CONCEPTUAL MODELS

A conceptual model describes the way things are likely to happen. A combination of conceptual models is used in performance assessment. The selection of conceptual models, therefore, directly affects the outcome of the exercise. The WIPP project investigators have not yet settled on which conceptual models to use on a number of issues. The following examples from the WIPP performance assessment illustrates this point.

Salado Hydrology

The WIPP host repository rock, bedded salt of the Salado Formation, yields more brine than was anticipated (8). Three conceptual models have been proposed to account for this, viz., Darcy flow from far field; flow from the disturbed rock zone only, as a result of excavation; and squeezing of clay layers. The results of investigations conducted to date appear to favor the far-field Darcy flow model, but the Project has not yet decided which model is correct.

Contaminant Transport in the Culebra

The Culebra Member of the Rustler Formation overlying the Salado Formation is a 8 meter thick fractured dolomite bed which is the most transmissive zone overlying the repository and has been identified as the most likely pathway for transporting radionuclides from the repository to the accessible environment. The performance assessment has assumed dual porosity flow with matrix diffusion through the Culebra. However, a conceptual flow-model based entirely on channeling with no matrix diffusion also fits the hydrological field data. Sandia National Laboratory is conducting a 7-well field tracer test to try to resolve these questions. Additional laboratory studies may be necessary to establish matrix diffusion mechanisms. Until these issues are resolved, there is no basis to favor a particular conceptual model.

Chemical Retardation in the Culebra

The performance assessment has assumed chemical retardation during flow through the Culebra based on values derived through expert judgment of Sandia National Laboratory scientists. The judgments were based on values of retardation coefficient derived from powdered rock samples and assumption of corrensite clay lining the fractures, without sound experimental data. Credit for retardation may be taken if laboratory experiments on fractured core currently in progress and the field tracer

tests with sorbing tracers yield positive results indicating chemical retardation. However, there appears to be little reason to assume that corrensite clay lining is present in the fractures of the Culebra dolomite along the expected flow path.

DATA

Data are needed for two purposes - to show that the proposed conceptual models are correct and to obtain parameter values. About 300 distinct parameters were used by the latest performance assessment for WIPP (5). For many parameters, a range of values has been used for probabilistic consequence analysis. A narrow defensible range of values generally indicates high confidence in the understanding of that parameter. A broad range typically indicates correspondingly less confidence in those values and in the understanding of that parameter. For a robust performance assessment, therefore, one should strive to narrow the range as much as possible. This is generally achieved through well designed experiments and analyses of the results.

The data sets used in the WIPP performance assessment include parameters for natural (geologic) systems, source term based on waste characterization, and engineered systems to contain the waste. Since up to 70% of the WIPP capacity waste is yet to be generated and the characteristics of the existing waste are known mainly through "process knowledge", the challenge to the project is to develop an envelope that covers the performance assessment assumptions of the source-term and waste characteristics. The waste acceptance criteria will then be developed to guide the waste generators in shipping their waste to WIPP. This has not yet been achieved.

Experimental data have not been obtained to validate some conceptual models. This includes radionuclide retardation during postulated flow of contaminants through the Culebra aquifer, discussed in the previous section, and radionuclide solubility in the WIPP brine. Few relevant measured actinide solubilities exist. The WIPP performance assessment has so far used values obtained through subjective elicitation. The resulting values span a wide range. For example, the estimated plutonium solubility spans 12 orders of magnitude. When these wide, subjective estimates are used in Latin Hypercube Sampling of input values, non-conservative solubilities in consequence calculations may result. It is therefore essential to use the experimental values to limit the range. Where experimental values are not available, it is better to wait for completion of the experiment rather than use a non-defensible performance assessment for the compliance application.

CODES

Sandia National Laboratories has in hand all computer codes that are needed for performance assessment - 15 modeling codes and 35 utilities that assist in analysis. However, the major modeling codes may undergo significant revisions before final versions are used in compliance calculations. Two analyses not yet completed may require the development of additional computer codes.

The discharge of brine contaminated by radionuclides into members of the Rustler Formation is likely to cause changes in the density of water in the aquifers. This effect has not been analyzed and needs attention.

In the disposal rooms in the repository, complex processes are expected to occur in time. Brine will flow into the rooms. Gas will be generated by corrosion, microbial action, and a-radiolysis. Salt creep will close the room. However, these processes are highly coupled. Some elegant analyses coupling 2 of the 3 phenomena have been done. Until a fully coupled analysis is done, there cannot be assurance that less complete analyses suffice.

RESULTS

In the last performance assessment for the WIPP (5), USDOE noted that the calculated CCDF's were well below the allowable limits in the USEPA Standards. For the case of total release from repository/shaft barrier only, and a [0, 30] boreholes per km2 over 10,000 years sampled intrusion rate, the mean CCDF comes to within a factor of two or three of the USEPA containment requirement (5, vol. 4, Fig. 9-1, curve 1). This suggests several vectors of CCDF lie in the zone of violation of the containment requirement. This mean CCDF is not as conservative as it may appear because subjectively elicited solubilities are incorporated. The non-conservative basis of curve 1 in Fig. 9-1 is illustrated in Fig. 1. Using BRAGFLO-calculated brine flow from the repository up to the Culebra (70 vectors for both the E2 and E1E2 scenarios), all actinide solubilities at 10-3, 10-5 and 10-7 M, and the human intrusion rate samples uniformly between 0 and 30 boreholes/km2/10,000 years, the mean CCDF's are shown in Fig. 1, along with curve 1 from Fig. 9-1 (5, vol. 4). If

the extremely low subjectively elicited solubilities are not used, then the mean CCDF for the case of engineered barriers alone may not meet the containment requirement.
It is essential that the performance assessment analyses address these concerns as soon as practicable.

CHECKING OUR PREMISES FOR REDUCING THE RISK OF INADVERTENT HUMAN INTRUSION
Norbert T. Rempe
Westinghouse Electric Company
Waste Isolation Pilot Plant
P.O. Box 2078, MS-005
Carlsbad, NM 88221
ABSTRACT
Current regulatory assumptions about the risk of inadvertent human intrusion into a deep geologic repository view natural resources as a significant potential handicap for long-term containment. An argument can be made, however, that natural resources actually enhance a repository's defense-in-depth against inadvertent as well as intentional disturbance. Physical evidence and records of resource use have often survived hundreds, in some cases thousands, of years. We tread more carefully in areas with identified resources or a history of exploration and extraction than in virgin territory. Resource depletion diminishes an area's attractiveness to future prospectors and leaves in its wake disincentives or even barriers to human intrusion. Identified natural resources may therefore play a positive role in the long-term containment of dangerous wastes. Adding to this fresh perspective the ongoing reassessment of the biological effects of low-level radiation, we may streamline existing regulations, expedite disposal projects, and save taxpayers' money with no compromise on safety.
CONSTRAINING REQUIREMENTS
The Waste Isolation Pilot Plant (WIPP) has been designed and constructed as a deep geologic repository in salt to permanently isolate radioactive mixed waste from the biosphere. Before actual waste can be brought to the site, however, the U.S. Environmental Protection Agency (EPA) and other regulatory and oversight groups need to be reasonably certain that the repository will safely contain the waste for at least 10,000 years. Research results and model calculations to date show that the containment requirements will not likely be compromised if the repository is not disturbed during that time. Therefore, the principal concern remaining to be

addressed is the so-called inadvertent human intrusion scenario, i.e., breaching the repository by exploratory drilling or mining for natural resources. Such a breach might conceivably expose humans and the environment to radioactive and hazardous materials in concentrations exceeding regulatory limits.

To gain the confidence needed for compliance with the long-term containment requirements for radioactive waste (1), the EPA specifically prescribes the following:

> Places where there has been mining for resources, or where there is a reasonable expectation of exploration for scarce or easily accessible resources, or where there is a significant concentration of any material that is not widely available from other sources, should be avoided in selecting disposal sites. Resources to be considered shall include minerals, petroleum or natural gas, valuable geologic formations, and ground water ..... Such places shall not be used for disposal of the wastes... unless the favorable characteristics of such places compensate for their greater likelihood of being disturbed in the future (1) (italics added).

This regulation is commonly known as the resource disincentive requirement (2). The WIPP faces an additional resource constraint as the result of an agreement between the U.S. Department of Energy (DOE) and the state of New Mexico. In the Second Modification to the Consultation and Cooperation (C&C) Agreement (U.S. DOE and State of New Mexico, 1981, as modified), the parties agreed that:

> The DOE will not permit subsurface mining, drilling, or resource exploration unrelated to the WIPP Project on the WIPP site during facility construction, operation, or after decommissioning. This prohibition also precludes slant drilling under the site from within or outside the site (2).

UNDERLYING ASSUMPTIONS

Constraining resource requirements are based on the general assumption that selecting deep geologic disposal sites which also contain natural resources may "result in the denial of access to important raw materials" and "lead to future disturbance of the geological/hydrological system through exploration or production, including direct intrusion into the repository" (2).

Addressing these twin conflicts of resource denial and attractiveness, the EPA's Science Advisory Board (ESAB) recommended

> that EPA not preclude consideration of a potential site because natural resources are at or near the site, but rather should note that the presence of such resources is a highly unfavorable factor which should be included in the site evaluation (2) (italics added).

In response, the EPA agreed

> that automatically precluding a potential site because of one disadvantage is not desirable. At the same time, the Agency still believes that proximity to important or unique resources is a serious problem.. .. proximity to resources should be considered a serious disadvantage, but not an outright prohibition, for site selection (2) (italics added).

Consequently, "the EPA expects that sites with resources would be used only if it is reasonably certain that they would provide better overall protection than the practical alternatives that are available" (2). Applying similar assumptions the Environmental Evaluation Group (EEG), which provides independent technical evaluation of the project, avoids using the unfavorable italicized terms but agrees that: "Because the WIPP Site is in an area rich in oil and gas resources, the integrity of the repository is inherently subject to the drilling, production, and abandonment practices of the oil and gas industry" (3).

KEY ISSUE

As the term implies, the resource disincentive requirement is based on a negative assessment of natural resources vis-a-vis deep geologic disposal. Pertinent U.S. regulations are the most detailed and prescriptive of all national regulations (4). But their pessimistic view is by no means shared universally. Waste repositories in Germany, for example, are operating in idle and still active underground mines whose very reason for being is the presence or former presence of resources in economically recoverable concentrations and quantities. Once we decide to dispose of waste in existing or former mines rather than in special and fresh excavations, the choice of areas rich in natural resources actually becomes inevitable. This begs the question: "Is a disposal site containing natural resources or mines or both really more likely than areas without those features to be disturbed inadvertently?" The regulatory record does not offer any foundation for an affirmative response. And

that conspicuous lack of empirical data compels us to re-examine the underlying paradigm, because the opposite may be true. In that case, we would have to stand the current regulatory assumption on its head and contend that identified natural resources at a site selected for deep geologic disposal are more likely to discourage than to promote inadvertent human intrusion. Several lines of reasoning provide a solid basis for this revisionist assumption.

RESOURCE KNOWLEDGE

We generally accumulate more extensive and detailed geologic information about those areas known or suspected to be rich in natural resources than about those that are poor. Several decades of petroleum and potash exploration and production near Carlsbad generated a wealth of geologic data ready to be evaluated against the WIPP's site selection criteria. State and federal agencies maintained drilling and mining records sufficiently accurate to preclude unpleasant late surprises. The Department of Energy (DOE) took all the available information into account before choosing the best of several alternative sites. Without the knowledge gleaned from exploration and resource extraction records, the area might not have been identified as promising for waste disposal; but if it had anyway, all the required information would have had to be generated from scratch.

Inadvertent or, for that matter, intentional disturbance by drilling will more likely result from random or wildcat exploration in virgin territory than from delineation and development activities in an area whose geology and extractive history are fairly to very well known. Safety and liability concerns motivate entrepreneurs to either stay clear of previously mined areas or to proceed with special caution. And a history of depletion of natural resources in a given area certainly does reduce if not eliminate its attractiveness to future prospectors. The conclusion is therefore inevitable: The better the prospects for natural resources, the more we know about the geology, the more thoroughly we check for past mining, and the less likely will we stumble into the unexpected.

EXTRACTION EVIDENCE

All extraction of natural resources leaves some evidence. We have located and archaeologically investigated the 5000 year-old so-called King Solomon's mines at Timna (5). Ancient documents first mention the Wieliczka salt mine in Poland in 1044 (6). And our U.S. Dollar still commemorates the silver mines of Joachimsthal in Bohemia where the first "Thaler" was minted in 1518 (6).

Evidence of past mining or drilling, or both, on a potential disposal site itself may or may not disqualify that site from further consideration. It certainly does not everywhere outside the U.S. But be that as it may, such evidence immediately adjacent or around a designated disposal site may actually form a negative permanent marker. The site's distinctive "footprint" - an area without signs of any extractive activity, surrounded by indications of heavy activity - would remain permanently visible. Future generations would wonder, before digging on the site, why this oddly - shaped spot (Fig. 1a,b), certainly not a natural feature, had not been exploited together with the rest of the neighborhood. This reflection would lead to a search of available records; but even if all records had been lost, our descendants would likely remain wary. And that is, after all, what we want them to be. Ergo, evidence of resource exploration and extraction adjacent or around a site should not simply be presumed a negative attribute.

Fig. 1a.

Fig. 1b.

SUBSURFACE DISINCENTIVES

Extracting identified resources from the deep disposal site before decommissioning will by itself create physical disincentives to future repository penetration. At the WIPP, several potash seams lie in a zone from 125 to 240 m above the disposal level. One or more of these seams could conceivably be mined. If that were permitted, the mining pattern with the highest potential to deter inadvertent penetration should exactly overlie the disposal level room-and-pillar pattern. Under this arrangement, drilling on the disposal site would encounter either solid salt all the way (in the pillars) or hollow or at least disturbed intervals above the waste rooms (Fig. 2). Only the latter case concerns us. Here, the operator may face loss of drilling fluid circulation. That would give him an effective warning, because there is no natural reason or precedent for losing circulation in the Salado Formation salt. The warning could be amplified by marker materials such as cellophane shreds, chemical dyes, or engraved discs, left in the mined-out rooms, to

be brought to the surface by the drilling fluid if circulation were reestablished. Fig. 2.
TOLAN (7) suggested a further enhancement of this scheme. Subsurface barriers could be emplaced as backfill in mined openings above the repository. Layers of rubber tires, steel fencing, or baling wire would at least temporarily stop all drilling progress. Truck-mounted drill rigs cannot penetrate these obstacles while characterizing old land fills. "The rotary drill bit was not able to cut its way through the still pliable rubber tires... In the case of steel wire, the wire literally bound-up the drill bit and disabled it" (7). Resource removal with or without ancillary measures can therefore be a significant part of a repository's defense-in-depth (pun intended) against inadvertent human intrusion.

RADIATION HORMESIS

Most if not all current concerns about inadvertent human intrusion into a deep geologic repository for radioactive waste may become irrelevant if a paradigm shift already in progress continues and accelerates. U.S. and international radiation protection standards are at present based on the non-threshold linear hypothesis which assumes that all levels of radiation, regardless how minuscule, are harmful to organisms and should be avoided. Ample scientific evidence (8,9) contradicts this unscientific assumption. For example, if the lung cancer rate corrected for smoking is plotted against radon exposure, the reigning notion predicts a positive slope, while the data result in a negative one (10). "Exposed nuclear workers had statistically lower cancer mortality rates than unexposed control workers in nuclear plants" (11). Most researchers are still reluctant to conclude that low-dose radiation is beneficial, i.e., has hormetic effects; but a growing number are becoming convinced that the optimum dose of ionizing radiation is higher than the natural background, possibly by a factor of ten to fifty (12).
Sandia National Laboratories (SNL) performed deterministic calculations of long-term radionuclide transport behavior at the WIPP (13). In response to inadvertent human intrusion by drilling, the likely releases would result in small additional exposure to humans: from 1.3 times the annual natural background spread over 50 years, to 8 times the natural background for just one hour. These dose calculations were conservative because they took no credit for radioactive decay of the waste prior to being disturbed. We can therefore project that, as the concept of radiation hormesis gains ground, health physics concerns about inadvertent human intrusion will diminish and could conceivably vanish.

CONCLUSION

Upon even cursory examination, some of our principal premises about the effect of natural resources on the long-term integrity of a deep geologic repository are found wanting. Knowledge of the presence of resources and of their extraction, if applicable, actually decreases a site's potential to be disturbed. The more past and present resources we can identify, the less incentive remains for human intrusion-inadvertent or intentional. This recognition, coupled with the ongoing re-evaluation of the biological effects of low-level radiation, may ease the path to regulatory compliance for the WIPP as well as other deep geologic disposal projects.

ABSTRACT

We address the problem of explicitly treating the uncertainty associated with the predictive models employed in a performance assessment. Model uncertainty comes from our inability to fully characterize the system itself and the physicochemical processes which govern it, as well as from deliberate simplifications which are inevitably introduced and affect the forecasting results of the model. In general, these uncertainties stem from gaps in current knowledge and understanding, and, as such, they are largely unknown. Moreover, this body of knowledge continuously evolves over time and, with it, so do our model representations of the physical systems. Therefore, no matter how adequate our characterization of model uncertainty is, it will always be limited by our current state of knowledge. We note that, for the models used in a performance assessment, their predictions cannot be observed over the time and space scales over which they are intended to be applied, so that model validation is generally of little significance. This paper presents and discusses two mathematical approaches to the quantitative treatment of model uncertainty, namely the alternate hypotheses and the reference model approaches. These approaches necessarily suffer from the limitations which inevitably affect the current body of knowledge and beliefs.

INTRODUCTION

Regulations for the long term disposal of nuclear wastes require that the repository system perform its containment and isolation functions for very long periods of time and for quite extensive spatial scales (1). Consequently, the analysis of the performance of disposal facilities relies on the application of predictive models and is inherently affected by the associated uncertainties. These uncertainties come from a variety of sources and are with regard to the future state of the disposal system, the models and codes used to simulate the relevant physicochemical processes and the numerical values of the parameters required to exercise the models (2). Inevitably, expert judgments need to be used, together with the available experimental data, to account for the uncertainties of a performance assessment.
The uncertainty associated with the models is often considered the most important one. However, traditionally, the majority of efforts have been directed towards the treatment of data and parameter uncertainty, while very little has been done to deal with model uncertainty. A model is a representation of a real system: as such, it is usually of approximate nature and uncertainties inevitably arise wherever there are possible alternative interpretations of the system and its phenomena, which are all plausible in light of the current knowledge of the system. It is important to note

that the model representation of the real system is necessarily dependent on the objectives of the particular analysis for which the model is to be used and the corresponding level of accuracy required (3).
Model uncertainty results from our inability to identify and fully characterize the physical processes and phenomena governing the system, so that there is not a definite single set of hypotheses describing the system. The uncertainties, stem from actual "gaps" in knowledge which can take the form of poor understanding of phenomena that are known to occur in the system, as well as complete ignorance of other phenomena actually occurring. Typical examples of this kind of uncertainties occur in a variety of scientific fields such as seismic hazard analysis, groundwater flow and transport, modeling of the biosphere for contaminant transfer, pharmacokinetic modeling, severe nuclear accident phenomenology. Reference 4, for example, reports a study of groundwater flow and contaminant transport, in unsaturated fractured tuff, for which the phenomena governing these processes are not fully characterized and different alternative descriptions arise. More precisely, the uncertainties in the fundamental assumptions on the actual mechanisms governing the groundwater flow and contaminant transport give rise, in this case, to six alternative conceptual models. In the medical field, Ref. 5 presents an analysis of model uncertainty associated with an investigation of the carcinogenic potency of chloroform. Once again, the uncertainty arises largely as a result of fundamental limitations in the understanding of the mechanisms by which chemicals induce cancer. This ignorance prevents us from defining appropriate measures of biologically effective dose and limits our ability to clearly specify the functional relationship between dose and response. Furthermore, it makes it difficult to extrapolate experimental results from animals to humans. Therefore, the situation is such as to inevitably lead to alternative interpretations of the key issues. In the arena of nuclear reactor safety, five different modes of reactor vessel breach have been considered at the Sequoyah Power Station, Unit I (6): an in-vessel steam explosion that fails the upper head of the reactor vessel and generates a missile of sufficient velocity to breach containment; a steam explosion adequate to fail the upper head, but not to damage the containment; a steam explosion that could fail the bottom head; ejection of a significant portion of the core debris at high pressure; melt-through of the vessel and gravity-driven pour of the core material. Clearly, each failure mode represents a distinct model based on a distinct set of phenomenological assumptions.
Model uncertainty can also arise due to our inability to fully characterize the system itself. This is typical of groundwater flow and contaminant transport problems in which the geology and hydrology of the site itself often cannot be adequately characterized, in the sense that the available data is not sufficient to uniquely determine the exact structure and properties of the soil (site characterization) and, consequently, the actual mechanisms of flow and transport occurring. Again, Ref. 4 provides, to some extent, an example of how a poorly characterized real system could make the development of a unique, defensible model a difficult task. Another example is given in Ref. 7, concerning a field experiment conducted at the New Mexico State University College Ranch, with the objective of studying water flow and tracer migration in shallow soils. A large amount of site characterization data was collected to assist in the interpretation of the experiment. As many as six hundred core samples and six hundred disturbed site samples were taken systematically over the experimental region. The post-test evaluation of the results indicated that despite the large number of soil samples, a thin layer of soil with distinct properties that permit transmission of water at low moisture contents was missed. It is quite clear that with this information missing, none of the many plausible models can replicate the resulting shape of the plume.
Finally, an inevitable source of uncertainty in models comes from deliberate simplifications that affect the forecasting results of the model. Typical examples of this situation are related to the dimensionality of the system representation and to the discretization of continuous space domains (parameterization). Reference 8 reports an example of the impact of different parameterization schemes, within the inverse problem of aquifer parameter identification for a two-dimensional unsteady groundwater flow. Another example is provided in Ref. 7 where three different models are depicted, which differ in the number of zones considered to capture the heterogeneities of the system. As previously noted, information is missing regarding a thin layer of soil which allows flow of water at low moisture content, so that

even the highly detailed 3621-zone model cannot replicate the bifurcation which actually occurs in the real plume. An important aspect of model uncertainty deriving from alternative parameterization schemes, is the inevitable trade-off which occurs with the uncertainty in the corresponding parameters, which are generally unknown and need to be reliably identified or inferred from measured data. As the dimension of the parameterization increases, the modelling inaccuracy in the system description typically tends to decrease but the reliability of the estimated parameters is also reduced. Reference 8 discusses this aspect and presents an approach to achieve the optimum dimension of parameterization.

Independently of its origins, three main issues arise when treating model uncertainty: i) identification of the uncertainties; ii) how can we feel confident that the uncertainty has been characterized to a sufficient level and iii) how do we quantitatively represent this uncertainty. These issues must be satisfactorily addressed by the modelers of a performance assessment.

The identification of possible sources of model uncertainty is of paramount importance and consists of making assumptions about the characteristics and behavior of the system, and recognizing processes and phenomena that are known to be uncertain. As model uncertainty is primarily due to insufficient understanding and knowledge of the system, it is very unlikely that this step of identification will lead to a complete and exhaustive set of sources of model uncertainty. Yet it should be performed as adequately as possible, in light of the existing body of knowledge. A systematic approach based on some sort of classification of the types of model uncertainty, as the ones previously discussed, might aid this task.

The second issue inevitably brings up the controversial, philosophical problem of model validation (3,9). However, regardless of the still largely unresolved ambiguity of the terminology and the lack of precise operational guidance, it seems fair to state that a complete model validation, in its strict scientific sense, cannot be obtained for performance assessment models because the predictive performance of such models cannot be observed over the time and space scales over which they are intended to be applied. However, it is important not to forget that what drives the whole performance assessment is actually the decision making process which is to be based upon it. In the model uncertainty example of Ref. 7, if the actual shape of the plume does not affect significantly the decision making process, then one may conclude that model uncertainty has been characterized to a sufficient degree. If, on the other hand, the final decision changes with the different, alternative parameterizations, then one must conclude that the uncertainty is not sufficiently characterized and further investigation is needed to resolve the matter. Therefore, it seems logical to attempt to characterize all the uncertainties inherent in the models of a performance assessment in light of their impact on the resulting decision. This seems to call for a somewhat different approach to model uncertainty and a methodology which aids in the assessment of the impact of the various model uncertainties on the decision making process. Furthermore, this way of approaching the problem is expected to ease the identification of those properties of the modelled system which necessitate further investigation, as indicated by the fact that the associated available and plausible alternatives lead to contrasting decisions.

Concerning the third issue, it calls for the development of mathematical models which enable to represent the uncertainty in a practical and useful way, according to the objectives of the overall performance assessment. A more detailed discussion of this issue is presented in the next section.

At this point, we emphasize that, no matter how adequately one addresses the problem of model uncertainty, and no matter how rigorous the mathematical treatment is, one will still not be able to place full confidence on the characterization of uncertainty thus achieved. This limitation is obviously due to the fact that these uncertainties originate from gaps in our knowledge and we actually cannot model what we do not know. As mentioned before, we might be leaving out of our model a process which actually occurs, or we might be applying a model under conditions for which it actually does not apply. Obviously, if we knew this we would perform our analysis differently; but we do not know it and, therefore, our characterization of the uncertainty cannot include such a thing. Furthermore, our understanding of the physical behavior of a system evolves over time, sometimes even quite drastically, and therefore new models might originate. These arguments lead to the conclusion that the characterization of the uncertainty that we can achieve is necessarily

limited. It is of fundamental importance that these limitations be clear to the analyst and explicitly communicated to the decision maker.
In the next section, we proceed with a discussion on some aspects of the mathematical treatment of model uncertainty and introduce, and compare, the alternate hypotheses and the reference model approaches (10).

QUANTITATIVE TREATMENT OF MODEL UNCERTAINTY

Consider the case in which N models are available for the description of the behavior of the dependent physical variable y=y(x), a function of the independent variable x. For simplicity we regard both y and x as scalar variables, the generalization to the multidimensional case being straightforward. A typical example of y could be the spatial distribution of the hydraulic head in an aquifer. We assume that the models provide an aleatory representation of the process of interest so that their predictive outputs are provided in the form of aleatory distributions for the quantity of interest y. Let Fi (y) = F(y|Mi ,ji), i=1,2,...,N, be the aleatory distribution for y provided by the available models Mi, containing the vector of parameters ji, i=1,2,...,N, which are all plausible in the light of the existing information and knowledge regarding the phenomenon under analysis. Given the available information, it is required to obtain a summary distribution which represents the best description of the behavior of y, in light of the objectives of the analysis. For this purpose, it is common practice to resort to the technical judgments of experts in the field. The experts are required to provide their opinions, within the framework of a given model for the aleatory distribution F(y) of the quantity of interest y.
Theoretically, there are two basic approaches to the problem of aggregating the results coming from multiple models (11). The first one focusses on the plausibility of the various models, i.e. on their likelihood to provide a correct representation of the real system. The other one directs its attention to the accuracy of the predictions of the models, which are considered as devices providing information helpful for the estimation of the quantity of interest. We refer to the first approach as the model-focused or alternate hypotheses approach and to the second as the prediction-focused approach. Both approaches are consistent with the Bayesian interpretation of probability and theoretically lead to the same results, as shown in Ref. 11. However, in practice the results obtained with the two approaches tend to differ due to the assumptions and simplifications introduced.
Given (M,j) e {Mi,ji}, where {Mi,ji} represents the set of models and corresponding parameter vectors, in the model-focused approach, the quantity of interest y(x) is obtained by looking at the likelihood with which each model M and vector of parameters j is "correct". The joint density function y(M,j) which expresses the analyst's beliefs regarding the numerical values of the parameters and the physical validity of the model assumptions can be expressed as y(M,j) = p(j|M)p(M), where p(j|M) is the probability distribution function (pdf) of the parameter vector j, conditional upon model M, and p(M) is the probability expressing the analyst's confidence in the set of assumptions underpinning model M. By applying the theorem of total probability, we can assess the unconditional aleatory distribution F(y) as Eq. (1)
The alternate hypotheses approach, (Eq. 1), is intuitive and consistent with the theory of probability and allows for Bayesian updating of its terms, upon collection of additional evidence. However, the interpretation of the quantity p(Mi) as the probability that model Mi is correct, or that its underpinning assumptions are valid, has raised much controversy from both a philosophical and a practical point of view. Although other interpretations have been proposed, two key issues are of fundamental importance here. First, it must be clear that probability is interpreted as a degree of belief: we accept the primitive notion of likelihood and use probabilities simply as numerical measures of our beliefs regarding the likelihood of a certain event. Second, as previously noted, the conditions under which we can declare that a model provides a good approximation to the real behavior of the quantity of interest depend necessarily on the objectives of the particular analysis and the corresponding level of precision required, so that we should re-write the model probabilities as p(Mi|O), where the objectives O are expressed explicitly or, as is often the case, implicitly ("everyone knows about them"). The dependence of the analysis on its objectives is a concept familiar to all analysts, so that we continue our presentation without explicitly expressing this dependence. The two issues just pointed out should provide insights on the meaning to be given to p(Mi)

and its assessment in practice. We also note that the average F(y) (over all epistemic uncertainties) is not necessarily the only information that a decision maker would rely on. The full distribution, which contains the complete information on the assessed uncertainty but still leaves unsettled the question of how a decision ought to be made, should in general be reported to the decision maker who may then choose his own summary measures upon which to base the decisions.
The alternate hypotheses approach is based on two fundamental assumptions: mutual exclusiveness and collective exhaustiveness of the set of models. While the first assumption can be often accepted in practice, the second one is harder to accept for it requires that a perfect model not only exist but it also be one of the N models considered. In general, the complexity of the phenomena is such that the list of plausible models considered is necessarily incomplete. Moreover, as noted earlier, progress in understanding the physical laws underpinning the process under analysis and the increasing computational capabilities are such that models evolve in time. One possible modification of this approach, which addresses the problem of exhaustiveness, demands that p(Mi) be considered as the probability of model Mi providing the best approximate description of the process within the objective of the analysis, and then allows for a correction factor in Eq. 1 which takes into account the possible existence of other descriptions not considered within the N models. In other words we would write
Eq. (2)
where the superscript o stands for other. Although this formulation seems to resolve in principle the problem of exhaustiveness, it still leaves open many issues from the practical point of view regarding the definition of the alternate hypotheses Mo and the assessment of Fo(y) , together with the associated probability p(Mo). Notwithstanding these difficulties, this approach, in the form of Eq. 1, has been used in the past in various fields of application supported by a somewhat implicit assumption of exhaustiveness. A typical example of application of this approach is given in Ref. 5. In this work, the concept of probability trees is used to decompose the problem into its underlying physical assumptions, and expert judgments are formally elicited to assign probability weights to the different assumptions constituting the branches of the tree. Distributional characterizations of cancer risk from exposure to chloroform are constructed by computing the risk estimates for all possible models represented in the tree as combination of branches, each complete pathway through the tree corresponding to one model. Each expert's distributional characterization of risk is then computed by means of the weighed sum of Eq. 1 in which the output of each model is weighed by the probability that the expert assigned to that model, this latter probability being obtained by multiplying the probabilities assigned to each branch along the complete pathway in the tree. This approach was used to construct a risk distribution for each expert participating in the project. The set of distributional risk characterizations obtained from the experts can then be combined in a composite risk measure reflecting the views of the entire group of experts. Similarly, in the reactor safety example of Ref. 6, expert judgment was used to assess how likely each mode of vessel breach is, i.e. p(Mi).
Concerning the prediction-focused approach, a simple framework previously employed is provided by the so called reference model approach which focuses attention on one single model of the process under study and aims at appropriately modifying its output so to allow for the inherent uncertainty in the model description (10). The appropriate modification is to be assessed with the available information which in most practical situations relies on expert judgments regarding the validity of alternate hypotheses and the reliability of the associated models.
Suppose that one single model M* is selected as reference to describe the process. Even though this model may represent the best and most advanced technology, there still are significant uncertainties associated with it. In other words, this model alone does not meet the objectives of the analysis, in a sense that its output gives only an approximate description of the real process and a modification is in order to account for the associated uncertainty. To formalize this situation, we introduce a factor D*=D*(x), which may be additive (D*a) or multiplicative (D*m), so that our assessed value for the quantity y can be written as
Eq. (3a)
Eq. (3b)
The factor D* is in general unknown and the uncertainty associated with it can be

represented in the form of a distribution g(D*). It is important to note that the uncertainty in D* could be of the epistemic type only or both epistemic and aleatory. In the first case D* simply represents the systematic bias of the model prediction and the uncertainty in its numerical value is strictly related to our lack of knowledge which could in principle be eliminated with a single observation of y. In the second case, the model bias D* itself exhibits aleatory variability, due to some random effects which have been neglected in the model M*. In this case, a single observation cannot eliminate the uncertainty and actually a sequence of observations, repeated under seemingly identical experimental conditions, would lead to different values. D* is then described by an aleatory distribution whose parameters are uncertain due to the epistemic uncertainty in their values. For example, in the additive scheme the distribution F(y) is given by,

Eq. (4)

where z(y*,Da* ;j) is the joint aleatory distribution of y* and D* with parameters jand w(j) is the epistemic distribution representing the state-of-knowledge uncertainty in the parameters j. A corresponding expression can be derived for the multiplicative version of the approach.

The general formulation of model uncertainty provided by Eqs. 3a-b has also been employed in other contexts. In the fire risk assessment area, the actual time to damage Td of an object can be considered to be the product of its deterministic reference model (drm) prediction, Td,drm, and a correction factor D which accounts for the inadequacy of the reference model, viz. Td = Td,drm D. In earlier applications, this factor was treated as deterministic with an epistemic probability distribution function reflecting the analysts uncertainty regarding the amount of systematic over-or underestimation of the damage time by the deterministic reference model (12). In a subsequent analysis, it was recognized that D itself may be an aleatory variable and its aleatory distribution was introduced in the form of a lognormal with parameters m and m (13). The epistemic uncertainty is in this case described by a pdf over the parameter vector (m,s), which can be updated using Bayes' theorem.

In seismic risk analysis, a similar formulation is applied for estimating the model uncertainty of predicted ground motion for future earthquakes (14). In this case, the data coming from recorded earthquakes can be exploited to quantify the goodness-of-fit of simulations of the recorded earthquakes by considering the differences in the response spectra of the observed and simulated ground motions. The natural logarithm of the average horizontal spectral acceleration, lnSAij for the j-th station and the i-th earthquake is given by lnSAij (f) = lnSAcij (f) + m(f) + eij(f) where f is the frequency, superscripts o and c refer to observed and calculated quantities, m(f) is the model bias and eij(f) is the error term, assumed to be a normally distributed random variable with zero mean and variance equal to m(f). In this case study, SAcij(f) represents the output of the model and it is corrected by a multiplicative factor Dijm(f) = exp[m(f) +eij(f)], to account for the inaccuracy of the model description. The correction factor Dijm(f) contains both aleatory and epistemic uncertainty, since it is meant to account for "modelling" uncertainties (differences in the actual physical process and the numerical simulation), as well as "random" uncertainties (detailed aspects of the earthquakes source and wave propagation that cannot be modelled deterministically on the basis of the current state of knowledge). In this particular application, the availability of the data allows one to resort to classical statistical techniques for the assessment of modelling, as well as parametric, uncertainty. In a more general case, the definition of these uncertainties will result from all available data, including information provided as experts' opinions, especially with regards to model uncertainty.

Finally, we conclude this section by comparing the two approaches presented so far, in the case of deterministic models providing predictions of the quantity y. For simplicity, we refer to the case with no parameter uncertainty, although the considerations that will follow can be easily generalized to the case with parameter uncertainty. In this case, Eq. 2 can be re-written as

Eq. (5)

We now observe that Eqs. 5 and 3a provide a very similar formulation for the model uncertainty. Intuitively, it is easy to see that the quantity yo p(Mo) in Eq. 5 has the same basic objective of the correction factor Da* in Eq. 3a and that is, to account for the inaccuracies and inadequacies possibly present in the description

provided. Also, it appears reasonable that this quantity contains uncertainty which could be epistemic or both epistemic and aleatory, and the same considerations made for D* apply. Hence, if we are willing to consider our single model M* as actually a "supermodel" which appropriately combines the output predictions of N submodels as in the summation term on the right-hand side of Eq. 6, and if we agree on accounting for possible "leftouts" through an additive correction factor Da* = yo p(Mo), then Eqs. 5 and 3a are formally identical.

ABSTRACT
The U.S. Department of Energy (DOE) is responsible for cleanup activities at the Fernald Environmental Management Project (FEMP) site in southwestern Ohio. The 425-hectare (1050-acre) site consists of a former 55-hectare (136-acre) Production Area, an adjacent Waste Storage Area and various support facilities. From 1952 until 1989, the FEMP processed uranium into metallic "feed" materials for other DOE facilities in the nation's defense program. In accordance with the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), the FEMP site is currently listed on the National Priorities List (NPL). To facilitate an expeditious cleanup effort, environmental issues associated with site cleanup are being managed under five operable units.
This paper summarizes the risk assessment strategy employed to determine baseline human health risks associated with K-65 and metal oxide residues currently stored in Operable Unit 4. The K-65 and metal oxide residues were generated during the 1950s as a result of the extraction of uranium from uranium-bearing ores and concentrates. These residues are currently stored within Operable Unit 4 in concrete silos. Silos 1 and 2 contain approximately 6,120 cubic meters [m3] (8,005 cubic yards [yd3]) of K-65 residues, while silos 3 contains approximately 3890 m3 (5,080 yd3) of cold metal oxides. These concrete silos are beyond their design life and require remedial action. The risk assessment conducted for Operable Unit 4 constitutes the first detailed human health risk assessment to be approved by the Environmental Protection Agency (EPA) for the CERCLA clean-up effort at the FEMP Site. This paper discusses the FEMP's use of a Risk Information Quality Objective process in concert with the traditional risk assessment approach to determine baseline risk to human health and the environment posed by Operable Unit 4. A summary of the baseline risks to human health is also presented.
DESCRIPTION OF PROBLEM
As part of the process of developing remedial action objectives for Operable Unit 4, an assessment of the baseline risks posed to human health and the environment, by the contents of the silos and the contamination in the surrounding soil, was conducted. Given the concern about the stability of the silos, and the fact that Silos 1 and 2 contain radium-bearing residues (also referred to as K-65 residues), and Silo 3 contains thorium oxides, the evaluation of the potential risk, to human health and the environment associated with these materials was necessary. Extensive sampling conducted during the remedial investigation (RI) revealed that the major radionuclides in the K-65 residues in Silos 1 and 2 include in excess of 3,700 Curies (Ci) of Radium (Ra)-226, 600 Ci of Thorium (Th)-230, 1,800 Ci of Lead (Pb)-210, and more than 28 metric tons of uranium. (1) The K-65 residues also contain significant amounts of barium, lead, arsenic, and polychlorinated biphenyls (PCBs). The K-65 residues also generate several million picocuries per liter (pCi/l) of radon (Rn)-222. Silo 3 metal oxides contain significant concentrations of radionuclides from the uranium decay series with the predominant radionuclide being Th-230 in excess of 450 Ci. The metal oxides also contain several metals including arsenic, cadmium, chromium, and selenium. Radionuclide contamination, consistent with the contents of the silos, was also detected in the Operable Unit 4 surface soil, subsurface soil, and perched water.
BASELINE RISK ASSESSMENT APPROACH
The baseline risk assessment evaluates the risks to human health and the environment in the absence of remedial action. The Risk Assessment Work Plan Addendum established the Operable Unit 4 and the site-wide baseline risk assessment approach for establishing constituents of concern (COCs), developing exposure scenarios, and conducting toxicity assessments. (2) In order to define the level of quality for the required risk information and also to ensure that the risk information developed was sufficient to effectively evaluate a wide range of remedial alternatives, a Risk Information Quality Objective (RIQO) strategy was formulated by the Operable Unit 4

risk assessment project team. The RIQO process is a very structured approach similar to the data quality objective (DQO) process traditionally used for establishing data collection quality objectives for field sampling programs. (3) The RIQO approach enables the establishment of clear objectives, decisions, impacts, and uncertainties for the overall remedial investigation and baseline risk assessment. This process also helped to establish the bases for discussion and negotiation of key issues with the EPA. As a result,mutual agreement on the risk assessment approach was reach between the site and the EPA. This enabled Operable Unit 4 to effectively determine: 1) whether action is necessary (baseline risk assessment), 2) what action is necessary to reduce risks (feasibility study risk assessment), and 3) the contribution of the residual risk to the entire site (comprehensive response action risk evaluation [CRARE]) (4).

DEVELOPMENT OF RISK INFORMATION QUALITY OBJECTIVES (RIQOs)

Based on the established end use for the risk information, the RIQOs helped to define the level of quality required through the following process:

Step 1.

Problem statement A clear statement of the area of concern (e.g., human health risk, compliance with Applicable Relevant and Appropriate Requirements [ARARs], nature and extent of contamination, contaminant fate and transport, etc.) and an evaluation of the practical limitations imposed by the data collection process was first established.

Step 2.

Identification of a decision that addressed the problem Once the stated concern was established, a decision/question was formulated which enabled the development of a list of alternative actions that addressed the problem. Examples of the types of decision/questions formulated include:

What contaminants are present both in the silos and within the environmental media and at what concentrations?

Where are the contaminants located within the soils surrounding the silos?

What is the migration potential of the various contaminants?

What are the pathways of exposure to people and the environment from these contaminants?

Step 3.

Identification of inputs that affect the decision The next step involved the identification of the specific variables or characteristics to be measured or investigated,in addition to any other information needed to make the decision (e.g. aquifer flow characteristics, or wind speed frequency and direction).

Step 4.

Specification of the domain of the decision This part of the process required a detailed description of the boundaries of the decision including spatial and temporal considerations and in particular those critical to ascertaining the impact of contaminant fate and transport on future land use scenarios.

Step 5.

Development of logic statement The logic statement discussed how the risk information was to be used in the decision process. For the Operable Unit 4 the end use of the risk estimates were used to determine the magnitude of the risk to sensitive receptors and also as a basis for evaluating the optimum approach to risk reduction. The logic statements included those used to screen COCs and to evaluate the upper end of the risk estimates for determining when action is needed and within what media.

Step 6.

Establishment of constraints on uncertainty This step involved placing constraints on uncertainty. Objectives for controlling decision errors were stated as limits on the acceptable probability of making an incorrect decision on the basis of the study findings. The limits on uncertainty were based on careful consideration of the consequences of incorrect conclusions.

Step 7.

Optimize design for obtaining risk information This step addressed mechanisms for optimizing the evaluation, collection, and presentation of the risk information by identifying the most efficient way one can be expected to achieve the desired results given the constraints on uncertainty.

RESULTS OF ASSESSMENT OF OPERABLE UNIT 4 BASELINE RISKS TO HUMAN HEALTH

Determination of Constituents of Concern
The primary source terms for Operable Unit 4 were the contents of Silos 1, 2 and 3, and the contamination in the surrounding surface soil, subsurface soil, and the earthen berms surrounding Silos 1 and 2. The RIQO process was used to first identify constituents of interest. Two statistical tests were then used in sequence to identify COCs: a "location" test (student's t-test to compare the mean of site-related data with the mean of the background data, or a Wilcoxon Rank Sum [WRS] test or Mann-Whitney U-test, a direct corollary to the WRS, to compare the two distributions of rank ordered data), followed by a "95th Percentile Test." The 95th Percentile Test was used to determine if any sample measurement (not the mean, upper confidence limit [UCL], or any other statistical parameters) for a given constituent exceeded the upper 95th percentile for the background concentrations. If so, the test indicated that the site has at least one relatively high concentration and that the constituent should be considered a COC. If either test rejected the null hypothesis, i.e., the distribution of measurements at the site appears to be shifted to the right (to higher measurements) of background, the constituent was considered to be a COC. The constituent was not included as a COC only if both tests indicated that there was not a "significant difference" between the two distributions. Constituents were omitted from the list of COCs if they were: 1) common laboratory contaminants found in concentrations less than 10 times the blank concentrations; 2) essential elements (eg. sodium, magnesium, iron etc.) and known to be non-toxic; 3) chemicals that are ubiquitous in nature (eg. silicon, chloride, etc.) and were inappropriate for hazard analysis; 4) chemicals found at very low concentrations (<1 part per million [ppm]) and known to be non-toxic; 5) chemicals that are identified only as a chemical group (eg. total organic carbon, chlorinated hydrocarbons, etc.) and cannot be properly addressed in a risk assessment; or 6) chemicals that are from off-site anthropogenic sources (autos, local factories, etc.) unless they presented a significant risk.
Exposure Assessment Scenarios
Three land-use scenarios and two source-term scenarios were developed. The land-use scenarios established 1) current land-use without access controls, 2) current land-use with access controls, and 3) future land-use without access controls. No remedial actions were assumed to have been taken, and no members of the public establish residence within the boundaries of Operable Unit 4 for the first land-use scenario. Potential receptors included an off-property resident farmer, a trespassing child, an on-property worker (groundskeeper), and an off-property user of surface water.
The second land-use scenario is similar to the first, except that, it was assumed that the site access restrictions currently provided by DOE are maintained. This scenario further assumed that DOE maintains a site-specific health and safety program to ensure that workers and visitors are properly protected. Potential receptors under this scenario included an off-property resident farmer, a trespassing child, and an off-property user of surface water.
The third land-use scenario included exposure routes that require development time, such as establishing a home and farm where members of the public were assumed to have established residence within the Operable Unit 4 boundaries. Access controls were assumed to be absent and again, no remedial actions have been taken. Hypothetical receptors under this scenario were a reasonable maximum exposure (RME) on-property resident farmer, a central tendency (CT) on-property resident farmer, an on-property resident child, an off-property resident farmer, and an off-property user of surface water.
In addition to the three land-use scenarios, two source-term scenarios were established: the current source-term scenario and the future source-term scenario. The current source-term scenario considered the silos as they exist today. The future source-term scenario assumed complete structural failure of Silo 3, resulting in the spread of its contents to Operable Unit 4 surface soil, and the collapse of the Silo 1 and 2 domes, consequently exposing their contents to the elements and increasing the leaching of their contents by precipitation.
Under the current land-use scenario without access control and under the future land-use scenario, risks were calculated using both the current source-term and the future source-term. Under the current land-use with access control scenario, the future source-term does not apply; the assumption was made that under institutional control of DOE, measures would be undertaken to maintain the current configuration

of the silos and implement mitigative action in the event of silo failure. Thus, under the current land-use with access control scenario, risk was calculated only for the current source-term.
These land-use/source-term/receptor scenarios provided the framework for conducting fate and transport modeling using the exposure pathways and transport mechanisms mentioned above. Exposure point concentrations for all of the COCs were then established. These exposure point concentrations established the amount of each COC to which human receptors could potentially be exposed. Figure 1 illustrates the conceptual model developed to represent the potential exposure pathways and routes for human contact with Operable Unit 4 Silo material. A similar conceptual model was developed for soils, berms, and other environmental media.
Fig. 1.
Toxicity Assessment
Intakes calculated in the exposure assessment were used in conjunction with EPA cancer slope factors to determine the incremental lifetime cancer risk (ILCR). Table I provides a summary of the cancer risks for Operable Unit 4. In accordance with CERCLA guidance, risks greater than 1x10-4 to 1x10-6 were considered unacceptable. Toxicity data were taken from the Integrated Risk Information System (IRIS)5 and the updated Health Effects Assessment Summary Table (HEAST). (6) For chemical toxicants, risk was characterized using dose thresholds or reference doses (RfDs). These values are also developed by the EPA to indicate the potential for adverse health effects from exposure to chemicals exhibiting non-carcinogenic effects. To determine if the exposure levels of Operable Unit 4 constituents may cause adverse health effects, the estimated intake of a particular constituent (calculated from the exposure assessment) is compared to the RfD. If the ratio of estimated intake to the acceptable intake is greater than 1, the site-related intake may cause toxic effects. This ratio is called the Hazard Quotient (HQ). When HQs for multiple COCs are summed, the resultant value is the Hazard Index (HI). Table II summarizes the hazard indices for Operable Unit 4.
TABLE I
TABLE II
Assessment of Uncertainty
Recognizing that uncertainty is a factor throughout the exposure and toxicity assessment process, a qualitative assessment of the uncertainty was done. The sources of uncertainty examined included the analytical data, the values of input variables for the models, the accuracy with which the models represent the actual environment or biological processes, the manner in which the exposure scenarios were developed, and the high-to-low dose and interspecies extrapolations for the dose-response relationships. Table III presents a summary of this qualitative uncertainty assessment and the potential impact and resultant bias imposed on the Operable Unit 4 baseline risk assessment.
TABLE III
CONCLUSIONS
Given the RIQO logic process and the uncertainty in the risk information developed, the results were found to be valuable in supporting the risk management decisions for Operable Unit 4. The risk information was then carried forward to support the development and evaluation of alternatives in the feasibility study. The RIQO logic process provided the basis for ensuring that the risk information carried forward was sufficient to enable site-wide risk management decisions. The methods, models, and cross-communication between operated units on risk information, set the stage for developing cleanup priorities for the site as a whole.

BfS
ABSTRACT
The Federal Office of Radiation Protection, BfS, is sponsoring the project "Radiological Registration, Investigation and Assessment of Mining-Related Contaminations from the Past - Register of Contaminated Sites", for which GRS (Gesellschaft fr Anlagen- und Reaktorsicherheit) is the main contractor. 5649 uranium ore and other mine-related objects were identified initially in 34 areas, totalling approx. 1500 km in the states of Saxony, Saxony-Anhalt and Thuringia. Following registration in the A.LAS.KA. data bank, 5352 of the objects occupying 38 km of the total area were assessed with respect to local dose rates and classified within three groups: Those considered to be irrelevant in the sense of federal task; those possibly relevant because of fulfilling radiological assessment criteria, and those possibly relevant due to the exceeding of other, non-radiological criteria. In all, about 60% of the original object area remains to be investigated.
TASK
Since 1991, on behalf of the Federal Office of Radiation Protection (Bundesamt fr Strahlenschutz, BfS), the Gesellschaft fr Anlagen- und Reaktorsicherheit (GRS) has been the leading organization working on the Project "Radiological Registration, Investigation and Assessment of Mining-Related Contaminations from the Past - Register of Contaminated Sites". Based on information about areas with remains from uranium ore mining and other past mining activities and on aerogamma measurements of the 1980s in the states of Saxony, Thuringia and Saxony-Anhalt, 34 suspected areas totalling 1500 km were defined. The aim of the first project phase was to register and secure all existing information and data about the facilities and remains (the so-called "objects") and to process them for inclusion in a data bank, after which they would be evaluated. The first result (1, 2) was that after the evaluation of the information and documentation from the various sources, more than 5000 objects - heaps, disposal plants, shafts etc - were registered, and a large amount of object-specific data was stored in the data bank. Moreover, areas with high gamma radiation intensity ("aerogamma abnormality areas") not associated with any previously known objects were identified. On-site inspections revealed that the data were incomplete and in part not up to date, thus requiring renewed examination; in general, the data sufficed neither for a characterization of the objects nor for a reliable radiological assessment.
VERIFICATION
In the "verification phase" that followed and which was completed in 1994, all existing data were checked on site with the help of experienced local expert companies, and the data for each object were supplemented by scoping and representative measurements of the local dose rate. Moreover, the aerogamma abnormality areas not associated with mining-related objects were investigated in order to find the reason for the high level of gamma radiation. In addition, the information required for the radiological assessment was compiled over the use of the objects and their environment as well about existing protected objects. The kind of objects and the situation within the suspected areas are shown on digitalized topographical maps on a scale of 1 : 10 000. The know-how of local and regional authorities was considered in the investigations. The assistance given by their representatives proved to be of much value.

A total of 5352 objects covering a total area of approx. 38 km were verified (3). Table I shows the distribution of the various kinds of objects.

WISMUT PROPERTIES

The 297 objects located on properties of the WISMUT GmbH were investigated by the company itself in preparation for making decisions about ecological restoration measures (Environment Register). The procedure followed during these investigations was basically the same as with the Register of Contaminated Sites; thus it was possible to integrate the objects into the data bank.

ASSESSMENT AND CLASSIFICATION

A radiological assessment of the 5352 objects was carried out on the basis of the criteria recommended by the German Radiation Protection Commission (SSK) (4) for areas that were used for storing heaps, and which were then used for other purposes, as well as for the areas that were contaminated by uranium ore mining and which were then also put to different use. In this context, a decision-tree was developed which, in addition to the local gamma dose rate output of 300 nSv/h for the consequent area use, also employs the relation of the local gamma dose rate that is measured on the object and in its surroundings as differentiation criterion. Furthermore, the size and volume, as well as any covering of the object, is considered (5, 6, 7, 8).

As a result of the assessments, the objects were classified in three groups. The objects in Group 1 are considered to be not relevant in the sense of the federal task. Their local dose rate measurements do not differ significantly from those of the surrounding area. The objects in Group 2 are considered to be possibly relevant in the sense of the federal task because of fulfilling the radiological assessment criteria. Objects in Group 2a were regarded as possibly relevant in the sense of the federal task since these objects were found to exceed other, non-radiological criteria.

1017 Shafts and galleries were not included in the classification due to the fact that they were investigated separately.

RESULTS

After the verification program was completed, there were registered 5649 objects in the 34 suspected areas - including the 297 WISMUT properties. The relevant parameters and information are included in their entirety in the data bank "A.LAS.KA." (acronym of the German term 'Altlastenkataster', which means Register of Contaminated Sites) (9). Thus, detailed and up-to-data data on all objects in the suspected areas, as well as a computer-aided possibility of identifying them on digitalized maps, now exists (10).

Beyond the defined suspected areas there are some indications of additional objects which are to be included in future investigations, if there is cause for concern due to the geological conditions or following from the findings of uranium prospecting.

The radiological assessment and classification of the 4335 objects (Fig. 1) shows that according to the current state of the project, 65% of the objects (Group 1 plus shafts and galleries) are irrelevant for the radiation exposure in these areas and are therefore not examined further.

The remaining 35% of the objects cover an area of approx. 34 km; this equals 89% of the total of all object areas originally considered. Compared with the number of remaining objects, the reduction in the size of the object areas that have to be further investigated is small. This results from the majority of Group 1 objects being very small heaps dating back to medieval mining activities. However, the area for future investigations is reduced by another approx. 11 km since investigations have already been carried out within the framework of other projects at 6 mill works in Saxony-Anhalt (approx. 5 km) and in a mining area in Saxony (approx. 6 km). There is, therefore, the need for further investigation of an area of approx. 23 km - approx. 60% of the original object area - in the form of measurement programs.

These site-specific measurement programs have already been carried out in Helbra (Saxony-Anhalt), Dittrichshtte (Thuringia) and in Lengenfeld, Aue- Hakenkrmme, Freital and Gottesberg/Schneckenstein (Saxony). These programs determine the kind, extent and magnitude of the possibly radioactive contaminations. As to the currently continuing measurement programs (Annaberg-Buchholz and Johanngeorgenstadt in Saxony) (7), and the ones planned for the future, the results of the verification program and classification of objects form an important basis for the definition of the investigation areas.

The causes could be identified for most of the aerogamma abnormalities, unassociated

with mining-related objects, that cover a total area of 22 km. To establish the causes in that small region of the aerogamma abnormality areas where so far no causes could be identified, further investigations are planned.

SUMMARY AND OUTLOOK

The results of the verification show that in the mining areas of Saxony, Thuringia and Saxony-Anhalt there is no large-scale radiation exposure exceeding natural regional levels. Investigations are therefore only necessary for small segments of the originally defined suspected areas. The kind and extent of the investigations required are determined and optimized on the basis of the verification results. During the course of the activities, furthermore, it turned out that there were also some individual objects related to uranium ore mining and other past mining activities found outside the defined boundaries of the suspected areas. These mainly concern areas in Saxony-Anhalt and Saxony, especially the 'Erzgebirge' region and mid-Saxony. An examination is currently going on as to whether or not these objects have to be included in the investigations.

ABSTRACT
According to the Radiological Protection Precaution Act, the investigation of the radioactivity in the new federal states of Germany, resulting from mining activities in areas of increased natural radiation, was defined as a federal task. The Federal Ministry of Environment, Nature Conservation and Nuclear Safety (BMU) gave the responsibility to Federal Office for Radiation Protection (BfS). For the implementation of the necessary tasks the project "Radiological Registration, Investigation and Assessment of Contaminated Sites from Past Mining Activities (Register of Contaminated Sites)" was initiated.
On the basis of the obtained results from paper work, site inspections and targeted measurement programs, recommendations founded on radiological evaluations can be given with regard to the need for ecological restoration of the investigated areas and objects.

FEDERAL TASK
When Germany was reunified four years ago, the Federal Government found itself confronted in wide areas of the new federal states with the legacies from uranium ore mining. The exact kind, number and distribution were unknown, and the population in these areas was deeply worried about the possible negative effects these legacies might have on their health, on the environment and on the economy. The Unification Treaty (1) as well as the correspondingly amended German Radiological Protection Precaution Act (2) therefore fixed the urgent need for the Federal Government to clarify the situation as follows:

"The investigation of environmental radioactivity stemming from mining in areas of natural radiation is the task of the Federal Government. The authority responsible is the Federal Office for Radiation Protection."

Although the written text of the law does not specify explicitly the kind and the scope of the governmental activities which the Federal Office for Radiation Protection (BfS) has to implement, they can be derived from the Radiological Protection Precaution Act:

1. In the legal sense of radiation protection, the task is to investigate an existing situation which can only be changed by intervention. No binding limit values of any legal regulations concerning prospective, plannable radiation protection measures can be applied directly; instead, they have to be replaced by reference levels.
2. The main focus of the investigations is to be on those mining legacies (hereafter referred to as "contaminated sites") where the parties that are responsible have ceased to exist or cannot be held responsible any longer. Any mines in operation and companies of the uranium mining industry (Wismut GmbH) fall under the supervision of the state authorities in their function as regulatory bodies for radiation protection.
3. The federal task is not only limited to the sites contaminated by uranium ore mining and processing but also includes sites of other mining activities that are suspected to be contaminated by radioactivity.
4. The federal task is to perform an investigation of the radiological situation over a wide area and to consider it as a national problem. It is thus not only limited to a mere analysis but also includes an assessment that is as thorough as it is required for a corresponding radiological classification of areas that are suspected to be contaminated and of relevant mining-related objects (buildings, plants, heaps, areas etc. will hereafter be referred to as "objects"). The task is also oriented on the need, aims and priorities of action. The decisions about ecological restoration and its objectives, the preparation of appropriate projects and expert analyses as well as the actual performance of ecological restoration measures are not part of the federal task. The tasks of the authorities that are responsible for carrying out radiation protection measures within the framework of ecological restoration are not affected by the government task.
5. Furthermore included are the tasks that are related to the methodology of the investigations as well as to the documentation and information about the mining-related environmental radioactivity.

FEDERAL PROJECT

Organization

In mid-1991 the BfS, financed and supervised by the Federal Ministry of Environment, Nature Conservation and Nuclear Safety, initiated the project "Radiological Registration, Investigation and Assessment of Contaminated Sites from Past Mining Activities (Register of Contaminated Sites)" to deal with the federal task. The Gesellschaft fr Anlagen- und Reaktorsicherheit (GRS) was commissioned by the BfS to coordinate the sub-contractors (mostly regional companies) that are involved, to develop and maintain the central data bank about mining-related environmental radioactivity, and to perform itself some technical work within the framework of the project. The German Radiation Protection Kommission (SSK) is taking part in the scientific assessment of the situation; it is constantly kept up to date with the results of the investigations. Regional, district and local authorities are involved wherever necessary. The investigation results are made available to them for decision-making. In all, this form of organization of the project, which is exceptional in its kind, scope and importance, has proved to be effective and has led to close cooperation among the parties involved.

Structure of the Task

Before work was begun, a project structure plan was worked out (Fig. 1) which served as a guideline for the working progress and the coordination needs with the sub-contractors as well as for drawing up a time schedule. Beside the commissioning and controlling of the sub-contractors it was the task of GRS to build up the data bank (ALASKA) and to supervise the collection of data as an expert consultant.

Fig. 1.

The data that were registered during the historical search mainly came from the evaluation of files and maps. A verification phase from 1992 to 1993 was meant to ensure that the data for all areas and objects were comprehensive, correct and up to date. In this context all the data about the suspected areas and objects were checked by interviewing contemporary witnesses and by local inspections and measurements.

In a number of cases, however, the existing data base after the verification phase is not sufficient for a final radiological evaluation of individual sites. Consequently, measurement programs were planned to be carried out from 1993 onwards. Three pilot projects were already carried out in 1991 and 1992 parallel to the securing of the already available data; they serve as models for site-specific measurement programs. The aim of the pilot projects was, alongside an initial site evaluation, to determine the necessary extent and content of a measurement program and to gather experience from the investigation methods and measurement techniques.

Time Schedule and Finances

A time schedule was developed for the planned duration of the project, and the necessary financial means were calculated. Figure 2 shows the current state (end of 1994) of the work performed and the financial means that have been used up so far.

Fig. 2.

RESULTS

The objective related to the federal task of clarifying the radiological situation in the mining areas on a large scale and the available resources of manpower, finances and time required a staggered procedure from the start. This is true of both the registration and the assessment procedure. The principle aim is to identify as early as possible those areas and objects that were not influenced by mining or which are irrelevant from the point of view of radiation protection and can therefore be excluded from the project's investigations, leaving only those areas and objects which still have to be investigated further to clarify the situation.

Definition of "Suspected Areas"

To start with, the areas had to be defined in which mining-related contaminations with higher than normal radioactivity were known or suspected to exist. These were mainly the areas involved in the uranium industry, but also some disused mining areas of the Erzgebirge mountain region (copper slate and black coal). Other areas that were included were those with abnormal gamma radiation levels which had been detected in the 1980s by measurements from the air.

Based on these activities, 34 "suspected areas" totalling up to 1500 km were defined in Saxony, Thuringia and Saxony-Anhalt as priority investigation areas. Concerning a radiological assessment this means that radiologically relevant objects and contaminated stretches of land outside these areas will, if ever, only have to be

expected in very few places and will have a considerably lower level of contamination.

Evaluation of Existing Documentation

The existing documentation, especially for the suspected areas, was obtained from the authorities, companies and other institutions of the former East Germany and was evaluated with regard to the information that was relevant for the project's objective. The result was that approx. 4800 mining-related objects, of which an approx. 4000 were heaps, were registered; their data (coordinates, size a.o.) were collected in the specially created data bank as far as they were available. The registered objects covered an estimated total area of approx. 60 km and the areas with abnormal gamma radiation levels one of approx. 170 km.

The radiological assessment in this project stage led to the result that for the areas outside the objects there were no indications of any mining-related and thus also of no radiologically relevant contaminations, so that these areas could therefore be assumed to be not radiologically contaminated.

Verification

During the following project stage, which was mainly carried out in 1993, the registered objects in the suspected areas were inspected on site, and scoping measurements of the local dose rate of the gamma radiation were performed on these objects and their immediate surroundings ("verification"). The verification phase yielded the following results:

- detailed and up-to-date data about all suspected sites and objects,
- details about the situation and the size of the areas and objects,
- a supplementation of the data bank by additional objects that had not been registered by the historical search,
- comprehensive photographic documentation for all investigated sites
- site-specific results of the radiological control measurements, and
- indications to further objects outside the suspected areas, which are included in the further investigation if they prove to be relevant, e.g. due to geological conditions.

The data bank entries were corrected and supplemented if required. A total of 5352 objects within the suspected areas were investigated with a total area of about 38 km.

Radiological assessment was carried out on the basis of criteria that were derived from SSK-principles and recommendations (3). The verification results as well as the kind, scope and application of the criteria derived from the verification for the radiological assessment of the contaminated sites are explained in another paper (4).

The results of the project stage are handed over to the governments of the affected federal states in the form of the ALASKA data bank whose data and user program have been brought up to date; it is explained to the authorities and comes complete with digitalized maps, with the objects and abnormality areas marked on them, and a summary report. After that, district administrations will be given the material as well as advice and guidance. Information brochures were produced for the general public.

Measurement Programs

After the large group of objects, which as a result of the verification have been classified as "not radiologically relevant", has been excluded, the remaining objects are investigated by considering the local relevance that has been allocated by the regional administrative bodies. The horizontal and vertical expansion of the contaminated areas is defined exactly in detailed measurement programs ("basic measurement programs"); the kind, concentration and inventory of radioactive materials is determined and the influence of the radiation exposure on these areas and their environment is estimated in order to achieve a precise radiological classification of the objects for an assessment of the problem by the Federal Government as well as for a basis for decision-making for state, regional and local governments and for other land owners. These investigations have been going on since 1993. The programs rest on the experience gathered during three previous pilot projects that were carried out at representative contaminated sites. Measurement programs of this kind were already finished in the areas Aue/Hakenkrmme, Freital/Gittersee, Dittrichshtte, Hettstedt and Gottesberg/Schneckenstein and are still going on near Annaberg-Buchholz and Johanngeorgstadt (Fig. 3). Further programs are being prepared. All relevant sites are to be analyzed and assessed by

1996/97. All measurement data are put into the ALASKA data bank.
Fig. 3.
On the basis of the already mentioned recommendations an assessment scheme was developed which helps defining the objects and areas that have to be considered as "radioactive contaminated". It follows from the results of the measurement programs that only a small part of the investigated areas actually has to be regarded as radioactive contaminated. Remediation measures for these partial areas will have to be initiated for reasons of radiation protection if the result of a site-specific investigation shows that this object, in its current state and under consideration of its actual use, causes an annual radiation exposure of more than 1 mSv. For the estimation of the exposure the BfS has drawn up the calculation basis with generic parameters which comply with the specific character of the problem through adaptation to official guidelines.
In the course of the investigations some limited areas were detected that had considerably high contamination levels (e.g. local gamma dose rate 1 mSv/h and higher) so that immediate measures must be considered. In such cases the state authority responsible for the implementation of radiation protection measures is informed immediately.
SUMMARY AND OUTLOOK
In the starting phase of the project "Radiological Registration, Investigation and Assessment of Contaminated Sites from Past Mining Activities (Register of Contaminated Sites)" decisive progress could be made in the estimation of the radiological situation in the uranium ore and other mining areas. After a historical investigation the existing data were initially checked as to their correctness and completeness in a verification phase by means of on-site investigations carried out by local firms. This was done in order to put the investigation need in defined terms. In a parallel step, an examination of the available information is carried out in cooperation with the state environment ministries and the local decision-making bodies. However, this state of knowledge does not suffice to determine the actual need for ecological reconstruction of the areas and sites of former uranium ore and other past mining activities. For preventive public health protection reasons and in order to support the economic development in the regions concerned, site-specific measurement programs were carried out.
On the basis of these measurement programs, recommendations founded on radiological evaluations will be given with regard to the need for ecological restoration of the investigated areas and objects.

ABANDONED URANIUM MINE RECLAMATION FOR DOE URANIUM LEASE MANAGEMENT PROGRAM
Edward T. Cotter
Rust Geotech*
U.S. Department of Energy
Grand Junction Projects Office
Grand Junction, Colorado
ABSTRACT
The U.S. Department of Energy Grand Junction Projects Office has developed a process for the reclamation of abandoned uranium mine sites located on lands under its administrative jurisdiction. This process allows mine sites to be reclaimed in a cost-effective manner while maintaining a practicable approach to the presence and cleanup of naturally occurring radioactive materials resulting from past mining activities.

OVERVIEW

The U.S. Department of Energy (DOE) Grand Junction Projects Office (GJPO) currently administers 43 uranium lease tracts located in southwestern Colorado (38), southeastern Utah (4), and northern New Mexico (1) consisting of approximately 10,000 hectares of land (see Fig. 1). These lands were withdrawn from the public domain, from 1948 until 1954, by the U.S. Atomic Energy Commission (predecessor agency to the DOE) to develop a source of domestic uranium ores for defense purposes. Subsequent to withdrawal, these lands were included in the Uranium Leasing Program. All of the mines were abandoned and many of the mine portals were temporarily closed when the Uranium Leasing Program ended in 1962. However, little else was done to reclaim the environmental disturbances resulting from the mining activities that occurred during this initial leasing period. As part of the present leasing program, DOE-GJPO adopted a policy for the reclamation of these undesirable environmental conditions.

RECLAMATION PROCESS

DOE-GJPO developed a process for the reclamation of abandoned uranium mines located on lands under its administrative jurisdiction. DOE's primary concerns for the reclamation of abandoned uranium mine sites are

To eliminate all physical safety hazards that have resulted from previous mining activities, including all mine openings and portals and all surface depressions that contain severe vertical drops of more than 1 meter.

To recontour the areas of disturbance to blend in with the natural topography surrounding the site while allowing as much vegetation regrowth to survive, as practicable.

To redirect all storm water away from the immediate areas where mine openings have been closed to eliminate the possibility of water flow and erosion into the mine workings and to contain and control all storm water that contacts the site.

To reduce the potential for the general public's exposure to radiological materials, as much as practicable.

ELIMINATE ALL PHYSICAL SAFETY HAZARDS

DOE-GJPO will use methods approved by the U.S. Bureau of Land Management (BLM) for permanent closure of all mine openings and portals (shafts, adits, inclines, and vent holes). These methods include man-made bulkheads or backfilling with rock (waste-dump materials) from the mine site. Selective placement of material within the mine opening and portals, according to size, will enhance slope stability and preclude future sloughing of the materials after closure is completed. After closure, all depressions surrounding or immediately adjacent to the mine openings and portals and all shallow open pits with severe vertical drops will be backfilled with additional waste-dump materials located at the site and then will be slightly mounded to preclude future subsidence.

RECONTOUR AREAS OF DISTURBANCE

After the mine openings and portals are successfully and permanently closed, all areas of disturbance will be recontoured to blend in with the natural topography, as practicable. This recontouring includes

Reducing the slopes of the remaining waste-dump materials to less than a 3 to 1 ratio, while providing a basin effect on the top of the waste-dump materials to collect and contain all storm waters that contact the site.

Removing waste-dump materials from the existing natural drainages, as practicable, and eliminating the potential for these materials to enter the drainages in the future.

Recontouring the immediate areas to provide an undulating surface that closely represents the natural surrounding topography.

Any area of disturbance that has revegetated naturally during the past several decades will not be redisturbed unless physical hazards exist that must be addressed. In either case, as much of the existing vegetation regrowth will be left (as practicable) during the reclamation efforts. Any topsoil that was previously stockpiled on the site or is in the immediate vicinity of the site will be spread across the disturbed areas to promote revegetation. If topsoil has not been previously stockpiled or is not available within the disturbed area, it will not be mined at another location and hauled in. A second area of disturbance will not be created to enhance the reclamation efforts or success of the initial area. All disturbed areas will then be reseeded with a BLM-approved mixture of native grasses and shrubs developed for the specific climatic conditions.

REDIRECT ALL STORM WATER

Several efforts will be undertaken to control the effects that storm waters have on the abandoned mine site. First, all mine entrance locations will be backfilled sufficiently to provide positive drainage away from the entrance area. Second, the waste-dump materials will be recontoured to create a basin on top of the waste-dump materials that will collect and contain all storm waters that come in contact with it. The basin will be constructed to create minibasins within the major basin feature to promote individual collection points that could enhance the revegetation efforts. Storm waters collected in the basins will be allowed to evaporate from or percolate through the basin. Third, all major drainage features leading onto the mine site will be diverted around the site or stabilized in place to reduce the overall effects that major storm-water events could have on the reclamation efforts and the abandoned site in general. The last step will be to place silt fences or other suitable devices within and across the drainages leaving the mine site to preclude the transport of sediments from the site to downstream locations.

REDUCE POTENTIAL EXPOSURE TO RADIOACTIVE MATERIALS

All abandoned uranium mines have naturally occurring radioactive materials (NORM) associated with them in the form of 1) low-grade materials that are uneconomic to transport and mill or 2) residual ore-stockpile materials. Outcrops of uranium-bearing formations often exist at the mine sites and represent the initial uranium discoveries that led to the mines' development. These radioactive materials are a potential source of radiation exposure to the general public and the environment. However, it is often cost prohibitive, if not entirely impossible, to eliminate these NORM sources from the environment.

It is DOE's policy to minimize the potential exposure to the general public resulting from mining-related radioactive materials. During reclamation activities on DOE lease tracts, the following measures will be taken to reduce or limit the potential for exposure to NORM:

A cursory radiological scan of the entire mine site will be conducted during the preliminary reclamation activities to identify those areas of greatest radiological concern.

All materials within the areas of greatest radiological concern will be used for the initial backfill of the existing mine openings and portals to place these radioactive materials below ground surface, leaving less-radioactive materials exposed at the ground surface.

Additional scans will be conducted during the entire reclamation process to locate other areas of radiological concern for control or burial. After final recontouring is completed, the potential exposure from these areas of radiological concern will be further minimized by covering the disturbed areas with any immediately available topsoil.

STAKEHOLDER INVOLVEMENT

Numerous Federal and State agencies are designated as potential stakeholders in the reclamation of the abandoned uranium mine sites located on the DOE lease tracts:

U.S. Department of InteriorBLM
- Colorado State Office, Denver, Colorado
- Grand Junction District Office, Grand Junction, Colorado
- Uncompahgre Basin Resource Area Office, Montrose, Colorado
- San Juan Resource Area Office, Durango, Colorado
- San Juan Resource Area Office, Monticello, Utah

U.S. Department of InteriorBureau of Mines, Denver, Colorado

U.S. Department of InteriorNational Park Service (NPS); Mining and Minerals Branch, Denver, Colorado

U.S. Department of AgricultureForest Service (USFS)
- Manti-La Sal National Forest, Price, Utah
- Manti-La Sal National Forest; Monticello District Office, Monticello, Utah

U.S. Environmental Protection Agency (USEPA)
- Radiation Studies Division; Radiation Studies Branch, Washington, DC
- Region 6, Dallas, Texas
- Region 8, Radiation Programs Branch, Denver, Colorado
- Region 9, Radiation Programs Branch, San Francisco, California

Colorado Department of Public Health and Environment; Radiation Control Division

Colorado Department of Natural Resources; Division of Minerals and Geology

New Mexico Environment Department

New Mexico Energy, Minerals, and Natural Resources Department; Mining and Minerals Division; Mining Act Reclamation Bureau
Utah Department of Environmental Quality; Division of Radiation Control
Utah Department of Natural Resources; Division of Oil, Gas, and Mining
Wyoming Department of Environmental Quality

A copy of DOE's proposed reclamation process was transmitted to each agency, along with a solicitation for review comments. To date, comments have been received from five agencies:

Wyoming Department of Environmental Quality
Colorado Department of Public Health and Environment
New Mexico Environment Department
BLM, Grand Junction Resource Area Office
USEPA, Radiation Studies Branch

The majority of comments received focus on two subjects: 1) endorsement of DOE's intentions and the general aspects of the proposed process and 2) the continuing concern for adequate protection of the general public and the environment from the effects of residual radioactive materials at the mine sites.

FIELD IMPLEMENTATION AND REVIEW

DOE recently completed reclamation activities on the first phase of abandoned mines to be reclaimed by this process. These activities include work at multiple shallow subsurface mine sites (less than 30 meters below ground surface) and shallow surface mine sites (less than 6 meters deep) on four lease tracts located in southwestern Colorado near the communities of Slick Rock (C-SR-14A, C-SR-16, and C-SR-16A) and Uravan (C-CM-24).

The lease tracts are accessed by Colorado State Highway 141 and several county roads. The regional topography consists of relatively flat-lying mesas that are broken up by the canyon features of the Dolores and San Miguel Rivers and their respective tributaries. The region is primarily vegetated with stands of pinyon pine and Utah juniper intermixed with open grass- and sagebrush-covered parks. The region has an arid climate with an annual precipitation of 30 to 40 centimeters. The primary land use in the lease-tract areas historically has been mining and grazing, although some dryland agricultural crops are grown adjacent to Lease Tracts C-SR-16 and C-SR-16A. Hunting is the only recreational use of these lands. The mine sites within the lease tracts are located at elevations between 1,700 and 2,200 meters above mean sea level. The uranium-bearing formation of interest in the region is the Salt Wash Member of the Morrison Formation. By the very nature of the geologic, hydrologic, and climatic conditions of the region, none of the mines associated with these lease tracts encountered groundwater; consequently, groundwater was not an issue in the reclamation of these mine sites.

The mine sites on Lease Tracts C-SR-14A and C-SR-16A were all similar because the ore horizon or zone of mineralization was shallow, if not exposed at the surface, and was first accessed by open pits. This near-surface occurrence of ore led to extensive surface workings. Later, as the ore-bearing formation dipped further below grade, adits leading from the bottom of the open pits were used to mine the ore. The overburden material and associated mine waste were scattered throughout the different mine sitessome in large dumps, others in small piles from single ore carts. The permanent closure of these mines and the subsequent recontouring activities were achieved with conventional construction equipment (front-end loaders, backhoes, and bulldozers). Mine sites with underground workings were left slightly mounded to prevent storm water from eroding into the underground workings. The shallow open pit areas were left slightly bowled to contain and control storm water.

Several of the mine sites on Lease Tract C-SR-16 were also similar because the ore horizon or zone of mineralization at each site was entirely below grade and was accessed by shallow, gently sloping inclines. These mine sites had mine-specific waste dumps. Two of the mine sites were somewhat unique because they had ventilation shafts. The permanent closure of these mines (including the ventilation shafts) and the subsequent recontouring activities were achieved relatively simply with conventional construction equipment. These mine sites were left slightly mounded to prevent storm water from eroding into the underground workings.

One mine site on Lease Tract C-SR-16 was distinctly unique from all of the other mine sites because it is located along and under the rim of Summit Canyon. This mine site consisted of eight adits located approximately 8 meters below the canyon rim.

During past mining operations, the mine waste materials were deposited along the outer edge of the mine-site access road that traversed along the south slope of the canyon to the different mine adits. The large boulders found above and adjacent to the mine portals along the canyon rim were considered to be extremely unstable, and worker safety became the primary concern during the reclamation of this site. These unstable conditions prompted the use of explosives to close the portals. Vertical holes were drilled along the rim above the portals, and angle holes were drilled into the adit walls from an area directly in front of the respective adits. The holes were then loaded with explosives and detonated. This method was successful at seven of the eight adits. However, the operation had to be repeated for successful closure of the eighth and largest adit. The entire rim area was then recontoured with materials that were available along the surface of the rim. A berm was constructed above and along the rim to divert all storm water away from the reclaimed area. The mine waste dumps were left intact to act as a berm along the canyon wall to control storm-water runoff and limit further erosion of this material into the canyon.

The mine site on Lease Tract C-CM-24 had two unique featuresit was the oldest of the abandoned mine sites reclaimed, and the ore horizon or zone of mineralization was at considerable depth. Mine access consisted of a small, but relatively steep incline that had been closed previously but was now showing signs of subsidence. The incline was permanently closed and recontoured with a conventional backhoe. To prevent storm water from eroding into the underground workings, the mine site was left slightly mounded. The rock-waste dump at this mine site contained substantial vegetation regrowth and was left untouched.

During this reclamation project, a total of 40 mine portals (adits and inclines) and three ventilation shafts were permanently closed with methods approved by the BLM and the State of Colorado (Department of Natural Resources, Division of Minerals and Geology). Approximately 38,000 cubic meters of material (mine waste, overburden, and topsoil) were backfilled into the depressions and open pits and recontoured to blend in with the surrounding topography. After the mine closures and recontouring were completed, the entire areas of disturbance (approximately 10 hectares) were reseeded with a seed mixture, approved by the BLM, that was distributed by mechanical and hand-held broadcast seeders.

Following the successful completion of reclamation activities, an invitation was issued to each of the stakeholder agencies to tour the associated lease tracts and review the results. Several agencies (listed below) participated in the on-site review of reclamation activities. Several other agencies expressed interest in reviewing the reclamation process results but stated that they would be unable to attend.

- BLM, Montrose District Office, Montrose, Colorado
- BLM, Uncompahgre Resource Area Office, Montrose, Colorado
- BLM, San Juan Resource Area Office, Durango, Colorado
- NPS, Land Resources Division, Mining and Minerals Branch, Denver, Colorado

Tour participants visited each mine site and were given a general overview of site activities. The unique situations encountered at the different sites were also discussed. Following the tour, all participants concluded that the DOE's process was practicable for the respective mine sites reclaimed.

CONCLUSION

DOE administers 43 uranium lease tracts with a land mass of 10,000 hectares that collectively contain a maximum of 200 abandoned and active uranium mine sites. In contrast, BLM, USFS, and other Federal and State agencies administer millions of hectares with a multitude of similar uranium mine sites. Currently, no regulations require the reclamation of most of the old, pre-law mine sites on Federal and State lands. However, the physical and environmental liabilities associated with these mine sites may prompt the appropriate administrative agency to address these reclamation issues. DOE believes that the aforementioned process provides a practical and cost-effective approach to abandoned uranium mine-site reclamation.

NATURAL FLUSHING STRATEGY: A RISK-BASED APPROACH TO MEETING GROUND WATER CLEANUP STANDARDS

Donald R. Metzler
U.S. DOE

Albuquerque Field Office
Uranium Mill Tailings Remedial Aciton
P.O. Box 5400
Albuquerque, NM 87185-5400
ABSTRACT
Developing and implementing a cost effective and community acceptable ground water cleanup strategy can easily become an insurmountable task. The primary challenge of any ground water cleanup program involves adequate actions that lead to protection of human health and the environment. Depending on the cleanup strategy selected, approaches that eventually lead to a cleanup goal can vary widely with regard to cost and many approaches result in little actual risk reduction.
An alternative to typical ground water cleanup approaches is "natural flushing". Natural flushing is a provision identified by the U.S. Environmental Protection Agency (EPA) for the U.S. Department of Energy's (DOE) Uranium Mill Tailings Remedial Action (UMTRA) Project. The EPA has issued final regulations to correct and prevent contamination of ground water beneath and in the vicinity of inactive uranium processing sites by uranium tailings (60 FR 2854, January 11, 1995). The regulations apply to tailings at 24 locations that qualify for remedial action under Title I of Public Law 95-604, the Uranium Mill Tailings Radiation Control Act (UMTRCA), on November 8, 1978 (42 U.S.C 7901 et seq.). They provide that tailings must be stabilized and controlled in a manner that permanently eliminates or minimizes contamination of ground water beneath stabilized tailings, so as to protect human health and the environment. They also provide for cleanup of contamination that occurred before the railings are stabilized (Fig. 1).
Fig. 1.
A hypothetical model uranium mill tailings site was created to assess the natural flushing strategy in a generic convention. The basic assumptions of the model are 1) the milling process operated for 30 years; 2) the tailings and associated contaminated materials have been relocated; 3) a significant ground water plume exists on-site and down gradient of the site; and 4) the site is located on shallow alluvial deposits that discharge to a nearby river. A rudimentary solute transport analytical model was used to predict if the site would flush to the standards within 100 years.
BACKGROUND & PURPOSE
Natural flushing can be a viable alternative in situations where water use and ecological considerations are not negatively impacted and cleanup will occur within a reasonable time. Further, institutional controls, when enforced by a local, state, or federal government entity can be relied upon for periods of time up to 100 years. Adequate safeguards are provided in the standards to prevent this alternative from being used to circumvent active cleanup of water that is foreseen to be used as drinking water by nearby populations.
Under conditions where active ground water remediation for completely achieving compliance with the standards is impracticable from an engineering perspective, environmentally damaging, or excessively costly, the natural flushing strategy is viable, if contaminated ground water can meet the standards within an acceptable time frame (less than 100 years). This strategy should be considered for sites where the attainment of the ground water cleanup standards can be met through partial or complete reliance on natural processes and no use of the ground water as a source for a public water system exists or is projected. The strategy must also consider the beneficial use of ground water, such as agricultural and industrial uses (Fig. 2).
Fig. 2.
The UMTRA regulations establish a time limit on the extension of the remedial period to limit reliance on the use of institutional controls to manage public access to contaminated ground water. The use of institutional controls is permitted for the natural flushing strategy only when the remedial period can be demonstrated to be less than 100 years. The application of institutional controls would be considered only when enforced by a permanent government entity that can be relied on for periods up to 100 years to provide adequate safeguards to nearby population centers. Natural flushing has the highest potential for success as a cleanup strategy when the contaminated ground water discharges to a surface water body that will not be adversely affected by the contamination.
NATURAL FLUSHING AS A CLEANUP STRATEGY

Using the natural flushing strategy, the hypothetical model site for the flow regime assumes the aquifer's ability to transport solutes is sufficient with respect to time to dilute the source concentrations to below an applicable standard under 40 CFR, 192.

A typical model site for natural flushing will have many or all of the following hydrogeologic attributes: 1) an alluvial depositional environment; 2) high saturated hydraulic conductivity; 3) high effective porosity; 4) matrix diffusion being a minor component to solute transport rates; and 5) the predicted plume within an area not projected for municipal water supply. The dilution phenomenon is a result of advective transport and hydrodynamic dispersion. Advective transport is the process by which solutes are transported by the bulk motion of the flowing ground water at a rate equal to the average linear velocity of the ground water. Coupled to the advective transport phenomenon is hydrodynamic dispersion. This results in the solute spreading out from the path that would be expected solely due to advection, Freeze and Cherry, (1979).

This spreading phenomenon occurs because of mechanical mixing during fluid advection and because of molecular diffusion due to the thermal-kinetic energy of the solute particles. These dilution processes and others are what natural flushing is based upon.

In addition to the processes of dilution and dispersion, geochemical attenuation processes also contribute to the efficacy of natural flushing. Chemical processes can affect the rate at which solutes are transported in the flow regime. Sorption is a well known geochemical phenomenon that includes adsorption and desorption of soluble ions to receptor sites on the surface or between layers of certain fine-grained aquifer matrices. Generally, ion exchange between soluble ions in a uranium mill tailings contaminated aquifer and the aquifer matrices is primarily limited to cation exchange.

There is no universal accepted theory of solute transport that encompasses all of the above phenomena of transport processes that can be used to predict the time rate of change in concentrations (natural flushing) of a contaminated aquifer. But, under certain assumptions, the three-dimensional, unsteady-state, homogeneous, aniotropic, mass transport equation using constant, uniform velocity and dispersion coefficients of a miscible contaminant subject to sorption, first order decay and injection sources R.W. Cleary, (1992) may be expressed in the cartesian coordinate system as: Eq. (1)

In summary, to mathematically derive the solute transport phenomenons for a given flow regime is very complex and almost always has to be represented by averages or ranges, acknowledging some degree of uncertainty. Therefore only basic mathematical assumptions and the construction of a simple analytical mass transport model is used to illustrate natural flushing at a hypothetical uranium mill railings site. In recent years much work has been done on the theories of mass transport in response to the great interest in problems of ground water contamination. One of the outcomes of this has been the development of what is essentially a new branch of subsurface hydrology, where the flow of fluid and solutes is treated by statistical models that can account for the role of varying hydraulic conductivity that accompanies aquifer heterogeneity Fetter, (1992).

As a preliminary evaluation, the analysis of the hypothetical model does not account for aquifer heterogeneity. It must be noted that this phenomena can significantly affect solute transport predictions.

ANALYSIS OF A MODEL SITE: IS IT A CANDIDATE FOR NATURAL FLUSHING?

In order to apply the natural flushing strategy to a given contaminated site, the flow regime should be well understood with regard to solute transport. The most direct and simple way to illustrate the effects of advection, dispersion, first order decay and sorption is through a one-dimensional mass transport analyses in which the results are plotted as breakthrough curves. Breakthrough curves typically plot normalized concentration (C'/Co, where Co is the maximum concentration) vs. aquifer pore fluids. The pore fluids may refer to a laboratory column or an aquifer. For the purposes of this illustration, consider saturated aquifer conditions in which constituents of concern have leaked into the groundwater from the milling and tailings seepage that occurred over a thirty year period.

To illustrate the application of the natural flushing strategy to a model site, a hypothetical uranium mill tailings processing site is described. To typify the model site as representing a Title I UMTRA processing site, common site conditions and

attributes are described. Conditions and parameters described in the generic model are similar to seven UMTRA sites. This screening tool is directly applicable to most of the UMTRA sites targeted for natural flushing. The tailings and other materials such as wind-blown and waterborne tailings, and contaminated soils have been removed and relocated to an engineered disposal cell. This eliminates the most significant source for continued ground water contamination. In addition, relocating the source-term eliminates any potential for transient drainage effects. Some finite amount of transient drainage will occur under unsteady state conditions at some UMTRA sites where the tailings have been encapsulated in-place or on-site. Often times the tailings exist in highly-saturated conditions. Transient effects are the direct result of seepage out the bottom of the cell and consolidation due to loading.

The seepage velocity during the operation of the mill was assumed to be substantial over the life of the operation. The tailings have been removed and the contaminated soils in the unsaturated zone below the footprint of the former tailings pile have also been removed to the water table or assumed not to be a significant secondary source-term contributor.

At the model site, tailings were placed on unconsolidated alluvial deposits and were exposed to the environment for 30 years. The alluvium is 25 meters thick and overlies bedrock characterized as an aquitard. For the purpose of this illustration, the alluvial system is assumed to be homogenous and isotropic. However, in real flow regimes this assumption can lead to erroneous predictions. The unsaturated zone is relatively insignificant, as the thickness is less than 1.5 meters and the wet tailings most likely created a ground water mound beneath the footprint.

The historical seepage that has exfiltrated out of the hypothetical tailings pile can be estimated based on a water budget for the model site and can be expressed as the following generic expression:

Qin = Qout + Qret,

where;

Q in is the amount of water from the processing activities and tailings, plus precipitation that has deep percolated over 30 years

= 9.1 x 105 m3;

Qout is the seepage that has exfiltrated out the bottom of the tailings pile over 30 years

= 8.9 x 105 m3;

Q ret is the volume of water retained in the tailings under gravitational forces

= 1.8 x 104 m3.

The Qin is the cumulative contribution from milling effluent and deep percolation as a result of precipitation. The total volume of milling water discharged with the tailings was approximately 4.6 x 105 m3. Average annual precipitation is 30 centimeters per year. Only 10 percent of the precipitation deep percolates. The area of the tailings pile is 50 hectares. The volume of precipitation that has deep percolated through the tailings footprint over 30 years equals 4.5 x 105 m3 The total volume of dry tailings equals 1.2 x 106 m3. The void space of the tailings equals 40%. The total volume of pore water in the railings, assuming 100% saturation and neglecting evaporation and any transpiration equals 4.6 x 105 m3. On the basis on published data, the amount of water retained beyond the pull of gravity, (Qret) if the saturated tailings pores is estimated to be 40% by volume based on grain size of the tailings. After the milling process had ended, it is estimated that 60% of the pore water can be expected to drain out, leaving 40% as (Qret), which equals 1.8 x 104 m3. The historical seepage discharge (Qout) over the 30 year period equals 8.9 x 105 m3.

The cross-sectional area through which the historical seepage discharge has occurred at the model site can be approximated by the following generic calculation:

A = Qout/[Kh x (H/L)], where;

Qout = past seepage discharge over 30 years = 8.9 x 105 m3

(3 x 104 m3/yr)divided by the horizontal saturated hydraulic conductivity Kh

(1.67 x104 m/yr) times the horizontal hydraulic gradient H/L = 0.0025

A = 7.1 x 102 m2.

If this cross-sectional area includes the entire 25 meter thick saturated zone and if the area is rectangular in shape, the width will be approximately 28 meters. The seepage flux was estimated to be 3.0 x 104 m3/year, which would produce a volume of seepage discharge of 8.9 x 105 m3 over 30 years. Assuming the model site's uppermost

aquifer has an effective porosity (Ne)of 20 percent (based on core analysis), and the seepage discharge travels with the natural ground water average linear velocity (209 m/yr), neglecting dispersion and retardation, the volume of contaminated aquifer at 30 years would be 8.8 x 105 m3. The latter value is equivalent to one aquifer pore volume. This is without regard to concentrations, assumes no mixing and a non-reactive contaminant.

To estimate how long it would take to flush one pore volume of contaminated aquifer, the following generic equation can be used for the model site:

Tpv = Vn/Q, where:

Tpv = time to flush one pore volume;

Vn = volume of contaminated aquifer and n is effective porosity

Q = Darcian strip discharge = cross sectional area at discharge point times hydraulic conductivity times horizontal gradient divided by effective porosity.

Tpv = 6.2 years* to flush one contaminated aquifer pore volume. * based on advection only

Advection is mathematically described by the following term: (V). Advection involves transport by bulk movement and is the primary mechanism responsible for contaminant migration in aquifers. The average linear velocity (Vs) of the slug of contaminants is the (horizontal hydraulic conductivity) 16,680 m/yr (45 m/day) times (horizontal hydraulic gradient) 0.0025 divided by (effective porosity) 0.20. If no longitudinal dispersion occurs, the seepage water would move downgradient at an average linear velocity (Vs) of 209 m/yr.

Dispersivity (aL) is the phenomenon of contaminants spreading out and attenuating in concentration due to molecular diffusion and stratification at the microscopic and macroscopic levels R.W. Cleary, (1992). At the microscopic level there is a distribution of velocities in the pore spaces due to frictional resistance caused by the solid surfaces of the porous material. At the macroscopic level there are large-scale heterogeneities which usually are the primary cause of contaminant spreading. Chemical species may also move from higher to lower areas of concentration within and between pore spaces due to molecular diffusion. Neglecting molecular diffusion, based on negligible effects due to relatively fast moving flow systems, the dispersion coefficient is a linear function of the average linear velocity. Dispersion values in porous media is currently under much research.

Longitudinal coefficient of dispersion (Dxx)can be expressed as:

Dxx = aLV, where aL= 0.1X

This is known as the one-tenth rule by some researchers, Lallemand-Barres and Peaudecerf, (1978). They were the first to study published values of dispersivities as a function of the distance traveled. The distance variable (X)could be measured from the source release i.e., railings pile and an observation well. Thus, dispersivity is a function that is related to scale and other considerations. For example, the greater the distance over which dispersivity is measured, the larger the value becomes. However, to conserve mass for an analytical solution, a deterministic dispersivity is selected for the model site. The dispersivity is chosen to be 10 m. The longitudinal dispersion coefficient (aLV) for the model site is 2090 m2/yr.

Many abiotic and biodegradable and radioactive reactions decay according to first order kinetics given by the following expression:

dC/dt = -KC

where K is the first order decay constant. It is equal to 0.693/T, where T is the half-life of the contaminant. Natural uranium with a half-life of 4.5 billion years is the mobile radioactive contaminant of most concern at uranium mill tailing sites. With such a long half-life, first decay reactions are considered insignificant to the other mass transport processes. For the model site, decay reactions are not accounted for.

Sorption (to account for adsorption and absorption) is the partitioning of a chemical species between the liquid and solid phase. The result of this partitioning from a modeling viewpoint is a phenomenon called retardation in which the effective velocity of the chemical species is less than that of the uncontaminated ground water. Retardation is characterized by a parameter called the retardation factor. Under equilibrium conditions a sorbing solute will partition itself between the liquid and the solid phases according to the value of Rf. The fraction of the total

contaminant mass contained in the aquifer which is dissolved in the solution phase can be calculated from the following expression:

Fd = 1/Rf

The "distribution coefficient" (Kd) is a laboratory determination of the amount of solute left on a soil sample after it has been mixed and allowed to reach equilibrium with the soil. It can be expressed by the following relationship:

Kd = C'/Co, where

C' = mass of solute per unit volume of dry bulk solid

Co = mass of solute per unit volume of liquid

Linear equilibrium adsorption isotherms are commonly used to describe the sorption of contaminants on the solid phase surfaces. The common unit for Kd is ml/g. If Kd for a given contaminant species equals zero, there is no sorption occurring. This is the case for some common contaminants related to uranium mill tailings. Contaminant species such as sulfate and nitrate are both anionic solute species that generally have a very low Kd and is the reason why these analytes are considered good indicator parameters or ground water tracers because they are transported at the same average linear velocity as the ground water. Note, biodegradation processes due to microbial reduction can be a significant process affecting concentrations of nitrate and sulfate.

If the distribution coefficient has been determined, (this can be done through laboratory batch leach experiments for each constituent of concern) and, the bulk density and effective porosity have been calculated, the retardation factor for saturated conditions can be expressed by the following equation:

Rf = (1 + Kd rb /ne),

where:

Rf = retardation factor;

Kd = distribution coefficient; varies with contaminant

rb = dry bulk density = 1.6 g/cc;

ne = effective porosity = .20.

For the model site, the bulk density was calculated by laboratory analysis. The bulk density equals 1.6 grams/cm3. The effective porosity was taken from the literature and is equal to 20 percent. For a non-sorbing species such as nitrate, Rf equals 1.0 while a sorbing species such as radium will have an Rf greater than 1.0. The solute (ion) velocity (V*) can be calculated by the following expression:

V* = V/Rf,

where:

V = the seepage velocity or average linear velocity.

For the model site, a list of common contaminants associated with uranium mill tailings has been developed. Associated with each contaminant is a Kd. If the contaminants have an EPA Maximum Concentration Limit (MCL), then it is listed, if not, the statistical background concentration must be determined.

TABLE I

Choosing a one-dimensional analytical transport solution for the conceptual model involved finding a solution for a point source. Because the tailings, in near saturated conditions, leaked contaminants into the ground water for 30 years, and then were subsequently removed, a continuous source solution would not be appropriate. A contaminant transport equation from Domemico & Schwartz, (1990) was used to estimate the time it would take to dilute to the MCL (for a given contaminant) at the centroid of the plume.

The equation does not account for retardation and therefore is very conservative.

Eq. (2)

t = time in years

Co = original concentration in mg/l

Vo = original volume in meters3

Co x Vo = mass of the discharge

Dxyz = coefficient of hydrodynamic dispersion in meters2 per year

Cmax = MCL for the contaminant

With this equation, an idealized three-dimensional point source spill, spreading occurs in the direction of flow, and the maximum concentrations occurs at the center of the "cloud," that is, where Dy = Dz, and is an order of magnitude smaller than Dx. Going to the contaminant list table and choosing uranium as the contaminant of concern and substituting into the equation results in an estimate of approximately 40 years for the aquifer to flush to the MCL for uranium at the centroid of the

plume. Note that this estimate does not account for retardation. Trying another contaminant for testing the potential for the model site to naturally flush to the standards within 100 years, nitrate is chosen. Plugging nitrate, which has a non-reactive retardation factor of 1, into the equation results in approximately 48 years for the model site to flush to the MCL.
For Uranium:
Eq. (3)
For Nitrate:
Eq. (4)
CONCLUSIONS FOR SELECTING NATURAL FLUSHING AS A GROUND WATER COMPLIANCE STRATEGY
The hydrogeologic attributes of the model site make it a strong candidate for natural flushing. However, this analytical exercise is only a screening tool for selecting a candidate site. Should other screening techniques also support the selection of natural flushing, detailed characterization, monitoring, and numerical modeling must be implemented.
Detailed characterization should be extensive enough to understand the gross system heterogeneities. Following the placement of a monitoring-well network, a period of "calibration monitoring" would establish a better understanding of the dynamic system with regards to seasonal variations. The number of monitor wells in the network should be minimized, yet provide sufficient coverage to delineate the areal and vertical extent of plume, and understand aquifer parameters and boundary conditions. A three year period of "calibration monitoring" might be sufficiently long to predict that the model site continue as a candidate for natural flushing. During the period of detailed characterization and monitoring a numerical simulation of flow and solute transport would be necessary to more accurately understand aquifer conditions and flushing predictions. Because the system uncertainties will never be reduced to zero, geostatistics should be incorporated into the modeling task. The results of the modeling would be most likely be presented as probabilities rather than as deterministic values.
At this point, a remedial action plan can be submitted to the regulatory agencies for review. Assuming the site has no technical deficiencies in support of the natural flushing strategy and the regulators and public agree with the compliance approach and institutional controls, a period of verification and compliance monitoring will be required. Most scientists and regulators agree that ground water models cannot be validated. Therefore, modeling results by themselves usually are not a sufficient demonstration that the site will flush as predicted and long-term compliance monitoring will most likely be required by the regulators.
Compliance monitoring needs to be optimized to account for areal and vertical coverage of the contaminated zone for the constituents of concern. A network of wells set on a grid coupled with quarterly sampling for a full suite of analytes is not an optimized compliance monitoring program. In such a case, it might be more cost effective to actively remediate the plume with an engineered remedial strategy. However, if the optimized compliance monitoring program provides adequate coverage with a minimal of wells, and the sampling frequency and duration is reasonable, coupled with a condensed list of contaminants to be sampled (based on risk), then natural flushing becomes a viable and cost effective strategy.
The DOE UMTRA Project has targeted seven sites for natural flushing. Detailed characterization is beginning at some of the sites along with initial modeling for screening purposes. The DOE continues an aggressive public outreach program for the UMTRA Ground Water Project to explain the pros and cons of natural flushing and the other ground water compliance strategies to the involved stakeholders.

EVALUATING THE ACCEPTABILITY OF SOIL TREATMENT METHODS IN THE DEPARTMENT OF ENERGY'S FORMERLY UTILIZED SITES REMEDIAL ACTION PROGRAM: A STAKEHOLDER ANALYSIS*

David L. Feldman
Larry Miller
Martha E. Castle
University of Tennessee

ABSTRACT

Can radiologically contaminated sites be treated to permit unrestricted public use? Can treatment methods satisfy the concerns of federal and state regulators who must ensure that residual radioactivity is low enough to permit site access and beneficial reuse of de-contaminated soil? Are these methods potentially harmful to cleanup workers or the public? And, if so, can they be made acceptable to people who live, work, or own property near these sites? This article examines the acceptability to stakeholders of two sets of options for treating contaminated soils in the U. S. Department of Energy's Formerly Utilized Sites Remedial Action Program (FUSRAP): immobilization techniques designed to prevent the further migration of contaminants, and volume reduction methods that reduce the amount of contaminated material for disposal. These selected options, originally developed for treating hazardous waste, recovery of heavy metals in the mining industry, or treating low-level radioactive waste, are potentially effective for treating radionuclide-contaminated sites. Treatment method vendors, cleanup contractors, federal and state regulators and other recognized experts--stakeholders affected by treatment--were interviewed on the technological maturity, public and regulatory acceptability, and environmental and public health impacts of these options.

BACKGROUND

FUSRAP sites comprise a diverse array of government- or privately-owned sites in the continental U. S., most of which were used by two of DOE's predecessors, the Manhattan Engineer District (1942-1946) and the Atomic Energy Commission (1946-1973), for processing uranium and thorium ores and storing radiological concentrates and residues. Activities at these sites contaminated equipment, buildings and soils with Uranium-238 or Thorium-232 and by-products of their decay (radon and thoron). Many sites are located in densely populated areas where the public is concerned that wind and rain threaten them with exposure to contaminants through inhalation or ingestion. In some instances, contractors have used contaminated soils in roadbeds or building foundations.

Congress initiated FUSRAP in 1974 to decontaminate and restore these and other sites to a condition suitable for human use. FUSRAP's objectives are to clean up sites by undertaking actions that reduce radiation exposure to the public. This is usually done by excavating and disposing contaminated material and certifying sites acceptable for unrestricted public use. Cleanup has been undertaken at nearly 400 sites. FUSRAP now encompasses 46 sites in 14 states.

Interim Storage, Disposal, and Transport

At sites with large volumes of excavated material, the most common management method for contaminated soils is interim storage. Interim storage facilities consist of large, compacted soil piles covered by fabric or plastic membranes (covers) secured at the sides. These piles may have separate cells for certain contaminants (e.g., radium) and they are monitored by health physicists (1). Historically, storage facilities have been susceptible to stormwater runoff and wind erosion, leading to the contamination of vicinity properties. Moreover, plastic membrane liners wear with age, can become damaged by severe weather, or act as shear planes during seismic events (2). In most instances, they fail to meet CERCLA and NEPA requirements.

Offsite disposal of contaminated soils is also problematic. It may be impractical due to the large volume of contaminated material involved. Moreover, while contaminated soils could be disposed of in Low-level Waste compact disposal facilities, no new disposal sites have been opened and considerable uncertainties surround the disposal capacity of new facilities and their availability (3). Offsite disposal may also pose transportation risks to worker and public health and the environment. Truck or train accidents can rupture barrels of contaminated soil, exposing drivers and the public to radionuclides. Spilled soils may wash off roads or railroad tracks and enter creeks or other waterways. Moreover, some chemical treatment techniques for contaminated soils require shipping acids and solvents to

contaminated sites. Spills of these materials may be hazardous to workers and the public. The risks of transporting contaminated soils vary depending on the distance of a disposal facility from a FUSRAP site and the number of shipments required (4). In short, problems with offsite disposal and interim storage have led to efforts to develop treatment methods which can decontaminate or limit the spread of site contamination, save money, and permit reuse of sites and soils.

FUSRAP TREATMENT METHODS: OVERVIEW

Volume reduction methods under investigation for FUSRAP include physical separation, soil washing and solvent flushing (removing contaminants by chemicals). These methods have as their objective the beneficial re-use of treated material through the physical removal of contaminants by water, surfactants or chelating agents (catalytic chemicals that bind contaminants with metals to make it easier to remove them from soils). They are sometimes referred to as "treat-and-put-back" approaches because the remaining residues can then be disposed on- or offsite. Bioleaching and biosorption are recently introduced volume reduction methods.

Immobilization methods include solidifying contaminated material through vitrification (a process that isolates contaminated soil in an epoxy or glass-like enclosure); dewatering (installing drains and pumps to achieve a dry environment around contaminants); grouting and other stabilization or solidification techniques that "cement" contaminants in place; chemical fixation techniques that employ heat or chemical neutralization to block further contamination of a site; bioremediation, the use of organisms to degrade organic contaminants in soil that are mixed with radionuclides; and, brickmaking (the extrusion of contaminated material into bricks).

Distinctions among all of these potential FUSRAP soil treatment methods are important because why, how, and where contaminated soils are treated partly shapes options for future site use. In addition, different methods have different impacts. Table I depicts principal treatment methods under consideration in FUSRAP. This table is a synthesis of U.S. EPA categories for treatment, other expert judgments, and our attempt to provide a coherent scheme based on radionuclide site concerns (5).

A treatment method that immobilizes contaminants within a site may have vastly different impacts upon the future use of a site than one that excavates contaminated material, treats it, and then transports the remaining residue to an offsite disposal facility. For example, an "in-situ" immobilization technique such as vitrification that effectively traps radionuclides in perpetuity might mitigate public concerns about radon gas venting through the soil and possibly threatening public health in nearby communities. However, because it literally melts the soil under the site, it might also prevent underground repair work on utilities, foreclosing site use by residential or commercial developers who desire access to water, sewer, or electrical power (6). By the same token, chemical treatments might destroy organic compounds in soil, lessening its fertility, and prohibiting its later use for farming or gardening.

Likewise, an "ex-situ" volume reduction method such as soil washing might generate large volumes of clean soil that can be used as fill dirt or ground cover. However, if there are no acceptable standards for determining how "clean" the soil must be to permit its beneficial reuse as, say, foundation fill for a housing development or highway, reuse might not be acceptable at a site intended for unrestricted public access (7). Furthermore, unless their characteristics are similar to the original waste stream, the remaining contaminants from soil washing--concentrated in volume and diluted in form--might be difficult to dispose offsite until solidified. These contaminants may pose a hazard to remediation workers responsible for treating, packaging, and shipping residues offsite.

Treatment methods also have different implications for future site use. For example, some forms of soil treatment are likely to be used in conjunction with the partial excavation and removal of FUSRAP soils (8). The idea behind partial excavation is to remove only those contaminants close to the surface, or on the exterior of buildings, that pose the greatest threat to human health. If partial excavation is combined with immobilization to ensure that remaining contaminants are stabilized, a site may then be used by the public. However, deed restrictions might be required to ensure that remaining underground contaminants remain permanently undisturbed, and to relinquish DOE from future liability if the site is improperly used by subsequent owners.

The environmental and societal impacts of treatment are site-specific. As a consequence, so too is their acceptability.
Some residents adjacent to FUSRAP sites in New Jersey, for example, contend that contaminated soil storage sites within eyesight of their homes has reduced property values, made it difficult to sell their houses, and threatened the economic stability and future development of their communities. This perception, in turn, has generated stigma--the belief that future economic opportunities may be lost because businesses will be deterred from moving to these communities out of fear they will become permanent storage sites for radioactively contaminated material (9).
The experience of other DOE remedial action programs suggests that stigma may have some effect on the willingness of local communities to accept treatment. In Richland, Washington, for example, workshops have been held with local community officials and others over the possible use of remedial action technologies to remove volatile organic compounds (VOCs) from contaminated soils at the Hanford site. These workshops reveal that the reputation and credibility of DOE as a developer of technology, as well as the desire to protect jobs and property values, affects public perceptions of these technologies' effectiveness and of the motives of cleanup technology protagonists (10).
Treatment method acceptability may also be time-dependent. For example, at the St. Louis FUSRAP site, an interim storage facility, coupled with site access restrictions, fully complies with regulations designed to protect worker and public health, if future uses of the site are restricted to transient, recreational uses. However, contemplated changes to land use could make it impossible to comply with current regulations without innovative methods of remediation. The following passage from the draft St. Louis Site Feasibility Study illustrates this dilemma:
Under current (i.e., existing use) scenarios, the St. Louis site is within the acceptable range EPA has specified for protection of human health for . . . members of the general public. . . . Under future risk scenarios (however), potential cancer risks are higher for . . . the public. . . . Accordingly, the overall objective of remedial action . . . is to eliminate or minimize the potential future health risks posed by contamination under assumed future changed use of the site (11).
Finally, a principal incentive for treatment is cost-savings. Current DOE estimates to complete remediation of FUSRAP sites project the expenditure of approximately $2.5 billion between now and 2016 for planning, environmental compliance activities, development, operation, closure of storage/disposal sites, and other activities. A 1986 projection pegged cleanup to be completed in 2001 at a cost of $700 million for disposal, while an earlier estimate pegged cleanup completion in 1995 at a cost of $300 million (12). Cleanup technology costs are difficult to accurately estimate. Most of the factors driving costs are site-specific and require field-testing in different soil types to determine if they can reduce volumes of contaminated material; halt the spread of waste material in groundwater and soil; can be used in conjunction with other methods or under different combinations of approaches (e.g., partial as opposed to total excavation); and produce concentrated hazardous waste residues that pose special management problems (13).
DETERMINING STAKEHOLDER ACCEPTABILITY: METHODOLOGY
A review of EPA, DOE national laboratory, and Nuclear Regulatory Commission reports has identified several bench-scale (experimental), pilot-scale (field-tested), and full-scale soil treatment technologies as well as salient criteria for their evaluation. A literature review also identified domestic and foreign vendors who offer treatment services. A survey was then drawn up which asked respondents to rate 5 promising volume reduction and 6 immobilization methods under consideration for radionuclide-contaminated sites. Eight criteria were used to evaluate the former while only the first six were employed for the latter (beneficial soil reuse and transportation are not factors in immobilization):
Technology maturity (e.g., ease of scale-up/demonstration experience/impact of lack of cleanup criteria).
Applicability to a range of thorium/uranium-contaminated sites.
Public acceptability.
Ability to reduce contamination or exposure to workers and nearby residents.
Likelihood of producing hazardous emissions or difficult to dispose residues.
Ability to obtain regulatory approval.
Ability to permit beneficial reuse of soils, and
Minimization of transportation risk.

A 1 to 5 scale was used for rating each method's performance on these above criteria with 1 representing the lowest appraisal of the technology and 5 the highest. Respondents also offered a wide-range of opinions on future use issues, standard-setting criteria, and worker and public impacts of treatment.
Over 100 DOE site remediation contractors in charge of cleaning up contaminated sites, vendors who develop and sell treatment methods, federal and state regulators, and other authorities were queried. Respondents were selected from participants at recent soil remediation conferences. Key individuals and organizations were identified as having expertise and interest in soil treatment issues. Care was exercised to select a broad-range of participant types (e.g., vendors, treatment contractors, federal and state regulators). Opinions on the impacts of treatment on additional stakeholders were also solicited, including residential and commercial property owners, the public, and those living along transport corridors traversed by waste material destined for offsite disposal. Comments were also provided on the importance of cleanup standard-setting criteria for hastening the broad introduction of treatment.
The survey was partly inspired by an earlier EPA study (14) which convened a small group of experts to evaluate the performance (i.e., reliability and effectiveness) and commercial potential of several technologies considered appropriate for treating radionuclide-contaminated Superfund sites. These technologies included physical separation, soil washing, chemical extraction, vitrification, land encapsulation (i.e., permanent onsite storage through capping), solidification, and mine disposal of uranium mill tailings. While that study employed a numerical rating system similar to ours to assess reliability, effectiveness, and R&D maturity, it did not encompass more recent technologies; nor did it attempt to rate public and regulatory acceptability, emissions, or residue-generation impacts of technologies. In addition it did not rate prospects for beneficial reuse or transportation risk. EPA concluded that soil washing and chemical extraction bench- and pilot-scale studies show some commercial promise but require further study and additional field testing at contaminated sites. It also recommended that priority be given to the design and performance of realistic treatability studies, including the sequential employment of multiple treatment technologies.
FINDINGS
While various in- and ex-situ soil treatment technologies show promise for cleaning up uranium and thorium contaminated sites, survey respondents contend that none is a panacea for removing or stopping the spread of contamination or for permitting beneficial re-use of sites or of cleaned soils. Moreover, none is without risk and each has shortcomings ranging from limited, inconclusive field experience to limited application to certain sites. Some may also impose potentially adverse impacts on the public, workers, and the environment (e.g., volume reduction may concentrate contamination in a less stable medium). Perhaps the most significant finding is that, despite divergent perceptions and varying "stakes" in treatment effectiveness, a general consensus emerged around these core conclusions.
Volume Reduction Findings
As shown in Table II, respondents concur that radiologically contaminated soils can be treated through volume reduction technologies. In varying degrees, these technologies can permit future use of contaminated sites and beneficial re-use of soils. Physical separation and soil washing are the treatment methods most favored by respondents for accomplishing these objectives. Vendors, remediation contractors, and regulators feel soil washing with offsite disposal is safer than soil washing with onsite disposal.
Most respondents believe the public is very concerned about decision maker assurances that contaminated soil will be removed from nearby neighborhoods and that "clean" soils can be beneficially re-used. Physical separation and soil washing with offsite disposal are viewed as most likely to accomplish these objectives. Most respondents do not favor solvent flushing due to its potentially adverse environmental and social impacts. Most also feel that bioremediation methods are still in an experimental stage of development for use at radionuclide contaminated sites. If successfully developed, however, they are likely to curry favor with the public due to the potential for greater safety over more established alternatives. While solvent flushing and bioremediation are not regarded with as much favor with regulators as with vendors or contractors, the former are unsure about the potential impacts of all methods.

Survey respondents generally feel that volume reduction methods have been concentrated at bench- and pilot-scale (i.e., demonstration stage) levels--not at full-scale levels adequate for investing confidence. While respondents have fairly high confidence in physical separation and soil washing, they are concerned about the impacts of aggressive chemical or biological methods that damage the soil matrix, leave toxic residues in their wake, fail to satisfactorily remove radionuclides, and minimize productive future site uses. Regulatory acceptability is generally tied to perceived public and worker acceptability and consensus over cleanup standards and future site use. Vendors and contractors tend to regard physical separation and soil washing as mature, adequately tested, and broadly applicable technologies.

Immobilization Findings

Immobilization technologies displaying promise, according to respondents, include site dewatering and stabilization/solidification. Dewatering's long-term effectiveness, however, is viewed more cautiously. As shown in Table III, stabilization/solidification is thought to be the safest immobilization technique due to its reliance on chemically inert means of isolating wastes (e.g., grouting contaminants in place). It is preferred over vitrification, which risks exposing workers to toxic vapors, and brickmaking, which compels workers to handle contaminated soils.

Comments by respondents suggest the need to employ conservative assumptions about contaminant solubility and mobility in any evaluation of immobilization. As a result, respondents appear unsure about the long-term effectiveness of these methods, except for sediment dewatering and contaminant fixation/stabilization. Comments also indicate concurrence among respondents over the availability of effective techniques to prevent worker and public exposure to hazardous emissions from treatment (e.g., protective clothing, adequate ventilation, toxic gas collection systems).

Vendors and contractors generally agree about the relative maturity, site applicability, and worker and public risks of dewatering and brickmaking. Both rank vitrification and bioremediation lower than other immobilization methods. However, vendors (who are closer than contractors to the technical developments in treatment) appear to have somewhat more faith in the ultimate viability of bioremediation.

Dewatering appears to be the preferred technology for immobilization. However, it is perceived to be the least effective for accomplishing long-term reduction of potential exposures, probably because--as several commenters indicated--water management practices are unlikely to remain effective for thousands of years.

Bioremediation appears to be the least favored immobilization approach. While biological methods are generally considered to be feasible treatment methods for organic contaminants, they are viewed as having limited utility for radioactive materials. Some success has been achieved through the use of bacteria for reducing or oxidizing contaminants which can obtain energy from the electronic transitions. These changes in oxidation states impact the mobility of contaminants. However, according to respondents, this characteristic of contaminants is not given enough consideration in risk assessments to make it possible to draw confident judgments.

CONCLUSIONS

There are notable differences in perceptions of public and regulatory acceptability of cleanup technologies by category of respondent. Contractors have greater confidence in the public and regulatory acceptability of vitrification than do vendors. Vendors, in turn, have greater confidence in the public and regulatory acceptability of dewatering and brickmaking. Satisfying the concerns of federal and state regulators, in almost all cases, is problematic. Regulators want proof of treatment effectiveness, prefer time-tested technologies, and are concerned about residual contamination and management of wastes generated by treatment. They are reluctant to endorse "new" or untested technologies.

Based on respondent input, overall treatment method suitability is dependent on resolution of several issues. These include: getting stakeholders to agree upon future site use; developing specific cleanup criteria appropriate to that desired use; negotiating target cleanup levels; determining the type and concentration of contaminants at a site; and adopting realistic, viable cleanup schedules. Treatment is more likely to be judged suitable if it reduces contamination to safe levels without exposing site workers to excessive risk; prevents the spread of contamination to other parts of a site or to offsite properties; complies with

federal, state, and local regulations designed to protect health and safety (especially with state regulations pertaining to land use); is easily understood by the public; and, ensures safe, final disposition of contaminated material.
Finally, according to respondents, there are many risks from treatment that must be resolved to ensure acceptability. Risks to cleanup workers during treatment include exposure to fugitive dust, toxic gases (from vitrification), chemicals, solvents, and waste residues; and the dangers associated with working near heavy machinery. Also, while treatment can satisfy property owners worried about land values, it must ensure minimal site disruption and satisfy future use aspirations. Related to this point, the ability to beneficially re-use soil, while having considerable economic advantage, requires agreement over cleanup criteria to establish "how clean is clean." Cleanup criteria affect future site use, cleanup cost, and the likelihood of 'scaling-up' a treatment method from pilot-scale to full-scale application at a given site. Agreement over cleanup standards, in turn, requires evaluation of potential doses from various pathways. The good news is that these issues are subject to negotiation within the confines of NEPA and CERCLA requirements (15).

ABSTRACT
A description is provided of a systematic approach currently being developed and deployed at the Department of Energy to obtain assurance that post-operational activities at nuclear facilities will be conducted in a safe manner. Using this approach, personnel will have available a formalized set of safety principles and associated question sets to assist them in the conducting of safety assessments and surveillance. Information gathered through this means will also be analyzed to determine if there are any generic complex-wide strengths or deficiencies associated with decommissioning activities and to which attention should be drawn.
INTRODUCTION
The U.S. Department of Energy (DOE) is committed to achieving the stated goal of cleaning up its complex and bringing all sites into compliance with applicable environmental regulations by the year 2019. Many facilities have already ceased operational activities and are in the transition to the post-operational phase of the facility life cycle. The final stages will involve, to various degrees, decontamination, dismantlement and decommissioning. Included in the complex are facilities that were designed and operated several decades ago and for which little consideration had been given at that time to the eventual need for decommissioning. The act of decommissioning a nuclear facility is a relatively recent concern, both within the DOE and in the commercial nuclear field, and only a limited set of decommissioning-specific standards and requirements have been issued. This has complicated the task of performing safety assessments and surveillance over these activities which must, nevertheless, be conducted in a manner that ensures the health and safety of the workers on the project, other site employees and the general public. In order to facilitate this, the DOE is employing a systematic approach developed specifically for use in evaluating the safety of the activities encountered while facilities are in the post-operational status. This approach is designed to provide the safety assessment personnel with a framework on which they can base their technical judgement, to assure a consistent approach to safety assessment of D&D operations and to enable the systematic collection of data during the post-operational part of a facility's life cycle.
METHODOLOGY
The approach adopted is founded on a set of decommissioning-specific safety principles from which has been derived a formalized surveillance plan and question set for use in the field. Both the principles and the surveillance plan and question set are directed predominately at facilities that could pose nuclear and/or radiological hazards. Consequently, the prime focus is on activities related to those hazards and the actions necessary to protect the health and safety of the workers and the general public from them. Protection against other types of hazards, such as chemical or construction/demolition hazards, has not been addressed in detail, except where a potential exists for these other hazards to affect the nuclear or radiological safety. However, in limiting the present approach to nuclear and radiological hazards, the importance of these other hazards to overall safety is not being ignored. In fact, experience to date indicates that non-nuclear hazards

are a leading source of accident and injury in the post-operational phase and a need exists to examine these other hazards in this specific context.

Safety Principles

The safety principles that underpin the evaluation process express both the fundamental philosophy that should guide a decommissioning operation in its entirety and the precepts applicable to the various facets of the operation. In this respect, the formulation and compilation of the principles owe much to those used by the Nuclear Installation Inspectorate branch of the Health and Safety Executive in the United Kingdom when evaluating the safety of the design, construction and operation of nuclear plants (1). The contents of a preliminary draft version of the decommissioning-specific safety principles have been described previously (2).

The safety principles can be roughly divided into two types: a group of fundamental principles and numerous groups of principles to be applied to specific areas. The fundamental principles are derived from internationally-accepted principles developed to ensure the conduct of safe operations at all times at any type of nuclear facility. Their roots lie in the recommendations of the International Commission on Radiological Protection (3), and the principles themselves address the need to keep radiation doses beneath the statutory limits and, in addition, as low as is reasonably achievable (ALARA). The fundamental principles also emphasize the importance of accident prevention and the minimization of the radiological consequences from any accident that might occur.

The fundamental principles are general in nature; translation of their intent into actual operations requires more specific direction. Thus other sets of principles were developed to address the various facets associated with decommissioning operations. These other, so-called "second tier," sets of principles have been built on the fundamental principles, taking note of relevant rules and regulations, and of associated statutory limitations. Beyond that, they are not intended to be prescriptive nor to be viewed as technical specifications. These second tier principles are presently grouped under three headings: "Safety Analysis," "Engineering Practice" and "Waste Management." The groups themselves contain several subsets to deal with certain individual subject areas. The "Safety Analysis" principles are classified according to whether they are intended to cover normal decommissioning operations or off-normal and accident conditions. The "Engineering Practice" principles are comprised of a set of basic principles that have application across the full spectrum of decommissioning engineering practice and several sets of principles that address more specialized topics (codes and standards, equipment, human factors, radiological protection, hazard analyses, etc.). The "Waste Management" principles deal mainly with the need to reduce the risk of radiation exposure and contamination during the generation, storage, handling and transport of radioactive waste. In particular, emphasis is placed on the need to minimize the quantity of waste as far as is reasonably practicable.

It is important to note that this adoption of a set of safety principles does not represent a radical breakaway from past methods of conducting safety assessments of operations at nuclear facilities. Rather, the set of principles represents a formalized statement of the criteria already in use by personnel conducting the assessments. In addition, the principles will be under continual review to ensure that they remain appropriate and applicable in the light of ongoing developments in relevant scientific and technical fields. In this context, feedback will be sought from personnel in the field and comments incorporated into revised principles as appropriate.

Surveillance Plan and Question Set

The term "surveillance" is used here to define the oversight activities applicable to a facility's many post-operational life cycles phases. As such, it has a broad context and should not be confused with the more narrowly-defined surveillance and maintenance phase. The purpose of the plan is to establish responsibilities and methods for conducting reviews and to provide a means for systematically collecting data on facilities that are in post-operational status. The activities to be performed under the surveillance plan fall under three principal categories: document reviews, personnel interviews and on-site observance and inspection.

The approach initially considered (4) was modified in the light of peer review but the focus has remained unchanged - the implementation of the safety principles. This implementation involves a graded approach consistent with the nature and magnitude of the hazards perceived to be present. Inherent in this approach is that the degree

of applicability of the principles will change as decommissioning operations proceeds. In most cases it is anticipated that the nuclear and radiological hazards will decrease but, because of the uncertainties associated with the post-operational condition of any facility, it is conceivable some conditions may be encountered that will bring about a heightened awareness of hazards and an associated increase in safety concerns.

The basic plan for conducting the surveillance activities involves partitioning a decommissioning operation into specific functional areas, such as management, radiation protection, packaging and transportation, fire protection, emergency planning, training and quality assurance. Standardized question sets, derived from the safety principles, have been developed for each area. Safety assessments can be conducted on an overall functional basis using a limited number of questions from each functional area, or, if deemed necessary, on a more detailed basis using most or all of the questions in a functional area. An additional option is to conduct the evaluation on a principle basis, in order to verify that the intent of a specific principle is being fully met. The question sets will also be subject to the same iterative review being applied to the principles in order to confirm their currency in the light of developments in all aspects of the decommissioning process.

In tandem with the evolution of the question set is the development of a guidance document for application of the principles in practice. This document is being designed to provide background information on each principle and give examples of how it might be applied in specific instances. This type of guidance is thought to be preferable to a standardized question set in some instances where engineering and scientific judgement play a prominent role (for example, in evaluating the content of a safety analysis report). However, the use of question sets will be more appropriate in other types of assessment, such as confirming that procedures are being used correctly.

In addition to providing assurance that the decommissioning procedure has been planned and is being conducted in a safe manner, the data generated through the post-operational facility surveillance plan will be evaluated and analyzed from a complex-wide perspective. The results of such analyses will be used to detect DOE-wide generic strengths and weaknesses (for example, by indicating the need for standards and training in specific technical areas) and thus be of assistance in expediting subsequent decommissioning projects.

Because of the evolutionary nature of the project, input is being sought from all parties concerned, from those responsible for preparing policies and standards to those charged with conducting the actual D&D operations. This kind of interactive communication is being strongly encouraged to ensure that the safety principles and question sets are appropriate, that there is general agreement and understanding of the methodology and that its application will be feasible and practical.

When finally developed and tested, it is planned to investigate the extension of this methodology to other aspects of post-operational activities at facilities, such as mission transition and environmental restoration. Eventually, it is envisioned that it could be adopted for surveillance of all phases of a facility's existence, including design, construction and operation of new facilities. Additionally, although the current plan is focused on nuclear and radiological hazards, the methodology and framework described can be applied generically to address other conditions, such as chemical and conventional industrial hazards.

SUMMARY

The DOE is developing and deploying a systematic approach to obtaining assurance that post-operational activities (specifically, decommissioning) at nuclear facilities will be conducted in a safe manner. Personnel will have available a formalized set of safety principles and associated question sets to assist them in the conducting of safety assessments and surveillance. The information gathered through this means will also be analyzed to determine if there are any generic complex-wide strengths or deficiencies associated with decommissioning activities and to which attention should be drawn.

HAZWOPER TRAINING AT THE DEPARTMENT OF ENERGY: A PARTNERSHIP BETWEEN GOVERNMENT, CONTRACTORS AND LABOR ORGANIZATIONS TO PROTECT WORKERS' SAFETY AND HEALTH

Kelvin J. Kelkenberg
U.S. Department of Energy
Priscilla Lee Seymour, Ph.D.
Belfort Engineering and Environmental Services

ABSTRACT

As the Department of Energy's (DOE) mission has shifted from weapons production to environmental restoration, the site worker will be exposed to new operations and hazards while conducting restoration operations. Protection of the health and safety of all workers is a Secretarial priority as well as a goal of Environmental Management (EM). To conduct restoration operations in a manner which protects worker health and safety, all workers must be trained to identify hazards and the appropriate way to safely conduct operations. All workers engaged in hazardous substance response or emergency response, a common element of restoration operations, are required to meet the Occupational Safety and Health Administrations' (OSHA) regulation requirements 29 CFR 1910.120 and the EPA Hazardous Waste Operations and Emergency Response (HAZWOPER) training requirements (40 CFR 300.150). Congress recognized this need and authorized the Secretary of Energy, through the National Defense Authorization Act for Fiscal Years 1992 and 1993, to award grants for training and education for persons engaged in hazardous substance response or emergency response at DOE nuclear weapons facilities and further authorized $10 million to carry out this mandate.

The Office of Environmental Restoration was charged with developing a program to meet the HAZWOPER training requirements and address the specific needs across the complex. The goal of the training program has been to provide site specific quality training to workers in a timely and cost effective manner. The first grantees to receive awards for this program were comprised of labor organizations and universities with prior experience in conducting joint labor-management HAZWOPER training programs. Training is provided at the site to address site-specific needs and is available to DOE and contractor employees, regulatory agency personnel, state, local and Tribal government officials and local emergency responders working in hazardous substances and emergency response operations at DOE sites.

A partnership between government, contractors and labor organizations works to ensure that the training is timely and site specific. A cornerstone concept of this program is workers training workers, such that the workers who are familiar with performing a given task in a hazardous environment are training other workers to perform that task in a manner protective of their health and safety. Added benefits of this partnership include the fostering of close cooperation between management and workers, improving efficiency and quality of training, improving the ability to address worker concerns, and empowering all stakeholders to address site-specific safety and health needs.

INTRODUCTION

Protecting worker health and safety is a priority of the Secretary of Energy and is a primary goal of the Office of Environmental Management (EM). As the Department of Energy's (DOE) mission has shifted from weapons production to environmental restoration, the site worker will be exposed to new operations and hazards while conducting restoration activities, many of which will be associated with potential exposure to hazardous substances and wastes. To provide protection to workers' health and safety, all workers at DOE sites engaged or potentially engaged in environmental restoration activities, including hazardous substance response or emergency response, are required by the Comprehensive Environmental Response, Compensation and Liability Act of 1980 (CERCLA) (42 USC 9604(f) and 9651(f)) and DOE

Orders 5480.4 Environmental Protection, Safety, and Health Protection Standards and 5483.1A Occupational Safety and Health Program for DOE Contractor Employees at Government-Owned, Contractor-Operated Facilities, to meet the requirements of the Occupational Safety and Health Administration's (OSHA) regulations 29 CFR 1910.120 and the EPA Hazardous Waste Operations and Emergency Response (HAZWOPER) training requirements (40 CFR 300.150). Congress recognized this need and authorized the Secretary of Energy, through the National Defense Authorization Act for Fiscal Years 1992 and 1993, Section 3131, to award grants for training and education for persons engaged in hazardous substance response or emergency response at DOE nuclear weapons facilities. For purposes of Section 3131, the term "hazardous substance" in addition to its definition under CERCLA includes radioactive waste, mixed radioactive and hazardous waste. The Office of Environmental Restoration, a separate office within the Office of Environmental Management, was charged with developing a program to meet the HAZWOPER training requirements and address the specific needs across the complex. The Regulatory Integration Division, within the Office of Environmental Restoration, has been tasked with program implementation.

The goal of the training program has been to provide site specific quality training to workers in a timely and cost effective manner. A partnership between government, contractors and labor organizations is in place to meet this goal. A cornerstone concept of this program is workers training workers, such that the workers who are familiar with performing a given task in a hazardous environment are training other workers to perform that task in a manner protective of their health and safety, for example electricians training electricians. Added benefits of this partnership include the fostering of close cooperation between management and workers, improving efficiency and quality of training, improving the ability to address worker concerns, and empowering all stakeholders to address site-specific safety and health needs. Training is available to DOE and Contractor employees, regulatory agency personnel, state, local and Tribal government officials and local emergency responders working in hazardous substance response and emergency response operations at DOE sites.

AUTHORIZATION FOR PROGRAM

Training Grant Program

The National Defense Authorization Act for Fiscal Years 1992 and 1993 (42 USC 7274(d)) authorized the Secretary of Energy in Section 3131(a)(1)(A)-(B) to award grants:

" (a)(1)(A) to provide training and education to persons who are or may be engaged in hazardous substance response or emergency at Department of Energy nuclear weapons facilities; and (B) to develop response curricula for such training and education."

Initially, the grant program was authorized for $10 million in 1992 to develop training curricula and to provide training and education.

The Secretary was further authorized in Section 3131(a)(2)(A)-(B) of the National Defense Authorization Act to award the training grants to non-profit organizations demonstrating capabilities in:

"(a)(2)(A)(i) implementing and conducting effective training and education programs relating to the general health and safety of workers; and (ii) identifying, and involving in training, groups of workers whose duties include hazardous substance response or emergency response."

Preference in grant awards is to be given to employee organizations and joint labor-management training programs that were grant recipients under Section 126(g) of the Superfund Amendments and Reauthorization Act of 1986 (SARA) (42 USC 9660(a)).

Any organization receiving a grant under this program is required to be in conformance with DOE Orders relating to employee safety and health, including but not limited to DOE Orders 5480.4 and 5480.11 Radiation Protection for Occupational Workers, when carrying out training, education or curricula.

Enforcement of Employee Safety Standards

Civil penalties may be assessed by the Secretary against any DOE contractor employing persons engaging in hazardous substance response or emergency response at DOE nuclear weapons facilities for failure to provide training for those activities or to certify that the employees are adequately trained for performing such response actions in accordance with DOE Orders on employee safety training. These penalties may not exceed $5,000 for each day in which a violation occurs. The Secretary is required to develop regulations to carry out the provisions of Section 3131(b).

Funding
For fiscal years 1992 and 1993, $10 million was authorized and appropriated for each year. In 1994 Congress authorized $11 million. The funding for fiscal years 1995 and 1996 will remain level at $10 million. Funding is through the EM budget, however training is not limited to EM employees or contractors.
GRANTS ADMINISTRATION
Selection of NIEHS as Grants Administrator
Under Section 126(g) of SARA the National Institute of Environmental Health Sciences (NIEHS) developed and administers a HAZWOPER training program in consultation with the Environmental Protection Agency (EPA). DOE evaluated the program developed by NIEHS for suitability of adaptation to DOE program and training needs. It was determined that the program would be suitable to adapt to DOE. In an effort to rapidly move to the program implementation stage and to leverage program resources, DOE considered the suitability of NIEHS as grants administrator for the DOE program. Based upon a review of the NIEHS program, DOE entered into an agreement with NIEHS to award and administer the grants and to adapt the HAZWOPER program to meet the DOE needs.
Administration Responsibilities
As grants administrator, NIEHS has several responsibilities. The first responsibility was to establish technically proficient training materials and to ensure that such materials addressed DOE's special needs specifically with regard to radioactive and mixed waste. They were to make announcement of grant availability, develop criteria for judging grant applications in conjunction with DOE, and finally, to make grant awards within the specified criteria for selection. They have an ongoing responsibility to ensure the quality control of all course content and presentations to maintain consistency across the complex.
Selection of Grantees
In 1993, NIEHS with DOE concurrence selected seven grantees from the grant applicants. All grantees met the requirements specified in Section 3131 of being non-profit organizations that were employee/labor organizations and/or experienced in worker health and safety training. The initial grantees were: University of California at Los Angles Labor Occupational Safety and Health Program (UCLA); University of Medicine and Dentistry of New Jersey (UMDNJ); International Union of Operating Engineers (IUOE); Oil, Chemical and Atomic Workers Union (OCAW); International Chemical Workers Union (ICWU); Laborers Associated General Contractors Education and Training Fund (L/AGC) (also teamed with the International Brotherhood of Teamsters); and United Brotherhood of Carpenters and Joiners Health and Safety Fund (UBC).
TRAINING
Training Objectives
There are several objectives that DOE desires to see met by the HAZWOPER training program. First and foremost, is to ensure that all workers in DOE nuclear weapons facilities that participate in hazardous substance response and emergency response receive quality safety and health training. It is an objective that all training offered in the HAZWOPER program be of the highest quality to protect life and health.
The training must also be geared to site specific needs and worker specific needs. Through the cooperation of management and workers, site specific needs can be identified based upon site configuration, geography, and planned work activities. The worker specific needs are addressed by workers training workers. A worker who is experienced with performing a certain required task under hazardous conditions is best suited to understand the constraints of the situation and the task requirements. For example, an electrician who has performed wiring tasks in Level A personal protective equipment would be best suited to train another worker who will perform a similar task under similar conditions.
A final objective is to train as many persons as possible in a cost effective manner through providing training locally. This reduces the cost of training through reduced travel costs, making funds available for additional training. It also reduces time away from the job allowing more persons to be trained. Local training also allows for site specific needs to be identified and more easily incorporated in the training.
Training Scope and Course Elements
The scope of the training covered in the curriculum is the worker protection

requirements for 40 hour training contained in 29 CFR 1910.120, the HAZWOPER standard. Additionally, the training contains modules on radioactive and mixed waste. The courses meet the requirements of Minimum Criteria for Worker Health and Safety Training for Hazardous Waste and Emergency Response, NIEHS, December 1991. All courses meet the minimum criteria delineated above. Examples of training course elements covered are:

Personnel responsible for site safety and health,
Safety, health, and other hazards present on-site,
Use of personal protective equipment (PPE),
Work practices to minimize risks from hazards,
Safe use of engineering controls and equipment on-site,
Medical surveillance requirements, and
Recognition of symptoms and signs indicating overexposure to hazards.

While the elements listed above are only representative of the course content, it is the intent that the course elements are such that the worker is prepared to recognize and analyze the hazards that may be present, take appropriate action and thereby protect their own and other workers health and safety.

Training Accomplishments

Training has been offered across the DOE complex primarily through the DOE Operations Offices and Headquarters. It should be noted that the HAZWOPER grantee training is not the only HAZWOPER training available in the complex and in fact represents only a portion of the training available. It was intended as a supplement to the existing training to assist DOE and its contractors in meeting the requirements of 29 CFR 1910.120 and DOE Orders. Further, contractors not in compliance will be faced with civil penalties. In Fig. 1 below, the number of workers trained by the Operations Offices is depicted. The total number of workers trained to date is 7468, with the Oak Ridge Operations having trained the greatest number of that total at 2594 workers.

Fig. 1. Number of workers trained by operations office- *Sept. 1, 1993-June 30, 1994.

These training statistics are undergoing further analysis to determine the reasons for the differences in workers trained by Operations Offices. The information will be used to increase the success of all the Operations Offices and to achieve full worker training at all sites.

CURRENT AND FUTURE PLANNED ACTIVITIES

New Grant Awards

New training grants will be issued in Fiscal Year 1995. The source selection process has already been initiated by NIEHS with a request for applications. Selections will be made in the last quarter of Fiscal Year 1995 in order to start the Fiscal Year 1996 program.

Advanced Notice of Proposed Rulemaking

The Secretary of Energy issued an Advanced Notice of Proposed Rulemaking on August 26, 1994 in the Federal Register (59 FR 44139), Enforcement of Employee Safety Standards at Nuclear Weapons Facilities. The purpose of the notice was to invite public comment on DOE plans to implement Section 3131(b) of the National Defense Authorization Act of 1992 and 1993, enforcement authorities to assess penalties against DOE contractors failing to provide training to employees who are assigned to hazardous substance response and emergency response duties or who fail to certify that the employees are adequately trained.

DOE particularly noted several matters of interest for comments. The matters of interest concern: training documentation content and format, including requiring wallet-sized photo identification documenting training; employer certification of employee training adequacy; the structure of an enforcement program to provide incentives to DOE contractors to comply; the development of criteria for assessing adequacy of contractor training programs; defining "hazardous substance" to include radioactive waste, mixed waste, hazardous waste and substances defined in Section 101(14) of CERCLA; defining "nuclear weapons facility"; and appropriate enforcement procedures, including integrating these procedures with the DOE program on nuclear safety in 10 CFR 820. Comments were due on October 25, 1994. The Office of the Assistant Secretary for Environment, Safety and Health (EH) is reviewing the comments received and is developing a Notice of Proposed Rulemaking.

EM/EH Safety and Health Assistance Initiative

Under the EM/EH Safety and Health Assistance Initiative, DOE is developing

standardized curriculum and instructor guidelines. Additionally, they are developing evaluation criteria for course assessment. The purpose of the standardization is to provide consistent training complex wide, assure all courses are of the same high quality, assist grantees in meeting DOE expectations for course content and presentation, and assure that all workers are receiving the highest quality training. Throughout the development process, grantees are involved with EH and EM to provide their expertise and input for an effective and cost efficient program.

Program Evaluation

The Oak Ridge Institute for Science and Education (ORISE) have been contracted to evaluate the grantee program. When completed, the evaluation will be shared with the Congressional Armed Services Committee having expressed a desire to receive a program evaluation. In performing the evaluation, ORISE will utilize existing evaluation materials from grantees, NIEHS and the Operations Offices. Specifically, they have been charged to review training utilization decisions at DOE sites, determine if training is reaching target audiences and evaluate the effectiveness of program management. The evaluation results will be available in late 1995.

CONCLUSION

The HAZWOPER program was developed with the support of government, contractors and labor unions to ensure that the workforce is trained to conduct restoration activities in a manner which protects worker health and safety. The training program has, over the course of three years, progressed through the development phase to the implementation phase with over 7400 workers trained by seven grantees. In each phase of program development, members of the partnership assumed larger or smaller roles based upon program needs. For example, in the earliest phases, government and labor organizations had a more active role during the development of curriculum. In the implementation phase contractors and labor unions have a more active role as training needs are identified and met. As rules are developed for implementation of the program, all three partners will have active roles.

The partnership between government, contractors and labor organizations works to ensure that the training is timely, site specific, and meets minimum criteria. A goal of this partnership is to protect the safety and health of the workers through the fostering of close cooperation between management and workers, improving efficiency and quality of training, improving the ability to address worker concerns, and empowering all stakeholders to address site-specific safety and health needs.

THE DYNAMIC HASP: A TOOL FOR DAILY PROJECT MANAGEMENT

Steve Bertness
U.S. Department of Energy
Paul Esposito
Environmental Profiles, Inc.

ABSTRACT

This paper will present a methodology to incorporate the requirements of the Health and Safety Plan (HASP) into daily management activities at hazardous waste sites. It is the author's contention that the HASP can be a "living document" and not a document that is merely developed as a regulatory requirement and then forgotten. The requirements of the HASP closely mirror the day-to-day functions of project management and a comprehensive safety and health program. The two can be blended together to provide a safer and more productive environment; better than either can provide alone.

INTRODUCTION

In 1986, the Superfund Amendment Reauthorization Act (SARA) tasked the Occupational Safety and Health Administration (OSHA) to develop a standard to protect workers at hazardous waste clean-up sites. OSHA responded by promulgating 29 CFR 1910.120, the Hazardous Waste Operations and Emergency Response Standard, commonly referred to as HAZWOPER, in 1986. This standard, which was issued as a final rule in March, 1989, sets forth the requirements of the HASP (29 CFR 1910.120 (b)(4)).

As written, the HAZWOPER standard is a performance standard, as opposed to a proscriptive standard, such as a permissible exposure limit (PEL) standard. This distinction becomes critical: in that performance standards mandate that employers execute certain functions (including, but not limited to, site planning, monitoring, medical surveillance and training) to protect employees from safety and health

hazards. Therefore, following this logic, it is imperative that management take an active role in operations covered in the scope of the HAZWOPER standard.
When discussing management functions, four specific activities are considered classical; planning, organizing, leading (directing) and controlling. Many corporations in the private sector, DuPont, Alcoa, ITT, and RJ Reynolds, to name a few, have recognized the benefit of management involvement in worker safety and health. The HASP provides an ideal transition vehicle to integrate management functions with safety and health activities at hazardous waste sites.
Within the HASP components of the HAZWOPER standard, there is a requirement for a "safety and health risk or hazard analysis for each site task and operation found in the workplan." This component provides a bridge between safety and health activities and daily project management. In order to perform a hazard analysis, a task must be broken down into steps or phases and each phase analyzed for potential safety and health hazards. This process parallels the overall project planning management undertakes for a major construction or demolition project. Typically, a major project is broken down into phases, with each phase assigned a completion date and a projected cost. Based on these principles, the melding of these two "phase systems" into a single project management tool, focusing on safety and health, is a simple process.
While the hazard analysis component provides the most obvious link to managing daily activities, the HASP contains other components that can be used to blend safety and health and daily project management. Several other sections of the HASP, as required by the HAZWOPER standard, that can be incorporated into daily management activities are: employee and supervisory training; personal protective equipment (PPE) requirements; personal and environmental monitoring; and site control and decontamination procedures. The remaining HASP requirements, emergency response procedures, confined space entry procedures, medical surveillance and spill containment, are important considerations at hazardous waste sites, but typically do not change from day-to-day.
The concept that the HASP can be used as a daily project management tool does not exist solely as an intellectual one, but as a practical one, as well. The DOE facility located at Weldon Spring, Missouri, integrates their HASP with day-to-day project management activities. The Weldon Spring Site Remedial Action Project (WSSRAP), where the sole mission of the DOE is to protect human health and the environment, has developed a program that successfully blends day-to-day project management and the HASP. All activity at WSSRAP has been classified into one of three areas: quarry operations, chemical plant, and overall maintenance. Each of these areas function independently of the other in order to achieve the final goal of the site, which is the remediation of all hazardous substances in the facility. However, there is one common element in all areas of operation at Weldon Spring, the HASP.
When a remedial action scope of work is identified at any of the three WSSRAP functional areas, a "boilerplate" HASP is created by DOE and the managing contractor. This HASP is provided to the contractors submitting bids for the project. It then becomes the contractor's responsibility to address the specific hazards associated with the scope of work and incorporate them into the "boilerplate" HASP using specified HASP addendums. This final document is the site-specific HASP that meets the requirements of the HAZWOPER standard.
CASE STUDY
Daily Project Management
In order to facilitate the HASP as a tool for daily project management, WSSRAP project managers work with their safety support staff and communicate the day's activities and precautions to all workers. The project manager is careful to document the discussion and ensure that all workers attend.
Daily project management encompasses a number of activities. First, the day's events are planned and reviewed, as well as the potential hazards and exposures created by the day's operations. Next, the proper teams and equipment are assigned ensuring that the right people and equipment are available for the job. Then, the work is assigned, to include the day's final objective, the type of air monitoring that will be performed, and exposure limits that will be in force. Finally, since the safety officer attends all morning meetings, daily inspections are scheduled, and any results from the previous days monitoring (air, personal, or environmental) efforts are reviewed and discussed. Thus, each element of management, planning, organizing,

directing, and controlling, has been incorporated into the morning's daily safety and project management briefing.
To facilitate the briefing, the site uses either one of two HASP addendums: the Safe Work Plan (SWP) or the Task Specific Safety Assessment (TaSSA) form.
Safe Work Plan (SWP)
In order to ensure that the HASP is site and task specific, WSSRAP requires each contractor to submit SWP's for each of their routine assignments. A SWP typically includes:

Description of Work	Work Location
Est. Start Date/Time	Subcontractor
Equipment	Crew
S&H Hazard Evaluation	Preventive Measures
Hazardous Conditions	Dosimetry Requirements
Air Sampling	Doffing Sequence
H&S Technician Coverage	Badge Color Required For Entry
Approvals	Inspections

Minimum Personal Protective Clothing and Equipment
Special Instructions and Requirements

These headings are specific subsets of the HASP, and help the site comply with section (b)(4)(iii), pre-entry briefing requirements. The SWP also helps the site comply with section (b)(4)(ii), effectiveness of the safety and health plan, by incorporating inspections into daily activities.
The SWP is reviewed during each morning meeting, if the day's activities include that specific task. Any changes or revisions are documented at that time by the project manager. A separate "Briefing Record" form is completed for each meeting and for each SWP, further documents activities and changes to the HASP.
Task Specific Safety Assessments (TaSSA)
The TaSSA provides: safety awareness at the worker level of task performance; an awareness of the requirements for safe conduct of the activity at the inspector level; and a method of control of field activities. A TaSSA is required for all field activities, typically non-repetitive tasks that were not specifically addressed in the HASP or SWP (See Fig. 1). The TaSSA must be revised, dated, and signed daily by those personnel performing the task.
Fig. 1.
The TaSSA includes:
- Authorization names and signatures
- Summary description
- Risk assessment
- Comments/discussion
- Crew and field supervisor signatures
- Inspection records

Once written, a TaSSA must be reviewed and signed off by a competent person, as defined in the written procedures, although not necessarily by the site safety officer. As a measure of control, copies of TaSSA's are maintained at the site and with the Access Control Monitor. Therefore, safety inspectors will always have the TaSSA available during planned and random inspections (See Fig. 2.). The original TaSSA's are logged into a tracking system and filed in the Construction Management office.
Fig. 2.
One of the other aspects of the TaSSA is it's flexibility to deal with work stoppage when a new or previously unidentified hazard is discovered. As long as the form is properly completed and reviewed, a competent person can make a decision to proceed. This procedure minimizes work interruptions, which places an incentive on the part of the contractor to properly analyzes new or previously unidentified hazards. Thus, the TaSSA closes the gap between planned conditions and activities (HASP & SWP defined tasks) and non-routine and unplanned conditions and activities, while expediting the project.
Authority and Approvals
Original SWP's require the review and approval of the Responsibility Assignment Matrix (RAM) Team. The Team is comprised of multi-disciplined members with safety, management, environmental and engineering backgrounds. Since the Team members are more than one individual per discipline, SWPs can be reviewed quickly, if necessary,

as backup Team members have already been selected. Revisions to SWPs must follow the same procedure as original submittals.
TaSSAs receive reviews and approval by a defined "competent person." Depending upon the nature and degree of the hazards, the competent person will consult with the relevant safety personnel, when necessary. Since TaSSAs are written on a daily basis, there are no revision requirements.
Documentation
All SWPs are assigned a log number and tracked in a computer database, to include the revision number and status of pending approval or if approval has been denied subject to revising the SWP. A copy of the SWPs is also onsite (in the field) whenever these operations are occurring. Files are maintained on all SWPs, to include inspection records and any corrective actions recommended as part of these inspections. The daily SWP review is documented using the "Briefing Review Record." The TaSSA is also computer tracked, although log numbers are not yet a part of the tracking system. Final copies are collected daily and filed in the Contract Management office. Although competent person approval is required, these documents are reviewed periodically and at random at the direction of the DOE safety officer, to help verify that the forms are being completed appropriately.
BENEFITS
At WSSRAP, Safe Work Plans (SWPs) have been used for the past 5 years, with Task-Specific Safety Assessments (TaSAAs) being used for the last two years. Over the years, there has been an evolution of the plans, forms, and procedures when using these tools, and the site is convinced that the efforts provide worthwhile benefits and compliment the management planning responsibilities of DOE.
The mission of WSSRAP is the "protection of human health and the environment." Site management is convinced that the proper planning and implementation of safety procedures not only save lives, but significantly contribute to the minimization of unplanned events and interruption of timetables and milestones. Some examples of benefits received are presented in the Fig. 3 and Fig. 4.
Fig. 3.
Fig. 4.
In Fig. 3, you can see a significant increase in the number of manhours (e.g., remediation activities). As a result, you would expect to see a significant increase in the number and rate of injuries. WSSRAP has experienced only some linear increases, where the expected trend was for the increases to extrapolate upward. In Fig. 4, the severity has definitely come under control, although there is a slight increase in the 1993 trend due to a single lost work day case.
Prevention
In addition, daily project management and review of records provide WSSRAP opportunities to mitigate (prevent) circumstances before they become threatening or cause injuries or damage. For example, urine bioanalysis, routinely performed on site workers, indicated an upward trend in 50% of the work crew to a radiological exposure. Upon review of these records, the safety staff investigated work activity and discovered that the work crew was inadvertently modifying their protective cloth doffing procedures, due to some discomfort caused by the clothing ensemble. A training meeting was scheduled, where revised protection and decontamination measures were communicated to the workforce. As a result of a well developed HASP, one that planned for appropriate medical surveillance and a daily management strategy that reviews monitoring data, WSSRAP was able to implement mitigation procedures before exposures were above limits.
LESSONS LEARNED
By incorporating safety into daily project management and SWP and TaSSA procedures, the site has been able to evolve and improve their safety efforts and procedures, further benefiting the work product, schedules, and milestones. A number of specific "lessons learned" initiated changes to procedures and business as usual.
Field Authorization for Quick Turnaround
The TaSSA was developed so any new or unplanned hazards could receive appropriate review and approval prior to the work activity proceeding, but not significantly impeding the process. During the past few years, the planning documents (HASP & SWP) have been much improved, reducing the frequency of TaSSA's for routine activities.
Fixed Fee Contractor Performance
Fixed fee contractors will typically debate any procedure which will slow down work completion, once the contract is signed and notice to proceed is given. WSSRAP found

that appropriate change orders due to change in conditions were easier to document using the information in TaSSAs. In addition, change orders were negotiated fairly, realizing that sometimes there are legitimate changes to conditions or activities.

Subcontractor Participation in Hazard Analysis

Another benefit the site received when implementing SWPs and TaSSAs was subcontractor involvement in safety. Subcontractors were made responsible for completion of safety documents (SWPs and TaSSAs). Since accountability procedures were in place (review, approval, and inspections), the contractor is better motivated to plan their activities safely.

Time Out for Safety

It is never an easy decision to exercise stop work authority. Contractors generally get upset (especially fixed price contractors) when stopping work, and the purpose of stopping the work sometimes gets lost in the subsequent discussion. In response, the DOE Safety Office and its site contractors agreed to a strategy of "time out for safety." Instead of an official stop work, safety concerns observed during inspection receive a time-out. If a solution is not quickly resolved, then stop work authority is exercised.

Inspection Evaluation Criteria

At first, inspectors were evaluated on the number of sites/tasks they inspected per month. It was determined that, although a lot of inspections were being performed, unresolved unsafe practices were still contributing to accidents. The safety office revised their evaluation criteria, holding inspections accountable for identifying corrective actions.

EVOLUTION

Obviously, the program in place at Weldon Spring has produced some very positive results. The record of performance, indicated by the lost workday case rate, revision records and escalating manhours, shows that the integration of the HASP with daily project management provides tangible benefits. However, some areas of the plan are still in the evolution stages. For example, it was discovered that emergency drills were conducted, but not on a regular basis. The determining criteria for emergency drills was a change in conditions that mandated a change in the emergency preparedness plan.

When using a system on a daily basis, an unavoidable result is the generation of paperwork. That in itself is not a major problem, but maintaining, tracking and trending this paperwork is a formidable task. Fortunately, as these problems became apparent at Weldon Spring, worker safety was not compromised.

The majority of these recordkeeping obstacles center around the TaSSA form. While the field use of these forms increased at all three areas of operations, a consistent tracking and documentation system has not yet been developed. TaSSAs are consistently monitored by field supervisors and foreman. What is still needed is a closure action by "corporate" safety personnel. By providing this final link in the chain, "corporate" safety & health personnel will be fully integrated with the TaSSA system.

As is common with hazardous waste site operations, unknown hazards are often revealed as work progresses. At WSSRAP, these occurrences are addressed using the aforementioned TaSSA system. These unknown hazards may result in changes in procedures that may last ten minutes or ten days. This uncertainty, especially in longer intervals, creates a potential duplication problem in the TaSSA system. In other words, no criteria exist for determining when to submit repeat TaSSAs or if a revision to the Safe Work Plan is necessary. An established decision chain or flow chart to determine when to continue submitting TaSSA's or to amend the SWP could eliminate this and help contain the paper explosion.

When a TaSSA is issued, a copy of that form is required to be posted at the worksite and be available for review during inspections by management. Any management official is authorized to conduct an inspection at any time during the operation. When an inspection is conducted, the inspector is required to sign-off on the TaSSA form indicating employees are adhering to the changes specified in the TaSSA. If the employees are not working according to the procedures outlined in the TaSSA, the inspector is required to note this and modify work practices as necessary. These inspections occur randomly and appear to have little established protocol. The creation of an inspection protocol, focusing on safety & health, would assist individuals who lack formal safety & health training in the identification of hazards present at the job site. A standard protocol may also streamline the

inspection process, allowing for more frequent and thorough inspections.
The integration of the HASP with daily project management at WSSRAP appears to be 95% complete. The use of this system has shown positive results in that worker injuries have been reduced while manhours worked have increased, and activities are more hazardous. Injury trend information would be readily available and easily documented by an established trending system. While statistics are kept at WSSRAP, there exists little formal trending process to measure the success of the program. A system that tracks and trends inspection results, lost work day rates, manhours worked or any other industry norm for evaluating safety and health performance would be a benefit to the site.

SUMMARY

The HASP, required by OSHA (HAZWOPER), is designed to be a management planning document, as well as an instrument for daily project management. In order to fully implement the regulatory requirements of a site specific safety and health plan, 29 CFR 1910.120 requires:

- site health and safety plan (HASP);
- pre-entry briefings; and
- effectiveness inspections.

As a performance standard, OSHA allows many methods available to contractors for HASP compliance. WSSRAP has not only developed a model HASP, but requires the integration and participation of project management, safety staff and contractors in regard to hazard identification and control. By implementing safety on a daily basis, the HASP becomes dynamic; part of daily project management. It also improves the working atmosphere not only toward safety, but also toward improving product quality and timeliness. The site has experienced a documented savings in terms of worker injury and has mitigated potential exposure problems. WSSRAP expects to continue evolving and refining the HASP process in order to fully achieve its mission objectives; to protect human health and the environment.

ACKNOWLEDGMENTS

The Office of Environmental Restoration and Waste Management, Regulatory Compliance Division, would like to extend a special thanks and express appreciation to Weldon Spring Site Remedial Action Project, its management, safety office and support staff, and the safety officers and support staff of M. K. Ferguson, its site operations contractor. WSSRAP management and staff have demonstrated a sincere commitment to safety, and were extremely helpful in collecting the necessary information and data for this presentation.

AN APPROACH TO SAFETY ANALYSES AND DOCUMENTATION FOR DECONTAMINATION AND DECOMMISSIONING PROJECTS AT DEPARTMENT OF ENERGY NUCLEAR FACILITIES

T.A. Kuykendall
E.J. Millikin
Parsons Engineering Science, Inc.

ABSTRACT

The requirements for documentation of safety analysis, safety impacts and hazards posed by the U.S. Department of Energy (DOE) facilities and operations are presented in a number of DOE Orders and related directives. In addition, the U.S. Nuclear Regulatory Commission (NRC) has been active in developing guidance for decontamination and decommissioning (D&D) activities for commercial nuclear facilities. However, specific guidance for application of DOE Orders, directives, and other guidance for preparation of safety documentation related to DOE D&D programs has not been developed. An approach to defining the requirements for safety documentation was needed to support D&D Program. This paper discusses the step-by-step approach developed for specifying safety documentation and for the integration of the safety analysis process into the D&D project sequence.

The step-by-step process is based upon the 'graded approach' as presented in DOE Order 5480.23. This approach utilizes the concept of addressing hazard identification and documentation of the safety analysis process. This concept is based upon an evaluation of hazards associated with the D&D activity to be implemented and the condition of the facility after deactivation, rather than the existing safety documentation prepared for production operations. Maximum use of existing project documentation, such as preliminary characterization information and preliminary hazards analyses, are considered in the safety analysis process. The

proposed approach integrates requirements of several DOE Orders including DOE Order 5480.11 5480.23, and 5481.1B, along with other relevant guidance (e.g., applicable NRC Regulatory Guides and NUREGS) into a logical sequence for defining safety requirements. This approach promotes development of safety documentation using the 'team concept'.

The result of this effort was the development of a decision-based process for defining the appropriate levels of safety evaluation and documentation for a facility, based on the existing [postulated] hazards and safety concerns at the time of initiation of D&D field activities. This process allows the safety analyst to make responsible decisions on how much and what type of analyses and documentation would be best suited for a project- or facility-specific situation.

There is no existing program within DOE for safety analysis that has been tailored specifically for D&D projects. As such, this process is of particular importance to the DOE Complex due to recent mission changes at many of the DOE field sites and the subsequent increase in growth of the national D&D program. Use of the proposed approach for development of safety documentation for D&D projects promotes early identification of issues and allows the use of existing standards, criteria, and project management system without creating unnecessary documentation and inhibiting the progress of these efforts.

INTRODUCTION

The requirements for documentation of safety analysis, safety impacts and hazards posed by the U.S. Department of Energy (DOE) facilities and operations are presented in a number of DOE Orders and related directives. In addition, the U.S. Nuclear Regulatory Commission (NRC) has been active in developing guidance for decontamination and decommissioning (D&D) activities for commercial nuclear facilities. However, specific guidance for application of DOE Orders, directives, and other guidance for preparation of safety documentation related to DOE D&D programs has not been developed. An approach to defining the requirements for safety documentation was needed to support the DOE D&D Program. This paper discusses a decision-based process developed for specifying safety documentation and for integration of the safety analysis process into the D&D project sequence.

CONCERNS WITH THE CURRENT SAFETY ANALYSIS APPROACH

The current safety analysis approach for DOE nuclear facilities was developed for facilities dedicated to producing nuclear materials for national defense. The mission of a majority of DOE sites has changed to environmental cleanup and D&D; as such, the requirements and content of safety analysis for production facilities may not be relevant and/or appropriate for D&D of facilities. The current approach for safety analysis for DOE nuclear facilities, along with concerns associated with this approach, are further discussed below.

Existing Requirements For Safety Documentation

A safety analysis must be performed for every DOE nuclear facility that develops and evaluates the adequacy of the safety basis for the specific facility. The safety basis parameters to be assessed include management, design, construction, operation, and engineering characteristics necessary to protect the public, workers, and the environment from safety and health hazards posed by the nuclear facility or nonfacility nuclear operations. The DOE has documented requirements for the safety analysis process in several Orders; however the Nuclear Safety Analysis Reports (DOE, 1992), DOE Order 5480.23 establishes safety analysis requirements for DOE contractors for the D&D of nuclear facilities.

The DOE Order 5480.23 defines the "level of concern" with respect to safety considerations within the framework of Hazard Classification, which drives the requirements for the preparation of safety analysis reports (SARs) for DOE nuclear facilities. All facilities classified as a Hazard Category 3 and above are required to comply with DOE Order 5480.23. Facilities that do not meet or exceed Hazard Category 3 threshold, but that still possess some amount of radioactive material, may be designated as Radiological Facilities. The Hazard Category is to be performed in accordance with the methodology specified in the Hazard Categorization and Accident Analysis Techniques For Compliance With DOE Order 5480.23, Nuclear Safety Analysis Reports (DOE, 1992a), DOE-STD-1027-92.

Radiological facilities are exempt from DOE Order 5480.23, but are not exempt from other DOE and DOE-related safety requirements. The DOE Order 5481.1B, Safety Analysis and Review System (DOE, 1986) identifies safety analysis requirements for facilities that possess significant nonradiological hazards that may not be

addressed by DOE Order 5480.23.
It is conceivable that many of the DOE facilities that have been deactivated and placed in a "D&D-ready" condition may be reclassified as Radiological Facilities and thus will not be subject to requirements of DOE Order 5480.23.
Hazard Categorization and Classification
The DOE Order 5480.23 requires an evaluation of the nuclear activities to be conducted and a classification of the processes, operations, or activities in accordance with the Hazard Classification criteria established in DOE Order 5480.23 and DOE-STD-1027-92. The hazards analysis should address (as a minimum):
Inventory of Hazardous Material - Including an inventory that envelops all radioactive and nonradioactive hazardous materials that are stored within the facility;
Evaluation of Potential Releases - Identification of energy sources that might contribute to the generation or uncontrolled release of hazardous materials;
Hazards Analysis Document - The Hazards Analysis Document (HAD) is the final document in the hazards evaluation process, and provides a more definitive hazards classification based on valuative data. The HAD consists of sections for: Hazardous Material Quantity, Form, and Location; Energy Sources and Potential Initiating Events; Preventative Features; and Mitigative Features;
Hazards Classification - The final facility Hazards Category is defined by the results of the HAD.
Traditionally, the majority of DOE production facilities have been designated as Hazard Category 3 and above. Per DOE Order 5480.23, the graded approach is to be used during the development of the Hazard Classification of a facility.
Graded Approach to Safety Documentation
To avoid the development of unnecessary and unwieldy safety documentation, DOE Order 5480.23 promotes a graded approach to the level of analysis required for a specific facility or operation. The graded approach was developed in an attempt to ensure that the level of information contained in safety documentation is consistent with the level of hazards posed by the facility or operation in question.
The objectives of the graded approach are to ensure that the requirements for analysis, evaluation, and documentation of safety requirements associated with a DOE facility are proportional to the potential hazards associated with the facility. The level of understanding and control of hazards to workers, the public, and the environment should be comparable for all facilities. For relatively simple, uncontaminated facilities, an acceptable level of understanding and control of hazards can be achieved with less sophisticated techniques and less detailed knowledge of facility characteristics than more complex operations. The key factors of the graded approach are:
Justification for the level of analysis and documentation for each hazard considered must be provided as part of the plan and schedule for SAR development and maintenance. The level of analysis and documentation for each facility must be commensurate with:
- The magnitude of the hazards being addressed;
- The complexity of the facility and/or systems being relied upon to maintain an acceptable level of risk; and
- The stage or stages of the facility life cycle for which DOE approval is sought.

The graded approach as addressed in DOE Order 5480.23 is specific for the development of SARs.
For D&D projects, as well as other nuclear operations, it is the evaluation of hazards that dictates the level and sophistication of safety analysis documentation. Although DOE Order 5480.23 generally requires that a new or upgraded SAR be developed for Hazard Category 3 facilities or activities, preparation and submittal of a SAR for environmental activities is required on a case-by-case basis. If a SAR is required, DOE Order 5480.23 allows the application of a graded approach according to the hazard category and the stage of the facility life-cycle. Also, facilities and activities may be segmented or partitioned to allow certain buildings, rooms within buildings, or individual activities to be managed under Hazard Category 3 while all other buildings and activities are managed as Radiological Facilities.
Safety Considerations During Deactivation
As defined by DOE Order 5480.23, the SAR is the focal document for definition of safety requirements for nuclear facilities, there are other documents and processes that must be considered when defining safety requirements for the deactivation of a

facility in preparation for D&D including: a Preliminary Characterization Report, Preliminary Hazards Analysis, and Technical Safety Requirements. Each of these documents are further discussed below.

Preliminary Characterization Report

The Preliminary Characterization of a facility involves the characterization of the hazardous wastes and materials that will be encountered during subsequent D&D operations. Information may be obtained by operating records, process knowledge, and operating personnel, and can be used to formulate the initial characterization of the radiological and nonradiological hazards associated with the facility. Information obtained from the Preliminary Characterization Report may be used to complete the Preliminary Hazards Analysis (PHA) for a facility.

Preliminary Hazards Analysis

The PHA should be performed upon turnover of a facility from deactivation to D&D. This analysis should be conducted based on assurance that the deactivation objectives have been met. The PHA is to compare the post-deactivation radiological material inventory to the hazard classification criteria of DOE-STD-1027-92. The resultant Hazard Classification should reflect the condition of the facility at the time of turnover to the D&D Program.

Technical Specification Requirements

Although preparation of a SAR may not be necessary to address the post-deactivation condition of the facility, a revised set of technical specifications and supporting safety analysis may be required. At a minimum, the existing Technical Specification Requirements (TSRs) or other equivalent safety limits which were used during operations should be revised or deleted to reflect the post-deactivation and pre-D&D condition of the facility. Revised surveillance and preventive maintenance requirements and procedures should be developed for the post-deactivation mode.

It should be noted that during the deactivation process, much of the radioactive substances, Special Nuclear Material (SNM), and hazardous chemical inventories are to be removed from the facility. This is performed to significantly reduce the total quantity of radioactive materials and hazardous chemicals that would be encountered during demolition and decontamination activities.

Safety Conditions for Deactivation

As defined in the Decontamination and Decommissioning Guidance Document - Draft (DOE, 1994) there are several safety conditions that should be addressed prior to transition of a facility from deactivation to D&D including the overall condition of the facility, radioactive and hazardous material inventory remaining, and existing (operational) documentation for the facility.

Ideally, facility deactivation will be planned and performed by the operating program as part of cessation of operations. This goal will be supported by an efficiently planned and executed deactivation program. Typically, the Office of Environmental Restoration (EM-40) will not accept a facility until completion of deactivation. Items that should be addressed during deactivation include (but not limited to):

Removal or stabilization of radioactive source terms;

Removal of SNM to meet less than level Category IV in accordance with DOE Order 5633.3;

Removal of hazardous and dangerous chemical inventories;

Ensure that confinement structures are structurally sound;

Deactivate, consolidate, or cascade the facility Heating, Ventilation, and Air Conditioning (HVAC) systems:

Control facility access to preclude personnel entry other than that required for quarterly radiation and other surveys;

Prevent personnel from utilizing the building and deactivate/clean all personnel support systems;

Remove, to the extent possible, all combustible materials;

Deactivate loss prevention systems and all other electrical systems; and

Install and monitor systems needed for surveillance until D&D activities commence.

The primary goal of deactivation is to meet the acceptance criteria of EM-40. A large part of the acceptance criteria is ensuring the facility is maintained in a safe condition following completion of deactivation activities.

PROPOSED APPROACH FOR D&D SAFETY DOCUMENTATION

The decision-based approach for documentation of safety analysis for D&D facilities focuses on maximum use of the graded approach and the condition of the facility

after completion of deactivation activities. For facilities approaching D&D, the safety documentation should be based on the activities remaining during D&D field activities. Documentation provided on facility operations that were terminated should be the minimum necessary to demonstrate the safety of the facility during D&D field activities. As shown in Fig. 1-1, a decision-based approach has been developed for safety documentation of facilities scheduled to undergo D&D. Elements of the decision-based approach, along with a comparison of the proposed approach to existing guidelines, is presented below.

Decision-Based Approach for Safety Analysis

The decision-based approach uses the graded approach in the development of safety documentation for D&D of facilities and focuses on hazards that exist after completion of deactivation activities. It is likely that most, if not all of the SNM will be removed during deactivation activities. Therefore; the proposed approach reflects the appropriate level of hazards associated with the facility scheduled to undergo D&D. In addition, the proposed approach allows for instances where EM-40 will accept a facility prior to completion of
Deactivation activities. The decision-based approach proposed in Fig. 1-1 is a seven-step process:

1. Review existing operational hazards/safety documentation;
2. Evaluate hazards of the deactivated facility;
3. Verify removal of hazardous/radioactive materials;
4. Determine whether the D&D facility exceeds Hazard Category 3 criteria;
5. Incorporation of the Safety Documentation into the Health and Safety Plan for D&D of the Facility;
6. Prepare a Safety Analysis Report per DOE Order 5480.23;
7. Integrate safety documentation into D&D project documentation.

Each of the key steps of the decision-based approach are further discussed below.

Step 1 - Review Existing Operational Hazards/Safety Documentation

The first step of the decision-based approach consists of reviewing the existing operational hazards/safety documentation. The review of existing safety documentation should focus on the factors used to formulate the existing Hazard Category to determine whether they are appropriate to support initiation of deactivation activities. Generally, the safety documentation for the operational facility will not have to be revised prior to initiation of deactivation activities; the operational envelope should be sufficient to address accidental conditions that may occur during deactivation.

Step 2 - Evaluate Hazards of the Deactivated Facility

The second step of the decision-based approach encompasses evaluating hazards of the deactivated facility. As discussed earlier, deactivation activities should address removal of nuclear and hazardous material from the facility. The types of hazards that would be expected to be encountered after completion of Deactivation would consist primarily of radiological exposure and occupational hazards (i.e. physical hazards). A thorough review of the remaining hazards is needed to ensure proper classification of the facility.

Step 3 - Verify Material Inventory

The third step of the decision-based approach includes verifying that the majority of radioactive and hazardous material has been removed from the facility. This step should be performed at the time of acceptance of the facility by EM-40. There may be instances where EM-40 accepts a facility prior to completion of deactivation activities. As such, the material inventories of the facility should be documented accordingly for identification of potential accidental conditions and proper classification of the facility.

Step 4 - Determine Whether Facility Exceeds Hazard Category 3 Criteria

The fourth step of the decision-based approach focuses on determination of the Hazard Category of the facility. The Hazard Category of the facility will determine the type and level of safety documentation to be completed for a facility scheduled to undergo D&D and should use the graded approach to the maximum extent possible. Because of the removal of nuclear and hazardous materials during deactivation, it is anticipated that the majority of facilities to undergo D&D will qualify as less than Hazard Category 3. The hazards of the facility are evaluated and subsequently documented in the remainder of the decision-based approach.

Step 5 - Incorporate Safety Documentation Into Health and Safety Plan

The fifth step of the decision-based approach encompasses documenting results of the

hazard classification process in the Health and Safety Plan for D&D of the facility. The Health and Safety Plan for D&D of a facility typically addresses the occupational hazards and radiological exposure issues that would be encountered during D&D activities. In addition, the Health and Safety Plan would address administrative requirements associated during implementation of field activities. If the facility does not exceed the Hazard Category 3 threshold, the Hazard Classification would be documented in the Health and Safety Plan and addressed as necessary to support D&D field activities. For facilities that still exceed the Hazard Category 3 criteria the safety analyst would perform the sixth step of the decision-based approach; preparing a SAR. The fifth step would not be applicable for those facilities that exceed the Hazard Category 3 threshold of the decision-based approach.

Step 6 - Prepare Safety Analysis Report Per DOE Order 5480.23

The sixth step of the decision-based approach entails documenting results of the safety analysis process in a SAR prepared in compliance with DOE Order 5480.23 using the graded approach. The review of safety conditions for the facility, radioactive and hazardous material inventories, Hazard Classification, and other elements of the safety analysis process, as required, are to integrated into formal documentation. The level of detail associated with the 21 elements of a SAR should be based upon the graded approach.

Step 7 - Incorporate Safety Documentation into Project Documentation

The seventh, and final step of the decision-based approach consists of incorporating the safety documentation into the D&D project documentation. Both the Health and Safety Plan and the SAR should be incorporated into the Decommissioning Plan for the facility. It is anticipated that for a majority of the facilities to undergo D&D only a Health and Safety Plan would be required; a SAR would not be required to be completed due to the level of hazards to be encountered during D&D field activities.

Evaluation of the Initial State Safety Conditions

A major element of the proposed decision-based approach is evaluation of the safety conditions that remain at the time of D&D of the facility. The evaluation of safety conditions should focus on the radioactive and hazardous material inventories that remain after completion of deactivation activities. Ideally, all of the nuclear and hazardous material should be removed during deactivation; however, experience has shown that many of the facilities scheduled to undergo D&D still have radioactive and hazardous material remaining in the facilities and process lines. A thorough and proper review of material inventories should be conducted and incorporated into the safety documentation. In addition, although Deactivation focuses on removal of energy sources from the facility, occupational hazards may still exist that would influence the level of detail required for the safety documentation. Both material inventories and occupational hazards should be addressed during development of the safety documentation.

Evaluation of D&D Project Safety Requirements

The Decontamination and Decommissioning Guidance Document - Draft (DOE, 1994) provides guidance on the overall DOE D&D process and delineates key D&D decision points for large projects. There are seven phases to a typical D&D project. Of those seven phases, safety documentation is developed primarily in the first and third phases: during transition of a facility to EM-40 (Phase I) and during the environmental review phase of a project (Phase III). Fig. 1-2 shows the interrelationship between the overall D&D process and the safety analysis process. Phase I of the D&D process starts with termination of operations, including establishment of a surveillance and maintenance program and ends with achievement of safe shutdown and transfer of a facility to EM-40. Project documentation associated with Phase I includes a preliminary characterization and hazards analysis, establishment of an effective S&M program, and initiation of the EM-40 budget cycle. Work performed in support of the proposed activity or project during Phase I is primarily preparatory in nature and provides the framework for development of the project plan and preliminary engineering work. Safety documentation associated with D&D of a facility may be prepared at during Phase I of the D&D process; however, it is anticipated that the majority of safety documentation would be completed during Phase III.

Phase III of the D&D process addresses environmental and safety documentation required to complete D&D of the facility. Engineering work is performed to define

and estimate the D&D alternatives and other engineering studies are performed to support the preparation of the appropriate National Environmental Policy Act (NEPA) documentation. Phase III of the D&D process ends at D&D key decision 2, Approval of the D&D Alternative and Approval to Start Detailed Engineering. During Phase III the safety documentation for the proposed activity or facility is completed and included as a part of the Decommissioning Plan. For those facilities that are below the Hazard Category 3 threshold the Health and Safety Plan may suffice as the final safety documentation.

Comparison of the Proposed Approach to the Existing Guidelines

The existing guidelines for safety analysis documentation were developed to support a production mission for national defense. As such, the requirements and guidelines address issues that would be associated with operational activities. The proposed approach was developed for facilities that have terminated operations and are to undergo D&D; therefore, issues associated with deactivation and D&D of a facility are addressed. These issues focus on declassification of a facility from Hazard Category 1 to below the Hazard Category 3 threshold and activities conducted during deactivation (i.e., removal of energy sources). The proposed approach fulfills the intent of DOE Orders 5480.23 and 5481.1B to establish and evaluate the adequacy of the safety bases of facilities and integrates safety documentation into the D&D process as defined in the Decontamination and Decommissioning Guidance Document - Draft (DOE, 1994).

CONCLUSIONS

The decision-based approach provides a process for defining requirements and developing safety analysis documentation for facilities scheduled to undergo D&D. The approach assists the project team in defining the appropriate level of documentation required to support D&D and maximizes use of the graded approach in completing safety analysis documentation. The seven-step process is a tool to be used by the safety analyst to focus the level of effort required to complete safety analysis documentation and assists integration of the safety analysis documentation into the overall D&D process.

Findings and Observations

There is no existing program within the DOE for safety analysis that has been tailored specifically for D&D projects. As such, this process is of particular importance to the DOE Complex due to recent mission changes at many of the DOE field sites and the subsequent increase in growth of the national D&D program. Use of the proposed approach for development of safety documentation for D&D projects promotes early identification of issues and allows the use of existing standards, criteria, and project management system without creating unnecessary documentation and inhibiting the progress of these efforts.

ABSTRACT

In recent years, U.S. Department of Energy (DOE) facilities commonly have been

classified as reactor, non-reactor nuclear, or nuclear facilities. Safety analysis documentation was prepared for these facilities, with few exceptions, using the requirements in either DOE Order 5481.1B, Safety Analysis and Review System; or DOE Order 5480.23, Nuclear Safety Analysis Reports. Traditionally, this has been accomplished by development of an extensive Safety Analysis Report (SAR), which identifies hazards, assesses risks of facility operation, describes and analyzes adequacy of measures taken to control hazards, and evaluates potential accidents and their associated risks. This process is complicated by analysis of secondary hazards and adequacy of backup (redundant) systems.

The traditional SAR process is advantageous for DOE facilities with appreciable hazards or operational risks. SAR preparation for a low-risk facility or process can be cost-prohibitive and quite challenging because conventional safety analysis protocols may not readily be applied to a low-risk facility.

The DOE Office of Environmental Restoration and Waste Management (EM) recognized this potential disadvantage and issued an EM limited technical standard, No. 5502-94, Hazard Baseline Documentation. This standard can be used for developing documentation for a facility classified as radiological, including preparation of an auditable (defensible) safety analysis.

In support of the radiological facility classification process, the Uranium Mill Tailings Remedial Action (UMTRA) Project has developed an auditable safety analysis document based upon the postulation criteria and hazards analysis techniques defined in DOE Order 5480.23, Nuclear Safety Analysis Reports. The auditable safety analysis focuses on hazards and potential accidents associated with relocation of mill tailings at UMTRA sites. The majority of hazards related to UMTRA activities are construction hazards. These hazards are addressed in the auditable safety analysis. The auditable safety analysis also demonstrates the limited need for backup (redundant) systems at UMTRA sites. This, in turn, expedites preparation of the auditable safety analysis by greatly reducing the need for discussions regarding adequacy and sufficiency of redundant systems.

INTRODUCTION

Within the last 10 to 12 years, views have changed regarding safety analysis documentation required for U.S. Department of Energy (DOE) facilities, including what must be addressed, what is adequate, and what approvals are required. This new perspective is due, in part, to the publics' demands for assurance that DOE facilities are operated in a safe manner and not endangering the workers or the public. At the same time, assurance must also be given that the environment is protected.

Partially in response to public demands, the DOE has issued two principal Orders pertaining to safety documentation: DOE Order 5480.23, Nuclear Safety Analysis Reports (Change 1, dated 10 March 1994)(1), and DOE Order 5481.1B, Safety and Analysis Review System (dated 23 September 1986)(2). DOE Order 5481.1B was the initial Order regarding development of Safety Analysis Reports (SAR). In the spring of 1992, DOE Order 5480.23 was issued, defining additional elements to be included in the SAR and superseding DOE Order 5481.1B, SAR Requirements for Nuclear Facilities. By the end of 1992, all DOE nuclear facilities were required to prepare SARs in accordance with DOE Order 5480.23.

Developing SARs at most DOE nuclear facilities was very time-consuming and costly. Different evolutions of the SAR document were required (Preliminary Safety Analysis Report [PSAR], Final Safety Analysis Report [FASR], and possibly a Safety Evaluation Report [SER]); backup (redundant) systems had to be identified so that critical safety systems could continue to function; and adequacy and sufficiency analyses were required for relevant structures, systems, and components (SSC) that were part of the facility operations or processes.

DETERMINING ADEQUATE SAFETY DOCUMENTATION

"Adequate" safety documentation continues to be a challenge at DOE facilities that have low hazards, have processes with the potential for only localized on-site consequences, and/or have a limited mission life. For example, the Uranium Mill Tailings Remedial Action (UMTRA) Project, based in Albuquerque, NM, is responsible for successful remediation of mill tailings (residual radioactive materials contained in sand or loose soil) generated during the processing of uranium ore. This DOE project includes 24 processing sites and over 5000 vicinity properties located in 10 states and on 2 Indian reservations. Remediation of the mill tailings is necessary because of potential adverse health effects from prolonged exposure to

residual radioactive materials.
The remediation process is divided into two distinct tasks: 1) either encapsulation on-site or relocation of the mill tailings, and 2) verification of effective containment of the mill tailings through a ground water monitoring program.
Task 1 ensures encapsulation of the mill tailings at a location that is considered to be geologically safe, either on-site or off-site. This geologically safe repository is referred to as a "disposal cell." The relocation process commonly consists of loading the mill tailings into large dump trucks, transporting them to and depositing them at the disposal site, shaping the deposited mill tailings into their final configuration using bulldozers and scrapers, and then placing a final cover of clay and rip rap rock over them. The majority of site activities relating to task 1 are those commonly encountered on a construction site using heavy equipment.
This construction orientation is also reflected in the lack of redundant systems for UMTRA Project site activities. The SSCs at UMTRA sites are not required to provide continuous operational support, as would be expected at a moderate- to high-risk facility. For example, at a to moderate- to high-risk facility, HEPA filtration systems might be required to operate continuously. This would commonly include a standby diesel emergency power system to ensure that HEPA filtration can continue to function. SSCs used at UMTRA Project sites are not required to be operational to maintain system integrity. For example, if a haul truck or conveyor system has a failure, the equipment is replaced, operations continue without the component, or operations cease until repairs can be made. In addition, no system failure can result in an unacceptable worker exposure or environmental release.
Task 2 site activities include regularly scheduled sampling of ground water from wells drilled adjacent to the disposal cell. While task 2 activities will continue well into the next century (2010), the personnel performing ground water sampling will not be exposed to any hazards other than those encountered in the general work place.
The majority of UMTRA sites are located in the southwestern portion of the United States where mills have been closed. Because of the mill closures, most of the towns adjacent to UMTRA sites are quite small or nonexistent. It takes approximately 2 to 3 years to accomplish task 1 at each UMTRA Project site. Actual periods of operation during each year of task 1 may only be 9 to 10 months long because of inclement weather.
When all of these factors are taken into consideration, it is readily evident that following the traditional PSAR/FSAR process for each UMTRA site would be cost prohibitive. In addition, the UMTRA site task 1 activities could conceivably be finished prior to receiving approval on the FSAR. Clearly, the UMTRA Project needed to have a more timely and cost-effective method of developing its safety analysis documentation.
As the UMTRA Project reviewed its options regarding developing acceptable safety analysis documentation without placing unacceptable constraints on project dollars, DOE-STD-1027-92, Hazard Categorization and Accident Analysis Techniques for Compliance with DOE Order 5480.23, Nuclear Safety Analysis Reports (3), was issued by the DOE in December of 1992. This standard provides a consistent method for determining the hazard category of a DOE facility, based on an "unmitigated release" of radioactive material. After reviewing UMTRA Project sites against the criteria specified in DOE-STD-1027-92, Project personnel determined that UMTRA sites could be classified as "radiological" verses "nuclear."
While this radiological facility determination relieved the UMTRA Project of having to develop a traditional SAR, the question of what would considered "acceptable" safety analysis documentation still remained. DOE Order 5481.1B does not apply to construction activities and it had insufficient depth and breadth to use for guidance in developing the safety documentation.
AUDITABLE SAFETY ANALYSIS (ASA) STRATEGY
In August 1994, while the UMTRA Project was evaluating guides to use for the safety analysis development process, the Office of Environmental Restoration and Waste Management (EM) issued a limited technical standard, DOE-EM-STD-5502-94, Hazard Baseline Documentation. In this standard, an auditable safety analysis (ASA) report is defined as the type of safety documentation required for a radiological facility. The ASA report must describe, in an auditable (defensible) manner, safety processes and programs used at the radiological facility.

To meet this requirement, the UMTRA Project used the principal safety criteria and SAR elements defined in DOE Order 5480.23. DOE Order 5480.23 was chosen for several reasons: its volume of definitive safety analysis content and structure, its recognition by the DOE community as the definitive written article on SAR development; and its guidance regarding what site activities should be addressed, how the SAR report should be structured, and how to focus SAR report development. Because the UMTRA Project chose to use DOE Order 5480.23 and it was not mandated by the DOE Headquarters, sections of the Order that were not considered applicable to the UMTRA Project did not have to have substantial objective evidence generated to justify their nonapplicability.

For example, Topic 8, "Inadvertent Criticality Protection," is clearly not applicable to the UMTRA Project. In a traditional SAR, this type of determination would require fairly extensive documentation to support it. In the ASA report prepared by the UMTRA Project, this section is simply not included. However, memorandums were generated for UMTRA DOE Project Office concurrence, documenting which elements of the Order would not be included in the ASA report. This approach allowed the ASA report to be focused on issues directly relevant to the UMTRA Project while still documenting all decisions made governing the report development process.

Because most of the UMTRA sites have the same basic types of SSCs, the UMTRA Project Office elected to develop a programmatic ASA report that addressed remedial action activities used at all of the sites. This allowed development of a single ASA report rather than 24 site-specific ASA reports.

The ASA report addresses site activities including those related to operation of heavy equipment, conveyor systems, and decontamination facilities. Site programs addressed in the ASA report include operations, training, maintenance, fire protection, quality assurance, decontamination, and emergency response. Project issues addressed in the ASA report include hazard analysis and facility classification, organization and administration, and derivation of technical safety requirements.

The ASA report includes an executive summary, a description of the process for development of the ASA report, a discussion of applicable elements of DOE Order 5480.23, a listing of applicable regulatory documents, and references. In addition, an integral element of the ASA report is a description of site hazards in sufficient detail to determine if existing controls used to limit target exposures are adequate.

In addition to the guidance provided in DOE Order 5480.23, the UMTRA Project also used the safety system analysis techniques contained in the Management and Oversight Risk Tree (MORT) fault tree process. The combination of these two types of review approaches allowed identification of appropriate hazards, review of existing barriers to control target exposure to the hazards, and a determination of the adequacy and sufficiency of the barriers. This same logic is used throughout the ASA report to provide a consistent technical baseline for the review process. It also allowed hazards relating to SSCs and programmatic elements to be discussed.

For example, SSCs of a area used for storage and dispensing of fuels (referred to on the UMTRA Project as a "fuel farm") are discussed as follows:

> FIRE PROTECTION: The quantities and types of fire protection equipment required to support UMTRA activities are based upon the fire hazard analysis techniques as defined in DOE Order 5480.7 and National Fire Protection Association (NFPA) 101. While each site hazard characteristics may vary slightly, all sites have potential fire hazards and use fire protection equipment as described below:
>
> Fuel Farm: Most of the UMTRA sites have a fuel farm area used for storage and dispensing of gasoline, diesel fuel, motor oils, and lubrication products. The fuel farm area is also used for storage of used motor oils for subsequent removal by an off site vendor.
>
> Hazards: Explosion and combustible fire hazards due to large volumes

of
flammable and combustible liquids stored in close proximity to each other.

Controls: Administrative controls include placing no-smoking placards at all fuel farms, developing site procedures, and training site personnel regarding the prohibition of parking construction equipment within 50 feet of fuel farm areas. Fuel farm storage tanks containing gasoline and/or diesel fuel are grounded in accordance with the requirements of NFPA 30, and dispensing containers are bonded in accordance with 29 Code of Federal Regulations (CFR) 1926.152.

Barriers: Earthen berms around perimeter of fuel farm; metal stanchions at fuel farm dispensing areas; and placement of fuel farms at remote locations.

Equipment: All fuel farms are provided with portable fire extinguishers (hand-held and/or wheeled). Sizes and quantity of the fire extinguishers are based upon volumes of flammable and combustible liquids stored. In addition, portable fire extinguishers (hand-held and/or wheeled) are placed in accordance with the spacing requirements defined in NFPA 10 and NFPA 30.

Governing Documents: Construction Environmental Safety and Health (ES&H) Management Plan, Training Plan, Site-specific Health and Safety and Hazard Communication Plans, Fuel Farm Operations Procedure, and Site Worker Course.

While this technique allows potential operational and/or process hazards to be readily identified and evaluated, programmatic elements (e.g., maintenance, operations, quality assurance, and training) need a slightly different approach. Programmatic elements commonly do not present hazards. Ideally, the level of detail developed for a programmatic element should be balanced with the type of work activity involved. For example, an overtly constrictive maintenance program for a low-hazard-level activity (e.g., changing light bulbs in a laboratory) is not desirable nor is it cost effective.
To determine what programmatic elements should be included in the ASA review process, the UMTRA Project used the functional area approach, as defined in the Environment, Safety and Health Configuration Guide (5), issued by the DOE in July 1993. The ES&H Configuration Guide provides uniform architecture for identifying and defining major ES&H topics, or "functional areas," based upon required activity. The UMTRA Project personnel determined that the following functional areas effectively control site activities or processes: configuration management; engineering, design, and construction; emergency preparedness; operational readiness review; environmental protection; fire protection; maintenance; management systems; occupational safety and health; operations; packing and transportation; quality assurance; radiological protection; safeguards and security; training; environmental restoration and waste management; and personnel.
Each of these functional areas was examined for potential applicability to the ASA report, and appropriate programmatic functions were included. For example, the maintenance management program is discussed as follows:

INITIAL TESTING, IN-SERVICE SURVEILLANCE, AND MAINTENANCE

The UMTRA Project has developed a maintenance management program using the graded approach criteria defined in DOE Order 4330.4B, Maintenance Management Program. The program has been implemented at the site level to ensure that equipment and components can operate dependably without excessive down time. While each site's maintenance management program can vary, depending on actual SSCs used, most of the

maintenance programs have the following elements in place:

Organization: UMTRA subcontractors are responsible for the day-to-day maintenance activities of all subcontractor equipment, including preventive, predictive, and corrective duties. The site maintenance group commonly consists of a supervisor and two to six support personnel.

Training: UMTRA maintenance personnel are trained by having new personnel work with experienced site staff. All training is performance-based to ensure that site personnel have been effectively trained prior to preforming tasks independent of direct supervision. Training records for maintenance personnel are retained at the site until completion of the contract.

Testing: All equipment, systems, and processes are tested in accordance with manufacturers' specifications and with site procedures.

Facility condition assessment surveys: Site management and subcontractor personnel perform daily and weekly walk-around inspections to verify condition of equipment and components. Selected pieces of equipment (haul trucks, scrapers, conveyors, rock separators, etc.) are subjected to a walk-around inspection prior to each use or daily start-up.

Work order system: Each site subcontractor is responsible for developing a work control system suitable for the equipment being serviced. As a minimum, all work order system(s) meet the applicable requirements of DOE Order 4330.4B and 49 CFR 396.

Maintenance procedures: Each site subcontractor is responsible for determining the depth and breadth of procedures required to support maintenance activities. All maintenance procedures are reviewed for adequacy and sufficiency by DOE Project Office personnel or a designee.

Preventive maintenance: Each subcontractor establishes a preventive maintenance program to ensure that all pieces of construction equipment, including haul trucks and supporting components, are effectively maintained.

Seasonal facility preservation: The majority of UMTRA sites have a winter shut-down program in place due to inclement weather. All heavy equipment is either removed from the site or winterized to prevent damage due to freezing temperatures.

Equipment repair history: All subcontractor maintenance programs are required to maintain relevant records of repairs to equipment. As a minimum, site programs meet the applicable requirements of DOE Orders 1324.2A and 4330.4B and 49 CFR 396.

Governing Documents: ES&H Management Plan, Standard Operating Practices (SOP) Manual, Maintenance Management Program Plan, and site- specific procedures.

All elements of the ASA report analyzing hazards and/or programs follow this same logic and all determinations of acceptability are supported by reference to adherence or implementing plans and/or procedures.

APPROACH TO THE DEFENSIBLE REQUIREMENT

As discussed previously in this paper, one of the requirements established by DOE-STD-5502-94 is that the ASA report be defensible. To meet this requirement, the UMTRA Project included in the ASA report a reference to the actual plan or procedure prepared to control site hazards or address programmatic issues. In addition, all plans and procedures referred to in the ASA report were reviewed for adequacy and

sufficiency in controlling the site hazard or governing the site program. This feature of the UMTRA ASA report also provides a convenient reference when procedures need to be revised or updated.

ASA REPORT RESULTS

The completed ASA report is approximately 75 pages long and is currently at the DOE UMTRA Project Office for final review and approval. Costs to the UMTRA Project have been minimal. Personnel responsible for development of the ASA report had previous experience in generation of SARs ,and the ASA report was generated over a period of months while other Project tasks were performed. This is significant because development and approval of a traditional SAR can take years.

The completed ASA report is already being used to orient new personnel or subcontractors to the unique aspects of UMTRA Project activities. It also allows site-specific activities or issues to be identified.

The ASA report will be reviewed on a yearly basis to ensure that all relevant safety processes are still identified. This yearly review also allows equipment or processes no longer used for UMTRA activities to be deleted from the report. This review process ensures that the ASA report reflects only current site activities.

CONCLUSIONS OF THE ASA REPORT PROCESS

The ASA report process has allowed the UMTRA Project to demonstrate that site processes are being conducted in a safe and defensible manner without placing undue constraints on budgets or site schedules.

By generating a Project-wide ASA report, individual sites with like processes can be addressed in a single document.

The ASA report can be used to identify potential equipment and procedure requirements for new UMTRA sites being started.

Because the ASA report is reviewed on a yearly basis, new processes or activities can be readily identified. In addition, processes no longer used can be readily deleted.

Due to the structure established for the ASA report, revisions can be accomplished in a timely and cost-effective manner.

ABSTRACT

There appears to be strong anti-press phobia among scientists and engineers. More often than not, the press is viewed as playing an adversarial role always looking for that "gotchya" sensational story attached with a tabloid headline. The press has

a role as a useful teacher, critic and ombudsman. The press actually can be a great tool for getting to the public. Journalists can be proponents or adversaries. And there are many venues other than daily newspapers for doing so: trades, education and scientific journals, university publications and local periodicals.

The scientific and engineering community, in many cases, does not have the universal acceptance by the public. How can this community increase its credibility and obtain a broad range of coverage on such pressing issues as environmental risk, implementing innovative cleanup technologies, economic and job development from the weapons complex's scientific resources?

A recent General Accounting Office analysis found new, innovative cleanup technologies are not being used at DOE sites. Once reason cited for this was how local stakeholders were often not familiar with these newer technologies and associated them with an unacceptable level of risk. Although numerous conferences have been held and thousands of papers have been presented on the technological capabilities for addressing U.S. environmental problems, the public is still not convinced the scientific community is credible.

This paper intends to address the need for scientists/engineers to move beyond just talking to each other in a vacuum, and to discuss options for developing an educational as well as political forum. Points and counterpoints will be made by a former DOE Assistant Secretary, a newsletter publisher and a journalist from the trade press who are experienced in both sides of the issues.

INTRODUCTION

Almost 50 years have passed since the end of World War II. The final events that ended the war were the bombing on Hiroshima and Nagasaki. The two Japanese cities were decimated with the birth of the nuclear weapons era. Although over 40 million people were killed during the period of the war from 1939 to 1945, the horrible legacy of the mushroom clouds emanating from the deserts of New Mexico and Nevada are indelibly scorched in the minds of each succeeding generation born after the war.

At the time President Truman made the decision to use the Atomic Bomb tens of thousands of engineers, scientists and craftsmen had contributed to what each thought was their contribution to ending the war. Nuclear energy was harnessed but the birth of a nuclear weapons industry emerged and was entwined with all future developments. Nuclear technology evolved into weapons, energy in the peaceful harnessing of the atom and medical isotopes for diagnostic and treatment applications never received supremacy of independence. The Manhattan Project was the acme of the technical application of a multidisciplinary capability-democracy and free enterprise at its finest. As the applications of nuclear technology developed, the weapons sites of the wartime production became multifaceted industrial incubators. Technology of chemical separation, major construction, scientific laboratories with the most complete grouping of the nations scientific excellence was assembled to maintain the peace through application of the weapons of mass destruction, nuclear energy for naval propulsion, nuclear energy for electrical generation and nuclear medicine.

In 1948, a select team was assigned the task of reviewing the operations of the wartime facilities in their transition to peace time application. The report, by the AEC Safeguard Industrial Health Advisory Board (1), conclusion was:

a. Methods used during war time emergency may not be acceptable for continued peace time applications;

b. Radioactive and hazardous materials are being discharged into the environment and will have long term consequences; and,

c. When these facilities are returned to the public, the public will be a hard taskmaster.

Now that the communist threat of massive force appears to be dissipated and the United States appears to at least be at a lower risk of a massive outside force threat, DOE, the agency that assumed the legacy of the Atomic Energy Agency and its successor, the Energy Research and Development Agency, is under attack from the four estates of the realm and at a crossroads for survival.

The benefit of nuclear deterrence is now castigated from all sides, the end products of its legacy, Uranium, Plutonium and radioactive by-products, are addressed as the most toxic substances known to man by a technically weak press.

President Clinton has targeted a major budget reduction for the Department of Energy (DOE), $26 billion over 5 years. Congress, in its effort to reduce the size of

government, has indicated a potential for eliminating the Energy Cabinet post and the agency. It appears that the hero of the cold war, the too-cheap-to-meter potential for nuclear energy, the hope for fusion energy , solar, wind, clean coal, human genome and the electric car may suffer the ignominious distinction of being eliminated in the first knee jerk reaction of the "Reinventing the Government" revolution.

The question raised by the authors is how could this happen when major efforts were being initiated to open research facilities of one of the largest scientific resources in the world, an agency that saved the world for democracy, now focusing 100,000 employees, 40,000 scientists and billion of dollars to environmental accountability, restoration and development of technology of which the Department of Commerce touts as a $300 billion year industry.

It may be serendipitous, coincidence or just bad timing, but there appears to be inadvertent or possibly a recognition by the Fourth Estate that the Department of Energy in the past two years had reached the end of its useful purpose.

The authors conducted an extensive review of two years of press coverage on the Department of Energy by the national press, the trade and scientific journals and media in general-not a scientific study but at least a sufficient cross-section-to attempt to identify any possible cause for the almost universal conclusion that something is wrong with the Department of Energy.

The authors reviewed two years of DOE-related articles in the three major national newspapers: The New York Times, The Washington Post and The Los Angeles Times. In addition, two years of trade periodicals, i.e., Engineering News, Science, Physics Today, MIT's Technology Review and the Oil and Gas Journal. Also researched were magazines such as OMNI, Popular Science, Popular Mechanics, Business Week, Fortune, Time, Newsweek and U.S. News and World Report. All were reviewed over the two year period to see if there was any obvious trend in national coverage of DOE while the nation was regrouping for "Reinvention", "Contract for America" or any other potential government evaluation.

It was interesting to see a developing pattern of self-inflicted bleeding and purging by the Department of Energy during this two year period resulting in a overwhelming impression of long-term mismanagement and public irresponsibility. The Washington Post and The New York Times, as expected, carried the most features on the Department of Energy in the two year period; twenty-two (22) major stories. Table I lists the various publications that were reviewed and the results of specific areas tabulated as positive or negative in presenting a view of the Department as would be perceived by the general public are tabulated in Table II. As can be seen from Table I the dominant inference of the articles is negative. The predominant negatives in Table II articles were on mismanagement, inefficiency and inept managing of programs. The second major area of national negative press was related to radiation experiments in the 40's, 50's, 60's and 70's. In the majority of reports no credit was given to DOE for internal findings, corrective actions that were implemented without GAO audits or Congressional Committee hearings. However, due to the wire services of the three major newspapers read inside the Beltway-The Washington Post, The New York Times, and the Los Angeles Times-the Local Constituency Daily receives the end product of these three major national reports. If their perception is negative, then the whole country gets a negative perception of DOE.

If one considers that The New York Times, The Washington Post, and the Los Angeles Times have the major wire services to the regional local newspapers and the dominant theme is negative then Congress and its constituents see a total negative impression of the Department of Energy and as a result the current "Knee Jerk" reaction to significantly reduce or eliminate the Department.

The authors then reviewed what are considered to be the prestigious trade journals that cover Department of Energy related items in science, technology and management. The periodicals reviewed were Science, Physics Today, Science News, Engineering News Record, Chemical and Engineering News, Oil and Gas Journal, and Scientific American. As would be expected of the 69 articles related to Department of Energy 60 were positive and 5 were negative, 4 were either neutral or non-committal.

One of the unusual aspects of the research identified a major deficiency in an area where the Department is committing $250 million to technology related to the electric car. Three publications, Science, Atlantic Monthly, and Business Week ran cover stories on the future of electric vehicles and battery research. None of the

articles reference DOE or the US Advanced Battery Consortium or National Electric Vehicle Program funded by DOE. GAO in GAO/PEMD-95-7 (2), Electric Vehicles stated that the US program is fragmented and that the US success may be overcome by foreign competition. If after spending $250 million with the major auto manufacturers and battery manufacturers DOE is not mentioned in any of the major stories investigative press is some what deficient to say the least. The Oil and Gas Journal Dec. 19, 1994 (3), praised former Deputy Secretary Henson Moore, current Deputy Secretary Bill White and wrote a five page laudatory article on Deputy Assistant Secretary Reginal Spiller, but wrote an editorial in the same issue saying it's time to get rid of DOE.

The Feb. 20, 1993 Science News (4) contained a cover story on technology and water purification and never mentioned one DOE facility even though DOE is spending a half-billion dollars per year in groundwater research. Bioscience Magazine Sept. 1994 (5), wrote a ten page article "Renewable Energy: Economic and Environmental Issues." The article referenced five DOE published papers out of 60 referenced documents, but failed to mention a single DOE energy lab even though DOE spends $2 billion on renewable energy and related areas per year. Hazwaste Magazine (6) wrote a cover story on "Nuclear Decontamination and Decommissioning" and failed to mention DOE experience although DOE has decommissioned over 50 reactors, West Valley Reprocessing Plant and innumerable hot cells and provided the major research and funding for the TMI-2 Decon. Talk about having your light under a bushel.

That now gets to the fundamental issue is the press friend, foe or ombudsman? The mass media in most cases appears technically inept. This, combined with the transition from the secrecy mentality, the subliminal technologist's fear of being used or misquoted and the big brother mentality of the Department of Energy's press office, the engineer/scientist has limited ability to provide technical articles to the press/media which can be understood by the average taxpayer. The New York Times runs a technology section once per week, The Washington Post runs a two column technology quarter page daily and a periodic technology supplement and DOE stringers are always looking for a one-up on their competitors. Of the three major publications that printed positive articles about DOE-Discovery, OMNI and Popular Mechanics-they published layman articles provided by federal laboratories to the magazine technical writers. DOE labs and lab contractors wrote over 3,000 technical papers last year; Waste Management '94 produced 900+; Spectrum, 94-600; American Nuclear Society, 150; American Chemical Engineers, 300; Society of Mechanical Engineers, 150; and another 800 papers were produced throughout the other major disciplines. Most were written for technical understanding and not for educational purpose.

It may be too late to save key elements of DOE from bureaucratic extinction, but it is imperative that the work being done within the various facilities of the Department become visible to the media, Congress and the taxpayer. The expenditure of $6-8 billion in research each year must compete with medicare, education, crime, AIDs and state and municipal infrastructure.

The authors found one publication issued quarterly by Lawrence Berkeley Laboratory, Research Review (7), which met the quality and educational level that could be used for publication in magazines of the class of OMNI, Popular Science and Sky (United Air Lines) that would provide a more balanced perspective for the expenditure of $6 billion of the taxpayers money. The LBL Review was able to publish in almost layman's terms articles on quarks, clouds and climate, cell aging, human genome and DNA mapping which could be published directly in any public technical or semi-technical magazine and could be a model for other DOE laboratories.

The press is neither friend nor ombudsman without input. From the limited study conducted by the authors, the FOE is the scientific community within DOE who publish only for other scientists, ergo providing hymnals to the choir. In today's diminishing funding availability in a reinventing knee jerk budget, the oft heard academic slogan "publish or perish" is the need of the future. It may be too late for the current DOE system but the future requires scientific literacy for public support and only the scientist and engineers can help the press/media become technically literate.

This could be accomplished by planning to have at least ten articles published each year in laymen or layperson journals from each laboratory or facility. That would be only 300 topics per year. To keep America competitive the utilization of 40,000 focused scientists supported by taxpayers requires more effort than hymnals for the

choir. The press to today's hyper environment thrives on "bad news is good news." To make the press's technical job easier and the scientific career more secure and, more importantly, recognized as a national resource of considerable economic return, requires directed effort layperson technical journalism and an understanding that the public trough supports hogs and chickens. The chickens are dedicated to continuous support and the hogs are committed to a one-time banquet. It appears that the banquet may be over and the chickens need to learn how to crow to continue to be fed and feed a technically deficient press.

HYPERMEDIA: A TOOL FOR EFFECTIVE STAKEHOLDER INVOLVEMENT

Mike Hart
Jason Associates Corporation
Bob Brown
DOE
Mathew Appelbaum
S.M. Stoller Corporation

ABSTRACT

Computer-based multimedia communication has recently emerged as an effective tool for many kinds of presentations, and its special features -- accessibility, consistency, user appeal, and clear communication -- make it especially effective for augmenting public participation activities. Jason Associates Corp., in cooperation with S.M. Stoller Corp. and Coleman Research, developed a multimedia product for the U.S. Department of Energy to summarize for general audiences the key information contained in the 3,400 page DOE Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Draft Environmental Impact Statement. This product has been and continues to be used to inform the public about spent nuclear fuel management. Experience deploying this application in venues throughout the country has resulted in some valuable lessons learned: 1) Location defines the amount of use, 2) Increased use of sound, video, and graphic enhancements does not always improve communication, 3) Use of kiosks can have significant advantages and disadvantages, 4) Youth can be a conduit to adults.

INTRODUCTION

Meaningful dialogue is critical to the success of decision-making processes, especially those involving public agencies, but dialogue requires that all involved parties first have a clear understanding of the issues at hand. While agencies are recognizing that effective communication produces better, more easily implemented decisions, the task can be particularly challenging when they must present audiences with large volumes of technical information.

Computer-based multimedia communication has emerged over the past five years as an accessible and effective tool for many kinds of presentations. While there are a variety of multimedia applications, they all share common characteristics. They typically bring together, in a common digital format, several media -- including text, illustrations, photos, sound, animation, and video -- so that a presentation becomes multi-sensory and user-driven, rather than simply a passive, linear experience.

Multimedia can be operated on a variety of platforms, including personal computers, kiosks, projection devices, interactive games, and Internet. Well-designed multimedia presentations -- whatever the platform -- get the attention of audiences and improve retention of ideas at a recall rate two or three times that of static presentations, making them ideal for educational or training purposes (1). By

employing a variety of media, they help users to understand concepts that are difficult to convey through text alone. More recently, the increasing popularity of laptop computers has made portable presentations possible for business.
The U.S. Department of Energy faced a particularly challenging communication task in 1994 as part of its preparation of a complicated environmental impact statement. The Department of Energy Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs Draft Environmental Impact Statement (SNF & INEL EIS), a 3,400-page multi-volume document issued in June 1994, covered spent fuel management decisions for the entire DOE complex as well as site-specific decisions about environmental restoration/waste management activities at INEL. Because the National Environmental Policy Act requires Federal agencies to obtain public comment on environmental impact statements and to involve stakeholders in making decisions about them, DOE sought innovative ways of communicating information to the public about this large, technically complex document and its subject.
As one tool for improving communication and encouraging public involvement in spent nuclear fuel management decision making, DOE elected to create a computer-based multimedia application. "Choosing a Course," the interactive multimedia (or hypermedia) product designed and developed for DOE by Jason Associates Corporation and S.M. Stoller Corporation, Coleman Research, summarized for general audiences the key information contained in the draft of the SNF & INEL EIS. Included were background information about the DOE weapons complex and the spent nuclear fuel issue, opportunities for citizen involvement, descriptions of potentially affected sites, alternatives to spent nuclear fuel management and their implications, and site-specific implications for the various alternatives (2).
The goal was to produce a multimedia product that was strictly consistent with the content of Volume 1 of the draft SNF & INEL EIS (the portion that dealt with DOE programmatic spent nuclear fuel management), but that was more user-friendly than the draft document itself. While the text and graphics for "Choosing a Course" were drawn directly from the SNF & INEL EIS, the multimedia format made it possible to select a level of information (and supporting photographs and graphics) appropriate for general audiences.
DOE elected to use different platforms for the EIS hypermedia for different purposes. Since DOE and the U.S. Navy planned to conduct public meetings about the SNF & EIS in potentially affected communities across the U.S., they chose a kiosk version of the product for those occasions. Kiosks are floor-mounted cabinet installations designed to make information accessible to many people and are commonly found in shopping malls, airline terminals, and other public places. Users typically operate multimedia products in kiosk form by making selections on a touch-sensitive monitor screen.
For individual use, hypermedia was made available on disk for home computers, where it can be operated by making selections with a mouse. Interested citizens may request copies of the product for either Macintosh or PC. In addition, the application "Choosing a Course" available on Internet via the INEL Home Page (http://INEL.GOV/).
Kenneth A. Chacey, deputy director of DOE's Office of Spent Fuel Management, noted that a multimedia product was particularly well suited to the task of providing information to stakeholders. " The power in hypermedia is the ability to make full use of a multi-faceted medium to convey complex activities to the general public through meetings, interactive workstations, and information superhighways, like Internet," he said.
TECHNICAL DESCRIPTION
Before any communication tool can be created, one must first identify the audience and messages to be communicated. DOE's goal was to provide information to the public so that they could make informed decisions about the complex issue of spent nuclear fuel management. They wanted to make available to the public a product that would enable average citizens to understand the problems that DOE faced in managing and storing spent nuclear fuel, as well as the various alternatives that DOE was considering as a solution.
The requirements for this particular product were that it be
  User friendly -- with a transparent user interface
  Platform independent (IBM/Macintosh) -- a run time version that did not require the user to purchase additional software

Lowest common denominator hardware requirements so that it could be run on a typical home computer.
In order to reach as broad an audience as possible and to make the product platform independent, the developers identified existing software that allowed creation of a run-time version that did not require the user to purchase special software to run the program and did not require special royalty fees from the client or the user. For use on garden-variety home or office computers the application was developed with certain constraints in mind -- including disk size, rapid access memory (RAM), and (primarily with IBM) the possible absence of a sound card. As a result of these constraints, the developers chose to limit this product to three media: text, photographs, and drawings.
The characteristics of multimedia that make it effective for communication in business, training, and education also make it ideal for public participation activities and help to overcome these barriers.
Accessibility: Navigating a series of technical documents in search of a particular item of information can be difficult for both agency representatives and stakeholders involved in decision-making processes. In these circumstances, well designed multimedia products can offer fast, user-controlled access to specific information.
The developers of "Choosing a Course," for example, approached information design from the user's point of view, using the items that DOE felt stakeholders would most want to know about as primary topics. The computer-based, menu-driven format allows users to locate and select topics quickly via the kiosk touchscreen or Macintosh/PC mouse. The advantage for DOE staff and representatives was that they could use hypermedia as a training tool to prepare themselves for public meetings, while stakeholders could get quick answers to many questions.
Opening with an initial animation screen, the body of information is contained under five key topics represented by icons (or buttons). This table of contents represents the first decision point in the program and gives the user the option of selecting one of five topics about spent nuclear fuel (Fig. 1).
Fig. 1. Flow chart schematic of first level architecture for "Choosing a Course."
Overview summarizes important information about the spent nuclear fuel program and the SNF and INEL EIS and provides other relevant background material.
Public Participation outlines the requirements of the National Environmental Policy Act relating to public involvement in decision making, as well as the relationship of the SNF and INEL EIS to various other NEPA documents.
By selecting Current Site Information , the user can get information about any site at which spent fuel management activities are, or may at some point be, taking place, including DOE sites, U.S. Navy facilities, university and research reactors, and potential ports of entry for foreign research reactor fuel. This section provides detailed information about the five DOE sites being considered for major roles in spent nuclear fuel management
Management Alternatives allows the user to select any of the alternatives to spent nuclear fuel management, to compare the alternatives, and to see the national implications of each. This selection includes maps illustrating the spent fuel transportation activities that would be required under each alternative
Selecting Site-Specific Information , allows the user to select a site, then see the implications for that site specifically for any of the spent fuel management alternatives. Included is information on the follow topics: transportation, environment, facilities, socioeconomics, health and safety, and risk.
Under each of the five topics in the table of contents more information is layered. Each topic expands into a tree of options with further options tiering off of successive sublevels. This layering of information allows users to browse deeper and deeper into the subject matter or allows them to stay at very summary level information. Multi-level design is one of the defining features of this system's architecture. A user can truly "get into" the information and spend hours perusing the system or just read the summaries and be in and out in 10 minutes. The advantage of the technology and architecture is that it allows different users to use the system to meet their individual informational needs in a non-linear way.
DISTRIBUTION AND DEPLOYMENT OF THE SYSTEM
An obvious target audience is the interested public, meaning those who are likely to attend public meetings, visit reading rooms, or ask to be placed on the mailing list. Providing this group with access to the kiosk and/or desktop version provides

them with the opportunity to quickly get to information of interest and as a result provide more meaningful and focused comments. By having the kiosk available prior to public meetings DOE hoped to increase the quality (i.e. on topic, and related to the decision being discussed) of oral comments received. The deployment of kiosks was targeted to both of these distinct audiences.

One goal of public information is to make information more accessible and digestible. Accessibility can be defined in terms of convenience and usability. Printed information is convenient because it can be delivered by mail to one's house, however, receiving a 3,400 page document by mail does not make the information accessible if you are only looking for answers to specific questions of interest. Summaries and brochures can be helpful, but often lack detail and are inherently linear in the way information is organized. Interactive multimedia can make detailed technical information more usable and convenient. As a result of improved communication to stakeholders, DOE would improve its chances of receiving better information from stakeholders.

Because the interactive multimedia system requires a computer system to run, distribution of the desktop version is limited to those who own or have access to computers. Kiosks, however, can be appropriately placed in nearly any venue from public meeting sites, public libraries, and reading rooms to shopping malls, public schools, public buildings, and museums. Kiosks, therefore, offer a significant advantage over other forms of information in that they can place the information where it is convenient for the public rather than forcing the public to find the information. This provides opportunities for outreach to an audience that is often referred to as the "silent majority."

Reaching the "silent majority" is not likely to move them to activism and may not result in additional public participation, but it does offer an expanded opportunity for individuals to become informed about the subject and allow them to make the decision as to whether or not they wish to become involved.

To reach these two distinct audiences, a kiosk deployment action plan that identified appropriate venues throughout the country specifically targeting communities being considered as alternatives for spent fuel management. Upon completion of the program, kiosks loaded with the system were sent to public meeting locations.

At publication, kiosks or systems were located at appropriate sites in 5 locations in Idaho including the Shoshone-Bannock Reservation, 2 locations in Georgia , 2 locations in Washington D.C., 1 location in Tennessee, and 1 enroute to Nevada. Kiosks have been placed in shopping malls in Idaho Falls and Pocatello, Idaho; the Eastern Idaho State Fair; Pocatello Idaho City Hall; the INEL Pocatello outreach office; the Shoshone-Bannock Public Library; the Idaho Falls public library, the Idaho Falls Airport; lobbies of SRS and INEL buildings; University of South Carolina , Ruth Patrick Science Center; and the American Museum of Science and Technology in Oak Ridge, TN. Additionally, kiosks or demonstrations have been provided at conferences and workshops including meetings of DOE's Transportation External Coordinating Group, the Whitehouse conference on Technology for a Sustainable Future; a DOE conference on diversity, several national meetings of the American Nuclear Society, the DOE NEPA Compliance Officers Meeting, the International Association of Public Participation Practitioners annual meeting, and the Waste Management 95 Symposium.

LESSONS LEARNED

Experience deploying this application in venues throughout the country has resulted in some valuable lessons learned: 1) Location defines the amount of use, 2) Increased use of sound, video, and graphic enhancements does not always improve communication, 3) Use of kiosks can have significant advantages and disadvantages, 4) Youth can be a conduit to adults.

Location. At public meetings and at conferences and workshops, the amount of use the system got was proportional to the convenience of its location. When the kiosk or system was place in traffic patterns or in open areas, it was used more frequently. When the system was in a separate room, away from a traffic pattern or meeting room, use decreased.

When possible, the location of the system should be optimized to ensure maximum exposure. Often, room design or space constraints limit control of location, but this variable should always be considered and optimized.

Use of audio, video, and graphics. While the ability to use the above media are

what sets multimedia apart from printed information and posters, they must be thought through with the communications objectives in mind. A similar system that had a more linear design but relied more heavily on sound and video was not as popular with a large group of students because it did not contain much depth of information in comparison to the subject system. The two systems, however, where designed with different communication objectives in mind. The key driver of choices to use or rely on audio, video, and graphics should always be communication goals and target audience.

Another lesson relating to use of sound is that it can be off-putting. Ambient noise levels vary in both location and time. If sound is an integral part of the multimedia design, volume levels must be adjusted at the deployment location to ensure it is intelligible under all or most conditions and is not too blaring when ambient noise levels are low. If sound is an augmentation not an integral part of the design, the system should allow sound levels to be adjustable and allow the option to turn sound off when it is not desirable or should allow users to "short-circuit" sound when it is not needed.

Advantages and disadvantages of kiosks. Use of kiosks can have significant benefits, but those benefits come with a price. Having the system in a kiosk allows placement in locations such as lobbies of buildings, shopping malls, libraries, etc., without staffing or security. This allows greater access and minimal labor effort. The system can also be operated on a standard computer but in that configuration requires staffing to deter theft. While the size of a kiosk is an inherent disincentive to theft, it also complicates shipping and handling logistics. To ensure maximum utility and realize greatest benefit, one should consider whether or not the staffing will be available and then determine which system configuration is most desirable.

Reaching adults through youth. Depending on where and how the system is deployed, it often attracts youth, in part because it may resemble a video game, and in part because youth are not as intimidated by technology as adults. While this may not seem like the intended use of the system, it does have benefits and provides some value added. First, youth are often accompanied by adults who often look over the shoulders of their children. Additionally, adults are frequently lured to the system by their children who have higher curiosity. Other parents use the system to teach there children about how the technology works. Finally, youth can carry messages back home to parents resulting in achieving some additional level of awareness and communication. While use of the system by youth does not always bring these benefits, they cannot be discounted.

CONCLUSION

While accurate public information is only one part of community decision making, it is a first step in building consensus (3). "Choosing a Course" enabled users to visualize and compare implications of all proposed alternatives side by side on a site-specific basis, thus allowing them to formulate their own ideas of a successful solution and encourage their participation in the decision-making process.

ADVANCED TECHNICAL TRAINING FOR AN INTERNATIONAL AUDIENCE OF PROFESSIONALS, SCIENTISTS AND ENGINEERS: VIDEOCONFERENCE/VIDEOTAPE FROM THE UNIVERSITY OF NEW MEXICO

Connie Callan
Executive Director, NETN
The University of New Mexico

ABSTRACT

Budget cuts and increasing demands for a technically competent work force are problems facing industry and government today. Training requirements must be met in a cost-effective manner. The videoconference format is a proven method that saves

money on training and travel costs. The videotapes produced from training programs extend the productivity in any facility.
However, designing a training series that meets the needs of a diverse audience composed of scientists, engineers, and management from government, industry and universities is extremely challenging.
National Environmental Technology Network (NETN), a department of The University of New Mexico's College of Engineering, has a proven track record in developing and producing effective videoconference training programs for industry, government, national laboratories, and universities. To date, seven successful series have been completed: Total Quality Management (two series, one for service organizations and one for manufacturing); Hazardous Waste Management; Waste Minimization and Pollution Prevention; Environmental Risk Management; Radioactive Waste Management, and Mixed Waste Management. Two series are in production: Decommissioning (6 parts) and Pollution Prevention (5 parts). National awards from the United States Distance Learning and the United States Environmental Protection Agency attest to NETN's leadership in providing advanced technical training using distance learning techniques.
This presentation describes how to develop, produce, and market an environmental television series and reveals the keys to successful videoconferencing by describing the past successes of NETN's videoconference training. The presentation characterizes how videoconferences can be used as university-developed advanced technical training for shifting the work force from defense projects to environmental remediation and protection. It also illustrates how the effectiveness of this training is enhanced by partnerships that evolve between the originating university and the receiving sites. Additionally, the presentation addresses the technical aspects of the production of past series.
INTRODUCTION
Professionals must continue their education throughout their careers to stay abreast of the latest technologies. For example, to keep up with developments in their field, engineers require retraining on an average of every four years. The need varies, depending on the precise discipline. Additionally, many technical professionals currently face significant changes in their careers, as their positions shift from defense-related activities to environmental fields.
With the budget cuts and increasing demands for a technically competent work force confronting industry and government today, the emerging training requirements must be met cost-effectively. The videoconference format represents a proven method for communicating the most up-to-date information concerning technical, environmental and management topics. According to Daniel Barron, distance education is a means of ". . .taking quality education to the people who need and want it. Distance education is to instruction what bookmobiles and branch libraries are to reading" (1).
Through this method, thousands of professionals can receive the most current information and participate in training programs simultaneously, via satellite, without incurring the cost of travel and perdiem expenses. The series are structured to stimulate creative interaction and promote a significant exchange of information among technical professionals and stakeholders confronting the increasingly complex environmental challenges of today's world.
Broadcast on Cband, Kuband, and through NTU, these videoconference series can be received anywhere in the United States. Most organizations already have the equipment necessary for receiving these instructional television broadcasts. Those not having this capacity can purchase a satellite dish for a minimum investment, a one-time cost for equipment. Videotapes produced from training programs and the accompanying instructional workbooks extend the capacity for training in any facility. Those who participated in the live training sessions have an opportunity to review material and clarify important points. Those who could not attend the live broadcasts can watch the videotapes and complete the training as their schedules permit.
During the live broadcasts, the training experience extends far beyond that of being a viewer. The programs afford every participant the opportunity to interact by means of question/answer sessions throughout each program, via a toll-free telephone number, e-mail, or the use of a fax machine. The interaction is amplified by accepting questions before the programs air, throughout the programs, and after the programs are completed.

Designing a training series that meets the needs of a diverse audience of scientists, engineers, and managers from government, industry and universities is extremely challenging. As Reza Azarmsa explains, "Much like any other area of mediated communication, teleconferencing is both a science and an art" (2). National Environmental Technology Network (NETN), a department of the University of New Mexico's College of Engineering, has an exceptional record for developing and producing effective videoconference training programs for industry, government, national laboratories, and universities.

NETN is part of an environmental consortium funded by the Department of Energy (DOE). The Waste-management Education and Research Consortium (WERC) is composed of New Mexico State University, University of New Mexico, New Mexico Institute of Mining and Technology, Sandia National Laboratories, Los Alamos National Laboratory, and Navajo Community College. Members have teamed together to help solve the environmental problems facing our nation, collaborating in three areas: research, education, and training.

In addition to a variety of videoconference series, six to eight full-credit environmental courses are broadcast from the three member universities on KU-band satellite each semester. WERC also sponsors a summer research lecture series and offers a certification program.

PAST SUCCESSES OF VIDEOCONFERENCE TRAINING AND THE TWO UPCOMING SERIES

To date, NETN has produced seven successful videoconference series: Total Quality Management (two series, one for service organizations and one for manufacturing); a 14-part Hazardous Waste Management series, an 8-part Waste Minimization and Pollution Prevention series; a 7-part Environmental Risk Management series; an 8-part Radioactive Waste Management series, and a 6-part series on Mixed Waste Management. During 1995, NETN will be producing and broadcasting two new series. The first, Decommissioning, is a six-part series addressing decommissioning within the Department of Energy's Environmental Management program. The second series, Pollution Prevention, examines technologies for applications from government installations to cottage industries.

These live, interactive videoconference series have been broadcast to over 167 sites with diverse audiences. The training has spanned the United States, reaching 8,000 participants in 48 states-100 industry sites, 64 military/government installations, 32 universities, and 46 hospitals.

National awards from the United States Distance Learning Association (USDLA) and the U. S. Environmental Protection Agency attest to NETN's leadership in providing advanced technical training using distance learning techniques. These series have received awards for the past three years, and most recently, NETN earned an award for "Most Outstanding Distance Education Network" from the USDLA.

HOW TO PRODUCE AN ENVIRONMENTAL TELEVISION SERIES

To select a topic for a videoconference series, NETN surveys DOE sites, requesting information about their current training needs. When sufficient interest is expressed in one particular area, and the funding for production procured, the topic becomes the focus of the next videoconference series.

In the early stages of developing a videoconference, NETN conducts an "Environmental Experts" workshop, where environmental professionals meet to listen to speakers and participate in panel discussions and question/answer periods. To simplify information transfer, workshop participants complete surveys for NETN. These surveys ask respondents to describe the issues they consider critical for professionals in these fields to address; list the concepts that need to be communicated to stakeholders; identify recognized national experts in the fields; and provide names of periodicals, national organizations, and associations important for people involved in this area of expertise.

The next step consists of advisory board meetings, which lay the foundation for the videoconference. National experts involved in previous programs, scientists from the institutions that represent WERC, and stakeholders are all invited to attend. To provide an overview of a series' production, speakers with past experience in televised training describe the roles and responsibilities of those involved in the process. For example, technical advisors identify program leaders and make sure they are willing to serve in that capacity. The technical advisors must see the overall program content and make sure all aspects of appropriate topics are covered. They also work with the NETN staff and provide the last line of review for participants' instructional manuals.

The individual program leaders recruit nationally recognized experts in the field for their program. They maintain a balance in the program content and may also serve as presenters.
The program presenters need good communication skills in order to deliver their material and to interact with the participants during question/answer periods. Presenters are encouraged to incorporate graphics, video clips, humor, and real-life examples to keep their presentations interesting. Each presenter submits charts, suggested readings, test questions, glossary terms, and a brief biography to NETN, which prepares the material in a standard format for the participants' instructional manuals.
During the next portion of the advisory board meeting, members begin the planning process by developing a proposed series outline. The outline consists of specific program topics, any particular emphasis to be considered for each topic, and possible case studies.
As the topics develop, the technical advisors and the advisory board suggest possible program leaders -- experts in the field with backgrounds in industry, business, and government. NETN contacts these individuals, and those who agree to lead join with the advisory board and NETN staff to form the nucleus of the evolving series. The program leaders then select five or six more people with expertise in their program topics to serve as presenters.
Because NETN seeks presenters from all over the United States, much of the program design occurs during a series of conference calls. Once a plan is established for the individual programs, the program leaders meet with the NETN staff in Albuquerque to fine tune the content of each program and assure continuity for the series as a whole. This not only reduces redundancy, it also confirms that the participants will receive an adequate amount of technical background information. Then, as the scheduled air dates approach, conference calls among those involved in individual programs continue as needed.
Meanwhile, behind the scenes, a team of graphics artist, writers, and editors prepare the presenters' material for the instructional workbooks and return the final draft to the presenters and the technical advisors for review. The workbooks for each program contain the following information: intended audience, program description, presenters' charts, suggested readings, test questions, presenters' biographies and addresses, various questionnaires, an information request form, and a participant's evaluation form.
The finalized manuals are sent to each site prior to the program broadcast. Two copies of the workbooks are sent -- one unbound, for duplication and distribution to all students planning to attend the training, and one bound, to serve as reference material and augment the site's videotapes of the programs.
Simultaneously, the video producer pulls together all the elements necessary for live broadcasts. Scripts are written and case studies are chosen. Arrangements for on-location productions at the sites are made, the case studies are shot and edited for the broadcasts. All elements for live broadcast are orchestrated with the studio, down to the selection of soundtrack music.
Prior to the first program's broadcast, NETN conducts a two-hour facilitator training program. Experience has shown that site facilitators contribute to the overall success of this televised training when they function as proactive members of the team. The facilitator training program covers a wide range of instructional material. Facilitators learn technical details, such as how to establish a comfortable environment for the viewers and how to check the operation of the equipment. They learn how to find the appropriate audience and publicize the upcoming training at their site. They receive tips about effective ways to interact with series advisors and are encouraged to seek experts within their organization who can enhance the learning experience.
In addition to the televised training, facilitators receive a training packet to serve as a reference during the course of the series. Given this overview of what to expect from the distance education experience and how to make it meaningful for the participants, the facilitator often serves as the foundation for the partnership that develops between the university and the receive sites.
One week after the facilitator training program, the first program is broadcast. Every program within a series contains a minimum of five or six presenters from industry, government, and universities with varied scientific backgrounds and expertise. Each program devotes one segment to regulations that pertain to the topic

of discussion. To increase effectiveness, live presentations are mixed with video footage that demonstrates the technology involved in the program topic, as well as relevant case studies that illustrate practical uses of the material. Customized workshops and on-site training are also available.

Publicizing this training event occurs at two levels. NETN can assist the sites with publicity by developing a customized brochure, news releases, and advertisements. A brief promotional tape is also available to the sites. On the broader spectrum, NETN notifies former participants of the upcoming series, writes press releases, and develops detailed brochures for distribution. To help ensure a wide array of participants, the NETN Director publicizes the videoconference training at trade shows and at national meetings on distance education and environmental issues.

THE KEYS TO SUCCESSFUL VIDEOCONFERENCING

The keys to producing effective videoconference series extend into every facet of production. In the preliminary stages, well-defined topics and carefully selected presenters with excellent credibility set the stage. Comprehensive instructional workbooks enable the audience to follow along easily and record their notes. Question/answer periods with ample time for discussion encourage interaction that facilitates technology transfer and lasting partnerships among the sites.

Regular feedback from the participants following each program enables the production staff to constantly improve on the quality of the series. When a program concludes, participants complete two forms: a Technology Questionnaire and a Participant Evaluation. The facilitator returns these forms to NETN, where a thorough review of the evaluations is completed. This direct input from the receiving sites allows the technical advisors, program leaders, presenters, and production staff to improve the quality of the series by capitalizing on what went well, and modifying the programs to make improvements where indicated.

Timing is also an important consideration. Experience shows that short programs, regularly offered, are the most effective. For example, NETN broadcasts these live videoconferences at regular intervals, on the second and fourth Wednesdays of each month. And finally, the role of the on-site facilitator cannot be overemphasized. Well-prepared facilitators can play a proactive role in distance education, as they bridge the gap between the television studio and the audience and promote an open exchange of ideas and technology transfer.

HOW VIDEOCONFERENCES CAN PROVIDE ADVANCED TECHNICAL TRAINING FOR SHIFTING THE WORK FORCE FROM DEFENSE PROJECTS TO ENVIRONMENTAL REMEDIATION AND PROTECTION

As the work force shifts from defense to environmental careers, working professionals need environmental information for current and future jobs. They require immediate, high-level training in specific environmental fields. NETN's goal is to assist the Department of Energy's Risk Management Program in complying with the Congressional mandate of a 30-year remediation initiative.

Advanced technical training and technology transfer represent a proven method of disseminating valuable information to engineers, scientists, researchers, hospitals, universities, and laboratories around the world. Videoconferences provide unique networking opportunities, allowing participants to exchange ideas with recognized environmental experts. During the interactive sections, participants are encouraged to ask specific questions that pertain to their particular site. Throughout the series, audience members develop the tools to change directions in their careers, with a strong emphasis on environmental clean-up and future use of a site.

Transmissions via satellite offer economic advantages, such as savings on travel, per diem, and workshop registrations. The price per site allows unlimited attendance during the live broadcasts. To prolong the life of the information contained in these series, the sites have access to videotapes of the programs and a bound copy of the instructional workbooks for their library.

After each series concludes, participants receive certificates of completion and earn Continuing Education Units (CEUs) through the University of New Mexico.

The Department of Energy currently receives NETN's environmental series in all DOE Operations offices across the United States and at DOE Headquarters. This is part of the DOE effort to retrain their work force from defense to environmental careers and to support environmental technology transfer.

Recognition and endorsement have been extended to NETN by the American Society of Mechanical Engineers (ASME) and the Hazardous Waste Action Coalition (HWAC).

HOW EVOLVING PARTNERSHIPS BETWEEN THE ORIGINATING UNIVERSITY AND THE RECEIVING SITES ENHANCE THE TRAINING

NETN achieves balance and diversity by seeking presenters from industry, government, and universities. Working closely with experts from such varied backgrounds has enabled NETN to develop strong partnerships among the presenters as well as the receiving sites.

The ongoing interactive programs promote mutual awareness and understanding. Unique partnerships can evolve through a distance education experience. For example, Sandia National Laboratories and Los Alamos National Laboratory subscribed to NETN's first series on Total Quality Management in 1990. Both organizations have participated in every subsequent series, and a mutually beneficial understanding has developed among the University of New Mexico and both national laboratories. Because individuals feel free to ask site-specific questions, participants throughout the nation come to understand each other better, discovering common ground and seeking common solutions.

TECHNICAL ASPECTS OF PAST SERIES AND THE UPCOMING DECOMMISSIONING AND POLLUTION PREVENTION SERIES

As mentioned earlier, the technical aspects of a videoconference series -- program content and specific emphasis -- are determined through the input from viewers of previous series, advisory board meetings, and an Environmental Experts workshop. NETN's first two distance education initiatives pertained to Total Quality Management (TQM). A 14-part series offered an engineering/ management approach to TQM, and a 6-part series focused on TQM as it applies to service organizations. Hazardous Waste Management, the next series, consisted of the following 11 programs: Program 1) Introduction: What Is Waste?; 2) Risks Associated with Hazardous & Radioactive Wastes; 3) Transport Processes Related to Wastes; 4) Waste Form Modification; 5) Site Characterization; 6) Sampling and Analysis; 7) Soil and Groundwater Remediation I: Physical/Chemical Processes; 8) Soil and Groundwater Remediation II: Biological Processes; 9) Radiation and Radioactive Materials; 10) Radioactive and Mixed Wastes Management; 11) Waste Minimization and Series Close.

Waste Minimization and Pollution Prevention - adhering to the logical progression of the content, NETN followed this series with an 8-part videoconference. The series began with an overview which defined waste minimization and described the need. Then the training progressed through the following topics: 1) Overview -- Why Minimize Waste?; 2) Where Do We Start Waste Minimization?; 3) How Does Recycling/Reuse/Reclamation Make Economic Sense?; 4) Are the Right Product/Process Designs Being Addressed?; 5) Solvents and Organic Chemicals; 6) How to Implement Minimization in Metals, Plating, and Electrical Interconnects; 7) How to Minimize "End of Life" Problems; and 8) Planning and Preparing for the Future.

Environmental Risk Management - a 7-part series sought to bridge the gap between technical issues and social concerns. Program titles included 1) Risk: Terminology, Concepts, Methods, Applications and Why Risk Communication Is Difficult; 2) How Do We Decide What Is Risky?; 3) Identifying the Gap: Divergent Technical and Social Methods for Risk Characterization; 4) Quantification of Models for Risk Assessment; 5) Risk Characterization: Synthesis and Communication; 6) Risk Assessment: Communicating Results and Public Perception; and 7) Risk-Based Decision Making: A Final Act?

Radioactive Waste Management was produced concurrently with the Environmental Risk Management series as an 8-part series (broadcast on alternating Wednesdays). This series began with 1) An Introduction to Radioactive Waste Management, and the following programs introduced 2) Interactions Between Radiation and Matter; 3) Decommission and Decontamination; 4) Transportation Issues in Radioactive Waste Management and UMTRA; 5) Low-Level Radioactive Waste Management; 6) High-Level Radioactive Waste; 7) Transuranic Radioactive Waste Management; and 8) New and Other Technologies for Radioactive Waste Management.

Mixed Waste Management, a 5-part series began broadcast on April 6, 1994, and concluded on June 1, 1994. Generated by government facilities, research laboratories, hospitals and universities, mixed waste is a major concern in remediation projects, including the clean up of Department of Energy weapons complexes and old radioactive waste disposal sites. The mixed waste dilemma became apparent as the course addressed the most basic questions: "What are the characteristics of mixed waste?" "What are our treatment options?" "How do we store mixed waste?" "Can we dispose of it?" and "What is the citizen's role in the process?"

The series consisted of 1) Generation and Characterization of Mixed Waste; 2)

Storage of Mixed Waste; 3) Minimization and Treatment of mixed Waste; 4) Technical Development of Mixed Waste Issues; and 5) Remediation Activities.
Decommissioning, a six-part series, began on February 8, 1995, with an introduction to the series with a goal and vision statement from U.S. Department of Energy. An inventory and history of the major decommissioning sites with overviews and the various phases of the decommissioning process were included.
Each program consists of technical presentations by experts focusing on Decommissioning terminology, problems involving contamination and radiation along with successful approaches. This series will stress the importance of good planning, pre-job briefings, and dress rehearsals with mock-ups to uncover problems and same time. Participants learn the techniques for dismantling and segmenting equipment and structural members and demolishing structure.
Pollution Prevention will be broadcast on alternating Wednesdays beginning on May 3 as a 5-part series. Pollution Prevention is far more powerful, more painless, less costly than continually degrading the environment by just "managing waste." Only through massive educational and awareness programs can the attitudes and values of the people be made sensitive to the need for waste minimization/pollution prevention and the seriousness of everyone's responsibility and moral obligation to protect the environment for future generations.
The end-of the pipe approach to waste management is a losing strategy. Striving to be in environmental compliance is not the answer; and managing waste is not only expensive, but poisonous to the environment and to the health of the public. Pollution prevention -- the front-end approach--makes business sense and is less destructive to the environment.
Communication and participation are critical elements in our national efforts to identify and explore environmental challenges. NETN develops distance education programs that highlight technologies and options for waste management and environmental remediation.

OHIO'S STATEWIDE LOW-LEVEL RADIOACTIVE WASTE EDUCATION PROGRAM: PHASE II - OUTREACH
A.W. Fentiman
K.M. Mancl
B.K. Hajek
J.E. Heimlich
R.N. Christensen
The Ohio State University
ABSTRACT
At The Ohio State University, a team of faculty members from the Nuclear Engineering Program and OSU Extension are conducting a multi-phase state wide low-level radioactive waste education program. The program's objective is to provide information that Ohio's citizens and their elected officials can use to participate in discussions and decisions related to low-level waste. In Phase I, the team developed a set of 27 fact sheets and four exhibits addressing a variety of topics related to low-level waste. The team's goal was to make these educational materials accurate, easy to understand, and unbiased. An extensive review process was developed to help meet these goals. A set of overhead transparencies was developed from the fact sheet materials to be used in presentations.
In Phase II, Outreach, the materials are being distributed across Ohio using a variety of channels with emphasis on the County Extension Offices, which are located in each of Ohio's 88 counties. Over 7,000 sets of fact sheets have been distributed to State Legislators and their aides, County Commissioners, hospitals, local health departments, civic organizations, high school teachers, college faculty, the media, and other interested people. Exhibits have been displayed at professional meetings, county fairs, mall shows, and the Ohio State Fair. Presentations have been made to a variety of groups, and a 20-minute slide/tape program has been prepared for use at short meetings. A day-long media workshop has been held, and a second one is planned. Summaries of the fact sheets have been prepared for use in the print media

and distributed to all newspapers.
Effectiveness of the entire program is difficult to determine at this early date. However, questions asked at the presentations and responses to pre- and post-presentation questionnaires indicate that participants understand the material discussed and use it when thinking about low-level waste.

BACKGROUND

In 1991 a team of faculty members from the Ohio State University (OSU) Nuclear Engineering Program and OSU Extension* recognized that over the next few years Ohio's citizens and their elected officials would be making decisions related to low-level radioactive waste disposal. The faculty members thought some Ohioans might wish to have a source of accurate, easy-to-understand, unbiased information as they began to discuss and make those decisions.
Accordingly, the faculty team designed a program to develop and distribute materials on low-level waste. Funding was sought, and the Midwest Interstate Low-Level Radioactive Waste Compact Commission agreed to support the program in phases. To date, two phases have been funded. In the first phase materials were developed, and in the second they are being distributed. This paper outlines the materials development phase and provides details of Phase II, Outreach, which is currently underway. (Phase I, Materials Development, was described in a paper presented at Waste Management '94.)

PHASE I - MATERIALS DEVELOPMENT

The primary product of the Materials Development phase was a set of 27 fact sheets. Each fact sheet addressed a single topic and was printed on one or two 8 1/2" x 11" pages. The topics were grouped into four categories:
1. Radiation science
2. Characteristics of low-level radioactive waste
3. Technology
4. Historical and legal aspects.

Radiation science fact sheets addressed sources and effects of ionizing radiation as well as key concepts such as radioactive decay, half-life, and shielding. Characteristics of low-level waste discussed in the fact sheets included sources, volumes, and typical contents. Storage, treatment, disposal, and transportation technologies were among those considered. Fact sheets in the "historical and legal" category presented information on the Low-Level Radioactive Waste Policy Acts, the Midwest Compact, and Ohio's activities to date with respect to low-level waste.
A very thorough review process was used for the fact sheets. Each one was reviewed by all members of the faculty team, three or four experts on the topic addressed, and a five-person panel consisting of a nuclear safety expert, a representative of a national environmental group, a science educator, a physician working in nuclear medicine, and a retired judge. Finally, all low-level waste generators in Ohio, all Ohio environmental groups the Project Team could identify, and anyone else who expressed an interest in the fact sheets' contents were invited to review the draft documents. About 20 groups and individuals accepted the invitation and received a copy of each fact sheet when the final draft was available. Each comment from every reviewer was cataloged and considered. Comments from such a diverse group of reviewers helped the authors provide more complete information, make the fact sheets easier to understand, and remove previously undetected bias.
Professional graphics were used to illustrate the fact sheets. The documents were printed in four colors on recycled paper using soy ink.
Using the material developed for the fact sheets, the Project Team prepared four table-top exhibits, one addressing each of the four major categories of fact sheet topics. Each exhibit is arranged on a 4' x 8' velcro board and can be folded to fit in a carrying case one person can easily handle.
In addition, overhead transparencies were prepared for presentations to groups requesting information on low-level waste. Materials were developed for presentations ranging from a 3-hour seminar for those interested in details to a 30-minute overview that might be appropriate for a civic organization's luncheon meeting.

PHASE II - OUTREACH

Ohio State University's Statewide Low-Level Radioactive Waste Education Program is unique in that it is a cooperative effort between faculty from the Nuclear Engineering Program with expertise in radioactive waste management and faculty from OSU Extension with expertise in environmental science and education. The outreach

phase of the program is heavily dependent on the County Extension Offices which are found in each of Ohio's 88 counties. County Extension Agents are well-trained and highly respected teachers who are recognized within their communities as sources of sound information on a wide variety of topics.

Three target audiences were identified for the outreach phase: local and state officials, the general public, and the media. Programs to reach each of those target audiences have been established at both the county and state level. County programs are conducted by the County Extension Agents while state level programs are carried out by Project Team members. Each of the 88 County Extension Offices has participated in a basic information program, while in some counties where interest in low-level waste issues is greater the Extension Office has undertaken additional activities. Activities at the state and county level are described in the following paragraphs.

County Level Activities

All County Extension Offices received 30 copies of each fact sheet. These fact sheets are kept in a file in each Extension Office and are distributed to people who request them. Extension Agents order additional fact sheets from the Project Team as needed. Several counties have requested additional fact sheets for use by community organizations.

Each County Extension Office distributed sets of fact sheets to all County Commissioners and local health departments. Bound sets were distributed to local libraries. In addition, a set of five summaries of the fact sheets written by a journalist working with the Project Team were distributed to the local newspapers and broadcast media in each county. Newspapers or stations with environment or science reporters received sets of the fact sheets to be used as reference documents.

A hotline was established by the Project Team in Columbus, Ohio, and County Extension Agents can use the line to get answers to questions people in their county may have about low-level waste.

Several County Extension Agents have developed additional programs to provide information to the public and officials in their counties. Using funds provided by the Low-Level Waste Educational Program, the Extension Agents in some counties have arranged half or whole day meetings at which Project Team members make detailed presentations on low-level waste to local officials. Other Extension Agents have set up the exhibits at mall shows and county fairs. One agent displayed the exhibits at an Earth Day Celebration.

State Level Activities

The Project Team in Columbus is responsible for the state level activities. Fact sheet distribution has been an important part of those activities. Sets of fact sheets have been sent to many groups including:

- State legislators
- Ohio's delegation to the U.S. Congress
- Ohio Hospital Association
- League of Women Voters
- University faculty
- Civic organizations
- High school science and social studies teachers
- Professional organizations.

Table-top exhibits have been displayed at a number of statewide meetings. In addition, a display on low-level waste was prepared for the Ohio Sate Fair which attracts about one million people annually. The display was attached to the sides of a wooden frame whose enclosed volume equalled the volume of low-level waste from Ohio in 1993. That exhibit was dismantled and reassembled at the Farm Science Review where the attendance is usually 30,000 to 50,000. One set of fact sheets was displayed, and order forms were provided so that people could request the sheets of interest to them. Two hundred requests were received.

A day-long media workshop was held in June 1994. Presentations were made by Project Team members and other university personnel on radiation science, low-level waste characteristics, waste management technologies, historical and legal aspects of low-level waste issues, methods of presenting technical concepts to a non-technical audience, and sources of information on low-level waste. Ohio's legislature had not yet begun to consider legislation on low-level waste, and only a dozen people attended. The workshop will be repeated March 9, 1995, and a larger turnout is

expected since low-level waste legislation was introduced in Ohio's Senate in January 1995. A media hotline has also been established and publicized. Questions on low-level waste may be faxed to the Project Team, and answers will be provided quickly.

Throughout Phase II, members of the Project Team have been traveling across Ohio to meetings at which they make two- or three-hour presentations to local decision makers. The purpose of the talks is to provide attendees with information they need to participate in discussions and decisions related to low-level waste management in Ohio.

Presentations to all audiences begin with a review of the basic science related to radiation. Key vocabulary is introduced, and the audience learns about topics such as half-lives, ionizing radiation, background radiation, and shielding. This segment of the presentation is followed by discussions of laws and regulations, characteristics of low-level waste, and related technologies such as treatment, storage, disposal, and transportation.

Questions from the audience are encouraged, both during and after the presentation. Covering the science at the beginning of the talk provides the audience with the terms and concepts needed to ask specific questions and establishes a framework within which the speaker can structure answers that all members of the audience will understand. All questions asked at the public meetings are noted, and a file is being kept of the types of questions people ask. It will be used to identify the need for new fact sheets or additional material in the presentations.

Reaction to presentations is quite positive. Project team members believe that some reasons for the positive reaction are:

The project team's goal is to teach fundamental concepts, not to persuade people to take a particular action or position

Great effort was expended to ensure that the teaching materials were accurate, easy to understand, and unbiased

Presentations focus on dealing with the waste that exists, not discussing whether it should exist

Fundamental scientific principles and key vocabulary are presented first - and in a manner that all members of the audience can understand

Questions are encouraged throughout the presentation, and all are answered respectfully and as thoroughly as possible

Audiences are small (10 - 50 people), affording an opportunity for personal interaction with all attendees.

As legislation on low-level waste is being considered in the Ohio Legislature, it is expected that more civic and professional groups will want short presentations on low-level waste at business or luncheon meetings. To date, Project Team members have followed the principles listed above in making these short presentations. However, if the demand for such presentations increases, it may not be possible for Project Team members to accept every invitation to speak.

To meet the anticipated demand for short, general presentations on low-level waste, a 20-minute slide/tape program has been prepared. It covers some of the main points made in the longer presentations. The slide/tape program will be available through the County Extension Offices. The first several times the program is used, a Project Team member will introduce it and answer questions after it has been shown. Questions asked most frequently and their answers will be provided to County Extension Agents so that they will be able to field some questions when a Project Team member is not present.

SUMMARY

A unique team of faculty from the Ohio State University Nuclear Engineering Program and OSU Extension has prepared a variety of educational materials on low-level radioactive waste. These include fact sheets, exhibits, and visual aids for presentations. A very thorough review process was established to help ensure that the materials were accurate, easy to understand, and unbiased.

The materials have been distributed throughout Ohio using the well-established and highly respected OSU Extension network and a variety of other vehicles. Seven thousand sets of fact sheets have been distributed; the exhibits have been used over 30 times, and an similar number of presentations have been made, primarily to local and state officials. Requests for materials and presentations continue to flow into the project office.

Response to the materials and presentations has been quite positive. The public

generally seems to find them to be accurate, easy to understand, and unbiased. The most direct evidence of the audience's reaction has come at public meetings where participants seem to quickly grasp the fundamental concepts and vocabulary and demonstrate their understanding by posing provocative questions or offering well-formed opinions and suggestions.

COMMUNITY ATTITUDES TOWARD EPA'S HANDLING OF THE MONROE COUNTY, INDIANA PCB SUPERFUND CLEANUP
Sona Chambers
Earth Tech
Lory Britt
Department of Sociology
Indiana University
ABSTRACT
For the past several years, the United States Environmental Protection Agency Region 5 (EPA) has been conducting cleanup efforts in Monroe County, Indiana, a community with widespread PCB contamination. The EPA, Potentially Responsible Party (PRP), City, County and State entered into a consent decree with the Federal District Court in May, 1985 requiring the PRP to destroy the PCB-contaminated materials in a municipal solid waste (MSW)-fueled incinerator.
Some citizens have vigorously opposed the incinerator, leading EPA to create some innovative community relations activities (Smith, et al, 1992). Most recently, the EPA and contractor staff teamed with the Indiana University Center for Survey Research to conduct a telephone survey of a random sample of Monroe County residents. The study assessed residents to measure their attitudes regarding communication between the EPA and the public and about selected local environmental issues.
The survey team completed 527 telephone interviews asking Monroe County residents a variety of questions regarding the PCB cleanup. In particular, questions targeted public knowledge of the technology suggested for the clean-up. Of those interviewed, 76.8% were aware of the proposed incinerator. Of these, almost 90% had concerns about incineration fueled by solid waste or some other fuel source.
EPA is perceived as a believable source of information; 68.7% affirmed EPA as a believable source. Before establishing a local office and maintaining a presence in the community, mistrust of the EPA was common. Survey results thus indicate that despite general opposition to incineration, public attitude toward the EPA is not similarly negative.
As a result of the survey, and some state legislation, EPA initiated new directions regarding the Bloomington area cleanup efforts to incorporate some of the citizens' concerns. EPA persuaded the other consent decree parties to explore alternatives to incineration and in February 1994, the parties officially launched a joint effort to assess alternative remedies.
BACKGROUND
Westinghouse Electric Corporation designed, manufactured and sold electrical capacitors and transformers containing polychlorinated biphenyls (PCBs) in Monroe County, Indiana from 1959 until the late 1970's. Their off specification PCB-laden capacitors and transformers were dumped in local landfills and quarries throughout the sixties and the early seventies (Lillich, 1981).
In the early eighties, the Indiana State Department of Health (ISDH), at the county health department's request, conducted a preliminary assessment/site inspection. Their sampling results indicated PCB concentrations to 330,000 parts per million (Osborn, 1991). The six Monroe County sites were then ranked using the Hazard Ranking System to determine the sites' potential hazards to the environment and public health. Four scored above the 28.5 required to be added to the EPA's National Priorities List sites (EPA, Sept. 1990). ISDH then requested that the EPA assist them in determining the extent of PCB contamination in Monroe County. After some of the EPA's preliminary studies were completed, both the city of Bloomington and the EPA filed suit against Westinghouse (Schmall, 1983).
The next step in the Superfund Enforcement Process requires that a remedial investigation be conducted to assess the extent and nature of the contamination (EPA, 1988). A feasibility study is then prepared to examine and evaluate various remedial alternatives. Following a public comment period on the EPA's preferred

alternative and the draft FS report, the EPA chooses a remedy and outlines it in the Record of Decision. No formal remedial investigation-feasibility study was ever done for the Monroe County PCB-contaminated sites by the EPA. The National Contingency Plan that the EPA was working under at the time, did not require a remedial investigation/feasibility study. Also, because the EPA was preparing a lawsuit against Westinghouse, many of the decisions made regarding alternatives assessment were not documented (EPA, July 1990). Consequently, the EPA did not issue a record of decision for the sites.

Early in the Superfund process, the EPA's method of developing case information for responsible party lead sites was done by conducting an Enforcement Decision Document so a record of decision was not performed for the sites (EPA, 1990). In addition, because the EPA was in litigation with Westinghouse, they kept many documents confidential. The citizens were not allowed to see the Administrative Record until the EPA had settled the case and then it was only made available through a Freedom of Information Act (FOIA) request.

These events led to public mistrust of the EPA. Most of the early public meetings regarding these sites were contentious and the EPA personnel were called names like "baby killer" and citizens, armed with pies, aimed them at the EPA personnel (EPA Public Meeting, 1988).

In May, 1985 a consent decree was signed among the EPA, the state of Indiana, Monroe County, the City of Bloomington, and Westinghouse. The consent decree identified six PCB-contaminated sites and outlined the terms between the above-listed parties in removing the contamination. One of the requirements of the consent decree is that Westinghouse design and construct a municipal solid waste fueled incinerator to destroy the estimated 650,000 cubic yards of PCB-contaminated soil and materials. Westinghouse is also responsible for disposal of the resulting incinerator ash. Once the consent decree was signed, initial removal actions were implemented in 1986 to stabilize the sites until the final remedy was permitted and executed.

After the initial removal actions were completed, Westinghouse submitted the incinerator and ash landfill permit applications (August, 1991). It seemed as though the cleanup would proceed, but the local and state officials began putting up roadblocks. The City of Bloomington and Monroe County passed ordinances and the State of Indiana passed a bill mandating that a study of alternatives to incineration be conducted before permit applications for a hazardous waste incinerator could be considered. All three of these parties are legally bound to the consent decree yet they have put into law statutes impeding the cleanup process.

During the early removal actions, the citizens accused the EPA of not keeping them informed of the ongoing cleanup actions. The main objection was that the EPA personnel were located in Chicago, therefore it was difficult for citizens in rural Indiana to communicate with them. In a bold administrative decision, the EPA began an aggressive Community Relations program in Monroe County, Indiana (See HMC '92 proceedings).

In January 1989, the EPA opened a Public Information Center/telephone hotline managed by an EPA contractor and staffed with a local resident. A Citizens Information Committee was established which required the EPA remedial project manager and the work assignment manager to meet monthly with local citizens in Monroe County. The meetings were videotaped and aired on the local public access channel. EPA contractor staff wrote fact sheets and distributed them via the local Sunday paper. Citizens were taken on site tours as the cleanup progressed and residents were visited before a cleanup action was taken in the neighborhood. Finally, the EPA set up and maintained four information repositories in the county so that a FOIA request was no longer needed to obtain site cleanup information. Residents could go to the local office or one of the four information repositories.

As a way to evaluate the public's perception of the cleanup remedies and the EPA's performance during the cleanup, a telephone survey of a random sample of Monroe County residents was conducted. Survey results indicate that the EPA's commitment to Monroe County has helped the agency to develop trust with the citizens and has helped them to get information to the public in an efficient manner.

METHODS

The EPA and contractor staff teamed with Indiana University Center for Survey Research to conduct a telephone survey of Monroe County, Indiana residents to measure their attitudes regarding communication between the EPA and the public and about selected local environmental issues. Some specific areas addressed in the

survey included awareness of the proposed incinerator to burn PCB contaminated materials in Monroe County and concerns about the incinerator.
Two independent samples of telephone numbers were randomly generated using a random digit dialing procedure. One sample contained 1377 possible residential telephone numbers from the exchanges that serve Monroe County. The second sample contained 190 telephone numbers in the 857 exchange (Indiana University residence halls and family housing). At each residential telephone number, a respondent was randomly selected when there was more than one adult in the household. There was no random selection of respondents when students in residence halls were reached. Because it is so difficult to randomly select respondents in fraternities/sororities, persons living in that type of household were not interviewed.
Data were collected by telephone using the University of California Assisted Survey Methods software. The questionnaire was pretested three evenings and the questions were modified based on the comments collected from the pretest sample group. The survey began on April 19th, 1993 and ended on May 9th, 1993. Interviews were collected seven days per week at various times throughout the day and night.
There were 527 interviews completed of randomly selected persons within Monroe County. There are approximately 48,000 residences with phones in Monroe County. About 12,000 of the telephones are in Indiana University residence halls and family housing. A fully proportional sample would overrepresent students living in residence halls, therefore the sample was stratified to produce 89 completed interviews with students living in residence halls and family housing and 438 with the remaining residents of Monroe County. The average length of the completed interviews was 15 minutes.
RESULTS
Of the 527 respondents interviewed, 84.2% claimed to be aware of PCB contamination in Monroe County. Of these, 87.8% voiced specific concerns about the presence of PCBs in Monroe County. The two primary concerns were possible health related problems and potential contamination of groundwater.
While 76.8% of respondents were aware that an incinerator to burn PCB-contaminated materials is supposed to be built in Monroe County, only about half of these were aware that the incinerator is required to be built by a federal consent decree.
In a number of public meetings, opponents of the incinerator have raised objections to the use of municipal solid waste as a fuel source for incineration. They suggest that solid waste used as a fuel source is an untested technology (Herald Times, Jan. 13, 1993). It has also been suggested that other fuel sources such as natural gas would be more feasible alternatives.
Survey questions were designed to assess public reaction to solid waste as a fuel source as well as to assess possible responses to alternative fuel sources. Also of interest was whether public opposition was limited to the incinerator's fuel source or whether there was a more basic objection to incineration as a technology.
Of those respondents who were aware of the proposed incinerator, 79.3% were either somewhat or strongly concerned about using an incinerator fueled by solid waste to destroy PCB-contaminated materials. It does not appear, however, that fuel source is the fundamental area of contention. Over 80% expressed specific concerns about the use of solid waste to fuel an incinerator. Similarly, over 80% expressed specific concerns about alternative fuel sources such as natural gas. Regardless of fuel source, respondents expressed concern about the use of an incinerator to destroy PCB-contaminated materials in Monroe County:
"It just concerns me that they would burn it and that dioxin (one of the byproducts from what I understand) [would be released]...the way the winds blow, it would blow right into Bloomington."
"It could disperse over a wide area...solving one problem [of] pollution with another form that would contribute to air pollution."
"I'm concerned about incineration of any [sort] because what is incinerated is going to go into our air and the air we must breathe and live in...[I am concerned about] any type of incineration fueled in any manner...I can't see whether it would make a difference if it was solid waste or gas. The residue will be in the air."
It is evident, then, that Monroe County residents generally oppose the use of incineration to destroy PCB-contaminated materials. It is likely that this public sentiment was influential in the decision of local and state government officials to halt the incinerator permitting process until alternatives to incineration could be assessed.

Despite public aversion with the consent decree remedy, dissatisfaction does not extend more generally to the EPA. Of Monroe County residents interviewed, 68.7% agree that the EPA is a believable source of information regarding PCBs in Monroe County. Since the local EPA Public Information Center in Bloomington was established, over half of respondents interviewed feel that communication between the EPA and the community regarding the PCB situation in Monroe County has improved. Of those who have ever contacted the local PIC about any environmental issue, 75.0% felt that the staff was helpful.
Shortly after EPA conducted this survey, the Indiana state legislature enacted a law which prevented the state from issuing a permit for the construction or operation of a hazardous waste facility used for incineration of PCBs unless the technology used at an equivalent hazardous waste facility has demonstrated a destruction efficiency of 99.9999%. The public's sentiment as demonstrated by their answers to the survey along with their pressure on the legislature to enact this law, effectively halted the process. EPA responded by persuading the other government parties and Westinghouse to examine alternatives to incineration. In February 1994, the consent decree parties announced that they would work together in a good faith effort for an alternative to incineration.
CONCLUSIONS
Despite an on-going public information campaign by the EPA to educate Monroe County residents about incineration as a technology, public perception of incineration remains overwhelmingly negative. Regardless of fuel source, residents oppose the use of incineration to destroy PCB-contaminated materials. Attitudes toward the EPA, however, have been positively influenced by local interaction between the EPA and the public.

Session 57 -- Innovative Approaches for Environmental Restoration

ERM
Los Alamos, NM
ABSTRACT
Los Alamos National Laboratory (LANL) is actively exploring more efficient and cost-effective methods of implementing the Environmental Restoration (ER) Project. Under this premise, the LANL ER benchmarking study was undertaken to compare characteristics of LANL's ER Project to similar ER and remediation projects at other Department of Energy (DOE), Department of Defense (DoD), and private sector facilities. A team of process experts from the LANL Environmental Management Program Office, worked closely with DOE and benchmarking consultants to identify ER-related elements, including performance measures and metrics, to be studied and compared. From this effort, a benchmarking protocol was subsequently developed with significant input and support from DOE. Data was gathered on each program element which enabled LANL to gauge the performance of its ER Project against the performance of similar environmental remediation efforts at other institutions, and to identify "best-in-class" characteristics of other environmental remediation programs. LANL is currently using the benchmarking results to assist in enhancing the performance of its ER Project.
BACKGROUND - INFORMATION GATHERING
The objective of the study was to identify opportunities to enhance performance of the LANL ER Project. To accomplish this objective, LANL's Environmental Management (EM) Program Office contracted with Environmental Resources Management (ERM) to jointly conduct a benchmarking study of the EM ER Project. The benchmarking protocol was developed with input from the Department of Energy (DOE). The protocol covered the following programmatic-level elements of the ER Project:

Status of Overall ER Effort	Procurement
Deliverables/Associated Penalties	Contractor Support
Analytical Chemistry Services	Staffing Costs
Waste Volumes/Management	ER Project Status
Technical/Regulatory Strategy	Site Closure
National Environmental Policy Act	Future Land Use
Corrective Action Management Units	Management Structure
Public Involvement Strategy	Temporary Units
Programmatic Technical Support	Support Functions
Site Prioritization	Pilot Studies

Participants in the ER benchmarking study included:
DOE Facilities: Idaho National Engineering Laboratory (INEL); Oak Ridge National Laboratory (ORNL) in Tennessee; and Nevada Test Site (NTS).
DoD Facilities: Tooele Army Depot in Utah; Pease Air Force Base (AFB) in New Hampshire; and Marine Corps Camp Lejeune in North Carolina. McClellan AFB in California and Tinker AFB in Oklahoma have also been asked to participate, but a response has not been received.
Industrial Facilities: FMC; Allied Signal; and General Electric (GE).
To date, completed protocols have been received from the three DoD facilities, two DOE facilities, and one industrial facility. One industrial facility submitted only a partially completed protocol, and the LANL protocol is also complete.

The Benchmarking Process

To facilitate identification of best-in-class performance among different ER programs, the four step process described below was followed.
Step 1: Develop Metrics - First, metrics were designed to facilitate comparison of performance among different ER projects. For example, in the present study, metrics were developed that allow comparison of the performance of ER programs with different start dates, lifecycles, and budgetary plans. These normalizing metrics facilitated "apples-to-apples" comparison of performance.
Step 2: Apply Metrics to Performance Data and Identify Performance Gaps - Metrics were applied to identify project element performance gaps. Metrics were developed for comparison of progress on investigations, designs, and cleanups. The metrics were also designed to normalize for differences in project budgets, timelines, and rates of budget expenditure.
Step 3: Interpret Gaps - If a performance gap was identified, differences in program characteristics (e.g., ER project strategy, regulatory framework, etc.) were examined to explain the observed performance gaps, and to identify and prioritize performance improvement opportunities.
Step 4: Review Additional Information - Best practices employed by participating DOE, DoD, and industrial facilities were reviewed, and follow-up interviews were conducted with participating facilities to explain the observed performance gaps, and to identify and prioritize performance improvement opportunities. Additionally, literature searches and discussions with environmental professionals were used as follow-up to further validate the explanations of observed performance gaps.

INTERPRETING THE FINDINGS - IDENTIFYING CAUSES OF PERFORMANCE GAPS

Regulatory Framework

Differences in the ER Project strategy employed by each facility and the resulting regulatory framework negotiated by each facility were reviewed. For example, ER programs at Camp Lejeune, Tooele Army Depot, and INEL are regulated by Federal Facility Agreements (FFAs), while Pease AFB operates under a Base Realignment and Closure Plan (BRAC). As part of their strategy, each of these facilities aggressively negotiated a flexible schedule with concurrent regulatory review of deliverables, involving the regulators as partners throughout the ER process.
In contrast to these flexible regulatory frameworks, the Hazardous and Solid Waste Amendments (HSWA) module driving the Los Alamos ER Project restricts LANL to following the traditional Resource Conservation and Recovery Act (RCRA) Facility Investigation/Corrective Measures Study (RFI/CMS) approach to characterization and remediation. Noncompliance results in a Notice of Deficiency, which, if not corrected, results in a Notice of Violation from EPA Region VI. To date, the Los Alamos ER Project has not successfully engaged regulators to obtain a more flexible regulatory framework.

PRELIMINARY RESULTS

The following discussion is limited to programmatic-level elements of the ER Project that are significant and for which sufficient information is available to adequately discuss and interpret the findings.

Progress on RCRA/CERCLA Activities

Findings: Fig. 1 compares facility performance on completed RCRA/Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) activities. Table I provides the background information for Fig. 1. The metric is designed to normalize facility performance for differences in planned schedules. The DoD facilities and DOE facility A show more progress on expedited site cleanup and no further actions (NFA) than LANL. DoD facilities and DOE facility A have already completed all planned expedited cleanups. The remaining DoD facility has completed approximately 75% of its planned expedited cleanups. Los Alamos has completed approximately 10% of its planned expedited cleanups. Progress on receiving approval on NFA recommendations is greater for all the DoD facilities surveyed than LANL. Similarly, DOE facility A has received approval for close to 45% of their planned NFA sites. Los Alamos has received approval for approximately 28% of its planned NFA sites. However, LANL has a greater total number of completed expedited sites and NFAs.

Interpreting the Findings: DoD's strategic approach places a greater emphasis on accelerated cleanups and obtaining approval for NFAs. Opportunities to accelerate cleanups are evaluated on an ongoing basis as a means of reducing risk and expediting the overall cleanup process. This tactic varies somewhat from the traditional emphasis on investigation, design, and cleanup activities.

DOE facility A's performance can be linked in part to the ER program strategy negotiated with regulators. As part of its FFA, DOE facility A negotiated (and successfully implemented) a formal regulatory process that emphasizes facilitating site investigations. The process also accelerates cleanups and NFA recommendations. In addition, at DOE facility A, sites are aggregated into common categories for NFA, Phase II investigation, or accelerated cleanup. This process of aggregation accelerates cleanups by incorporating concepts that are functionally equivalent to presumptive remedies.

LANL has developed strategies to accelerate site investigations, cleanup, and NFA determinations. These strategies were submitted to EPA Region VI in the LANL ER Project Installation Work Plan (IWP). However, these strategies have not been accepted by EPA, primarily because Region VI mandates compliance with traditional HSWA module RFI/CMS process requirements. Similar strategies were proposed in the recent ER Project Action Plan, but have yet to be successfully negotiated or implemented.

It is important to note that the Los Alamos ER Project consists of more individual sites than the other ER programs in the study. Since the majority of these sites are potential candidates for NFA or accelerated cleanup, a negotiated strategy within the regulatory framework on accelerated cleanup and NFA recommendations will enhance performance.

Analytical Chemistry Services

Findings: Analytical chemistry services are an example of an ER Project element where LANL compared unfavorably and immediate performance gaps (costs and turnaround times) were identified.

Interpreting the Findings: Los Alamos ER Project analytical chemistry services have resulted in excessive costs and delays in receiving analytical chemistry results. Excessive analytical chemistry data turnaround times and internal data validation turnaround times cause delays in decision making contributing indirectly to some of the observed performance gaps (e.g., delaying NFA determinations).

Deliverables and Associated Penalties

Findings: In contrast to Los Alamos, none of the other participating facilities have received Notices of Deficiency (NODs) for their deliverables (e.g., RFI Work Plans, RFI Reports, etc.), nor have they received Notices of Violation (NOVs). To date, Los Alamos has received NODs for most major deliverables submitted to EPA Region VI.

Interpreting the Findings: The performance gap between LANL and the study participants appears to be the result of the regulatory framework negotiated by the other facilities, which includes flexible program schedules with concurrent regulatory review of deliverables. This involves the regulators early and throughout each facility's ER process. In contrast, Los Alamos is regulated by EPA Region VI under the relatively inflexible HSWA module.

ER Project Waste Management

Findings: The ER programs of facilities participating in the study vary significantly in terms of their current level of integration with waste management (WM) activities. DOE facility A, like LANL, does not have low-level mixed waste disposal capacity, while DOE facility B has onsite low-level mixed waste disposal capacity. DOE facility A and B representatives indicated that while the ER and WM activities are separate, waste management strategies are thoroughly integrated. In contrast to the DOE facilities, the industrial and DoD facilities do not separate waste management from ER functions.
Interpreting the Findings: Currently, LANL WM waste treatment, storage, and disposal (TSD) capacity is constraining the LANL ER Project. Additionally, the LANL WM Program focuses primarily on TSD for wastes generated by Laboratory operations, not ER Project-generated waste. Improved integration of waste management planning and funding for TSD of ER Project-generated waste at LANL is essential to enhancing ER Project performance.
NEPA
Findings: The policy of the three participating DoD facilities is that the CERCLA process is functionally equivalent to the National Environmental Policy Act (NEPA) and, therefore, the requirements of NEPA are satisfied by completing CERCLA processes. DOE facility A indicated that NEPA requirements are integrated in a manner similar to the DoD facilities because the CERCLA process is deemed to be functionally equivalent to NEPA by DOE.
Interpreting the Findings: NEPA requirements are explicitly excluded from the LANL HSWA module relative to EPA decision making; however, NEPA is still a DOE requirement for RCRA-regulated ER projects. As a result, approximately 2 to 5 percent of the Los Alamos ER Project budget is directed at meeting NEPA requirements. The updated Los Alamos ER Project FY95 baseline projects significant expenditures for NEPA compliance.
Table I
IMPROVEMENT OPPORTUNITIES - WHERE DO WE GO FROM HERE?
Strategic Planning
A primary root cause of performance gaps identified during the study is the lack of a comprehensive ER project strategy that is properly formulated, negotiated and implemented. Figure 2 is a cause-effect diagram outlining some of the key elements that must be addressed. The study indicated that regulatory strategy (and tactics for achieving strategic objectives) is a key element of a comprehensive ER project strategy. The study pointed to the need for DOE and LANL to reach consensus on a regulatory strategy for aggressively and continuously negotiating with regulators on specific issues. Figure 3 summarizes several of the regulatory issues that should be considered in formulating a regulatory strategy. The strategy must be developed with stakeholder input.
Additionally, institutional requirements and waste TSD options (see Fig. 4), should also be considered during formulation of a comprehensive strategy. Policy decisions, such as acceptable cleanup goals, acceptable levels of risk, cost and liability for offsite waste TSD must be negotiated as part of the ER Project's regulatory strategy.
Negotiations with Regulators
Several negotiating positions and tactics to address performance gaps (i.e., improvement opportunities) in LANL's current regulatory strategy are presented in Table II. In addition to the areas presented in the table, negotiating positions are being developed in areas such as analytical suites and detection limits for chemical analyses, Corrective Action Management Units and Temporary Units (CAMU/TU), and land disposal restrictions (LDRs).
Analytical Chemistry Services
The Los Alamos ER Project recently formed a Sample Management Process Problem-Solving Committee to address analytical chemistry service issues. Additionally, improved turnaround times and reduced analytical chemistry costs are being negotiated aggressively with contract laboratories, and included as contract clauses, with penalties for late submittal of data.
ER Project Waste Management
The ER Project Manager has identified a Waste Management Coordinator within the ER Project to deal with waste management planning and funding for TSD of ER Project-generated wastes. The Coordinator is tasked with integrating waste management and pollution prevention strategies within EM.

NEPA

Addressing duplicative NEPA requirements for major remedial/corrective action decisions in the future will have a significant impact on the Los Alamos ER Project budget (5 to 10 percent) and schedule. If DOE was to remove this requirement, between $60 million and $130 million could be saved over the life of the ER Project. A determination must be made on the NEPA functional equivalency issue and use of HSWA decision documents and activities (e.g., proposed plans, corrective measures studies, etc.) to meet public participation requirements.

SUMMARY

As a result of the benchmarking study, performance gaps were identified in several LANL ER Project areas, the most significant being: analytical chemistry services, strategic planning, regulatory strategy, waste management, and NEPA. Steps are underway at LANL to address each area to enhance the cleanup schedule and cost performance of the ER Project.

IMPLEMENTING THE HANFORD ER BASELINE DURING A TIME OF FUNDAMENTAL CHANGE

Jim Goodenough
U. S. Department of Energy
Marv Wollin
Bechtel Hanford, Inc.

ABSTRACT

Establishing a sound project control system during dynamic change is critical to the success of the Richland Environmental Restoration Project (RERP). Once a baseline is established, it is equally important to implement it effectively. The RERP baseline is complex, involving hundreds of activities at the 560-square-mile site.

The major challenge to implementing the Hanford ER baseline is the dynamic environment that continually impacts the program. This environment includes evolving regulatory priorities, extensive stakeholder involvement, budget restraints, workforce restructuring, and contract reform. This paper describes how the RERP baseline was developed and how DOE and Bechtel are using a disciplined process to implement the baseline in this changing environment.

INTRODUCTION

Environmental restoration at the Hanford Site is a major technical challenge involving large quantities of contaminated soil, numerous burial areas with radioactive and mixed wastes, extensive areas of groundwater contamination, and more than 100 buildings to be decontaminated and decommissioned. An equally challenging task is implementing a baseline to manage the scope, schedule, and cost of the program.

The "cleanup" work at Hanford can be divided into two major mission categories -- waste management and environmental restoration. Waste management includes the treatment, storage, and disposal of wastes, such as the high-level liquid wastes stored in 177 underground tanks, and management of spent fuel. Westinghouse Hanford Company, the Hanford M&O contractor, is responsible for waste management, along with the associated maintenance and operations necessary to manage the 560-square-mile Hanford reservation.

Environmental restoration includes restoration of areas contaminated during past production and disposal activities. It includes remediation of buried waste sites, contaminated soil columns, contaminated groundwater plumes, as well as decontamination and decommissioning of surplus defense production facilities and associated infrastructure support facilities.

Prior to 1994, Westinghouse Hanford Company was responsible for both waste management and environmental restoration at Hanford. In July 1994, Bechtel Hanford, Inc. (BHI), became the Environmental Restoration Contractor, assuming responsibility for a portion of the work that was being performed by Westinghouse.

The Environmental Restoration Contract is a demonstration of a new type of contract at DOE sites. The concept of having a separate contractor to manage environmental restoration originated in 1990 with the Department of Energy's Alternate Contracting Task Force, which looked at ways to lower costs and improve efficiency in DOE's nationwide environmental restoration program. One concept the task force developed was a separate contractor with the single mission of managing the remediation of a contaminated site to the final end-state condition.

Prior to BHI's start of work as the ERC, a detailed baseline for the RERP had been

developed using a strategic planning effort termed the Optimized Baseline Project. This baseline was viewed as a pre-conceptual level baseline; it was adopted by BHI for purposes of configuration management and contract performance measurement. As the Hanford ER project moves forward, the challenge will be to successfully implement this baseline during a time of rapid and dramatic change.

CURRENT CHALLENGES

As the Hanford ER project moves from the "assessment" stage to "cleanup," there is no significant experience base to guide the way. Work of this type has not been done on a large scale before, so there is little experience to indicate what to do and how to do it (scope management), how much it will cost (cost management), and how long it will take (schedule management).

In addition to the lack of an experience base, conditions surrounding the project are changing. These changes stem from a combination of technical, financial, and political issues. Some of the major factors being experienced include:

Restructuring of the Tri-Party Agreement (TPA). The TPA is an enforceable agreement signed in 1989 between DOE, the Environmental Protection Agency, and the Washington Department of Ecology, specifying milestones for Hanford cleanup. Major changes in the ER portion of the TPA were negotiated between the three parties in the summer of 1994.

Changing funding scenarios. The ER scope of work for FY 1995 was budgeted at about $233 million. DOE productivity challenges reduced funding for this work to about $201 million. Further reductions due to internal DOE funding decisions and actions by the Office of Management and Budget have reduced funding to about $150 million. All of these changes have taken place since October 1, 1994.

Increasing budget restrictions. DOE's nationwide environmental management program enjoyed rapidly increased funding in the early 1990s, reaching an annual budget of about $6 billion. By 1994, projections were that this growth would slow, roughly matching the rate of inflation for the rest of the decade. Following the election of November 1994 and the resulting emphasis on reducing the Federal budget major reductions in future funding are anticipated.

Changing priorities. The focus of Hanford ER activity has shifted over the past two years. A program that once was heavily oriented toward assessment work on many parts of the site has become a program focused on doing actual cleanup at the part of Hanford close to the Columbia River. D&D work, which had been projected as a future activity, has been accelerated to reduce the cost of "mortgages," the annual expenditures needed just for surveillance and maintenance of aging buildings.

Recognizing limitations of technology. A significant part of the Hanford ER effort was directed at groundwater remediation. Experience was showing that there was minimum payback from many of these expenditures. This has resulted in a reevaluating the actual risk posed by groundwater contamination and deciding whether it would be better to work on improving technologies before tackling the groundwater issue.

DEALING WITH CHANGE

Each of the environmental conditions listed above presents a formidable challenge to successful implementation of a project management system. Taken together, they pose enormous challenges for managing the Richland ER project.

To deal with this changing environment requires a disciplined project control process. There are many factors that can trigger a change in the baseline. New data or regulatory actions can cause a change in scope. Budget changes due to actions by DOE, OMB, or Congress can cause change in funding and schedules. Actual field experience can cause a change in scope, cost and schedule simultaneously.

ESTABLISHING A PROJECT CONTROLS SYSTEM

Validated Baseline

When BHI assumed responsibility for the Hanford ER project in July 1994, the existing baseline had been developed under an M&O contracting system that evolved from a production paradigm. BHI is changing the project controls system toward a project management approach, developed by Bechtel through experience on other DOE programs, on Department of Defense environmental projects, and on commercial projects.

This "projectized" project controls system was developed in three months through a cooperative effort between DOE and BHI. The BHI staff included Bechtel employees who transferred to Hanford and Westinghouse project controls staff who moved to BHI during the contract transition.

To avoid the cost of software development, the system uses off-the-shelf software

(Primavera Parade). To ensure that all recipients of data (DOE-Richland, DOE-HQ, regulators, public) get accurate information, the former system and the new system will operate in parallel until March 1995.

Change Control Process

As these changes develop, they are analyzed and are incorporated into the baseline through a change control process. The process begins with the project teams. The BHI organization is structured around matrixed project teams. Each project team is composed of the engineering, construction, environmental compliance, health and safety, quality assurance, project controls, and support personnel needed for a specific task. The DOE-Richland Environmental Restoration staff, which oversees BHI, is also organized along project lines. This "mirror image" between DOE and BHI results in an efficient working relationship.

Trending and Variance Analysis

When a project team recognizes a potential change that is likely to affect the baseline, they identify it as a trend and begin to collect data to support the trend. Each project team has a DOE representative, who can attest to the correctness of the potential trend. The trend is then taken to a Change Order Review Board, made up of BHI and DOE staff, which reviews the change and recommends action. The change is then formally submitted to the appropriate DOE official for approval. DOE and BHI have developed a close working relationship which allows for timely identification and action.

CONCLUSION

Hanford environmental restoration is a complex program that has undergone major changes in the past two years. This climate of change is likely to continue and accelerate. To continue making cost-effective progress during this time of change requires a proven baseline, a project-oriented controls system, and a disciplined change control process.

57-3

VALIDATING THE CONCEPTUAL SITE MODEL:
A FOCUSED ALTERNATIVE FOR REMEDIAL INVESTIGATIONS INVOLVING RADIOACTIVE, MIXED AND HAZARDOUS WASTE SITES

Jeffrey B. Cange
Timothy C. Adler
Bechtel National, Inc.
Oak Ridge, Tennessee

ABSTRACT

Remedial action decisions for Superfund sites are compounded by uncertainties regarding future land use and, particularly for sites involving radioactive and mixed wastes, a shortage of cost-effective clean-up options. Remedial investigations (RIs) for such sites typically are resource-intensive field investigation efforts that attempt to fully characterize all aspects of the site. This type of RI often fails to meet its intended purpose--to provide information to assess risks to human health and the environment as needed to support the development, evaluation and selection of appropriate remedial response actions. An alternative approach, based on the conceptual site model, allows the RI to focus on the most important components of the site: contaminant sources, release mechanisms, migration pathways, and receptors. The conceptual model is "validated" by quantifying the relationships between these components and integrating the results of the baseline risk assessment, resulting in a quantitative description of the source term, release rates, migration rates, flux and exposure (risk).

INTRODUCTION

For sites listed by the U.S. Environmental Protection Agency (EPA) on the National Priorities List (NPL) and thus consigned to the Superfund cleanup program, remedial investigations (RIs) typically constitute the most costly phase of the program prior to the actual remediation or cleanup of the site. The basis for the RI is provided in regulations under the National Oil and Hazardous Substances Contingency Plan (NCP), which are based on the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA). EPA published guidance on the conduct of RIs that details the scope and objectives of the RIs as well as the suggested format for preparing RI reports (1). As stated in the regulations and guidance manual, the purpose of the RI is to collect sufficient data to support the assessment of risks (to both human health and the environment) as well as the development, evaluation and selection of

appropriate response (cleanup) actions.
The traditional RI, as established by EPA guidance and precedent at hundreds of NPL sites nationwide, involves 1) a "scoping" (planning) phase, the primary output of which is a Work Plan that establishes the objectives and rationale for the RI; 2) a field investigation, where data are collected through such activities as sampling and analysis of a site's soil and groundwater; 3) data evaluation, in which the data collected for the field are reduced and evaluated; and 4) preparation of the RI Report, which documents the results of the field investigation and data evaluation efforts. Most RI Reports are developed with the following elements:

an introduction with background discussion
a description of the investigation focusing on field sampling, analysis and measurement activities
an analysis of the physical characteristics of the site
a description of the nature and extent of contamination (by media)
a discussion of contaminant fate and transport
the baseline risk assessment (human health and environmental)
summary and conclusions, including remedial action objectives

A recurring criticism with the traditional approach to conducting RIs is the disconnect between the characterization and risk assessment: project teams responsible for deciphering the physical characteristics of the site or delineating the nature and extent of contamination typically have only limited interaction with the risk assessment teams responsible for the human health or ecological risk assessments. Consequently, the characterization and risk data are not well integrated, leading to RI Reports where all contamination is defined and discussed, even where trivial, and all risks are calculated, even where such exposures are highly unlikely.
At most Department of Energy (DOE) facilities on the NPL, implementation of the Superfund program is complicated by the presence of radioactive wastes, uncertainties regarding future land use and a shortage of cost-effective cleanup options. Most DOE facilities on the Superfund list contain a large number of sites that need to be evaluated to determine the need for and scope of appropriate response actions. Unfortunately, it is not always clear just how clean the sites have to be or what methods will be used to do the actual cleanup. Developing the scope of work and objectives for an RI at such sites inevitably requires the project team to anticipate all the data needs for the full range of possible land use or remediation scenarios, resulting in a poorly focused RI that strives to characterize and document, in sometimes excruciating detail, all aspects of the site--physical, biological, chemical and radiological.
A poorly focused RI produces vast amounts of data that can not be effectively evaluated and integrated into the decision-making process for the site. Almost anyone who has been involved with RI activities at DOE sites has seen the products of this labor--typically an immense, multi-volume treatise laden with hundreds of data tables, charts and figures that fill entire bookshelves. The trend toward gigantism in the RI trend challenges even the most assiduous technical reviewers and is especially alarming to the stakeholders (e.g., surrounding communities), who in most cases are clearly intimidated by the sheer volume of information.
Generating data is an expensive activity: the more data that are generated, the more the project will cost, and not just in terms of field sampling and analysis, but also in the validation or verification of the data, managing the data in databases, evaluating the data for the RI report, and developing interpretations and summaries of the data to be included within the report. The disproportionate resource requirements required for overly ambitious characterization efforts are a significant drawback to conducting traditional RIs, particularly at large or otherwise complex sites. Depending on the conditions at the site, an RI may take several years to complete, from planning to issuance of the final document, and run up costs in the tens of millions of dollars. The upward pressure on costs continues as subcontracting expenses, health and safety burdens and layers of oversight and management increase.
Many RIs fail to meet their intended purposes, which is to efficiently provide information needed to assess risks and support the development, evaluation and selection of remedial alternatives. Even with the trend toward smaller, more manageable projects and broader use of removal-type response actions, RIs (or analogous site characterization efforts) will continue to be a key step in the

cleanup process and a principal foundation for remedial action decisions. An alternative approach that better integrates characterization and risk data, resulting in a more focused, user-friendly RI document, is clearly warranted. Development of this method is timely, given the efforts in DOE (and elsewhere in the Federal government) to streamline the environmental restoration process, accomplish more with the same or smaller budgets and more effectively communicate site conditions and risks to the public.

DESCRIPTION OF CONCEPTUAL SITE MODEL

Conceptual site models are widely used to illustrate the relationships between contaminant sources, migration pathways and potential receptors at a site. These qualitative models are often used in the scoping process for site investigations to guide sampling activities or sometimes to merely demonstrate a cursory understanding of the site. In its latest guidance on the Data Quality Objectives (DQO) process, EPA identifies developing a conceptual site model as a key step in the planning process for data collection activities (2). Risk assessments may also use conceptual site models but generally adhere to standard EPA guidance that complicates efforts to integrate risk-related findings on exposure pathways and receptors into the characterization-based understanding of the site.

The limitations associated with the conceptual model's uses usually stem from the non-specific manner in which they are often constructed. Typically, qualitative models proposed for sites do not maximize the use of existing, site-specific knowledge and as such may depict dimensionless source areas, and every (or nearly every) conceivable contaminant release mechanism, secondary source, migration pathway, and exposure point. This type of all-inclusive model sets the stage for an overly ambitious sampling plan and, once the data are collected and the interpretations begin, the models are usually discarded in favor of the standard approach that says that any data worth collecting is worth discussing.

Proper construction to ensure maximal usefulness of the initial site conceptual models during the scoping or planning phase of RI work requires a thorough integration of historical data into the characterization objectives and rationale for the proposed RI. The search for historical data should include searches for site records regarding source characteristics, environmental setting (e.g. geology, hydrology), site operational history, previous investigations or other environmental studies and aerial photographs. It is important to recognize the usefulness of historical data for preliminary modeling purposes even in instances where the quality of data is less than ideal or unknown. All too often investigators dismiss historical data sets based on a desire to ensure rote compliance with current analytical methods or data quality expectations. Instead, emphasis should be placed on the ultimate quality goal of maximizing data usability. Though historical data may have to be qualified it is often quite useful in the planning phase of the RI for constructing a qualitative conceptual model that focuses on the likely contaminant sources, probable release mechanisms, expected pathways, and realistic receptor locations.

Conceptual models, whether applied to an entire site or an individual source of contamination within a site, generally include the following components:

Contaminant Sources are wastes or areas of contamination that have released contamination to the environment or have the potential to do so; in some cases, the source areas also are associated with risks to human or environmental health (e.g., an area of highly contaminated surface soil). Primary sources are typically the wastes themselves; secondary sources are highly contaminated media (soils, sediment, etc.). For preliminary conceptual models, details on the nature and extent of source areas will vary based on the amount of historical (background) information found.

Release Mechanisms are defined as any process that results in the transfer or migration of a contaminant from the source into environmental media such as air, soil, sediment, surface water or groundwater. Typically there is enough information available for a site and its environs to generate a list of known, probable, or potentially active release mechanisms.

Contaminant Migration Pathways are environmental media (e.g. air, surface water, groundwater) that have become contaminated and are capable of carrying the contamination away from the source to the point of exposure. Migration pathways can serve directly as exposure pathways in risk assessments.

Exposure Points are the locations where human or environmental receptors may come into contact with or otherwise be affected by the contaminants from the site.

Examples include contaminated soils in a source area and a creek or stream that receives contaminated run-off or groundwater discharges.
An example of an initial conceptual site model for a site in a relatively humid climate that has buried waste, shallow groundwater circulation and perennial streams and rivers nearby is shown in Fig. 1. On-site receptors are limited to site workers (assuming an industrial-type land use) and environmental receptors (wildlife, vegetation); downstream receptors include residential and recreational users of surface water and environmental resources.
Fig. 1.
VALIDATING THE CONCEPTUAL SITE MODEL
Refining, verifying and quantifying the relationships and processes identified in the conceptual site model is analogous to the validation process used to confirm analytical data and numeric-based models. Validating the initial conceptual site model involves quantifying the relationships between the model components, transforming the qualitative model developed during the scoping phase into a quantitative description of the source term, release rates, migration rates, flux and exposure. The process begins when the first data are coming in from the field and ends with the production of the RI Report. The specific activities associated with the validation process will vary depending on the physical setting, contaminant dynamics, characterization objectives and follow-on decisions to be supported by the RI data. An overview of the validation process is presented in the example site description.
EXAMPLE SITE
An RI based on a conceptual site model was recently completed for a site used for the disposal of radioactive and chemical wastes during the late 1950s and 1960s. The site is a burial ground where low level radioactive waste, transuranic wastes, fissile wastes and hazardous chemical wastes (e.g., spent solvents) were buried in hillside trenches and auger holes in an area of approximately 30 hectares. In addition to the trenches and auger holes, the site included several small landfills, surface impoundments with contaminated sediments and sludges, and underground waste storage tanks. In addition to on-site soils and groundwater, contamination from the wastes have impacted adjacent streams, which are the principal conduits for the off-site migration of (and potential exposure to) site-related contamination.
RI Planning
The initial conceptual site model developed during the scoping phase identified buried wastes as the major source, percolation of precipitation liquids through the wastes as the predominant release mechanism, transport in shallow groundwater as the primary migration pathway, and discharge into a perimeter stream and downstream river as the primary exposure points (for off-site human receptors; exposure points for environmental receptors occurred both on- and off-site). Additional sources (impoundments, landfills and underground tanks) and release mechanisms (interflow during storms and surface runoff) were also identified, but their relative significance was not known.
The initial model was qualitative in nature, consisting of little more than a series of cross-sections depicting the spatial relationships of the model components with directional flow indicators (e.g., downward arrows indicating percolation). It was used to establish the characterization objectives for the RI field investigation, specifically to focus the data collection efforts on information needed to confirm the various hypotheses associated with the conceptual model. These objectives included:
  Source term definition focusing on an inventory of waste types and contaminants of concern as well as waste packaging, placement methods, dates, and locations.
  Identifying principal and secondary release mechanisms, including the partial inundation of trenches by a rising water table, formation of transient, perched zones of saturation in trenches and auger holes, and direct leakage from impoundments and tanks.
  Delineation of surface and subsurface contaminant migration pathways and use of a calibrated hydrologic model to define the relative contributions of run-off, interflow and groundwater discharge to surface water flow from the site.
  Quantifying current and predicted, pathway- and contaminant-specific fluxes from each source area.
  Defining contaminant concentrations at primary exposure points both on- and off-site (as needed to determine concentration terms for use in risk evaluations).

The RI field investigation was designed to address these objectives and conducted using the observational approach to ensure maximum flexibility in the field. Flexibility was an essential component due to the uncertainty associated with most components of the initial conceptual site model. For example, flow monitoring and sampling after storm events early in the field program indicated that these events were major contributors to the overall flux of contamination from the site. The storm event monitoring and sampling program was expanded significantly to facilitate a better understanding of this mechanism. Conversely, it was shown that surface water sampling in the perennial streams that border the site was a more useful measure of the contaminated groundwater discharge than sampling of seeps, and therefore the seep sampling program was significantly reduced.

Data Evaluation

Data evaluation efforts were the principal activity of the RI. The framework for data evaluation was provided by the need to refine the site conceptual model to reflect, as accurately and completely as possible, the principal contaminant types and sources, release mechanisms, transport media and routes, and intermedia transfers, and then to link this model with risk-based considerations of present and potential exposure pathways, exposure point locations, and receptors. This approach entailed a much more rigorous analysis of the site conditions and contamination data than is typically performed for an RI.

The site was divided into two separate drainage basins and further subdivided into smaller study areas based on surface water and groundwater drainage divides because most of the release mechanisms and transport media (as described in the initial conceptual model) were water-based. Divisions within drainages were influenced by previously established solid waste management unit (SWMU) designations and knowledge of source characteristics and/or containment techniques. Each study area contained at least one contaminant source area.

A hydrologic model was constructed for each study area. The model was needed to define and quantify (when possible) the hydraulic processes associated with existing or potential releases of contamination and the subsequent movement of that contamination within the site. These models were depicted using cross sections through contaminant source areas and parallel to the predominant or most likely contaminant migration path(s). Each model extends to the nearest perennial stream or on-site drainage discharge point. In addition to presenting the source's position relative to migration routes (potential and observed), the models identify release mechanisms and intermedia transfers, and present the annual water budgets for individual flow pathways.

A focused sampling and analysis program had generated a large database of analytical data that was then pared down to a smaller subset of contaminants based on input from the human health and ecological risk assessment activities as well as an analysis of background concentrations of chemicals and radionuclides. A listing of analytes of concern for each study was developed for each study area and subsequent data evaluation efforts focused only on the specific occurrences of those analytes determined to represent actual contamination and/or a potential risk.

Analytical results and hydrologic models were combined into a study-area-specific conceptual model that identified the principal sources and contaminants, primary release mechanisms, and the distribution of contaminants within active migration pathways (Fig. 2). The model also presented the results of flux calculations performed for primary analytes (based on contribution to risk). Flux calculations were pathway specific (i.e., surface runoff, interflow, and groundwater) and based on the average annual flow rate and the average concentration detected in that pathway (if available). Flux calculations for surface runoff were based on average soil concentrations, erosion potential, and sediment/soil transport in surface runoff.

Fig. 2.

A separate conceptual site model package was prepared for each study area, which were then used to construct conceptual models for each of the 2 main drainage areas. In addition, fluxes from each study area were combined with the data from downstream receiving waters to generate overall surface water release contributions, which were presented on an area-specific, drainage-basin-specific, and site wide basis for the major contaminants of concern.

RI Report

A major goal of the RI was to generate a comprehensive, yet user-friendly document

that summarized the current knowledge of the site's contaminant dynamics, exposures and risks. To this end, a site-wide conceptual model, based on a compilation of the area- and drainage basin-specific models, was developed and presented in a Technical Summary Volume (<100 pages) that also summarized the environmental setting, included a detailed remediation and operable unit strategy as well as remedial action objectives for the site.
Important features of the model were its ability to identify, illustrate, and rank the sources of contamination (i.e., wastes), the applicable secondary sources/migration pathways, and the release mechanisms that link the two, as well as the pathway-specific on-site risks for both residential and industrial exposure scenarios. The model reflected the hydrologic processes (primarily shallow groundwater) that govern the spread of contamination from the sources to the on-site and off-site groundwater, surface water, sediments, and soils, creating the potential for risks. Release mechanisms were primarily bathtubbing in trenches and inundation of buried wastes with groundwater, particularly during wet season (high base) conditions and, to a lesser extent, surface runoff, storm flow, and percolation of rainwater through the wastes. To facilitate the assessment of the relationships between contaminant sources, release mechanisms, secondary source media, and area-specific contributions to off-site risks, the source areas were ranked by contribution to the total off-site risk.
CONCLUSION
Use of the conceptual site model offers many advantages to the traditional approach for characterization activities, namely the effective integration of risk with the contaminant sources and physical-based processes governing contaminant release, transport and exposure. Although successful application of the method requires a significant level of data evaluation and understanding, the end product will more clearly address project objectives and better support the follow-on decision making activities for remedial action.

MEETING THE CHALLENGE OF MOVING HANFORD ENVIRONMENTAL RESTORATION TO A PROJECT MANAGEMENT APPROACH
Roger Freeberg
Julie Erickson
U. S. Department of Energy
Edward S. Keen
Joseph F. Nemec
Bechtel Hanford, Inc.
ABSTRACT
Implementing the Environmental Restoration Contract (ERC) at the Department of Energy (DOE) Hanford Site is a major step in the process of moving the Hanford Environmental Restoration Project from operations to environmental restoration. This paper describes how the DOE Richland Operations Office and Bechtel Hanford, Inc. (BHI), the new ERC, are working together to implement this change.
BHI assumed responsibility as the Hanford ERC on July 1, 1994, after a four-month transition period. Since the contract began, DOE and BHI have taken a series of steps to set up an organization and establish management systems tailored to the environmental restoration mission. These include: 1) organizing by projects to establish clear lines of accountability and responsibility; 2) establishing project teams and providing them with the resources needed to complete their assignments; 3) implementing productivity improvements and cost savings; 4) forging a partnership between DOE and BHI; and 5) establishing relationships with regulators and stakeholders.
BACKGROUND
The Environmental Restoration Contract (ERC) at Hanford is a demonstration of a new type of contract at DOE sites. The concept of having a separate contractor to manage

environmental restoration originated in 1990 with the Department of Energy's Alternate Contracting Task Force, which looked at ways to lower costs and improve efficiency in DOE's nationwide environmental restoration program. One concept the task force developed was a separate contractor with the single mission of moving a contaminated site to full and complete restoration, rather than having environmental restoration managed by the management and operations (M&O) contractor.

Goals of the new contracting strategy included improving management control of the environmental restoration program, reducing cleanup costs, and facilitating more timely restoration of the sites. Two demonstrations of this concept were planned, one at Fernald and one at Hanford.

The Fernald Environmental Restoration Management Corporation (FERMCO), a subsidiary of Fluor Daniel Corporation, became the Fernald ERC in September 1992. A team headed by Bechtel Hanford, Inc. (BHI) was selected for the Hanford assignment in January 1993. Start of work was delayed by a protest from unsuccessful bidders. Selection of the Bechtel team was reaffirmed by DOE in February 1994; BHI started a transition in March; and the full contract took effect July 1. The Bechtel team includes three preselected subcontractors: CH2M Hill Hanford, Inc.; IT Hanford, Inc.; and TMA Hanford, Inc.

In contrast to Fernald, where FERMCO has responsibility for the entire site, BHI is responsible for only one part of the Hanford mission. There are two major categories of "cleanup" work at Hanford -- waste management and environmental restoration. Waste management includes the treatment, storage, and disposal of wastes, such as the high-level liquid wastes stored in 177 underground tanks. Westinghouse Hanford Company, the Hanford M&O contractor, is responsible for waste management, along with the associated maintenance and operations necessary to manage the 560-square-mile Hanford reservation. These activities account for more than 80% of the Hanford budget.

Environmental restoration, BHI's area of responsibility, is the cleanup and restoration of areas contaminated during past production and disposal activities. It includes cleanup of burial areas, liquid waste disposal sites, and contaminated groundwater, as well as decontamination and decommissioning of reactors and other facilities no longer in use. These activities account for approximately 20% of the Hanford budget.

TRANSITION

Environmental restoration at Hanford is a complex task, and making the transition into the new contract was also complex. Previous contractor transitions at other DOE sites normally involved a complete changeover from one company to another, with the new contractor bringing in a management team, assuming full responsibility for the site, and hiring the full existing workforce. For the Hanford ERC, Bechtel was assuming only a portion of the work being performed by Westinghouse.

This set of circumstances posed many challenges in the areas of management systems, health and safety, milestone compliance, and human resources. Westinghouse and Bechtel worked together to identify employees directly employed by Westinghouse in the ER program and determine their role in the new organization. An equally complex task was identifying the Westinghouse indirect and part-time support staff and determining which would move to the new organization. Effecting this transfer of several hundred employees was made even more difficult because they were transferring from an operations organization into a project management organization.

Personnel from DOE-Richland and Bechtel met early in the transition with their counterparts at Fernald to learn from their experience in making the transition there. The information provided by Fernald was extremely helpful to Hanford in making a successful transition.

A steering committee made up of managers from DOE, Westinghouse, and Bechtel was formed to provide guidance during the transition. Managers from Bechtel met with their counterparts in the Westinghouse organization to learn about activities in their areas of responsibility, review staffing, and identify critical tasks to be completed during transition.

The sheer volume of work in the human resource area was challenging. Westinghouse provided Bechtel with lists of employees who worked full-time in the ER program, and additional lists of people who provided indirect support to the program. BHI invited the Westinghouse employees to orientation sessions of about 50 people each, held in the evenings, to explain the new organization and describe the process that would be used to screen and hire employees. At these meetings, employees were given a phone

number to schedule individual interviews. The BHI team interviewed almost 600 Westinghouse employees, hired about 500, and determined where they would be employed in the new organization. Throughout the process, the two companies worked together to provide information through the site employee newspaper and other channels. During this period Bechtel also set up program controls, safety and health, environmental compliance, procurement, and accounting systems. All of these functions had to be fully operational by July 1.

A key to success during this period was a detailed transition plan, developed by BHI and approved by DOE. This plan listed all actions that had to be completed for BHI to be ready for full contract operations, and designated points of contact within DOE, Westinghouse, and Bechtel for each item. A series of formal readiness reviews were held in June. In these reviews, BHI described actions that had been taken to achieve each requirement in the transition plan. DOE management determined if the area was ready for operations and identified action items to be completed after transition. DOE determined in the readiness reviews that the BHI team was ready to assume full responsibility for the Hanford ER program effective July 1.

ACTIVITIES TO DATE

Since the contract began, DOE and BHI have taken a series of steps to set up an organization and establish management systems tailored to the environmental restoration mission. These include: building a partnership between DOE and the BHI team; organizing by projects to establish clear lines of accountability and responsibility, giving project teams the resources needed to complete their assignments; implementing productivity improvements and cost savings; negotiating agreements with organized labor; and establishing relationships with regulators and stakeholders.

The organization of the Hanford ER project illustrates a fundamental difference between an operations approach and a project management approach. An operations approach is organized by operating functions, using an in-house workforce focused on repetitive tasks. It makes minimal use of subcontractors and has numerous management layers. A project management organization has few management layers, is built around project teams, and uses specialty subcontractors to perform much of the work.

The BHI organization at Hanford is built around project teams. Each project team is composed of the engineering, construction, environmental compliance, health and safety, quality assurance, and support personnel needed for a specific task. The Environmental Restoration staff of DOE-Richland, which oversees BHI, also organized along project lines. This "mirror image" between DOE and BHI results in an efficient working relationship.

The working relationship was further enhanced by a project management retreat held in June. This facilitated retreat was a very worthwhile exercises. Purposes of the retreat were to:

- Build a solid foundation of mutual respect and partnership between BHI and DOE
- Identify the primary expectations each organization had of the other, and use these expectations to define the distinct roles of DOE and BHI
- Identify the issues and opportunities facing the project and put the organization interface in place to resolve these issues
- Create and then commit to an overall "Commitment Statement" for the project

This retreat introduced key players in DOE-RL and BHI to each other and helped motivate both organizations to focus on common goals and to better define roles and responsibilities. The working relationship developed during this exercise has been continued through a "Results Management Team" made up of managers from the DOE and BHI organizations. The team meets weekly to:

- Enhance the velocity and effectiveness of the transition
- Instill unified, integrated project leadership
- Focus on accountability for results and managerial control
- Challenge the team to reach for and begin producing breakthroughs in results
- Instill a "project" culture and build momentum in the team
- Identify and resolve issues openly and effectively
- Create a win-win context among the DOE and the contractors

After this teaming arrangement was in place and working at the upper management level, it was then instituted at the project level in December. Representatives from each project team met to build a foundation of partnership, identify priorities and expectations, identify issues and opportunities, and create a commitment statement for each project.

The first measurement of the effectiveness of this "win-win" relationship between DOE and BHI came in December with DOE's fee determination report for the first three months of the contract (July through September). The BHI contract is a Performance Based Fee contract, in which a fee pool is available based on performance only. DOE-RL's Performance Evaluation Committee defines specific performance objectives and criteria prior to each rating period and then monitors BHI's performance to each of these criteria. Based on the ratings, BHI can earn anywhere from zero to 100 percent of the available fee. For the July-September period, BHI earned 88% of the available fee. This high rating, despite the many difficulties posed by the transition, indicates that the teaming arrangement between DOE and the contractor is working.

During the last three months of 1994 and the early part of 1995, the Hanford ER program has focused on funding issues. Reductions in the FY 1995 funding and projections of further reductions in FY 1996 and beyond have resulted in a series of budget studies. The ability to perform these studies has been enhanced by having a defined, project-oriented baseline in place.

CONCLUSION

DOE and BHI have made the transition into this new type of contract and are showing progress in expediting remedial action and improving cost-effectiveness. There are, however, still many challenges remaining. These include:

Further refining the contract to remove provisions that were appropriate for an M&O contract but not for environmental restoration.

Closing on a labor agreement.

Developing an environmental restoration strategy for the site that focuses on "doing the right things" and not merely "doing things right."

The biggest challenge for the Hanford ER project will be to continue showing progress during a time of reduced funding and continued regulatory and public pressure to show results.

ISSUES RELATED TO UNCERTAINTY IN PROJECTIONS OF HAZARDOUS AND MIXED WASTE VOLUMES IN THE U.S. DEPARTMENT OF ENERGY'S ENVIRONMENTAL RESTORATION PROGRAM*

K.C. Picel
Argonne National Laboratory
Argonne, Illinois

ABSTRACT

Projected volumes of contaminated media and debris at U.S. Department of Energy (DOE) environmental restoration sites that are potentially subject to the hazardous waste provisions of the Resource Conservation and Recovery Act are needed to support programmatic planning. Such projections have been gathered in various surveys conducted under DOE's environmental restoration and waste management programs. It is expected that reducing uncertainty in the projections through review of existing site data and process knowledge and through further site characterization will result in substantially lowered projections. If promulgated, the U.S. Environmental Protection Agency's Hazardous Waste Identification Rule would result in potentially even greater reductions in the projections when site conditions are reviewed under the provisions of the new rule. Reducing uncertainty in projections under current and future waste identification rules may be necessary to support effective remediation planning. Further characterization efforts that may be conducted should be designed to limit uncertainty in identifying volumes of wastes to the extent needed to support alternative selection and to minimize costs of remediation.

INTRODUCTION

Identifying quantities of contaminated environmental media that are subject to hazardous waste regulations under the Resource Conservation and Recovery Act (RCRA) is an issue confronted at most hazardous waste sites being addressed under either RCRA corrective actions or under the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA). At U.S. Department of Energy (DOE) sites, the further presence of radioactive contaminants in such media adds the prospect that media may be considered both hazardous and radioactive waste, or mixed waste. The administration of the hazardous waste regulations for a given site, including DOE sites, is usually the province of the environmental protection agency of the state in which the site resides. Authority over radioactive wastes, on the other

hand, has traditionally been the responsibility of federal agencies, principally DOE and the U.S. Nuclear Regulatory Commission (NRC). With the 1992 passage of the Federal Facility Compliance Act (FFCA) amending RCRA to bring federal facilities into compliance with applicable federal and state laws, the administration of mixed waste is conducted jointly under both federal and state authorities.

Identifying and quantifying hazardous and mixed wastes is an important activity within DOE's waste management (WM) program and within the environmental restoration (ER) program, in particular. Such activities have major implications regarding the cost of remedial activities and regarding waste management and waste treatment decisions within the program.

This paper discusses the general nature and sources of uncertainties in projections of volumes of environmental media and debris (i.e., contaminated equipment and structures) potentially requiring management as hazardous or mixed wastes within the ER program and suggests means for reducing them. Hazardous and mixed wastes have been singled out for evaluation because of the inherent difficulty in estimating quantities of such wastes in environmental media and debris, because of the large number of technologies available for the required treatment of such media, and because of the high costs associated with treatment and management. In addition to evaluating the nature, sources, and general level of uncertainty in the volume estimates, the nature of impacts of uncertainty on various waste management options are suggested. Lastly, recommendations are made as to what relative levels of uncertainty may be acceptable for supporting various action alternatives and how such levels may be attained through reevaluating current information and through conducting further characterization.

MANAGEMENT OPTIONS FOR HAZARDOUS AND MIXED WASTES

Application of Waste Regulations to Contaminated Environmental Media

Under RCRA, states with authority can classify contaminated environmental media as hazardous waste under two basic provisions of the rules (40 CFR 261): 1) the medium is a characteristic hazardous waste because it has failed a specific characteristic test; or 2) the medium is a hazardous waste under the mixture rule. The mixture rule provides that any product of the mixing of a listed hazardous waste with another solid waste is itself a hazardous waste (not to be confused with mixed waste, i.e., waste that is both hazardous and radioactive). Listed hazardous wastes are derived from specific industrial processes and activities and include many of the substances that often contaminate environmental media, including, for example, spent solvents. Consequently, under the mixture rule, regulations for listed wastes can, in certain circumstances, be extended to environmental media. Given these two provisions, states have had, and continue to have, broad authority to classify contaminated media as hazardous waste. Similarly, by extension, such authority also applies to the classification of media contaminated with mixed waste.

With respect to characteristic wastes, definitive classification requires testing of hazardous characteristics, principally the toxicity characteristic, which is tested using the toxicity characteristic leaching procedure (TCLP; 40 CFR 261, Appendix II). (The characteristics of ignitability, corrosivity, and reactivity can be ruled out for most environmental media and debris.) Preliminary or presumptive classification, on the other hand, can be done on the basis of general information (including process knowledge, spill logs, and material inventories) or even by applying standard assumptions regarding releases from vessels and the like. But definitively establishing that a particular medium is not a characteristic hazardous waste, once brought into question, requires specific characteristic testing.

To establish that a particular medium is hazardous waste under the mixture rule is a less definitive process. The mere presence of a listed hazardous waste constituent may cause a medium to be classified as hazardous (or mixed) waste. No de minimis levels exist under the mixture rule. Once a waste (medium) is classified as hazardous waste under this rule, it can only be declassified by petitioning the U.S. Environmental Protection Agency (EPA) to delist the waste, a time-consuming process. Changes to the hazardous waste identification rules are being considered that will offer relief from the mixture rule, as discussed in a later section of this paper.

Regulations under the mixture rule are not explicitly directed to environmental media, e.g., soils or groundwater, but are applied to such media to the extent they can be considered solid wastes. The mixture rule does, however, specifically address contaminated debris, under the so-called debris rule (40 CFR 268.2[h]). Debris is a significant waste element in the ER program because many restoration projects

involve the demolition of buildings and other structures. It is assumed that the mixture rule applies equally to debris and environmental media in the ER program. In the identification of mixed waste, the above hazardous waste criteria, along with prevailing radioactive waste criteria, are applied independently. Mixed wastes are usually initially established to be radioactive wastes on the basis of NRC regulations and DOE Orders and later determined to be also hazardous wastes under RCRA.

With respect to radioactivity, much of contaminated media at ER sites falls into the category of low-level waste, which is defined as radioactive waste not classified as high-level radioactive waste, transuranic waste, spent nuclear fuel, or byproduct material as defined in Section 11e.(2) of the Atomic Energy Act (uranium or thorium tailings and waste) (10 CFR 61). Two other classes of radioactive wastes of importance at ER sites are 1) transuranic (TRU) wastes, defined as containing more than 100 nCi of alpha-emitting transuranic isotopes with half-lives greater than 20 years per gram of waste (DOE Order 5820.2A), and 2) 11e.(2) byproduct material (primarily uranium mill tailings), referring to the portion of metal-bearing ore remaining after extraction of uranium (DOE Order 5820.2A). As the identity of such wastes is already well established at most ER sites, details of the application of radioactive waste classification criteria will not be presented here.

Management and Treatment of Generated Waste

Contaminated environmental media are not technically wastes until "generated" through, for example, excavation as in the case of soils. Once generated, that which is classified as either hazardous or mixed waste is subject to the treatment, storage, and disposal regulations under RCRA (40 CFR 262, 40 CFR 263, and 40 CFR 264). Such wastes that are being considered for disposal are subject to land disposal restrictions (LDR) under RCRA. The LDR rules (40 CFR 268) prohibit the disposal in or on land of wastes that exhibit toxicity or the potential to leach contaminants into groundwater above specific thresholds. Characteristic hazardous wastes are explicitly prohibited from such disposal unless treated to the point that they no longer exhibit the characteristic. Wastes with listed hazardous constituents are subject to treatment standards specific to the constituents or to treatment by a specified technology. Verifying that such treatment standards are met for either waste again requires that the waste be characterized. Often it can be established that wastes, including environmental media, identified through the mixture rule already meet treatment standards in the absence of any treatment.

Alternative Management Strategies

One avenue that has been opened to reduce the administrative burden of LDR rules is the institution under RCRA of the corrective action management unit (CAMU) concept. Under this concept, placing remediation wastes generated at a facility as part of a RCRA corrective action into or within a CAMU is not considered land disposal and such wastes therefore are not subject to LDR (40 CFR 264, Subpart S). Remediation wastes (media) may be excavated within a CAMU, treated in a second CAMU, and redeposited in the excavated area of the original CAMU without triggering LDR. Also, waste disposal units within a CAMU are not subject to minimum technological requirements under RCRA. The responsibility and authority for protecting health and the environment under this approach is assumed under the prevailing RCRA corrective action program. The use of CAMUs is expected to reduce delays in cleanup efforts.

A second development currently under way that addresses the issue of identification and management of hazardous waste is EPA rulemaking aimed at reform. The proposed Hazardous Waste Identification Rule (HWIR) (57 FR 21450, May 1992) addresses, among other things, wastes classified as hazardous under the mixture rule, and should benefit environmental restoration efforts. The proposed HWIR would establish an entry and exit system for prospective wastes. The rule would employ health-based, contaminant-specific concentration limits, termed "bright line" numbers, as criteria for entry or exit of the system. The limits could be used to identify hot spots in environmental media that would be subject to RCRA hazardous waste rules, while removing those requirements for media falling below the criteria. The latter media would still, however, be subject to site-specific cleanup standards.

The rule was proposed in 1993, then withdrawn after comments were reviewed. It is expected to be reproposed by September 1995. Large quantities of contaminated media at ER sites currently subject to RCRA regulations, including the mixture rule, could be affected by the new HWIR. Similarly, characterization efforts related to identifying hazardous and mixed wastes in environmental media would have to conform

to the new rule, if promulgated, possibly requiring reevaluation of existing data and/or recharacterizing media in light of the "bright line" numbers.

NATURE AND SOURCES OF UNCERTAINTY IN ESTIMATES OF MEDIA VOLUMES SUBJECT TO RCRA

Several surveys of ER sites have been conducted within DOE's environmental management (EM) program, gathering information on estimates of contaminated environmental media and debris that are potentially subject to subject to hazardous waste regulations under RCRA. Surveys include the Contaminated Media/Waste Data Call, the estimates prepared to support the Programmatic Environmental Impact Statement (PEIS), and estimates gathered to support the Baseline Environmental Management Report (BEMR). The surveys relied on site characterization data and process knowledge available at ER sites. The current analysis does not examine any particular estimate but describes the nature and sources of uncertainty in estimates of this type in general. The volume estimates generated are assumed to be inherently conservative, both with respect to the volumes of media that might ultimately be removed for remediation, and thus generate solid waste under RCRA, and with respect to the volumes of solid waste that may ultimately be determined to be hazardous or mixed waste under RCRA. This conservatism arises in general from a desire on the part of waste managers to include all media that will have to be addressed in the future, whether or not it is technically hazardous or mixed waste, and as a result of the generally small amount of characterization data available with respect to current or future hazardous waste criteria.

Many surveys to estimate volumes of contaminated media are conservative by design, often forcing the assignment of suspect media into a particular waste class. Volume estimates, particularly of hazardous and mixed wastes, therefore may start from a conservative base. Moreover, the estimated volumes of contaminated media and debris are often just a first approximation based on limited data or on simple modeling. Such volume estimates are often done in a conservative manner so as to avoid misidentifying any contaminated areas.

With respect to identifying regions within contaminated media that may be potentially hazardous or mixed waste, authoritative data needed to make such identifications are often sparse and, where available, may not have been collected for the purpose of characterizing media according to hazardous waste criteria. Further data needed to define the boundaries of such regions are particularly lacking or may be completely absent. Often, simply the known or suspected presence of a characteristic or listed hazardous constituent is all the information available as a basis for classifying media and developing volume estimates.

In cases where the mixture rule may apply, a particular medium can be classified as hazardous or mixed waste on the basis of very low levels of hazardous constituents. At many contaminated sites, the mere presence of a listed constituent has been used to preliminarily identify a medium as potentially subject to RCRA without regard to the origin of the constituent. However, if the source of the hazardous constituent was not a listed waste, such as spent solvents, for example, in the case of certain volatile organic constituents, then the medium is not subject to the stringent criteria of the mixture rule. Instead, the quantitative criteria for characteristic hazardous wastes apply. In that regard, data for determining the status of environmental media with respect to hazardous waste characteristic criteria using the TCLP are particularly limited at ER sites.

Because a final determination of the sources of hazardous constituents may not have been fully established at many ER sites, large quantities of contaminated media may be assumed to be subject to RCRA under the mixture rule that in fact are not. The low levels of hazardous constituents in much of this media indicate that the media may be identified as nonhazardous after hazardous characteristic testing using the TCLP.

Current estimates of waste volumes potentially subject to regulation as hazardous or mixed (hazardous and radioactive) waste under RCRA may therefore be considered to represent a reasonable upper bound on hazardous and mixed wastes that may be generated in the ER program. The level of uncertainty varies from site to site and from medium to medium according to the level of information available. The greatest volumes as well as the greatest relative uncertainties are probably associated with groundwater and soil.

The volumes of media that will ultimately have to be addressed in the program, however, are probably substantially less than these upper bound projections, even if changes in waste identification rules are not forthcoming. Efforts to refine the

boundaries of contaminated areas will surely reduce volumes. Given the economic incentives, characterization efforts to support such refinements will be easily justified. Much greater reductions in volumes are possible, however, under scenarios that provide relief from the mixture rule, such as under the proposed HWIR described above. Some forms of rule changes are to be expected over the multiyear course of the ER program. With respect to some mixed waste, volume reductions would in fact reflect reclassification from mixed waste to the prevailing radiological waste class, although refinement of the volumetric extent of the radiological component through further characterization or monitoring during excavation is certainly also possible.

MANAGING UNCERTAINTY IN VOLUME ESTIMATES

Impacts of Declining Volume Estimates on Action Decisions

If existing volume estimates of hazardous and mixed wastes represent an upper bound, as asserted above, then reductions in uncertainty in these estimates will correspond to declining estimates of volumes. As volume estimates decrease, management decisions addressing the wastes may change.

There are three major factors influencing any scenario under which hazardous and mixed waste cleanup actions might proceed under the ER program: 1) the extent to which the current action plan under current RCRA waste rules is carried out, 2) the extent to which the CAMU concept can be applied to additional ER sites, and 3) and the extent to which proposed revised hazardous waste identification rules affect the ER program. Declining volume estimates will have impacts on cost estimates and associated action decisions under the various possible scenarios.

Under any scenario, significant reductions in hazardous and mixed waste volumes from current estimates will impact the budgeting of remedial actions, the selection of action alternatives, and the selection of treatment technologies and process options. Table I presents the nature of impacts of declining volume estimates on these activities in terms of the three scenario factors. The impacts increase according to the degree that volume reductions are realized through improved characterization and to the extent that the CAMU concept and revised hazardous waste rules apply to a given scenario.

Preliminary selection of both the general alternative actions and specific treatment processes at various ER sites may be expected to change in the directions suggested in Table I as cleanups progress and requirements change.

Reducing Uncertainty in Volume Estimates

Refinements to volume estimates will be required on a continual basis as the ER program is carried out. For initial planning purposes, current volume estimates may have to be evaluated and revised before major planning decisions are made. That is, the uncertainty in current estimates may be too high to support a comprehensive action plan relative to an environmental medium that is potentially hazardous or mixed waste. In general, reducing uncertainty to support planning will require 1) reexamining existing data available at the sites with the expressed purpose of improving volume estimates and 2) conducting further characterization to improve estimates where existing data are insufficient. The extent to which these activities need to be carried out varies from site to site.

Several measures can be taken to reevaluate existing site data. First, if characterization data are available, those data should be evaluated for representativeness. The inferences drawn from the data can then be applied to the volume of medium represented by a given sample. Second, it is very important that in cases where RCRA characteristic hazardous waste criteria are being applied, rather than the mixture rule, this fact be firmly established and characterization data applied according to the applicable concentration criteria. In such cases, a particular medium can be classified on the basis of available TCLP data or, lacking that, to a great extent on the basis of direct analysis of the medium. In the latter case, a solid medium can be determined to be nonhazardous if contaminant concentrations in the medium do not exceed 20 times the TCLP criteria. (This criterion ensures that TCLP leachate could not possibly exceed the criteria.) For instance, if all soil samples representing a given volume of medium have no concentrations exceeding 20 times TCLP criteria, it may be inferred that none of that volume is hazardous or mixed waste. In cases where wastes are identified on the basis of the mixture rule, improvements in estimates may be accomplished through careful review of sample locations.

Beyond these steps, where data are sparse, the application of process knowledge may

improve volume estimates. Such knowledge might include spill logs, area use patterns, chemical inventories, or a mass balance analysis. In some cases, site-specific contaminant transport modeling, in which existing data and process knowledge are applied, may be appropriate to refine volume estimates of contaminated media.

In cases where additional characterization is required, either to support planning or implementing an action, a focused and efficient sampling and analysis plan should be developed with well conceived data quality objectives. In such development, the sampling problem and action decisions should be well defined and measurement uncertainty goals set accordingly. The first step in this process is to identify the leading action alternative for the affected media. Next, consideration of costs per volume of media and total volumes of media affected should be used to indicate the levels of uncertainty in volume estimates that may be acceptable and thus the level of characterization required. Table II presents a qualitative ranking of uncertainty as driven by overall costs that might be acceptable under various action alternatives for a given volume of waste.

The general observations shown in Table II would further be a function of the total volumes of waste ultimately identified. For example, percentage uncertainties in media volumes acceptable at a 1,000 m3 level may be unacceptable at a 100,000 m3 level. An additional factor to be considered relative to uncertainty in volume estimates of mixed waste is whether further characterization will result in reducing volumes of the media that are either potentially hazardous or radioactive, or both. Another factor that will affect characterization requirements is the extent to which new hazardous waste identification rules are adopted in the future. Given concentration-based criteria, increased levels of characterization will be required to define areas of media above and below the criteria. The levels of uncertainty attained in these efforts will depend on a balance of the costs of characterization versus those of treatment and/or disposal of excess media.

SUMMARY AND CONCLUSIONS

Contaminated environmental media at DOE ER sites are subject to the provisions of RCRA and may be classified as hazardous or mixed waste on the basis of characteristic testing or the mixture rule. Estimated volumes of such media that are potentially hazardous or mixed waste are large and are assumed to be conservative because 1) surveys are generally based on first-order approximations of the boundaries of contaminated regions, 2) current levels of characterization do not support identification of subregions, or hot spots, of media exceeding RCRA criteria, and 3) some media may be classified as hazardous waste on the basis of a misapplication of the mixture rule. It is expected that improving media characterization and reviewing RCRA criteria will result in declining volume estimates. Reduced waste volumes, in turn, will have impacts on cost estimates and on the selection of remedial action alternatives. Improved volume estimates, therefore, may be necessary to support remedial action planning. Such improvements may be effected through review of existing characterization data and process knowledge, or through further characterization of contaminated media. The levels of uncertainty acceptable in further characterization efforts will depend on the nature of the contamination, the volume of contaminated media involved, the type of remedial alternative selected, and the overall costs of the remedial actions.

CHARACTERIZATION OF HAZARDOUS WASTE RESIDUALS FROM ENVIRONMENTAL RESTORATION PROGRAM ACTIVITIES AT DOE INSTALLATIONS:
WASTE MANAGEMENT IMPLICATIONS*

ABSTRACT

Investigators at Argonne National Laboratory (ANL), with support from associates at the Pacific Northwest Laboratory (PNL), have assembled an inventory of the types and volumes of radioactive, toxic or hazardous, and mixed waste likely to be generated over the next 30 years as the U.S. Department of Energy (DOE) implements its

nationwide Environmental Restoration (ER) Program. The inventory and related analyses are being considered for integration into DOE's Programmatic Environmental Impact Statement (PEIS) covering the potential environmental impacts and risks associated with alternative management practices and programs for wastes generated from routine operations. If this happens, the ER-generated waste could be managed under a set of alternatives considered under the PEIS and selected at the end of the current National Environmental Policy Act process.

As the ER Program progresses over the next 20 to 30 years, it is estimated that areas identified for restoration within certain DOE installations will generate about 2.5 106 t (1.7 106 m3) of nonradioactive solid waste through site restoration activities. The ER residuals will typically include process residues and sludges; contaminated debris, soil and concrete; bulk metals; and stabilized monolithic solids. A significant fraction of this waste will require solid landfill space for disposal, and a portion will need to be treated and/or disposed of at specially permitted facilities. Because DOE has little or no on-site capability for treating and disposing of the types of nonradioactive or hazardous wastes that the ER Program will generate, the current practice is to transport wastes of this type off-site for treatment and disposal. Conceivably, under the currently structured PEIS alternatives, nearly all of the nonradioactive ER waste inventory could be targeted for off-site commercial facilities for treatment and/or ultimate disposal. This practice could result in unnecessary, costly, and potentially risky site restoration actions, including the transportation of approximately 120,000 truckloads of nonradioactive ER wastes over the next 30 years.

INTRODUCTION

The U.S. Department of Energy (DOE) has supported the compilation and analysis of an environmental restoration waste inventory for consideration in the preparation of the Programmatic Environmental Impact Statement (PEIS) for its Environmental Restoration (ER) and Waste Management (WM) Programs. The information presented in this paper is taken, in part, from this effort. Under the PEIS, the DOE is evaluating and comparing the risks associated with current practices and programs for managing its wastes with those associated with alternative waste management scenarios. The specific risks and environmental impacts being evaluated are human health risks and costs associated with transportation and/or treatment, ecological risks, land-use impacts, and other impacts.

Routine operations at DOE facilities generate radioactive, nonradioactive, and mixed waste. These wastes are managed under DOE's WM Program. Wastes that are nonradioactive such as those that exhibit the hazardous characteristics of corrosivity, ignitability, reactivity, and/or chemical toxicity are managed in accordance with regulations implementing the Resource Conservation and Recovery Act (RCRA), the Toxic Substance Control Act (TSCA), and hazardous and toxic waste legislation at the state level. The DOE commonly refers to wastes covered by RCRA or TSCA regulations and by state regulations as hazardous waste (HW). Radioactive wastes generated at DOE installations are grouped by the level and type of radioactivity present and are managed separately in accordance with special regulatory programs set forth in the Atomic Energy Act and by the U.S. Nuclear Regulatory Commission. The PEIS is assessing the risks and costs associated with the transportation, treatment, and disposal of HW, high-level radioactive waste (HLW), transuranic waste (TRUW), low-level radioactive waste (LLW), and low-level mixed waste (LLMW). Waste that has both radioactive and hazardous components is known as mixed waste. Mixed waste potentially includes all radioactive waste types, but typically LLMW and TRUW, and must be managed in accordance with both sets of rules. This paper focuses on the characteristics of the nonradioactive HW that will be generated under the ER Program, and examines the impact such waste will have on DOE's current practice of sending virtually all nonaqueous HW off-site for treatment and disposal.

Wastes that will be generated under DOE's ER Program (ER wastes) are nonroutine, meaning that the wastes will be generated once in the course of remediating DOE facilities. These wastes will include HW, LLMW, LLW, and TRUW, although in proportions substantially different from those generated by routine operations. The quantitative and qualitative relationships between wastes generated under the WM Program (WM wastes) and ER wastes are shown in Fig. 1. These values represent the best estimates currently available on the amounts of hazardous, mixed, and radioactive wastes that DOE is likely to generate each year over the next few

decades (1-4). Figure 1a shows the projected annual quantities of HW, LLMW, LLW, TRUW, HLW, and other wastes that will continue to be generated yearly by routine, ongoing DOE operations and managed under DOE's existing WM Program. Figure 1b shows the quantities of HW, LLMW, LLW, TRUW, and other wastes that can be expected each year, on average, over the next 30 years under the ER Program. The values for the WM wastes have a higher level of confidence because they are based on studies of actual waste generation records (e.g., waste manifests) and therefore are rooted in historical experience. The values for the ER wastes are less certain because they are based on incomplete waste characterization data and computer-generated projections. No allowance has been made in either group for future reductions due to waste minimization initiatives or regulatory changes, such as the expected 1995 redefinition of RCRA hazardous wastes, which might exclude many of the contaminated media wastes from regulation in later years.

The focus of this paper is on the group of HW that will be generated under the ER Program and the impact this waste could have on DOE's current practices for managing HW under the WM Program.

WASTE MANAGEMENT PLANNING ALTERNATIVES

The DOE is considering alternative waste management scenarios for each of the five waste types (HW, LLMW, LLW, TRUW, and HLW). These scenarios differ mainly as to how the 45 DOE sites could manage their chemical wastes, including transportation, and treatment, storage, and disposal (TSD). Portions of the waste might be handled on-site and the rest handled off-site (by outside commercial firms). Determining how to distribute the waste between on-site treatment and off-site TSD facilities leads to a comparison of multiple alternatives requiring the evaluation of human health risks, costs of treatment and transportation, and ecological, land-use, and socioeconomic impacts. The alternatives currently under consideration by DOE include:

Baseline (No Action) Case The baseline or no-action alternative refers to the continuation of the current distribution of chemical hazardous wastes between on-site treatment and off-site commercial TSD vendors and the continuation of current (as of 1992) routing of hazardous waste trucks from the DOE generation site to the final TSD location.

Decentralized Case Under decentralization, treatment activities at DOE sites would increase between 5 and 10%. As a result of this increase, use of commercial TSD vendors would decrease, likely reducing the risks from transportation.

Five-Region Case (Regionalized No. 1) The five-region case builds upon the decentralization alternative by treating, at DOE installations, approximately 50% of the waste that is currently treated, stored, and disposed of off-site. Instead of being transported to commercial facilities, this waste would be transported (if necessary) to one of five designated DOE-owned-and-operated hazardous waste treatment facilities. The five DOE installations selected for this treatment (for evaluation purposes) are the Hanford Site (HS), Idaho National Engineering Laboratory (INEL), Los Alamos National Laboratory (LANL), Oak Ridge Reservation (ORR), and Savannah River Site (SRS). All treated waste would be disposed of at permitted commercial landfills.

The Two-Region Case (Regionalized No. 2) Under the two-region case, 90% of all chemical hazardous waste (nonwastewater [nonaqueous] hazardous waste) currently treated by commercial TSD vendors would be transported to one of two DOE-owned-and-operated hazardous waste treatment facilities. The two DOE installations selected for this treatment (for evaluation purposes) are INEL and ORR. All treated waste would be disposed of at permitted commercial landfills.

The appropriateness of these alternative strategies for managing the ER wastes, especially the ER HW, is currently being evaluated. The key issue is the fact that none of the current alternatives include a provision for on-site disposal capability at strategic DOE installations. Even though varying degrees of treatment capacity changes are explored, none of the alternatives considers whether the resulting treatment residues should be disposed of on-site and, if so, what impact this would have on existing landfill capacity. The question of whether more on-site landfill space should be built into future planning for DOE waste management is important, given the large volume of wastes expected to be generated under the ER Program. The systems now in place to manage HW from routine operations and the potential application of these systems to the management of HW that will be generated under the ER Program are examined below.

HAZARDOUS WASTES FROM FACILITY OPERATIONS

Hazardous wastes that arise out of routine ongoing operations at DOE installations are generated in more or less the same quantities year after year. These wastes, also called "as generated" HW, are managed under DOE's WM Program. Recent updates to the HW inventories, compiled in the hazardous waste risk assessment modeling database (5), show that about 1.26 106 t of HW is being generated each year in the course of weapons manufacture and retirement, nuclear fuel processing, research, electroplating, photographic work, building and equipment maintenance, and other normal activities at DOE facilities nationwide.

Nearly all of this waste, over 98% (1.24 106 t) of the WM HW total, is hazardous wastewater derived from production or laboratory operations. Wastewater produced in large volumes is readily treated on-site, and DOE has several large on-site wastewater treatment plants to process virtually all of the hazardous wastewater it generates. These plants are located at the ORR, Kansas City Plant (KCP), Sandia National Laboratory-New Mexico (SNL-NM), SRS, Rocky Flats Plant (RFP), and INEL.

The remainder of the WM "as generated" HW produced each year is relatively small in volume compared with the hazardous wastewaters. Data from 1991 to 1992 indicate that DOE produces between 0.02 and 0.09 106 t of other HW each year, including undiluted or concentrated waste chemicals, chemical mixtures and solutions, spent solvents, oils, greases, ordnance chemicals, acids, caustics, photographic chemicals, plating wastes, and other types like petroleum- or mineral-based waste materials (5). Such wastes including solids, liquids, and compressed gases that are corrosive, toxic, reactive, explosive, and/or ignitable are generated in relatively small quantities within the DOE complex and are contained in drums, tanks, cylinders, and lab packs. Occasionally, this group of HW includes a few truckload quantities of polychlorinated biphenyls (PCBs) or asbestos-contaminated equipment, soil, and debris from cleanup operations at various DOE facilities. Although a small part of these wastes is being incinerated or deactivated at existing on-site facilities, most of the HW requiring organic destruction or organic removal and recovery is transported off-site to commercial RCRA and TSCA facilities for treatment and disposal. As a result of this relatively low demand, DOE has few active on-site RCRA-permitted hazardous waste treatment facilities and no RCRA landfills.

HAZARDOUS WASTES FROM ENVIRONMENTAL RESTORATION

The nonradioactive ER wastes are nonroutine wastes that will be generated when site-specific environmental restoration plans are implemented. These plans call for the long-term cleanup of previously buried wastes and contaminated soil, groundwater, surface water, buildings, structures, and equipment at over a dozen DOE facilities within the next 20 to 30 years. These ER wastes may be hazardous under RCRA or state regulations, toxic under TSCA, or solid waste with low contamination levels that can be disposed of directly in landfills. The data currently available suggest that a significant fraction of these wastes may not be hazardous or toxic under RCRA, TSCA, or state regulations. Thus, until more definitive information is available, the authors of this paper have chosen to discuss all nonradioactive ER wastes together and to conservatively refer to them collectively as ER HW.

Environmental site survey data (e.g., borehole characterization data) were used as input to the automated remedial assessment restoration (ARAM) computer model (6) to create a database on the types and volumes of ER HW that will be generated throughout the DOE complex under the ER Program (7). Similar ER databases were created for the mixed waste and radioactive waste types. The data identify the DOE installation where each hazardous waste stream will be generated, the activity responsible for generating the waste, the physical type of each waste stream, the projected total volume, and, where known, the chemical constituents likely to be present and the estimated average concentration of each chemical constituent expected in each waste stream.

The ER Program is expected to generate over 80 separate waste streams producing a total of nearly 2.5 106 t (or 1.7 106 m3) of HW over the next 20 to 30 years. These wastes are expected to come from remediation of buildings, structures, equipment, pits, lagoons, disposal sites, land, and groundwater at 14 DOE installations. A rank order of those installations by the projected amounts of HW expected is given in Table I. The restoration activities projected for INEL are estimated to produce the largest volume of ER HW, over 1.5 106 t (1.0 106 m3), in the DOE complex.

Unlike the HW in the WM Program, most of the waste streams listed in the ER HW

database are not wastewaters. The ER HW is listed either as solid residuals from on-site treatment of buried wastes and contaminated media or as untreated contaminated debris from facility demolition and other decontamination operations. Analyses of these data indicate that five basic types of projected ER wastes will be generated, as follows:

Monolithic solids (900,000 m3) These solid wastes consist primarily of asbestos and metal-contaminated soils or treatment residues (such as contaminated clay and silt soil fractions from soil-washing operations) that have been solidified and stabilized by grout/lime/flyash fixation or by vitrification. More than half (54%) of the ER wastes from all sources are expected to be in the form of monolithic solids.

Contaminated debris (773,600 m3) The debris is primarily composed of previously buried asbestos abatement waste. It also includes chemically tainted concrete dust from decontamination or surface scraping of concrete structures, as well as contaminated metal parts from dismantled equipment, linings, and frames. About 46% of all ER wastes will be debris.

Solid process residues and sludges (3,140 m3) These wastes are typically wastewater treatment sludge solids or spent activated carbon residues from groundwater and soil vapor extraction treatment systems. Solids or sludges from solvent recycling operations may also be included.

Contaminated soils (85 m3) A small amount of lightly contaminated soil will be produced that will not be stabilized due to its low level of contamination.

Aqueous wastes (22 m3) The aqueous wastes originate from incinerator scrubber waters, ash quench waters, or aqueous streams containing dilute amounts of solvents from solvent recovery operations.

Essentially all of the ER HW will be secondary or by-product waste (i.e., relatively dilute) because it will be derived from the cleanup or treatment of previously buried HW and remnants of those wastes that were generated, leaked, spilled, released, stored, dumped, removed, or disposed of sometime in the past. The ER HW differs physically from the WM HW that is associated with normal or routine operations. The ER HW will be mostly solid in form (monoliths and debris), whereas the WM HW will be mostly aqueous in form (wastewater). In terms of their intrinsic hazards and risk management requirements, the ER wastes will be comparable to the hazardous wastewaters that are generated every day by normal operations because, like the wastewaters, the hazardous constituent concentrations will be relatively dilute. Much of the waste included in the ER HW group may, in fact, be appropriately classified and managed as nonhazardous solid waste.

PRELIMINARY TREATMENT AND DISPOSAL FINDINGS FOR ER HAZARDOUS WASTES

A preliminary treatment and disposal allocation plan was developed to identify the most appropriate way to manage the projected wastes generated by the ER Program. It must be recognized that this plan is based upon the limited data available for proper waste characterization, which necessitated some basic, but reasonable, assumptions to be made about the data available on waste chemical profiles and the hazardous or toxic characteristics likely to be exhibited by each ER hazardous waste stream. The assumptions used in developing the allocation plan are described below:

Assumption 1 None of the ER HW will be listed RCRA wastes. None is known to have been generated by listed RCRA waste processes (described in 40 CFR Part 261), and none is known to be mixed with, contain, or be derived from listed RCRA wastes. Therefore, treatment and management of the ER HW has been assumed to be guided strictly by the hazardous waste characteristics exhibited by each waste. This assumption may not apply if any of the ER wastes are derived from treating listed RCRA wastes or mixed with listed wastes, or are found to contain listed RCRA hazardous wastes. Examples to be checked include incinerator ash solids, scrubber water residues, and solvent recovery sludges.

Assumption 2 The aqueous ER HW was assumed to be not characteristically corrosive (i.e., will not have a pH of <2 or >12). This is very likely to be true given the nature of the processes generating the aqueous wastes (oil/water separator or scrubber water).

Assumption 3 The ER HW was assumed to be nonexplosive, nonreactive, and nonignitable. This assumption is reasonable on the basis of the chemical profiles observed so far and the available knowledge about the typical characteristics of remedial wastes involving soil, water, debris, and process solids.

Assumption 4 All stabilized wastes (monoliths) and unstabilized soils were

assumed to pass the toxicity characteristic leaching procedure (TCLP) test and to be ready for landfill without further treatment or handling. This assumption may be questionable for some of the wastes that contain relatively high levels of toxic heavy metals. Examples are monolithic solids of soils and other stabilized wastes, such as those at the RFP and SRS installations. These wastes are shipped for disposal as bulk monoliths at RCRA-permitted landfills after TCLP testing.

Assumption 5 Wastes containing <50 mg/kg PCBs were assumed to be exempt from TSCA regulations and may be disposed of as solid wastes, unless other hazardous characteristics or contaminants are present. Waste sludges and liquids containing >50 mg/kg PCBs will be incinerated, and PCB-containing soils and monoliths will be landfilled at off-site commercial facilities with TSCA permits. The treatment of PCB-contaminated waste at one of DOE's on-site incineration facilities is possible if a TSCA permit to allow thermal treatment of PCB-containing waste can be obtained. An exception to this set of assumptions was made for ER waste sludge/solid process residue at the Portsmouth Uranium Enrichment Center (PUEC). This waste is very unusual in that it will probably have high PCB levels (7,500 mg/kg) in combination with very high levels of mercury (10,000 mg/kg) and other toxic heavy metals. It was assumed that it could be treated on-site with solvent extraction to remove PCBs as a special handling procedure and that the PCBs could be extracted from the mercury and metals, allowing each to be treated or recovered separately. This waste was not assigned directly to incineration because incinerators that are permitted to burn PCBs may not be permitted to accept the waste due to its high mercury level. It was also not assigned to metal recovery because mercury recovery furnaces (which could be used to recover the mercury from this waste) may not be able to take the waste contaminated with PCBs.

Assumption 6 All surface-contaminated bulk metal scrap was assumed to be sent to a metal recycler for metal recovery. This assumption is probably valid, although it will depend on the type and amount of contamination present. The RCRA rules governing the management of contaminated debris should be consulted when dealing with this type of waste.

Assumption 7 All contaminated concrete debris was assumed to require stabilization prior to disposal. In fact, depending on the type and degree of contamination, some might require other forms of treatment and some might need no treatment at all before disposal. The RCRA rules governing the management of hazardous debris should be consulted when handling this waste.

With these assumptions and the information available in the database, ER wastes with apparent hazardous RCRA profiles were assigned to one or more of the following treatment and disposal groups:

Stabilization, incineration, or aqueous treatment;
Organics removal and recovery for fuel-blending or recycling;
Metals removal and recovery for recycling; and/or
Direct disposal at a RCRA-permitted landfill.

Wastes with clearly nonhazardous RCRA profiles (such as asbestos debris or soil with an elevated aluminum content and no other contaminants) were allocated to direct disposal at solid waste landfills.

On the basis of the assumptions provided and the preliminary data available, the assigned treatment and disposal groups for each ER hazardous waste stream appear to be reasonable choices for the large majority of the waste streams evaluated. As additional information becomes available, some redirection of wastes to other forms of treatment prior to disposal should be expected. This might occur through further site characterization, where necessary, before site restoration was initiated. Further refinement of the most appropriate treatment and disposal options could occur at the time of generation of the ER HW. This might be done with testing to confirm identification and characterization of the waste streams. With this testing, a more clear determination could be made of the appropriateness of the assigned treatment group(s) to ensure compliance with federal and state regulations.

The quantities of ER HW that are expected to require treatment and land disposal, or direct landfill, are summarized in Table II (the values shown for direct landfill do not include treatment residues that would also require landfill, although these residues would ultimately have to be considered). These ER waste management requirements are compared to recent estimates of HW routinely generated and managed (in the WM Program) by DOE in the course of normal facility operations. The data show that DOE is currently treating about 1.2 106 t/yr (1.2 106 m3/yr) of

hazardous wastewater in on-site aqueous treatment systems. Virtually no aqueous hazardous wastes are sent off-site. The DOE also provides a few on-site facilities for deactivation of explosive and other ordnance wastes it generates, as well as some incineration capacity. For the most part, however, DOE sends its nonaqueous hazardous wastes off-site for treatment and disposal. Currently, there are no permitted on-site RCRA or TSCA landfills, or landfills with the required capacity, available within the DOE complex for disposal of toxic or hazardous wastes.
Analysis of the data in Table II reveals that the distribution of ER HW among the various treatment or disposal options is quite different from the current HW pattern. For example, only very small amounts (about 1 t/yr) of HW from the ER Program will need to be incinerated, deactivated, or sent to aqueous treatment systems. However, about 4,000 t/yr will be appropriate for metal or organic recovery operations. These treatment systems, including some removal and recovery operations, are currently operational at certain DOE installations and/or are being considered for expansion at designated DOE treatment centers under the evaluation of WM HW alternatives for the PEIS. By far, the bulk of the ER HW (almost 80,000 t/yr) will require stabilization and/or direct landfill. Stabilization and land disposal options at DOE installations are not currently being considered in the PEIS for the HW alternatives. Without this type of on-site treatment and disposal capacity, nearly all of the ER wastes would need to be directed to commercial facilities for ultimate disposal. This practice would result in over 113,000 truckloads of waste requiring transportation to off-site commercially permitted facilities over the next 30 years. Most of this waste would originate at INEL and ORR.
The data in Table II show little or no evident impact from the ER-generated waste in 1991 and 1992 on the off-site treatment and disposal requirements under the WM Program. If the ER Program had been in full operation in 1992 (at the generation rate indicated in Fig. 1), the values shown for off-site WM treatment and disposal would be much larger, approaching the projected off-site values shown for ER waste treatment and disposal. The amount of ER wastes generated in 1992 is likely to have been between 2,000 and 3,000 t, certainly no more than 6,000 t, which is less than 10% of the potential ER waste loads projected for future treatment and disposal. As the ER Program is more fully implemented, the average annual quantity of ER wastes projected to be generated and require treatment or direct disposal will increase dramatically, approaching 84,000 t/yr (56,000 m3/yr or 3,772 truckloads per year) at steady state.

THE ER PROGRAM: IMPLICATIONS FOR HAZARDOUS WASTE MANAGEMENT

Three key points can be made to distinguish the differences between the HW generated by the ER Program compared with that generated by the WM Program, as it relates to management requirements for waste treatment and disposal. First, on a relative basis and considering the total waste generated, nearly all of the WM-generated HW is wastewater. On the other hand, ER-generated HW is predominantly in solid form. Second, due in part to the waste form, the management of ER wastes would involve much more direct land disposal than the management of WM wastes. Finally, much of the ER wastes might not be hazardous or toxic and, if necessary, could be stabilized and disposed of on-site. These distinctions that is, WM HW being dominated by treatment requirements (e.g., wastewaters) and ER HW being dominated by disposal requirements lead to the conclusion that alternatives for waste management of one group of waste may not be appropriate for the other. Because the current HW alternatives are treatment-oriented, they apply more to the management of WM HW than to the management of ER HW.
The basis for these findings can be clarified by examining the annual waste treatment and disposal projections for all waste types under both WM and ER Programs. This will provide an overall view of the magnitude of the need for treatment systems compared with disposal systems. Figure 1 helps provide this perspective. Focusing on the WM waste treatment and disposal requirements (Fig. 1a), two important observations can be made. First, treatment technology is the dominant practice in the management of the WM wastes. At least 95% of the WM wastes require treatment. Second, LLW and hazardous wastewaters are the predominant waste types that must be managed, accounting for approximately 94% of all wastes in the WM Program. It is important to note that the residues (sludges) from wastewater treatment requiring land disposal would amount to less than 0.1% of the treated wastewater volume. These data clearly indicate that the current structure of the WM Program is not appropriate or easily adaptable to the disposal (landfill) of large

volumes of waste typical of the ER Program. Switching our focus to the overall management of all ER wastes (Fig. 1b), it is clear that treatment and disposal requirements are split 70/30 between ER wastes needing the application of treatment technology and ER wastes that can be disposed of directly in landfills. Nearly 900,000 m3 of ER wastes will require land disposal, somewhere, every year for the next 30 years. This waste volume is approximately 56% LLW, 37% LLMW, and 6.9% HW. These landfill waste estimates probably include most of the residues from treatment of the ER wastes, which will also need to be disposed of in landfills. Finally, the available data for the ER HW indicate that because of the very low contamination levels present and the stable form of the waste (e.g., monolithic solids), much of the ER HW may in fact not be hazardous or toxic as defined under RCRA and TSCA and therefore may require little or no treatment prior to disposal.

Even if these compelling data are not considered in decisions involving how the ER Program will be fully implemented and how the ER waste loads will be folded into the WM Program, the ramifications of such decisions should be carefully considered. For example, looking at HW management alone, if DOE continues its current practice of shipping most of its nonaqueous HW off-site for treatment and disposal, the result would be a sharp rise in the combined annual off-site shipments of ER HW and WM HW from current levels of about 10,000 t/yr (6,700 m3/yr) to about 90,000 t/yr (60,000 m3/yr). When this ER HW generation rate reaches steady state, DOE will be shipping wastes off-site at nearly nine times the current shipping rate for a period of about 30 years. Nine of every ten truckloads leaving DOE sites will be transported to commercial landfills where the wastes will be directly landfilled or stabilized first and then landfilled. Only one in ten will be directed to a commercial treatment facility.

Looking from another angle at the ramification of a waste management practice that relies almost entirely on off-site disposal and incorporating the projected LLMW disposal loads with the HW disposal loads, over the next 30 years the amount of WM and ER HW trucked off-site to commercial landfills would fill 240 football fields one yard deep from "goalpost to goalpost." It would take 4,000 truckloads per year traveling millions of highway miles over the next 30 years just to move all the HW off-site for stabilization and disposal. It would take another 68,000 truckloads per year to transport the other ER wastes off-site for disposal. That is 72,000 truckloads per year filling over 4,000 football fields one yard deep from "goalpost to goalpost" with HW and LLMW.

In view of this prospect, on-site options to stabilize and dispose of these wastes at DOE facilities over the next 30 years needs to be carefully examined. The great majority of the projected ER HW (and LLMW) that is designated for stabilization and disposal is relatively low-hazard waste, much of which might actually be nonhazardous. Two DOE facilities in particular, INEL and ORR, are expected to generate almost 80% of the ER HW that will require stabilization and landfilling. Managing these wastes on-site at INEL and ORR might be more sensible than sending them off-site. Certainly, on-site stabilization and disposal could eliminate the hazards and risks associated with highway or railway transportation and would avoid generating most of the air pollution associated with such transportation.

Alternative management scenarios are needed to provide options for developing on-site stabilization and disposal facilities at key DOE installations. Such scenarios are especially important in planning for the ER Program wastes. In particular, the feasibility, costs, risks, and public acceptability of creating on-site stabilization and landfill facilities for the ER HW at ORR and HS and for the LLMW/LLW at ORR and INEL should be carefully examined and weighed against the alternatives currently under consideration.

CONCLUDING REMARKS

On the basis of these considerations, careful attention should be given to the option for on-site treatment and disposal over the next 30 years of the bulk of DOE's nonradioactive ER HW. The preliminary projections of the mostly high-volume, relatively low-hazard ER wastes suggest that the feasibility of installing on-site stabilization and landfill facilities with sufficient capacity for managing the ER wastes and other hazardous wastes should be carefully considered and planned for prior to the initiation of full-scale restoration actions. Such planning is especially important for installations like INEL, HS, ORR, which within the next two to three decades are projected to generate a large portion of the ER wastes that would be targeted for direct landfill. Certainly, in-situ stabilization and

landfilling could eliminate the potential hazard and risk associated with waste excavation, handling, loading and unloading, and over-the-road transportation. The feasibility, costs, risks, and public acceptability of creating on-site stabilization and landfill facilities for managing nonradioactive ER wastes at ORR, HS, and INEL should be carefully examined and weighed against the costs, risks, and public acceptability associated with the off-site transportation, treatment, and disposal alternatives. Depending on how the ER Program is fully developed and implemented, considerable potential exists for significant reductions in costs, safety hazards, and health and environmental risks.

PROTOCOLS FOR IN SITU FIELD SCREENING AT THE COMPLETION OF DECONTAMINATION OR REMEDIATION

Mahmoud H. Haghighi
Edward Walker
Bechtel Environmental, Inc.
Oak Ridge, TN

ABSTRACT

Current practice for assessing the effectiveness of surface decontamination or soil remediation is to obtain an in situ beta/gamma or alpha measurement for residual activity assumed to be on the surface, or to obtain a sample for radiochemical analysis for residual assumed to be distributed in the medium of interest. However, as decommissioning regulatory standards become increasingly more restrictive, current practice may not provide sufficient assurances, during the conduct of the work, that the decommissioning standards have been met and the decontamination and decommissioning (D&D) workforce can be demobilized. The alternative, laboratory sample analysis with longer count times, is not sufficient or desirable for operational surveys for the following reasons:

1. Laboratory sample analysis becomes prohibitively expensive, if expanded to provide "close" support to D&D activities.
2. Laboratory sample analysis is not appropriate for verifying the decontamination effectiveness on surface intended for unrestricted release for recycle or reuse.

This work is intended to provide an in situ technique that can be used for screening surveys of residual surface activity and to supplement limited sampling for residual volumetric activity. This protocol is based on measuring all pertinent particle emission rates including alpha, beta, and photon. By observing surface flux of the various particle emission at different distances from the surfaces, applying basic principles of beta and photon shielding/attenuation, and performing isotopic analysis to identify the isotopes present, the following information could be obtained:

1. Extent of residual activity (size of source)
2. Uniformity of source distribution (hot spots)
3. Source geometry (surface vs. volume distribution)
4. Isotopic ratio (limited to 2 or 3 different isotopes)

5. Estimate of surface or volumetric residual activity level.
This protocol, when coupled to proper instrument selection and use, should provide a cost effective alternative to extensive laboratory sample analysis for assessing decontamination or remediation efforts while work is still in progress.

INTRODUCTION

Radiological measurement requirements of this protocol for decontamination and decommissioning (D&D) or remediation in general, are very much the same as the requirements of the operational activities handling similar isotopes. The differences between operational radiation measurements and D&D or remediation radiation measurements, that the health physics professional must be sensitive to, are the degree to which a particular requirement must be addressed. This sensitivity becomes progressively more acute during the course of the D&D or remediation activities with greatest emphasis on the requirements for completing and documenting the final survey accurately and cost effectively. This paper is directed more toward the issues involving in situ measurement rather and correlation of different types of measurements to one another to find the extent of residual activity (size of source), uniformity of source distribution and determination of hot spots, source geometry (surface vs. volume distribution), isotopic ratio (limited to few isotopes), and surface or volumetric residual activity level. Sample acquisition and analysis and correlation to these measurements will not be discussed in this paper. Sample analysis is an area deserving a separate presentation.

PERFORMANCE CHARACTERISTICS

During the course of decommissioning, a number of factors impact the interpretation of measurement results from a source of residual radioactivity present in contaminated surfaces or volumes. Factors that are significant to proper understanding of the measurement results include:

1. Source-detector geometry
2. Type of radiation and its energy range
3. Survey protocols
4. Relationship between calibration or source check and in situ measurement results

Of the four factors listed above, the first three are of the main concern of this paper. The last factor is considered to be of a universal consideration and concern under any protocol and should follow the proper procedures according to the accepted standards.

The first factor includes the geometry and self-attenuation of the in situ source and attenuation characteristics of intervening materials between the source and detector. Source geometry and self attenuation are significant for gamma, beta, and alpha emissions. In most in situ measurement situations, intervening materials (e.g., dust, air, surface coatings, etc.) are more significant for beta and alpha measurement interpretation than for gamma measurements. The effects of source geometry, source composition, and proximity to a point of interest have been developed and applied to field measurements from the beginning. In the 1950's, relationships for source geometry and attenuation for gamma emissions were developed initially for reactor design (1), and relationships for beta emissions were developed for medical applications (2).

The second factor is significant because most calibrations and/or source checks data are obtained from a single source calibration or check source, hopefully, somewhat representative of the conditions anticipated in situ. However, many decommissioning and remediation projects involve more than a single radionuclide, requiring the health physics professional to pay detailed attention to the results of in situ and/or calibration measurements as a function of site specific isotope energy ranges.

The third factor relates to the manner in which a particular survey is performed to detect and evaluate the intensity and geometry of a particular source. Specifically, the factors of significance implied here are source-detector distances, expected source geometry, etc.

GAMMA SOURCES

The relationships for gamma attenuation for unshielded (air only) sources, or sources external to interspersed shielding, are generally described by one of the following conditions:

  point source - attenuation 1/r2
  line source - attenuation 1/r
  planar source - attenuation = 1.0 for r < ~5x

attenuation 1/r for ~5x < r < ~10x
attenuation 1/r2 for ~10x << r
where:
r - distance from source
x - primary dimension of source

When shielding or self attenuation is involved the following formula could be used:

$$Ji(r,Ei) = J(0,Ei).B.\exp\{-ml(Ei).r\}$$

Eq. (1)

Ji(r,Ei) = Attenuated photons of Ei at a distance r
J(0,Ei) = Photons of Ei at a distance 0 (source)
ml(Ei) = Photon linear attenuation coefficient
r = Distance from source to detector
Ei = Photon energy
B = Material build up factor

From these relationships, it would appear feasible to obtain an indication of an unknown source geometry by taking measurements at various distances from the source. This approach would be most useful where a spill or leakage has occurred and the extent of the activity can be estimated, where accessibility may be a problem (e.g., subsurface soil or behind barriers). The other factor that could impact such an approach is the effects of photon energy on the relationship. To study these effects, a series of shielding models were devised and executed using a computer shielding code (MICROSHIELD 4.0, Ms 92) to compute the photon flux and exposure rates at various distances from the source. Three source geometries were selected for the purpose of these models: point, disk, and cylindrical. For each geometry, three different exposure locations (1, 33,66,100 cm) were chosen from source surface. For the point source geometry, the source was shielded by three different shield thicknesses (5, 15, 30 cm) for each exposure location. The shield material was concrete with a reduced density of 1.7 g/cm3 to simulate soil. For the disk source geometry, the seven different radiuses (5, 20, 50, 100, 200, 500, and 1000 cm) were used for each exposure location. For the cylindrical geometry, both source thickness and source radius were varied for all three exposure locations. Three different source thicknesses (5,15, 30 cm with same density as used for point source geometry shield) and seven different radiuses (5, 20, 50, 100, 200, 500, and 1000 cm) were selected. The source in each geometry case consisted of six photons with energies ranging from .1 to 3 MeV (.1, .2, .5, 1, 2, 3 MeV) and each with a strength of 1 photon/s, 1 photon/cm2, and 1 photon/cm3 for the point, disk, and cylindrical geometry, respectively.

Table I shows the effects of source size, distance between source and detector, and shield on particle exposure attenuation for the above described source geometries for a 1 MeV photon. It was noted from results of the photon fluxes in air that photon energy is a small effect (<1%) over an energy range from ~100 keV to ~3 MeV for planar source (disk). For the point source, photon energy has a more pronounced effect on the photon flux at the exposure locations as the distance from source increases. For volumetric source, this effect depends on the source radius and thickness, and varies from 10-50%. From these observations, extension to a field situation for measurements at ~0.6 m and ~1.0 m from the surface of the source would enable an estimate to be made of the source geometry. The only unknown remaining is whether the source is planar or a volume. This can be determined by coupling the photon measurements to a series of beta or alpha measurements, particles which are normally present in addition to the photons (gamma). This approach will be expanded after discussion of beta source attenuation effects.

TABLE I

BETA SOURCES

The following discussion is based upon the Loevingers equations for beta dosimetry (4). The basis for the beta dose distributions from a particular source is the point source function:

$$J(x) = ke\text{-}vx/(vx)2$$

Eq. (2)

J(x) is the dose in rads per disintegration at a distance x from a point source of beta particles, and v is the beta absorption coefficient in the medium surrounding the source, and k is the constant of proportionality that is a function of the beta particle energy. The beta dose function is extended to provide solutions to dose

distribution relationships for area and volume sources.
The solution to the beta dose distribution function is dependent upon resolution of parameters that vary with the beta particle energy. Two parameters that must be determined prior to the beta dose solution are the average (effective) beta energy for a beta spectrum, and the beta attenuation coefficient.
Average Beta Particle Energy and Beta Attenuation Coefficient
The radioactive decay by beta emission is characterized by a continuous energy spectrum of beta particles with a discrete endpoint energy for each specific isotope. Since the absorbed dose in a medium is directly proportional to the energy of the beta particle undergoing the energy loss transformation, the absorbed dose distribution for a spectrum would involve integration of the distribution function over the energy range of the spectrum. It is, however, practical to characterize the spectrum by a single average, or effective, energy that results in the same absorbed dose distribution. In general, the average beta spectrum energy (Eb) is approximately one-third of the spectrum endpoint energy (Eo). More specifically, the average beta energy is a function of both the atomic number (Z) of the initial nucleus, and the spectrum endpoint energy. This relationship is explained in detail in Hi 58. For an isotope of interest, the beta endpoint energy (5,6) along with this information could be used to determine the average spectrum energy.
Empirical relationships have been derived to express the beta energy response for the attenuation coefficient (v) in various media. Loevinger (2) gives the formula
Eq. (3)
where E/E* is a measure of distortion of the beta energy spectrum (beta particle emission tangential to nucleus) and the "allowed" spectrum (beta particle emission radially to nucleus). Values for the constants a1 and a2 in various absorbing media are given in Table II.
TABLE II
Beta Dose Rates in Air
The point source beta rate function given by equation (2) is expanded and solved for attenuation in air for a point source; a zero thickness; infinite planar source; and an infinitely thick, infinite area source.
Point Source
The point source beta dose rate function for a distance x in air is given by the expression.
Eq. (4)
where:
J(x) - Beta dose rate at distance x (Rad/disintegration)
x - Distance from source to dose point (gm/cm2)
v - Attenuation coefficient in air (cm2/gm)
k - (1.28 x 10-9) p2 v3 Eb a
p - 0.001293 gm/cm3
Equation (4) may be rearranged with unit conversions to produce an expression of the form:
Eq. (5)
where:
Db (Eo, d) - Beta dose rate at distance (d) for beta energy (Eo) - Rad/Hr/Curie
d - distance from source to dose point - cm (=x/p)
The generalized expression for beta dose rate as a function of beta endpoint energy is plotted and presented in Ref. 7.
Infinite planar source of zero thickness
The generalized beta dose rate function at a distance x in air for a zero thickness source of infinite planar area is given by the expression:
The function D(Eo,d)/Ebs is in units of Rad/hr/mCi/cm2/MeV
where:
s - Surface activity in mCi/cm2.
The generalized infinite plans source function is plotted and presented in Ref. 7.
Infinite planar source of infinite equivalent thickness
The generalized beta dose rate function at a distance x in air from an infinite area, infinitely thick source is
This generalized function is in units of Rad/hr/mCi/cm3/MeV
where
t - Volume Source in mCi/cm3
This beta dose function is descriptive, for example, of the dose distribution above

water pools more than several centimeters thick. The volume source relationship as a function of beta endpoint energy is presented in Fig. 1.
Fig. 1.
FIELD APPLICATION PROTOCOL: CONCLUSION
The following protocol is offered as an example of the application of combining the gamma and the beta source geometry relationships to estimate an in situ source geometry. The sample to follow is for a situation involving a source of contaminants in soil with the strength of 1 gamma (E = 1 MeV) and 1 beta (E0 = 1 Mev) emission per second.
1. Scan areas, using a NaI detector and ratemeter to find location(s) of elevated readings.
2. At highest reading point, take the following measurements:
  a) Beta- contact, 0-1 cm [Go(b)]
        - 15 cm from surface [G6]
        - 30 cm from surface [G12]
b) Gamma- contact, 0-1 cm [Go(g)]
        - 50 cm from surface [G50]
        - 100 cm from surface [G100]
3. Form the ratio G50/G100 from the gamma readings and use Fig. 2 to estimate an approximate source radius. This is useful for comparing the measurements to the hot spot criteria.
4. Form the ratio G15/G30 for the beta readings and, using Fig. 1 and gamma flux/dose information in Table I (also Fig. 2) to estimate the contaminant depth in the soil. This is achieved by comparing flux/dose behavior of the beta and gamma readings and model prediction at various locations above the contaminated surface and correlating these results to the ratio of the beta reading to gamma readings and corresponding model predictions at the same location.
5. Determine the response function (conversion factor) for the gamma detector as a function of effective gamma energy. This becomes important for interpretation of measurement results and correlation of these results to shielding model results.
6. Combine these functions with measurement results in Step 2 and Step 4 to estimate the total dose rate for the measurement and corresponding source distributions. Note that this approach is based on the assumption that the activity is uniformly distributed.

A REVIEW OF SUPERFUND RECORDS OF DECISION FOR RADIOLOGICALLY CONTAMINATED SOIL SITES
Carolyn K. Abbott
Richard Marty
Harry Fugate
Jason Associates Corporation
ABSTRACT
Thirty-nine Records of Decision written on radiologically contaminated Superfund sites were reviewed in the process of developing a presumptive remedy for soils contaminated with radionuclides. Twenty-five of the RODs were for actions taken to

remediate contaminated soil and/or sediments.

INTRODUCTION

The purpose of this study was to review technologies used at other radiological contaminated sites in the United States as described in Superfund Records of Decision. Records of decision signed for sites contaminated with radionuclides during the period of 1985 to 1993 were analyzed in-depth. This review in turn was intended to support the development of a presumptive remedy for soils contaminated with radionuclides. The review also examined the effectiveness of decisions made for radiologically contaminated soils.

Objectives of the study were:

to determine the use of and importance placed on risk assessment in deciding the remedies for radiologically contaminated sites,

to determine the drivers used in past decisions, and

to determine the technologies which have been used successfully to remediate radiologically contaminated sites.

A total of fifty one radioactively contaminated Superfund sites were identified. Thirty-nine CERCLA RODs published for those contaminated sites between 1983 to 1993 were reviewed for this report. Two additional RODs were written and approved during that time period, but were unavailable for review (Denver Radium Superfund Site Streets and Weldon Springs Chemical and Raffinate Plant). The thirty-nine RODs and one declaration reviewed, were tabulated for media type, the primary action selected, and for any additional actions listed. Of these RODs

25 addressed radiologically contaminated soil and/or sediments (such as pond),

7 primarily addressed surface and/or ground water issues only,

1 of which included other contaminated materials other than soil or water, such as buildings, construction material or debris, sludge, bulk packaged waste, etc.;

4 addressed other contaminated materials only, such as buildings, construction material or debris, sludge, bulk packaged waste, etc., and

3 RODs addressed non-radiogenic contamination only, such as heavy metal, or VOC contamination.

The majority of radioactively contaminated sites for which RODs were available had either radium (and daughter products) or thorium (and daughter products) as the primary contaminants of concern. The most common radionuclides listed as contaminants of concern were radium and members of its decay series, including radon gas, then thorium-228/230/232, uranium-234/235/238, cesium-137, plutonium-238/239/240, americium-241, strontium-90, cobalt-60, actinium-227, protactinium-231, and tritium (listed by high to low number of occurrences)(Fig. 1). The primary and additional remedial actions selected, and the media contaminated for the 25 RODs that primarily addressed radiologically contaminated soil and/or sediments are summarized in Table I. These RODs also addressed other contaminated media or contamination as follows:

3 included surface and/or ground water issues,

14 included other contaminated materials other than water, such as buildings, construction material or debris, sludge, bulk packaged waste, etc., and

11 were also contaminated with heavy metals and/or VOCs.

The primary actions selected for the radioactive contamination sites are as follows:

75% of the RODS (18) selected excavation and disposal for the primary treatment.

one of these RODs addressed contamination at multiple sites and listed two primary actions dependent upon the level of contamination, some sites were to be excavated with permanent off-site disposal, and some sites determined to have low level contamination with risks within EPA's "acceptable range of risk" were listed as no action;

20% of the sites (5) selected containment and/or restricted access.

contamination at two sites was left in place with improved administrative controls and restricted access, and

the selected action for three sites was containment (leaving contamination in place with capping and/or institutional controls).

the remaining 5% (2 sites) selected physical separation and/or chemical extraction for the preferred treatment.

Both sites are located on the Idaho National Engineering Laboratory; one is in the process of implementation, and at the other site, Post-ROD treatability studies did not show that the treatment option would meet disposal criteria and a consolidation and containment option was substituted.

Twenty-one of the RODs provided for a total of 23 additional actions to be taken to either mitigate immediate risks or to remediate other contaminated media (Table I). The alternatives considered and the non-compliance criterion/criteria were tabulated. Five of the documents also provided for continued monitoring and maintenance of site contamination. Of the eighteen sites with planned excavation and/or removal of contamination, temporary onsite storage was provided for at seven sites. Additional treatment actions were selected at 4 sites; the treatments were described in two of the documents as providing for shielding of residents and reduction of radon emissions, and the other two documents provided for stabilization of the contaminated soil prior to disposal. Other secondary actions were relocation of residents, reconstruction of residences, pump and treat water, and decontamination of other media such as contaminated roofs and equipment.
In the detailed analysis of alternatives, nine criteria are used to rate or compare the efficacy of each alternative. The number of times each class of criteria (threshold, primary evaluation, or post-public comment) were the basis for rejecting an action are tabulated in Table II. Of the 82 alternatives described, 43 were rejected because of non-compliance with the threshold criteria (protection of human health and environment or ARARs), 29 non-compliance with the primary evaluation criteria, and 7 because of post-public comment criteria. The 29 instances that alternatives were eliminated for non-compliance with the primary evaluation criteria were distributed mostly among the first three of the five (5) criteria (long-term effectiveness & permanence, reduction of toxicity, mobility or volume, and short-tern effectiveness). Three alternatives were rejected because of unproved reliability or because off-site disposal sites were not available for either the type or volume of waste.
In two of the RODs, the selected action did not comply with the ARARs, but waivers were granted. Two other RODs also documented non-compliance with primary evaluation criteria (in both cases it was the short-term effectiveness criteria), and additional actions were taken to circumvent any problems or mitigate the risks the selected action posed. The availability of off-site disposal was recognized to be a problem at seven (7) sites, and the additional action was the provision of temporary on-site disposal.
In the 25 RODs addressing radiologically contaminated soils, risk assessments were not presented in detail but results from risk evaluations or assessments from other documents (such as the remedial investigation) were summarized. In 4 of the documents, no risk values were given, and it was concluded that there was no risk or that the risks were insignificant without any evidence offered. Baseline cancer risk levels (current risk no-action conditions) were identified for either current occupational or current residential cancer risks for the other 21 RODs reviewed. Additional future cancer risk values were reported in 12 of these RODs.
The risks reported in the RODs represent individual excess cancer risks associated with lifetime chronic exposure to carcinogenic contaminants present at the sites. Theoretically, a 1E-6 (10-6) risk indicates that if an individual were exposed every day throughout life to the concentrations associated with the risk level, his or her individual probability of developing cancer resulting from that exposure is unlikely to exceed one in one million.
Exposure point concentrations were generally estimated conservatively for all pathways assessed. Only two (Maxey Flats, and Monticello) sites reported that population studies had been conducted. Children were the only sensitive sub-population evaluated in any of the risk assessments.
Few of these sites involved actual current exposure of workers or residents that were working or living on-site. Due to the time frame (prior to the publication of applicable guidance) when many of these RODs were written there was little consistency in what risks were reported or how risks were calculated. Potential current exposure scenarios used were the same or similar to the EPA standard default assumptions for both occupational and residential scenarios in most of the RODs. Potential current exposure to an intruder was assumed at one site (BOMARC). Assumptions made were in some cases not adequately described and the determination could not be made as to the appropriateness of the assumptions. Current risk was often based on exposure pathways, or scenarios, which may or may not exist.
Current cancer risks for 15 of the 21 (71%) reporting sites were greater than 1E-04 (Fig. 2). Six of the 21 (29%) of the RODs reported current risk values within the NCR acceptable range of risk or less (1E-06 to 1E-04). Current risks for two of the

sites were less than 1E-06. Additionally, for five of the RODs there were hazard indices with values greater than 1, indicating possible non-carcinogenic health hazards to current occupational receptors at four of the sites, to current residential receptors at two sites, and via other scenarios at two sites.
The difference between current and future risks involved a future change in site use that would involve more frequent exposure, additional or new receptors or additional pathways of exposure. Residential development was the most often cited future-use scenario. Future risks were based on current concentrations of radionuclides in surface soils allowing for 30 to 100 years of decay for the majority of sites.
Future residential risks were discussed quantitatively in only 12 of the RODS (Fig. 3). Nine (75%) indicated future potential cancer risk greater than 1E-04 and three (25%) were within the NCRs acceptable range of risk (1E-06 to 1E-04). Future risk values for two sites were within the acceptable range. Hazard indices of greater than 1 also were calculated for 4 of the 12 sites. All of the future risks were based on hypothetical exposure scenarios.
Of the six RODs reporting current risk values within the NCR acceptable range of risk, two also reported future risk values within the acceptable range. This indicated that risk was not one of the criteria used in deciding the remedial actions described in these RODs.
There was a lack of assessment of the degree of risk reduction associated with remedial alternatives. This constitutes a major weakness in the decision-making process. Of the RODs reviewed, risk reduction was evaluated quantitatively for only two sites and was mentioned qualitatively in five other RODs. Risk reduction played a limited role in the evaluation of the remedial alternatives. The degree of risk reduction associated with the alternatives evaluated were not well-defined in the majority of decisions reviewed, and the cost-effectiveness of the remedies selected could not be determined. However, most RODs concluded in some way that the selected alternative was cost effective.
From the detailed analysis of alternatives, what appeared to be the most significant factors in the selection of remedial alternatives was the compliance with the Threshold Criteria (protection of human health and environment and ARARs compliance) and technical feasibility. However, all RODs planned for remedial actions to taken even for the sites with risks lower than 1E-06.
Twenty seven (27%) percent of the RODs selected the least costly alternative other than no-action, and thirty-two (32%) percent selected the most costly remedy. The geometric mean for cost of remediation per ROD was 7.4 million dollars. The cost of the selected actions for most (14 of 21) of the sites was less than 7 million dollar each as shown on Fig. 4. In 73 percent (16 of 22) of the RODs, the average additional cost of the more costly alternative over the selection action was $31 million additional.
Ecological risk was not well developed in any of the RODs reviewed. Again in most cases there were simple summaries of other documents stating no risk, or risk not unacceptable. In five cases, there was no presentation of ecological or environmental risk. In one ROD, no ecological risks were evaluated because the assumption was made that if human health was protected, there would be no environmental or ecological risk. Cleanup levels that assure protection of public health may not always assure protection of surrounding ecosystems, and the lack of extensive assessment of ecological risks, which is sometimes warranted, is another major weakness in determining appropriate remedial alternatives.
Of the 25 documents reviewed, only one discussed in detail the uncertainties of the risk assessment and the assumptions made. Most of the documents mentioned that the evaluation of risk was uncertain or did not mention uncertainty. The one document that developed the discussion of uncertainty well, did not draw any conclusions. Therefore risk and uncertainty could not have played a determining role in the decision process.
Most (16) selected excavation with off-site disposal as their preferred alternative. With the problems in finding a facility for permanent disposal, many sites have had to store excavated materials on-site. Permanence of the selected alternative but actual is far from permanent.

ABSTRACT
A remediation of a gas cylinder disposal pit at Sandia National Laboratories, New Mexico has recently been completed. The cleanup prevented possible spontaneous releases of hazardous gases from corroded cylinders that may have affected nearby active test areas at Sandia's Technical Area III.
Special waste management, safety, and quality plans were developed and strictly implemented for this project. The project was conceived from a waste management perspective, and waste minimization and management were built into the planning and implementation phases. The site layout was planned to accommodate light and heavy equipment, storage of large quantities of suspect soil, and special areas to stage and treat gases and reactive chemicals removed from the pit, as well as radiation protection areas.
Excavation was a tightly controlled activity using experienced gas cylinder and reactive chemical specialists. Hazardous operations were conducted at night under lights, to allow nearby daytime operations to function unhindered. The quality assurance plan provided specific control of, and documentation for, critical decisions, as well as the record of daily operations. Both hand and heavy equipment excavation techniques were utilized. Hand excavation techniques were utilized. Hand excavation techniques allowed sealed glass containers to be exhumed unharmed.
In the end, several dozen thermal batteries; 5 pounds (2.3 kg) of lithium metal; 6.6 pounds (3.0 kg) of rubidium metal; several kilograms of unknown chemicals; 140 cubic yards (107 cubic meters) of thorium-contaminated soil; 270 cubic yards (205 cubic meters) of chromium-contaminated soil; and 450 gas cylinders, including 97 intact cylinders containing inert, flammable, toxic, corrosive, or oxidizing gases were removed and effectively managed to minimize waste.
LIST OF ACRONYMS
INTRODUCTION
Beginning in 1984, several investigations and assessments, including a Resource Conservation and Recovery Act (RCRA) Facility Assessment (RFA), were conducted at Sandia National Laboratories, New Mexico (SNL/NM) as part of the Department of Energy (DOE) Environmental Restoration (ER) Project. These investigations revealed 172 potential release sites which required investigation and possible corrective action.
One site, known as the Gas Cylinder Disposal Pit (GCDP), was located in the southeast corner of the environmental test range known as Technical Area (TA) III (Fig. 1). The dimensions of the excavated pit area were approximately 80 by 180 feet (24 by 55 meters) by 10 feet (3 meters) deep. The pit-bottom configuration and depth suggested that fill material was likely to be less than 6 feet (1.8 meter) thick, and this indicated the volume of the affected soil was no more than 3,200 cubic yards (2,443 cubic meters).
Fig. 1.
The pit was reportedly dug in 1963, but prior to its excavation, the area in which the site was located may also have been used to dispose of high-explosive (HE) residues by detonation. Following its excavation, the pit was used for the disposal of lithium hydride and other reactive chemicals from various SNL/NM laboratories, and from 1980 to 1984, the pit was used for the disposal of 400 lecture-size [2 by 12 inches (5 by 38 centimeters)] gas cylinders by detonation with shaped-explosive

charges. The cylinders reportedly contained a variety of gases, including some toxic materials and unknown materials which could not be shipped off site. This site also had been used occasionally for temporary storage of potentially explosive chemicals, including picric acid. Visual surveys revealed glass shards, bottle remains, and gas cylinder remains. Table I lists chemicals thought to have been disposed in the pit. Based on the survey of historic activities, no radioactivity was suspected.

TABLE I

The GCDP site was originally scheduled to be investigated during the course of a RCRA Facility Investigation (RFI) by drilling shallow boreholes into areas likely to have aggregations of gas bottles or chemicals. Because of health and safety concerns during drilling, this type of intrusive characterization was not considered to be the optimal course of action. In addition, hazardous wastes were thought to be present in unstable storage containers that could pose a threat of spontaneous release, resulting in possible explosion and/or potential for exposure to hazardous waste as a result of a container failure.

Two non-intrusive investigations, a walk-over health and safety survey and a surface geophysics survey of the pit, were undertaken to provide more information for the appropriate course of action. The initial walk-over survey was conducted in Level B personal protective equipment (PPE) and served to identify partial and intact lecture bottles, amber glass containers containing unknown solid and liquid materials, and previously unidentified radioactive material. Drilling in the pit was determined to be unacceptable; therefore, complete exhumation and removal of the contents of the pit in association with an accelerated and voluntary corrective action for site cleanup was planned.

WASTE MANAGEMENT PLAN

SNL/NM is required to practice pollution prevention as part of activities associated with investigation and remediation of sites. Consideration is given to the costs and liabilities associated with management of wastes produced as a result of these activities at the beginning of each planning phase. The remediation of the GCDP was planned from the perspective of waste minimization and waste management, as well as careful attention to aspects of safety, construction, and remediation. The management plan for investigation-derived waste (IDW) was developed with the cooperation of the SNL/NM Generator Interface and Waste Operations Departments, and was formulated to be consistent with existing guidelines of the U. S. Department of Energy (DOE), U. S. Environmental Protection Agency (EPA), and New Mexico Environment Department (NMED).

The excavation operations conformed to specific objectives outlined in the quality assurance project plan prepared for this project. Various field tests and inspections were required during excavation and material segregation. The field inspections typically required a pass/fail decision. These decisions included: 1) identification of pit materials; 2) removal and segregation of clean and suspect soils; 3) removal and segregation of breached and unbreached material containers; and 4) evaluation of cylinder contents. The decision tree for these operations is shown in Fig. 2. Following a surface clearance, excavation proceeded from north to south with iterative magnetic surveys.

Fig. 2.

The majority of waste to be created during pit excavation at the GCDP was believed to be soil and debris, decontamination water, personal protective equipment (PPE), ordinary trash, and gaseous and solid chemicals. Waste to be produced during operations was expected to be contaminated with metals, chemicals, pressurized gases, high explosives (HE) residues, and radioactive soils. Waste was categorized as nonregulated, hazardous, radioactive, and mixed (radioactive with hazardous). The majority of waste by volume was expected to be nonregulated.

Field screening was performed during all soil excavation activities to facilitate segregation. Both real-time instrumentation and field test kits were used to screen for various constituents during the course of the project. Metals in soils were evaluated using X-ray fluorescence (XRF); volatile organic compounds (VOCs) were evaluated using Drager tubes, photoionization (PID) and flame ionization (FID) detectors; HE was evaluated using EXSPRAYTM; and radiological constituents were evaluated using a pancake Geiger-Muller (GM), an alpha scintillometer, and a sodium-iodide (Nal) gamma spectrometer (Table II). Screening for various gamma-emitting radionuclides was also performed using gamma spectroscopy. Action levels for field screening included mean background plus 2 standard deviations for

XRF and radioactivity, and any positive reading for volatile organics and HE. Detection of constituents above the action levels triggered material segregation and resulted in possible additional sampling. Soils and debris were staged in specific engineered locations (Fig. 3) until results of laboratory analyses were available and the waste types were determined.
TABLE II
Fig. 3.
Prior to soil placement in the staging area, a grab sample of up to five aliquots of material was collected randomly from the bucket of the front-end loader. These grab samples were combined to form a single composite sample representing the soil contained in the staging area. Excavated soil was stockpiled onsite in prepared staging areas east of the disposal pit. These areas were bordered by reinforced concrete barriers ("Jersey" barriers) on three sides, an earthen berm on the fourth side, and a lining of very low density polyethylene sheeting. The staging areas were built to accommodate 60 cubic yards of soil each, but could be modified easily to accept more. All soils were covered with fiber-reinforced poly sheeting secured by sandbags for protection against wind and rain. Stained or discolored soils were segregated in separate areas, and sampled to determine possible hazardous or radioactive characteristics. Analysis of the suspect soils included HE (EPA Method 8330), VOCs (EPA Method 8240), SVOCs (EPA Method 8270), TAL metals (EPA Methods 6010 and 7000 series), and isotopic uranium, thorium, and plutonium. Table II also provides a list of the laboratory analytical methods used during this project.
Debris (wood, metal scrap including breached cylinders, thermal batteries, glass, and bulk chemicals) from the pit was staged in small engineered staging areas. Pressurized gas cylinders and intact chemical containers recovered from the excavation were staged separately, individually, and away from all other materials. Before packaging, all debris and scrap removed from the pit was screened for radioactive contamination using a Nal radiation detector, and swiped and counted using a gas proportional counting system.
The section of the pit containing radioactive soil was sectioned into four quadrants approximately 30 by 40 feet (10 by 12 meters). Each quadrant was investigated and excavated separately, in the interest of waste minimization. Every bucket of soil and debris was screened in the field using a Nal radiation detector. Soil having readings greater than background plus 2 standard deviations was considered to be contaminated and was removed. Upon excavation, radioactive soil was segregated and drummed in the pit itself.
All containers and staging areas were marked with appropriate labels. All unknown materials, pending analytical results, were labeled "Investigation-Derived Waste." Materials whose characteristics were known were labeled as nonregulated, hazardous, radioactive, or mixed, as appropriate. Container labels were marked in permanent ink and included waste source, suspected contaminants, results of field screening, contents, the dates accumulation began and ended, associated sample numbers, and the project manager's name and telephone number. Labels were numbered sequentially. All solid waste drums were stored on wooden pallets.
Decontamination water was produced during heavy equipment decontamination. This decontamination was performed at a temporary decontamination pad constructed for the project. Decontamination water was collected in open-topped, lined 55-gallon drums for ease of handling and sampling. Once full, drums were sampled and analyzed for TCLP metals, VOCs, and SVOCs. Personnel decontamination was largely conducted on a dry basis, but contingency for wet decontamination (3-gallon sprayers with soap and water, and 3-gallon sprayers with water only) was available. In addition, a decontamination trailer was installed at the site at the boundary of the controlled area; this facility housed two showers which could be used as a contingency for personnel decontamination. Personnel decontamination water also was collected in open-topped, lined drums, and analyzed for TCLP metals, VOCs, and SVOCs. Liquid waste drums were stored on secondary containment pallets to contain spills or leaks.
All disposable PPE was field screened for radioactive contamination, HE, and organic contamination by PID and FID, and stored as IDW in open-topped, lined, 55-gallon drums upon completion of each day's work. Uncontaminated PPE was segregated from all other wastes. The drums were labeled according to their contents (e.g., "suspect clean as indicated by field screening"). PPE suspected to be radioactive was double-bagged in yellow plastic at least 3 millimeters thick and placed in drums visibly printed with the word "radioactive."

All ordinary trash was stored in plastic household or lawn trash bags upon completion of each day's work. Ordinary trash was considered to be nonregulated and was placed in a commercial dumpster labeled "Nonregulated."

WASTE MINIMIZATION

Federal and state laws, as well as DOE Orders, require that SNL/NM plan, implement, and document the minimization of all types of waste, including such things as water discharges and air emissions. Therefore, waste minimization practices were incorporated into field activities at the GCDP site to reduce the quantity of waste generated.

The following list includes specific methods of waste minimization implemented during the project.

Waste management and decontamination procedures were written in order to document activities, provide preplanning and quality control, reduce time in the field, avoid the use of unnecessary equipment, and avoid the generation of excess waste.

Nonintrusive investigations were completed before intrusive work; no hazardous or radioactive waste was produced during these investigations. These investigations also focused attention and subsequent remediation activities on problem areas which included only 56% of the total pit by surface area.

Daily activity/health and safety "tailgate" meetings included waste minimization and disposal topics, and described specific tasks which site workers were to perform during that work period. Site workers were encouraged to become a part of the planning team and to identify additional waste minimization opportunities.

Dry decontamination procedures were used to avoid creating decontamination fluids for personnel decontamination.

All excavation equipment was kept in the pit during excavation activities, and only when excavation was completed was the equipment removed and decontaminated. Only materials that could easily be surface surveyed were used for PPE.

All PPE and decontamination rags were surveyed for radioactive contamination as part of personnel decontamination. Wherever possible, PPE was reused. Typically Level "A" and "B" suits were sanitized and reused 15 times.

All debris, scrap, and soil were screened for radioactive contamination, and an aggressive program of field screening was employed for HE, organic and inorganic gases, and metals. Continuous air monitoring was performed for gaseous releases in the controlled-atmosphere of the special operations area to which cylinders of gas removed from the pit were taken. If material screened "positive," it was segregated and containerized with like materials.

An onsite laboratory for gas analyses, as well as onsite treatment capability for these gases, provided immediate identification and decision making regarding the management of gases, and eliminated the need to ship unknown samples offsite. Only nonregulated treatment-process wastes were ultimately produced.

Site personnel did not mix waste types or mix soil and decontamination fluids. Daily efforts to prevent cross contamination were practiced. The key to this capability was site setup and preparatory activities which provided a large area for segregated storage.

Waste was stored in the smallest appropriate containers, often 5-gallon plastic pails for scrap metal and bulk chemicals.

Aliquots of soil were taken from every loader bucket and composited for waste classification analyses, and the bulk of the material was stored onsite prior to disposal; much of this material was segregated as a result of field screening. This process was time-consuming, but resulted in the minimum amount of regulated waste being sent offsite for disposal. Uncontaminated soils were returned to the pit.

Investigative geoprobing was used exclusively for subsurface verification sampling. This method removed only the amount of soil necessary to advance the core barrel and eliminated waste cuttings and drilling fluids, and produced little or no dust.

RESULTS

Excavation was a tightly controlled activity using experienced construction crews and gas cylinder specialists. All field crews had additional specialized training in waste management and waste minimization, as well as Radiological Worker training. Remediation proceeded from north to south in the pit, following the slope contour. A trackhoe excavator was used for coarse excavation during nonhazardous phases of removal. The trackhoe was positioned in the pit itself. Soils were placed 1) in the bucket of a front-end loader positioned out of the pit; 2) directly in drums brought

into the pit via the loader; or 3) directly into 40-yard rolloff bins. All soils were passed through a 2-inch mesh screen before removal or containerization. Archaeological-type hand excavation of gas cylinders, reactive chemicals, and thermal batteries was performed by experienced crews using non-sparking shovels after the trackhoe could not continue. Excavation activities were performed in either Level "A" or Level "B" PPE, including work in the trackhoe or backhoe, and during archaeological-type hand excavation. A total of 48 person-hours were spent in Level "A" PPE, 1,728 person-hours in Level "B" PPE, and 612 person-hours in Level "C/D" PPE for support purposes during the excavation phase of the project.
A total of 140 cubic yards (107 cubic meters)of thorium-contaminated soil was drummed directly in the pit and subsequently staged onsite. A total of 270 cubic yards (205 cubic meters) of chromium-contaminated soil (associated with a group of ruptured and intact thermal batteries) was removed from the pit. A total of 1,200 cubic yards (1,096 cubic meters) of suspect soil was removed and staged until waste characterization was made (this soil was to be placed back into the pit).
Several dozen thermal batteries; 5 Ib (2.3 kg) of lithium metal; 6.5 Ib (3.0 kg) of rubidium metal; several kilograms of unknown chemicals; and 450 gas cylinders, including 97 intact cylinders containing inert, flammable, toxic, corrosive, or oxidizing gases were removed and effectively managed to minimize waste. Thermal batteries were disposed of as hazardous waste. Lithium metal was repackaged and disposed. Rubidium metal was given to the SNL/NM "Metals Reapplication Program." Based on evaluation, no intact cylinder was in condition to be shipped offsite, because of corrosion, nonfunctional valving, dents, or other miscellaneous damage. These cylinders were deemed unstable and unsafe, and the contents had to be rendered safe.
Cylinder evaluation was a multi-step process (Fig. 4). Initially, when cylinders were excavated, each underwent an in-field visual inspection; cylinders which were breached were discarded as scrap metal, and those which appeared to be intact were subject to closer inspection in the pit itself. This inspection included a survey using common field-portable direct reading instruments (including a GOW-MAC gas leak detector, and Gastech Model 1314 in the ppm combustibles mode), as well as a soap film solution to determine if leaks were present. Cylinders were stored in the special operations area and visually checked and monitored daily using the PID and FID.
Fig. 4.
The next phase of cylinder evaluation was similar to the initial evaluation, but was performed under controlled conditions, and cylinder cleaning was included as an initial step. Each container was given a unique identification number. All leak testing was repeated. Each container was examined in detail, and physical measurements including specific defects, wall thickness, color codes, special construction or special metal alloys, and type and construction of the valve were recorded on preprinted forms. All cylinders were photographed using a Polaroid instant camera. Color copies of the pictures together with a copy of all field data were mailed to the ETSC-Schaumburg, Illinois, office for review and consultation on possible courses of action.
Cylinder content analysis was performed in an onsite mobile laboratory containing an Infrared Spectrophotometer and a Mass Spectrometer. Cylinders were connected to the instruments by a vacuum manifold, using either their existing valving, or a new valve installed on the side of the cylinder wall using proprietary "hot tapping" called high pressure container access (HPCA). The HPCA installation is somewhat similar to installing an in-line saddle on an existing conventional plumbing system. Small quantities of gases were allowed to bleed through the system if still pressurized; alternatively, helium gas was used to purge the cylinder if the pressure in the cylinder was at zero pounds per square in. gauge (psig).
The fourth step was management, or on-site stabilization, of gases from cylinders. On-site stabilization of reactive gases from unstable cylinders was performed after registration with the City of Albuquerque Air Quality Division. Either registration or permitting with the City of Albuquerque was required because of the contents of certain cylinders. A permit would be required if the City determined that a significant amount of hazardous air pollutants were being emitted (case-by-case basis, no emission limit set) or the precontrolled emission rate exceeds 10 pounds per hour or 25 tons per year; otherwise registration was required. Registration was the method of choice because of the small quantities of materials found. This course

of action was also consistent with SNL/NM's existing agreements regarding permitting of potentially explosive and unstable chemicals. In that agreement, NMED determined that the treatment of potentially explosive and unstable chemicals to render them non-hazardous was exempt from permitting and substantive requirements as outlined in the New Mexico Hazardous Waste Management Regulations. All treatment process residue was disposed through the Permitted Hazardous Waste Management Facility at SNL/NM. Management of any specific gas from a cylinder depended on the gas identified. A multiple decision pathway on the management and disposition of contents of each group of cylinders was initially compiled. A decision on the "best" option for the management of gas from a particular cylinder was then determined, although contingencies were also retained. In addition, the possibility of making an immediate on site decision to protect human health and the environment if a toxic release, explosion, or fire occurred during handling was retained as an option for all cylinders.

The preferred option for flammable, toxic, corrosive, or oxidizing gases was transfer of the gas to a DOT-shippable container, if the original cylinder contained sufficient quantity of gas (Table III). The next options for some reactive or toxic gases included neutralization, oxidation, or hydrolysis. For non-toxic or halogenated flammable gases, another option was flaring. Certain very toxic materials required special handling or transfer of contents to a new package without treatment. For inert gases, the preferred option was release to the atmosphere. Descriptions of management methods for pressurized gases are detailed in Table IV.

TABLE III

TABLE IV

CONCLUSION

The voluntary corrective action remediation of a Gas Cylinder Disposal Pit at Sandia National Laboratories, New Mexico was recently completed. This facility operated from 1963 to about 1984. The project was planned from a waste management perspective, waste management and waste minimization were built into the planning phases, and were aggressively implemented throughout the course of the project. The original scope of the project was for the removal of 20 intact gas cylinders, and the removal of 3,200 cubic yards (2,443 cubic meters) of contaminated and uncontaminated soil.

A site-specific, written waste management plan was produced at the start of activities. The site layout was planned to accommodate heavy equipment, storage of large quantities of suspect soil, and special areas to treat and dispose of gases in cylinders recovered from the pit during operations. Continuous geophysical investigations and radiological surveys focused the investigation on "hot spots" only and immediately reduced the investigation to 56% of the original estimate. Excavation was tightly controlled and managed, employed both hand digging and heavy equipment to maintain safe operations, and, as a result, further reduced the quantities of waste generated. All debris and soils were field screened before comprehensive laboratory analyses were performed to confirm and quantify contamination. Waste segregation was strictly enforced for all waste streams. Contents of cylinders were determined using an onsite mobile laboratory, and the management of gases, including treatment of hazardous gases, was performed onsite. Steps were also taken to minimize the generation of decontamination fluids and used personal protective equipment.

Several dozen thermal batteries; 5 pounds (2.3 kilograms) of lithium metal; 3.7 pounds
(1.7 kilograms) of rubidium metal; several kilograms of unknown chemicals; 140 cubic yards (107 cubic meters) of thorium-contaminated soil; 270 cubic yards (205 cubic meters) of chromium-contaminated soil; and 450 gas cylinders, including 97 intact cylinders containing inert, flammable, toxic, corrosive, or oxidizing gases were removed and effectively managed to minimize waste. These figures amounted to a four-fold increase in the amount of intact cylinders removed from the pit, yet only 12% of the original estimate of 3,200 cubic yards (2,443 cubic meters) of soil waste generated during the course of the removal. A summary of waste streams and waste quantities is provided in Table V.

TABLE V

Pre-planning was the key ingredient in a successful recipe for remediation. Efficient site layout allowed ease of operations, generous contingency for the unexpected, adequate temporary storage space, and the facilities to allow treatment

of hazardous and toxic gases. Effective and usable waste management documentation provided for smooth and efficient operations, a high level of quality assurance and quality control, and the flexibility to modify operations when needed. Finally, application of the principles of waste minimization showed that remediation could be focused and selective, minimize cost and schedule, and guaranteed that waste volumes were as small as possible. These approaches, or parts of them, could be applied immediately, even to sites which are currently in the process of being remediated, throughout the DOE complex or elsewhere. The cost savings would be significant, quality control would be improved, and disposal volumes would be decreased.

ABSTRACT
The Hanford K Basins contain roughly 2,000 tons of uranium metal fuel previously irradiated in N Reactor. Current plans call for the fuel to be moved to a new storage location in the next few years. This paper describes near term activities to gather data on the mechanical condition and chemical state of the fuel and associated sludge. These on-going in-situ, nondestructive, examinations are intended to complement hot cell examinations which are planned for the near future. Characterization data will feed decisions on interim storage, long term storage and the environmental documentation process as the fuel is relocated.
Several techniques have been, or are planned to be, employed during the conduct of examinations in the K Basins.
1. A video survey using underwater cameras has been made for the open top canisters which hold fuel in the K East Basin. These data have given early assessments of cladding degradation, canister corrosion, fuel swelling, and canister/fuel interactions.
2. Ultrasonic measurements of the water level in gas traps connected to sealed canisters have been used to provide indications of gas generation in or water leakage into the canisters.
3. Sampling of gas and water from closed canisters of fuel in the K West Basin will furnish indications of fuel corrosion, fission product release, and canister integrity and will guide choices of fuel to be retrieved for detailed hot cell examinations.
4. Depth measurements and qualitative properties assessments for the sludge on the floor of the basins and in the bottom of canisters have been made using underwater video techniques.
INTRODUCTION
Two water-filled Hanford K Basins are currently utilized to store 2,000 tons of zirconium alloy clad uranium metal fuel assemblies irradiated in N Reactor prior to 1987. Each of the two basins is 38 m long by 20 m wide and is filled with water to a depth of 4.9 m. Half of these fuel assemblies (i.e., those in the K East Basin) are stored in open top canisters made of aluminum or stainless steel and half (in the K West Basin) are in sealed vented water-filled canisters made from the same materials. The design of a canister is shown in Fig. 1.
Fig. 1.
The individual N Reactor fuel assemblies each consist of two concentric circular fuel elements separated by an intervening coolant channel. Assemblies are up to 66 cm long and 6.14 cm diameter. Optimally 14 inner and 14 outer elements are stored in one canister. A canister consists of two identical barrels welded together with seven fuel assemblies per barrel. In practice fewer than 14 fuel assemblies are often found in one canister.

Efforts are under way (1) to gather information on the mechanical condition and chemical state of the metal fuel and associated sludge stored in the Hanford K Basins. These characterization data are intended to support the eventual transportation, processing, and interim storage of this fuel. Most of the current data gathering activities are being performed in the basins without fuel movement. These in-situ nondestructive examinations are intended to complement hot cell examinations which are ongoing or planned for the future. The techniques employed include a video survey of open storage canisters, determination of water/gas interface levels in gas traps for sealed canisters, sampling of gas and water from sealed canisters, (for chemical analysis) and measurement of sludge depth and sludge volume.

NEAR TERM CHARACTERIZATION DATA

Video Survey

Using an under-water camera a survey has been made of the open-top canisters which hold fuel in the K East Basin. These data have given early assessments of the degree of cladding degradation, endcap damage, canister corrosion, fuel swelling, and canister/fuel interactions. An example of fuel corrosion associated with a broken or detached endcaps is presented in Fig. 2.

Fig. 2.

A quantitative assessment of the percentage of deteriorated fuel has been made and a significant fraction are damaged. However the majority of the fuel elements appear to be intact and uncorroded (as far as can be determined from an overhead view). Those elements which show evidence of deterioration probably are those which sustained endcap damage during reactor discharge. Oxidation of uranium fuel by water has caused deformation and detachment of endcaps due to fuel expansion caused by formation of low density oxides relative to the original metal. A small minority of fuel elements have split cladding with major segments of missing fuel. Table I summarizes the amount of fuel damage observed during the video survey of the K East Basin.

Corrosive and mechanical interactions between fuel and canisters are not seen. Stainless steel canisters appear to be essentially uncorroded in the K Basin water environment. The older aluminum canisters show large numbers of corrosion nodules which predate the institution of strict water chemistry control measures in the basins.

TABLE I

Water Level Measurements for Gas Traps Associated with Sealed Canisters

The canisters in K West Basin have sealed lids as shown in Figs. 1 and 3. These closed canisters contain a venting device which allows excess gases (such as hydrogen liberated during fuel oxidation) to escape. Ultrasonic measurements of the level of the gas/water interface in these devices have been used to provide indications of gas buildup due to fuel corrosion or of water intrusion due to a failure of the canister seal. Figure 4 is a plot of the data obtained which indicates that the majority of the gas traps contain largely gas while a smaller population contain predominantly water (perhaps indicative of leaking canister lids).

Fig. 3.

Fig. 4.

Gas and Water Sampling from Sealed Canisters

Strategies and equipment have been developed for sampling of gas and water from the closed canisters of fuel in the K West Basin. Entry into the canisters will be made through valves (Fig. 1) originally designed to load canisters with water and covergas. The samples obtained in this manner will furnish indications of fuel oxidation, fission product release and canister seal integrity. These data will also guide choices of fuel to be retrieved from the K Basins and examined in detail at the Hanford hotcells.

Sludge Depth Measurements

The sludge on the floor of the basins (mainly in K East) consists of a mixture of canister/rack corrosion product, oxidized fuel, sand, and other debris of external origin. The range of characteristics ascertained to date is summarized in Table II. Analysis of sludge inside of the canisters has not yet been done but is planned for the near future. Depth measurements and qualitative properties assessments of K East Basin sludge have been made using under water video techniques. These measurements are summarized in Table III. Large expanses of the K East Basin are covered by a

depth of only a few cm of sludge with isolated accumulations of up to 18 cm deep. Small pit areas appended to the basin contain sludge up to 100 cm deep in isolated spots. Integration of the depth measurements yields the sludge volumes listed in Table III, for the basin proper and the pits.

TABLE II

TABLE III

Hotcell Examinations

Examinations in hotcells of fuel with a history of K Basin storage are expected to commence in the very near future (2). Initial examinations will focus on the fuel stored in the sealed K West canisters. Damaged and pristine elements will undergo optical and dimensional measurements. Follow-on destructive examinations for fuel will include metallography, thermogravimetric measurements, and radiochemical analysis. It is also expected that determinations of the physical, chemical, and processing characteristics of basin and canister sludge will be performed in parallel with the fuel examinations.

CONCLUSIONS

Accelerated in-situ characterization of K Basin spent metal fuel will influence near term facility decisions (3) and allow informed choices of fuel and sludge samples targeted for more extensive hotcell examination. The condition of the elements in the K East Basin ranges from pristine to corroded fuel with ruptured cladding. The magnitude of the sludge mitigation campaign has been bounded through determination of sludge volume. Finally data pertinent to the choice of wet and dry storage options are being obtained from sealed canisters in the K West Basin.

ABSTRACT

The Hanford Tank Farms, and in particular the single-shell tanks (SSTs), are one of the U.S. Department of Energy's (DOE) most important facilities in terms of environmental management and remediation. Until the high-level nuclear waste is removed from the SSTs, this waste requires proper management to minimize releases to the environment. Contamination present in the vadose (unsaturated) zone also is of concern. Accurate and defensible information is needed for current tank management decisions and for longer term tank waste disposal and closure. Tasked with conducting a monitoring program to measure the subsurface contamination, the DOE Grand Junction Projects Office (GJPO) intends to acquire spectral gamma-ray data from nearly 800 boreholes at the Tank Farms. GJPO personnel will collect these data

with specially designed logging trucks equipped with high-resolution Spectral Gamma Logging System units to measure radionuclide concentrations. This nonintrusive measurement method will provide data for Hanford's cleanup mission, monitoring program, and baseline characterization.

OVERVIEW

Large quantities of high-level nuclear waste were produced during the processing of plutonium for national defense at the Hanford site in southeastern Washington State. From approximately 1943 to 1987, large underground storage tanks were used to store millions of liters of high-level radioactive liquid wastes. The term "Tank Farm" refers to the areas on the Hanford site where groups of these subsurface tanks are located. U.S. Department of Energy Richland Operations Office (DOE-RL) officials estimate that 67 of the 149 single-shell tanks (SSTs) have leaked in the past, releasing approximately 1 million liters of high-level mixed waste into the vadose zone sediments under and surrounding the tanks.

DOE-RL started the Hanford Tank Farms Vadose Zone Monitoring Project in 1994. The project is a scientific investigation to determine the types and extent of radioactive contamination in the subsurface as a result of SST leaks. Subsequently, DOE-RL tasked the DOE Grand Junction Projects Office (GJPO) and its contractor, Rust Geotech, with this investigation.

GJPO's background in subsurface measurements and calibration is based on 50 years of experience that includes the National Logging Program conducted in the late 1970s and early 1980s. During this program, millions of borehole-feet were logged in support of the National

Uranium Resource Evaluation (NURE) program. GJPO constructed and maintains a complete suite of subsurface calibration facilities that are recognized as the national standards for calibration of subsurface logging equipment. Scientists at the GJPO used these calibration facilities to develop innovations in calibration and data analysis methods that will also benefit this project.

TANK FARMS BACKGROUND

Constructed between 1943 and 1964, the tanks are known as SSTs because their walls are a single shell of steel-lined concrete (1). These SSTs, located in Tank Farms in the 200 East and West Areas at the Hanford site (see Fig. 1), are as much as 2.5 meters below ground surface and more than 46 meters above the unconfined groundwater table beneath the Hanford site. Sixteen of these tanks have individual capacities of about 52,250 liters, and 133 tanks have individual capacities that range from 503,500 to 950,000 liters.

Fig. 1.

The 149 SSTs reside within seven waste management areas, with each area containing between 10 and 40 SSTs. Waste management areas A-AX, B-BX-BY, and C are located in the 200 East Area. Waste management areas S-SX, T, TX-TY, and U are located in the 200 West Area.

An estimated 67 of the 149 SSTs leaked in the past, releasing approximately 1 million liters of high-level waste into the vadose zone sediments surrounding and under the tanks. The addition of waste to the SSTs was halted in 1980, but the tanks continued to serve as waste storage vessels. Double-shell tanks, first put into service about 1968, are the only tanks currently receiving waste. A double-shell tank has two steel-lined concrete shells separated by an annulus. None of the 28 double-shell tanks are known to have leaked, and they are not included in this monitoring program.

DOE-RL installed nearly 800 steel-cased boreholes in the sediments around the SSTs. For many years, gross gamma-ray logging was performed in these boreholes to detect leaks from the tanks. Because detecting leaks in the sediment really is detecting a problem after it has occurred, DOE-RL initiated new programs to provide in-tank monitoring data for leak detection. The role of vadose zone monitoring for leak detection diminished during succeeding years as the tanks were pumped of free liquid and as better in-tank monitoring methods were established.

Current data needs focus on determining the types and distribution of contaminants under and surrounding the SSTs. This information is necessary to determine which tanks have leaked in the past and to use as a basis in making decisions about tank operations. Subsurface radionuclide concentration data represent part of the characterization information required to prepare an Environmental Impact Statement (EIS) and an SST closure plan required by the Resource Conservation and Recovery Act (RCRA). Data from this project will serve DOE's Hanford cleanup mission and will

increase the ability to meet scheduled milestones in the Hanford Federal Facility Agreement and Consent Order (2), also known as the Tri-Party Agreement because it was co-signed by DOE, the Washington State Department of Ecology, and the U.S. Environmental Protection Agency (EPA), Region 10, in May 1989.

PROJECT OBJECTIVES

The three primary technical goals for the project are

To obtain baseline monitoring data for the SSTs with the new high-resolution Spectral Gamma Logging System (SGLS) units.

To develop recommended improvements to the existing gross-gamma monitoring to provide defensible, scientific methods to enhance routine leak detection.

To evaluate promising new technologies for determining the nonradiological hazardous constituents in the vadose zone and for studying geologic formation properties as an essential component of transport modeling.

Federal and State agencies and Hanford stakeholders approved these project objectives. The Washington State Department of Ecology, the 1990 DOE Tiger Team, EPA, and the U.S. General Accounting Office reviewed and prepared reports on the viability of vadose zone monitoring and the effectiveness of the existing gross-gamma leak-detection program. These reports, as well as reviews by DOE-RL, determined that borehole geophysical logging is a technically viable and cost-effective method for monitoring and characterization purposes.

Spectral Gamma Logging Systems Baseline Monitoring

Greenspan Inc., Houston, Texas, built two new SGLS units for the Westinghouse Hanford Company specifically for this project. GJPO personnel will operate the units at the Hanford site to collect data for characterization and monitoring needs. Characterization data needs include

Determining the types, concentrations, and distribution of radionuclides under and surrounding the SSTs.

Identifying contamination sources (which tanks have leaked).

Establishing a baseline for comparison of data for short- and long-term monitoring objectives.

Knowing the types and concentrations of radionuclides will help in understanding the scope of the current environmental remediation problem and in evaluating the economics of remediation alternatives required by RCRA. Identifying sources of contamination is important for current operations because special controls or operations may be performed on those tanks that are known or suspected to have leaked. At present, the number of tanks and the areal extent of the leakage are not well known. An established baseline is necessary to use as a basis for evaluation of future short- and long-term monitoring data.

Monitoring data needs include

Performing leak detection.

Providing tank surveillance.

Assessing long-term performance and risk.

Monitoring changes in the distribution of contamination in the vadose zone is a primary objective. SGLS data collected in the boreholes can detect new, or previously undetected, areas of contamination. Surveillance aspects involve determining any near-term changes of contaminant concentrations in the subsurface and the cause of those changes. Long-term monitoring will provide data for input into performance and risk assessments that are needed for integration into the EIS and RCRA investigation and closure plans.

If adequate long-term monitoring data can be obtained to show that radionuclides in the vadose zone are stable during an established institutional control period, a leave-in-place remediation option may be justified. Such an option would result in a savings of billions of dollars compared to any type of removal action.

GJPO personnel will collect SGLS baseline monitoring data from all boreholes surrounding the SSTs. These data will be reduced to radionuclide concentration profiles for correlation between boreholes. Computer software programs will model the cross-borehole correlations to show the three-dimensional (3-D) contaminant distribution. These 3-D diagrams (see Fig. 2) provide a powerful interpretation tool to locate contamination sources. Determining the sources is an important key in identifying which tanks have leaked and, as a consequence, which tanks may require special management considerations.

Fig. 2.

The final product of the SGLS baseline monitoring project is a series of reports to

provide radionuclide concentration data and 3-D interpretation diagrams and to identify, as well as possible, which tanks have leaked. Establishment and maintenance of an extensive database will permit comparisons with future data to address the long-term migration monitoring aspects of the project.
Data, reports, and conclusions from the SGLS baseline monitoring project will be available for integration into various site-wide monitoring programs, systems engineering studies, risk assessments, the EIS, and the SST Closure Plan. SGLS project data will increase the understanding of the magnitude and scope of any cleanup operations and will designate which tanks may deserve special treatment during waste retrieval operations to prevent further degradation of the vadose zone environment.

Review of Previous Monitoring Program

As part of the Tank Farms Vadose Zone Monitoring Project, GJPO will review the previous gross-gamma leak-detection program. Review components include data acquisition, reduction, interpretation, and instrumentation calibration and maintenance to determine the utility of the program as a leak-detection tool for the Tank Farms.
On the basis of the evaluation of previous logging practices, GJPO will prepare a scientific-based test plan for selected procedures, instruments, and methods. The goal of the test plan is to select ways to optimize previously used measurement systems, procedures, and data-reduction methodology to support the current in-tank leak-detection program.

Technology Evaluation and Demonstration

Several new technologies currently being developed may benefit the Tank Farms monitoring program. GJPO will evaluate new technologies for capabilities to identify hazardous constituents and to determine soil formation properties and will select technologies that could be immediately beneficial to the project. Four promising areas of investigation are

- Multispectral neutron-gamma logging
- Neutron porosity measurements
- Prompt-fission neutron logging
- Gamma-gamma density measurements

Following the demonstration of the selected technologies at Hanford, GJPO personnel will calibrate the methods and the hardware.

FEATURES AND CAPABILITIES OF THE SPECTRAL GAMMA LOGGING SYSTEMS

Westinghouse Hanford Company, a DOE-RL contractor, designed two logging units specifically for this project, and Greenspan Inc. of Houston, Texas, built the units to those specifications. Greenspan and GJPO personnel performed testing and calibration of the units at the GJPO calibration facility.
Future calibrations of the SGLS units will be conducted at the Hanford site. Data will be collected from borehole models moved to Hanford from a DOE calibration facility at Spokane, Washington. The calibration factors determined from the GJPO measurements will be applied to the Hanford data to establish a correlation between the Hanford models and the GJPO standards, thereby certifying the Hanford models for future calibrations of the SGLS units.
Each logging unit is installed on a four-wheel drive, diesel-powered truck (see Fig. 3). The truck engine powers an electrical generator that supplies all of the required electrical power, and the hydraulic system drives a cable winch and logging boom. The winch and boom handle the cable that suspends the gamma-ray sensor package, or sonde, in the borehole. This cable also contains electrical lines that carry signals from the gamma-ray detector to the recording apparatus in the truck.
Fig. 3.
In a typical operation, the sonde is moved to the bottom of the hole, then gamma-ray data are collected as the sonde returns to the surface. Typically, the sonde moves to a particular depth, stops and gathers data for approximately 100 seconds, then ascends to the next depth, which is usually 15 centimeters higher. Because a typical borehole is about 36 meters deep, a borehole log will consist of about 240 individual readings. About 6 to 8 hours will be required to log one borehole.
After placing the sonde in the borehole, the logging system computer completely controls the logging process. The computer is programmed to control sonde movements and data gathering processes and to continuously monitor essential mechanical and electrical logging components. The computer responds to a malfunction by sounding an alarm. If the logging engineer fails to correct the problem, the computer dials a

cellular telephone and sends a message to an operations control center, then terminates the logging operation.

Gamma-ray detectors within the sondes are crystals of high-purity germanium. The gamma-ray energy resolution of these semiconducting detectors is far superior to that of scintillation detectors, such as sodium iodide or cesium iodide, customarily used in petroleum and minerals industry gamma-ray logging. This excellent energy resolution allows the data analyst to identify the gamma-ray radionuclides, in most cases, and to calculate the concentrations of the radionuclides precisely.

Because germanium detectors must be maintained at the temperature of liquid nitrogen (-200 C) during operations, each sonde contains a metal flask, or dewar, that holds enough liquid nitrogen to cool the detector for about 12 hours. Each logging truck carries a 94.6-liter dewar of liquid nitrogen that permits replenishment of the sonde dewars in the field.

PROJECT MANAGEMENT

The Hanford Tank Farms Vadose Zone Monitoring Project is planned and will be managed as a project with established scope, cost and schedule baselines, and performance measurement elements. GJPO-prepared documentation requisite to the performance of this project include, but are not limited to, calibration and operating procedures, monitoring plans, and management and operating plans to ensure the integrity and defensibility of the collected data. The following specific documents represent the types of documents GJPO personnel will use to conduct the Hanford Tank Farms Vadose Zone Monitoring Project:

The SGLS Calibration Plan describes data collected at the GJPO calibration facility that were used to determine the appropriate calibration and environmental correction factors for the SGLS. The properties of the standards are compiled in Field Calibration Facilities for Environmental Measurement of Radium, Thorium, and Potassium (3).

The Calibration Report contains (1) descriptions of measurement methods; (2) calibration constants for potassium, uranium, and thorium; (3) calibration functions for analysis of artificial nuclides; (4) casing correction functions; (5) corrections for variations in diameter of a water-filled hole; and (6) other measurement factors, such as spatial deconvolution parameters. Standard propagation-of-uncertainties methods will be used to estimate experimental uncertainties associated with all measured and calculated quantities. This report will be a "chart book" for the logging systems.

The Interim Operating Procedures designates the procedures to be used during extensive field testing of the SGLS units following calibration and before initiation of the Tank Farms baseline monitoring. Field testing will be conducted with the GJPO calibration and maintenance facilities. This testing will consist of logging the calibration boreholes and testing the electronics, draw works, hydraulic systems, software programs, and data management systems. Operators will use this document during training to operate the systems, verify the quality of data, and process data. GJPO personnel will modify the interim operating procedures during the field testing to prepare the Operating Procedures for Logging. These final operating procedures will be reviewed and approved before baseline monitoring is initiated at the Tank Farms.

The Baseline Monitoring Plan presents the scope and objectives of the technical program, including data quality objectives, methodologies, procedures, and instrumentation used for data collection with the new SGLS units in the Tank Farms. Other elements of this plan are analytical requirements, quality controls, required reports, personnel qualifications, data handling, data reduction, and data quality assessments. This plan will be implemented following completion of the field testing.

The Data Processing and Storage Plan describes management of borehole data acquired at the Tank Farms with the SGLS units. GJPO personnel will reduce and interpret these data and prepare results for presentation in reports. These postacquisition tasks will be performed with specialized data processing hardware and software systems other than the onboard computers in the SGLS units. The Database Interface Plan will define the Hanford databases that should receive raw log data and reduced data and the databases that should support data processing.

CONCLUSIONS

The SSTs at Hanford are one of DOE's most important environmental concerns. Until the waste is removed from the SSTs, it must be properly managed to minimize releases

to the environment. Information is needed for current tank management decisions and for long-term tank-waste disposal and closure. A vadose zone monitoring program at the Tank Farms is necessary to provide that information for both monitoring and characterization data needs.
DOE-RL will benefit from GJPO expertise in borehole logging. The Hanford Tank Farms Vadose Zone Monitoring Project is based on more than 50 years of experience in subsurface measurements combined with many years of experience in successful project management.
Development and implementation of this vadose zone characterization and monitoring project will enhance the success of DOE-RL's efforts to meet scheduled milestones in the Hanford Federal Facility Agreement and Consent Order (known as the Tri-Party Agreement because it was co-signed by DOE, the Washington State Department of Ecology, and EPA, Region 10, in May 1989). By implementing a vadose zone monitoring program for the SSTs, along with evaluating and upgrading the existing leak-detection monitoring program, DOE-RL will demonstrate a commitment to meeting the Tri-Party Agreement by providing data useful for Tank Farms operations, environmental remediation planning, and postclosure monitoring.

NEW METHODS FOR DETERMINATION OF INTERSTITIAL LIQUID LEVELS IN HANFORD WASTE TANKS

Paul D. Whitney
Senior Research Scientist
Pacific Northwest Labs
ABSTRACT
The key to the leak detection program for many tanks at Hanford is the method used to evaluate the apparent interstitial liquid interface (ILL) within the pore space of the solid waste medium (either crystalline or sludge). Three new approaches were introduced in the summer of 1993 (count rate, derivative, and sigmoid), all of which significantly improved the accuracy and repeatability of interstitial liquid level values from neutron survey data. This paper summarizes the three new methods and details a case study in which, as a direct result of this improved analysis, a tank that had been declared an "assumed leaker" was reclassified as "sound" for the first time in Hanford's 50 year history.
INTRODUCTION
Many of the 177 underground nuclear waste storage tanks at Hanford do not have liquid waste surfaces, and potential leakage must be evaluated by determining the Interstitial Liquid Level (ILL). The in-tank photograph shown in Fig. 1 indicates why a surface level measurement alone cannot be used as a valid leak detection indicator in many tanks. Since 1985, a total of 61 liquid observation wells (LOWs) have been installed for the purpose of leak detection, with additional installations continuing. A LOW is a hollow tube made of fiberglass, steel, or "TEFZEL" (Registered trademark of DuPont), which is capped at the bottom, and inserted into the waste to a point near the bottom of the tank. The interior of this tube can be opened to the atmosphere via surface risers, but is isolated from the waste, thus providing a surveying environment which is free from direct contamination (as shown in Fig. 2). These LOWs are surveyed weekly, using wireline logging techniques common

to the geophysical and petroleum industries. Both thermal neutron and gross gamma ray probes are used, but the neutron probe normally provides higher quality data. The resulting surveys, (plots of depth vs. count rate), are then evaluated using interpretation software to determine the exact depth of the liquid interface. Plotting the derived liquid interface against time can document trends and changes in liquid levels. These interface changes, when analyzed with statistical methods, provide the basis for an effective leak detection program.
Fig. 1.
Fig. 2.
As mentioned above, the two probes most commonly used for this analysis are the thermal neutron probe and the gross gamma probe. The gross gamma probe at Hanford consists of a single Geiger-Mueller detector and its associated electronics, which acts very much like a point-source detector. Since the waste in Hanford's single-shell tanks was generated from 25 to 50 years ago, any short-lived isotopes have long since decayed, and are present only at insignificant levels. The primary gamma-producing isotope that remains is Cs137, which is in a highly water-soluble form in most cases. Although this solubility normally results in a clearly identifiable change in gamma activity at the liquid interface, the change in count rate is not normally as definitive as that provided by the neutron probe. In most cases, the gamma profiles are less sensitive to changes in fluid saturation, and are normally used to support and verify the primary neutron data. The remainder of this paper will focus on a new and more detailed analysis of the neutron count profiles.
The underlying physical principle behind a thermal neutron probe is its response to moisture, more specifically, to the hydrogen associated with water. The neutron source, located near the bottom of the probe, consists of 1.5 Curies of americium/beryllium (AmBe), which emits "fast" (high-energy) neutrons at approximately 4.5 MeV. Two of the most common neutron detectors are made from either helium 3 (He3) or boron trifluoride (BF3), both of which are gasses and emit an alpha particle when a thermal neutron is absorbed. The initial energy level of the source neutrons, however, is much too high to allow capture by either detector. The neutrons must achieve a significantly lower energy level before they can be detected. It is the rate of this neutron "thermalization" process that is of primary interest.
One of the most effective fast neutron moderators known is hydrogen, primarily because its mass is virtually equal to that of a neutron. In a high-hydrogen environment a fast neutron will slow to thermal energies nearer the source, and will thus be captured by a detector (yielding high count rates). In virtually all other environments, the neutrons will maintain their initial energy levels far longer (i.e., yielding lower count rates at the detector). Since high hydrogen densities are normally associated with liquid water (or organics in some cases), this makes the thermal neutron probe a very sensitive moisture detector. In practice, the BF3 detector is used at Hanford instead of the He3 detector because of its superior level of discrimination in high-gamma environments. A typical neutron probe response across a liquid/solid or liquid/vapor interface goes from high counts in the liquid phase to low counts in the solid or vapor phase, and normally exhibits an "S", or sigmoid-shaped response curve (unless modified by nearby porosity and saturation changes).
BACKGROUND
The initial LOW survey program was formally established in 1985, along with basic software to determine the liquid interface from neutron and gamma scans. This interpretation software was designed primarily for ease of use, and was expected to yield only rough approximations of liquid levels. The major elements of this original analysis are summarized below followed by the resulting limitation.
  The data was collected only at intervals of 0.1 foot (1.2 inches), and the results were also recorded in these increments. No interpolation between data points was attempted. Limitation: interpolation could have improved resolution.
  The computed liquid interface was obtained by visually setting crosshairs on a monitor screen. Limitation: graphical resolution was poor and the depth scale was not expanded adequately, leading to potentially large errors in depth.
  Results often could not be repeated, even by the same technician. Limitation: increased data scatter, particularly when different technicians were used.
  If there was no significant visible difference between the established baseline plot (taken several years earlier) and the current scan, the difference was recorded

as "zero", and no quantitative analysis was attempted. Limitation: the difference was often significant, although barely visible on the compressed graphic scale then in use.

A flaw in the software allowed the interface to be established at a data point which was not on the recorded data curve. Limitation: data could be offset by as much as 1 to 2 inches.

Analysis of the "top of tank" marker was not attempted. Limitation: Without a fixed internal depth reference all systematic errors in the van depth system translated directly into ILL calculation errors.

Baseline values used for leak detection (both surface level and ILL data) were fixed single values. Most of these values had been set several years earlier. Limitation: If natural evaporation, condensation or settling is occurring the baseline should change with time at a relatively constant slope. In the past, this inflexible approach led to some naturally evaporating tanks being declared "assumed leakers" when fixed and outdated limits were exceeded.

Since tolerances were large, however, this method was considered acceptable for many years. Over time it simply became the "standard", and the limitations of this approach were not questioned or re-evaluated. Most tanks were stable enough so that this method was adequate for gross leak determinations.

The primary focus of this paper is waste tank SX-102. This is a single-shell tank constructed in 1954 which began receiving waste as soon as it was completed. The tank exhibits a relatively thin solid crust (approximately 1.0"-1.5" thick, most likely floating on liquid), and the liquid observation well (LOW) data is the official means of leak detection. Although a surface level conductivity device is operable, it has been in the "intrusion mode" for several years, with only occasional surface level measurements taken (Fig. 3).

Fig. 3.

In the summer of 1993 the ILL on SX-102, as determined by LOW neutron surveys, exhibited a sharp decrease (based on the established evaluation technique at the time), ultimately exceeding the decrease criteria set for leak detection. As shown in Fig. 4, the data indicates a relatively constant level for several years (with a few notable variations) followed by a sharp decrease. The apparent sudden decrease follows a classic leak profile, and as a result of this profile and the official leak detection criteria being exceeded, the tank was declared an "assumed leaker". Preparations for emergency pumping of this tank were initiated, which is a very expensive and manpower-intensive operation. Tank SX-102 was on the "Hydrogen Watch List", a safety classification which requires a special safety analysis and associated precautions prior to allowing work in or around the tank.

Fig. 4.

CURRENT METHODOLOGY

The apparent leakage of SX-102 prompted a fresh look at the ILL interpretation techniques in use at the time. It soon became apparent that a significant amount of error could be generated (as outlined in the "Background" section), and that a much more accurate analysis was technically feasible. One of the most damaging past practices was that of calling the change in level "zero" if no separation was clearly visible between the baseline plot and the current survey. (Some of these apparent "zero changes" resulted from the poor graphic presentation available.) It was this practice that generated most of the flat portion of the ILL plot prior to the sharp decline. Once the decline became large enough to be identified, the rate of decrease was magnified as a result of the other systematic errors in the interpretation technique, as previously discussed.

As a direct result of identifying the limitations of the existing system, three new analysis techniques were developed. The methods are summarized below, followed by a corrected interpretation of the SX-102 ILL data.

Determination of the exact depth of the liquid interface currently involves three distinct analysis techniques. All three approaches (count rate, derivative, and sigmoid) have been applied to each tank, and the technique indicating the most consistent, stable and repeatable results has been chosen as the "official" method for that tank. Fortunately, the historical database of raw survey data extends back to 1985, and a thorough evaluation is possible to determine the most applicable method.

An important part of all three new approaches is analyzing the "top marker". This feature is identified by the sharp increase in counts at the interface between the

tank vapor space and the cement structure of the dome. Figure 2 illustrates this feature for SX-102. Since this feature cannot move it is used as an internal depth calibration. Where this feature is sharp and well-defined (typically in 4 inch risers) the software shifts all of the raw data by the amount required to place the top marker exactly on depth. The resulting ILL values exhibit far less data scatter, since most depth problems associated with the LOW survey van have been removed. Where the LOW has been installed in a riser larger than 4 inches (up to 12 inches) the sharpness of this feature degrades, and cannot be used reliably in about one-third of the tanks.

Most neutron survey data generates acceptable results with all three approaches, but difficult analytical situations occasionally occur. In some tanks, one or two of the available methods fail for various reasons. The profile of every tank, however, has been successfully analyzed using at least one of the three approaches outlined below.

The Count Rate Method

The first method is known as the "count rate method". This simplistic but accurate approach relies on taking an average count rate immediately below the expected interface (100% liquid saturated) and an average count rate immediately above the expected interface (<100% saturated) across a pre-determined depth "window". The two values are then averaged, and the depth corresponding to this "average" count rate is designated as the ILL depth. In practice, this is an iterative process, with the initial "estimate" of the liquid interface being the extrapolated current baseline for the tank, which represents the best guess at the expected depth on the survey date. (Remember that a sloped baseline is used, and the "expected" ILL varies with time.) An "offset" is then assigned above and below that depth to establish a "count rate window" on either side of the expected interface. The resulting windows are intended to represent the stable counts above and below the expected interface. Total count rates are taken in both of these windows, to provide a liquid-filled count rate below the interface and a partially-saturated count rate above the interface. A midpoint count rate is determined by averaging the two and comparing the result with the initial depth estimate. If the two depth values do not match within the convergence criteria, then the newly-determined value is used as a starting estimate and the process is repeated until the values converge. Deviation from the expected baseline is then computed and presented as part of the quality control and data reporting process. (A typical count rate interpretation is shown in Fig. 5.)

Fig. 5.

The Derivative Method

In the derivative method, a "depth window" is established which symmetrically covers both sides of the feature to be evaluated. This is the only method which is not iterative, and does not tie the initial guess to the baseline extrapolation. Within this window, the raw survey data (taken at 0.1 foot increments) is smoothed using a cubic spline function; this function is then broken into equal 0.01 foot increments to improve depth resolution. The resulting output function has a smooth and continuous first and second derivative. (This is one of the inherent mathematical characteristics of a cubic spline curve fit.) The derivative of this function is then calculated every 0.01 feet, and the liquid interface is defined as either the minimum or maximum value of the derivative (depending on slope). This method defines the liquid interface as the exact point (within 0.01 feet) of maximum slope (maximum rate of change). In most cases, the derivative method yields a slightly different absolute value than the count rate technique, but both methods are comparable, and the long-term data trends do not differ significantly. The derivative method is illustrated in Fig. 6.

Fig. 6.

The Sigmoid Method

Any time raw data follows a predictable pattern, it can be evaluated by curve fitting to a mathematical function of similar shape. In most cases, this mathematical function will behave more consistently and will exhibit less scatter than the original raw data. This approach was applied to the classic "S" shaped response of a neutron probe measuring a liquid interface. Equation 1 is the exponential function used to simulate this response.

Eq. (1)

Virtually any sigmoid shape can be fit to this function by appropriate adjustment of

the variables a, b, c, and d. In practice, a non-linear optimization routine is used to adjust the values of these four variables in order to maximize the regression coefficient (R2) between the raw data and the resulting curve-fit function. Once the best possible fit is achieved, the midpoint b (point of symmetry) is defined as the liquid interface, (as illustrated in Fig. 7). As with the count rate method, the resulting answer is fed back into the equation as a starting value, and the routine iterates to convergence. In approximately 50% of the tanks, the sigmoid method proved noticeably superior to the other two methods.
Fig. 7.
Determining the Best Method
To determine the best method, each tank is analyzed by all three methods, with all historical data being re-evaluated. The resulting outputs are plots of the liquid interface (level) vs. time. From these plots, the analyst can determine increasing and decreasing linear trends, as well as the standard deviation of the data points about the trend line. The most appropriate method is the one which produces the tightest data cluster about the linear trend line (minimum standard deviation), while also providing the fewest number of data analysis failures. (The most common problem is a "failure to converge".)
Variations from baseline greater than 2 standard deviations are considered "suspect", and the surveys are repeated. Repeatable variations greater than +/- 3 standard deviations are considered legitimate anomalies, and are reported as potential leaks or intrusions. Once the optimum method and analysis parameters are chosen for a tank, they are stored in the central computer control file, ensuring that the analyses for all past and future surveys will be made on a comparable basis.
CASE STUDY, TANK SX-102 LEAK DETERMINATION
In May of 1993, waste tank SX-102 appeared to experience a sudden downturn in the interstitial liquid level (ILL), primarily due to the poor resolution of the existing analysis technique (as previously discussed). Because of the apparent sudden decrease in ILL, the tank was declared an "assumed leaker", and preparations were being made to perform an "emergency pumping" of the tank. During these preparations, the data was re-analyzed using the techniques just described, and a steady, long-term decreasing trend became apparent, with no major changes in slope. Although the new analysis techniques were in their infancy at the time, they proved conclusively that the decrease in liquid level was due to evaporation, which had been taking place for at least nine years. This was the first time a sloping baseline (taking into account natural evaporation and/or condensation trends) had been applied to raw tank data. A psychrometric study of the apparent evaporation trend was commissioned, resulting in a calculated evaporation rate which very closely matched the new ILL interpretation shown in Fig. 8. The study included physical, thermal, and hydraulic modeling, and yielded a best estimate of evaporation rate equal to 0.68 inches/year. The linear correlation of ILL data provided a slope of approximately 0.63 inches/year. These numbers match within the expected errors of the two methods used. As a result of this new interpretation, the tank was re-categorized as "sound", and a multi-million dollar emergency pumping operation was avoided.

VITRIFICATION OF ACTINIDE SOLUTIONS IN SRS SEPARATIONS FACILITIES
R.L. Minichan
W.G. Ramsey
Westinghouse Savannah River Company
ABSTRACT
The Savannah River Site (SRS) Separations Canyons will eventually undergo Decontamination and Decommissioning (D&D). In order to D&D these facilities, material (such as Americium and Curium) currently in tanks must be dispositioned. Actinide solutions in these tanks contain extremely valuable nuclear isotopes for which viable applications exist. The National Heavy Element and Advanced Neutron Source (ANS) program at Oak Ridge can use this material; however, a process to convert this solution to a solid form for safe transport does not currently exist. Actinide glass compositions were developed through Office of Technology Development (OTD) research. This research formed the cornerstone of a process to vitrify the

Americium and Curium (Am/Cm). This process has been recommended by Westinghouse and Savannah River Company as the most favorable option for Am/Cm disposition. Work continues towards developing a full scale prototype system to demonstrate the process and train operators.

The system would be installed in the Multi-purpose Processing Facility (MPPF) of F-Canyon. This is an ideal location since it provides viewing windows, good shielding and access to the process with manipulators. The system will consist of a melter capable of at least 1-2 kg/hr glass output, feed systems, and an off-gas system. The glass will be poured into small canisters so the material can be safely stored or shipped to its destination. Two feed streams will ne directed to the melter; glass marbles and a nitric acid solution which contains the material to be vitrified. The two streams are designed so that they will mix in the melter and form the appropriate composition to produce as a result of wet feeding which dictates the requirement to handle condensate in the off gas. The condensate will be collected, sampled for fissile material and discharged to the canyon waste tank. The melter proposed for this program is a platinum/rhodium alloy bushing melter commonly used in the glass fiber industry; however, this is a new and unique application for this melter technology. The melter is an alloy box with tabs on each end for an electrical connection. Current is passed through the bushing and heats it similar to a resistance heater. The unique features of the bushing melter for this application include the following: It will be enclosed so the off-gas can be contained and processed. The melter feed will be wet, that is the melter will be required to supply adequate power to vaporize the liquid portion of the feed and then melt the solids along with the glass beads entering the melter in a separate feed stream.

There are many specialized waste forms in the DOE complex which can not be easily processed in facilities like the Defense Waste Processing Facility (DWPF) at SRS or have a potential future use. The process being developed will provide the capability to convert specialized or unique forms of nuclear material into a stable, solid and safe form which can be stored indefinitely, shipped or reprocessed as the need arises. The successful demonstration of this technology to vitrify isolated actinide material could have future application in numerous locations across the DOE complex.

INTRODUCTION

The actinide vitrification system is being developed for several reasons. A long term goal for the Savannah River Site (SRS) is to Decontaminate and Decommission (D&D) facilities. At least one tank in the F-Area Separations Canyon contains valuable isotopes which the National Heavy Element and Advanced Neutron Source (ANS) program at Oak Ridge can utilize. A minimum of three options were investigated for dispositioning the Americium/Curium (Am/Cm) solution currently stored in an F-Area Separations facility tank. The evaluation determined that vitrification was the favored option since the end product is a solid glass log which can be safely stored or transported.

In order to D&D F-Canyon, stored and inprocess material must be processed or removed from tanks in the facility. This program was initiated to process a specific tank which contains Am/Cm in a nitric acid solution. Some tanks in the facility may be emptied to waste tanks. However, the solution in question could impose adverse effects if this were done. The replacement value for the Americium and Curium isotopes was estimated to be between one and two billion dollars. The quantity of material in this tank will supply all of the ANS program's needs for these isotopes for the foreseeable future. This program is serving two goals of dispositioning the tank of solution and supplying Oak Ridge needed isotopes. By stabilizing the isotopes in glass, they can be safely stored indefinitely for future use.

ACTINIDE VITRIFICATION SYSTEM DISCUSSION

The vitrification system must be operated remotely due to the radioactivity of the Am/Cm solution. The design of the equipment used in this system must ensure high reliability to minimize the amount of maintenance required. The vitrification system will be installed in the Multi-Purpose Processing Facility (MPPF) in F-Canyon. The MPPF is a unique facility in section eighteen if the canyon. It is the only section which has shielded oil filled windows for viewing the operation. Master Slave Manipulators are used for operating equipment in the shielded cells. There are eight window / manipulator stations in the facility, however, only one or two will be required for the vitrification system.

Each station has a removable rack that process equipment is mounted on. Two of the current racks which are no longer in service will be removed to accommodate the vitrification system. New racks will be fabricated to support the vitrification system. The new racks will be fully assembled and tested in a non-radioactive facility to ensure all the integrated systems function properly prior to installing them in the MPPF. Current estimates indicate that it will take approximately 300 hours of operation to process the Am/Cm solution. The expected process parameters are shown in Table I. Table II and III show anticipated glass compositions for this process to vitrify Am/Cm. A schematic of the system is shown in Fig. 1 and each major system is described in detail below.

TABLE I

TABLE II

TABLE III

Fig. 1.

Feed System

The feed consists of two components, a nitric acid solution which contains dissolved Am/Cm and a glass forming frit. The two feed streams must be fed in the correct proportion to make an acceptable glass product. Frit is a dry material similar to sand. Separate systems will be used to feed each stream into the melter lid. The two feed materials will be mixed in the melter and be poured out the bottom as a glass product.

The nitric acid solution will be pumped from a storage tank to a smaller feed tank in the MPPF. The solution is fed using a constant head arrangement as shown in Fig. 1. The solution is airlifted from the bottom into a small vessel above the feed tank at a rate slightly higher than will be fed to the melter. An overflow from this small vessel is returned to the feed tank and a outlet below the liquid level feeds the melter. The fluid head pressure delivers the liquid feed to the melter through an orifice to regulate flow. The liquid feed system has a fixed flow as determined by the equipment setup. Orifice changes can be made as required to alter the process parameters or feed a completely different solution. The liquid feed tube at the melter top will likely require cooling to prevent the solution from boiling in the feed line.

The dry frit feeder will have an adjustable feed rate which must be coordinated with the fixed solution feed rate so the ratio is in the target range. The frit will be fed using a weight loss feeder which determines the feed rate by monitoring the weight loss in the frit hopper over time. This stream will be delivered to a conveying system that will transport the material to the top of the melter where an air lock transfer device will ultimately discharge the dry feed into the melter. The air lock is necessary to maintain a seal on the melter and minimize the quantity of air infiltration so the melter off-gas system is not overloaded. It will also prevent the vapors in the melter head space from contaminating or possibly plugging the dry feed system.

Melter

The melter chosen for this vitrification system is called a bushing melter, which is basically a platinum/rhodium alloy box with tabs on each end. Electrical bus bars are connected to the tabs on each side of the alloy box which acts like a resistance heater when current is passed through it. Up to 15,000 amps at 2 volts are used in the glass fiber industry for drawing glass fibers. The vitrification bushing will have one drain hole as opposed ti several hundred fiber drawing holes in a typical glass fiber bushing.

The novel attributes of the bushing melter that will be used for vitrification include wet feed and an enclosure above the melt. The feed for this melter includes dry frit and a solution of material to be stabilized as opposed to standard bushings which are fed glass beads or molten glass. The vitrification bushing must provide the heat of vaporization for the transport fluid as well as the heat necessary to melt the glass frit and oxides delivered in the feed solution. Using wet feed creates off-gas which must be contained and treated. A top will be installed on the melter which will seal the system so the off-gas can be drawn into the off-gas system. The top will also have two feed nozzles, one each for the wet and dry feed to enter the melter. In addition, a large port in the melter top directs the off-gas stream into the treatment system. The glass product is poured into stainless steel canisters through a single nozzle in the bottom of the melter. The nozzle is sized to ensure the desired pour rate at the expected glass viscosity.

Pouring is controlled by an air jet that freezes the glass in the pour nozzle and/or a platinum alloy flow stopper which acts as a heat sink.

Off-Gas System

This system will function to contain and treat the off-gas originating from the melter. It is desirable to maintain control over the stream coming from the melter since it may contain some small amount of radioactive particulate. The system will operate to cool and scrub this process byproduct and any air introduced into the system for pressure control purposes. The volume of off-gas is dictated by the vaporization of the nitric acid solution and the plant air introduced to control pressure in the bushing melter. A slight negative pressure is maintained inside the system to ensure that if a leak occurs the flow is into the system not out. This feature minimizes the possibility of further contamination of the shielded cells facility.

The off-gas system originates with the melter. A melter top is used to contain any volatiles emanating from the melter. This is a unique feature which has not been used on bushing melters before. The melter top has a port where the off-gas exits and enters the treatment system. There is a control air connection in the off-gas line immediately above the melter. An automatic valve that supplies control air is directed by the signal from a pressure transmitter connected to the melter vapor space. As dynamic changes effecting the melter pressure take place, a closed loop control system reacts to supply more or less air to the off-gas system which maintains a pressure of negative five inches of water vacuum inside the melter. The stream then travels through the pipe to a quencher where the off-gas is quenched with a water spray. The quencher acts to cool, remove particulate and dilute the condensate. The two phase flow from the quencher flows into an off-gas condensate tank (OGCT) where particulate settles out and condensate is collected. The condensate level is monitored and pumped to a waste tank as needed. The vapor fraction of the off-gas stream exits the condensate tank through a port in the top and is directed into a high efficiency mist eliminator (HEME) where particulate is entrapped. The HEME condensate is drained back to the OGCT.

Once the off-gas exits the HEME it is directed to a heater which raises its temperature about ten degrees Celsius. This raises the temperature above the stream's due point to prevent condensation in the High Efficiency effectiveness and increases the pressure drop across the filter. The HEPA filter is the last component the off-gas flows through prior to entering the canyon process vessel vent system (PVVS).

Glass Storage Canister System

The glass product will be poured into stainless steel canisters which are approximately three inches in diameter and fifteen inches high. An automated system for handling the canisters remotely is required due to the radioactivity of the vitrified material and the fact that it will be performed in a shielded cells facility. A turntable capable of holding approximately eight canisters will be used to position empty canisters under the melter drain nozzle. Once a canister is filled, glass flow from the melter is terminated and the turntable rotates to position a new canister under the melter pour spout. Glass pouring can then be resumed so the next canister is filled.

Several of the turntable positions will hold full canisters and allow them to cool. Heat transfer from these canisters will be evaluated to determine the cooling rate. Insulated canister slots on the turntable may be required if the cooling rate needs to be adjusted to ensure the glass anneals properly. One station on the canister turntable will be setup to weld a cap on each canister. A mechanism to inventory and position canister caps so they can be welded is necessary in this remote application. The turntable location after cap installation is used to remove the full canister and insert an empty one.

A material handling system for the canisters must be developed. It will include a pick and place type device to automatically remove the full canisters and insert a new one. The full canisters must not only be removed from the turntable but transported to a location where they can be removed from the shielded cell facility and transported to their destination. Empty canisters will be delivered to the turntable to replace the full ones that are removed. The outer surface of the sealed canisters will be decontaminated to facilitate transportation of the sealed vitrified material.

CONCLUSION

The actinide vitrification system being developed at SRS provides the capability to convert specialized or unique forms of nuclear material into a stable solid glass product that can be safely shipped, stored or reprocessed according to the DOE complex mission. This project is an application of technology developed through funds from the Office of Technology Development (OTD). This technology is ideally suited for vitrifying relatively small quantities of fissile or special nuclear material since it is designed to be critically safe. Successful demonstration of this system to safely vitrify radioactive material could open up numerous opportunities for transferring this technology to applications throughout the DOE complex.

ABSTRACT
As part of the Defense Waste Processing Facility (DWPF) Startup Test Program, approximately 90 canisters will be filled with glass containing simulated radioactive waste during five separate campaigns. The first campaign is a facility acceptance test to demonstrate the operability of the facility and to collect initial data on the glass and the canistered waste forms. During the next four campaigns (the waste qualification campaigns) data will be obtained which will be used to demonstrate that the DWPF product meets DOE's Waste Acceptance Product Specifications (WAPS).
Currently 12 of the 16 canisters have been filled with glass during the first campaign (FA-13). This paper describes the tests that have been carried out on these 12 glass-filled canisters and presents the data with reference to the acceptance criteria of the WAPS. These tests include measurement of canister dimensions prior to and after glass filling, dew point, composition, and pressure of the gas within the free volume of the canister, fill height, free volume, weight, leak rates of welds and temporary seals, and weld parameters.

INTRODUCTION
The Defense Waste Processing Facility (DWPF) will vitrify high-level nuclear waste currently stored in underground tanks at Savannah River Site. After processing, the nuclear waste and glass frit will be mixed and then fed into the DWPF melter. The molten radioactive waste glass will be captured by stainless steel canisters as it pours from the melter pour spout. After glass filling, the canisters will be sealed by insertion of a temporary plug in the nozzle. The temperature of the nozzle will be at least 167oC higher than the temperature of the plug at time of insertion. The nozzle (with inserted sleeve) will then contract during cooling to form a

water-tight seal with the plug. The leak rate of the temporary seal of the canistered waste form will then be measured in the Melt Cell. When the leak rate is acceptable, the canistered waste form will be moved to the Canister Decontamination Cell where it is decontaminated using an aqueous slurry of glass frit. Smears will then be taken to ensure that the amount of smearable radioactive materials present on the outside surface of the canistered waste form is within specification. After this is confirmed, the canistered waste form will be transferred to the Weld Cell where the plug and sleeve are pushed down into the nozzle. A final weld plug will be inserted into the mouth of the nozzle, and a final weld will be made by simultaneous application of force and electric current for a short time duration (upset resistance welding). Smear tests will again be taken at this time. The canistered waste form will then be transferred to the Glass Waste Storage Building.
This report summarizes the results of testing of the canistered waste forms produced during the first campaign of the DWPF Startup Test Program. Durability results of the waste glass from this campaign will be reported separately.

CANISTER DIMENSIONS BEFORE AND AFTER GLASS FILLING

The vendor procurement specifications for length and diameter are:

Height: 117.94 to 118.06 inches or 299.57 to 299.87 cm
Diameter: 23.88 to 24.12 inches or 60.66 to 61.265 cm

The diameter (measured at 36 different locations) and the length of canister S00004 were measured prior to glass filling and the results demonstrated that the length was within the specification, but several diameter values were lower than the specification by a maximum of 0.02 cm. Perpendicularities for this canister were also measured

The ranges and the maximum changes in dimensions for canister after glass filling (canistered waste form) were:

Canistered waste form length:	117.994 to 118.001 inches or 299.705 to 299.723 cm
Maximum change over empty canister:	0.007 inch or 0.018 cm
Canistered waste form diameter:	23.896 to 23.957 inches or 60.696 to 60.851 cm
Maximum change over empty canister:	0.039 inch or 0.099 cm
Canistered waste form perpendicularity:	-0.114 to +0.093 inch or -0.290 to +0.236 cm
Maximum change over empty canister:	0.039 inch or 0.099 cm

It is interesting to note that after glass filling, all of the measured diameters were within specification. This implies that the canister became more round after filling, which is consistent with previous findings by SRTC. The canister became slightly less perpendicular with filling.

The Waste Acceptance Product Specifications (WAPS)(1) requires that the unfilled canister shall have an outer diameter of 61.0 cm (+1.5 cm, - 1.0 cm) and an overall length, after accounting for the closure method, of 3.000 m (+ 0.005 m, - 0.020 m). The maximum plug height using upset resistance welding for final closure is 0.092 inch or 0.234 cm. The unfilled canister S00004 readily met these requirements.

The WAPS also requires that the canister after glass filling and final closure shall be such that it will stand upright without support on a flat horizontal surface and will fit completely without forcing when lowered vertically into a right-circular, cylindrical cavity, 64.0 cm in diameter and 3.01 m in length. This specification was also met. In fact, the changes in these canister dimensions after being filled with glass are insignificant and provide assurance that canisters procured to the current DWPF specifications will readily meet the WAPS.

ICC LEAK RATES BEFORE AND AFTER DECONTAMINATION

After filling a canister with glass, a temporary heat shrink seal is made between an

Inner Canister Closure (ICC) plug and the sleeve in the nozzle. This temporary seal is intended to prevent water from entering the canister during the decontamination process. This ICC seal must be leak tight to less than 2 x 10-4 atmcc/sec for helium, a limit demonstrated to preclude inleakage of water into the canister. Water exclusion from the canister is important in order to prevent internal corrosion of the stainless steel canister. Decontamination is then carried out by frit blasting the canister surface with an aqueous slurry of glass frit.
The helium leak rate of the normal ICC seal on canister S00145 was measured three times before and after decontamination. The results were:

Before:	8 x 10-6 atmcc/sec	After:	9.3 x 10-5 atmcc/sec
	6 x 10-7 atmcc/sec		9.0 x 10-5 atmcc/sec
	-3 x 10-7 atmcc/sec		8.6 x 10-5 atmcc/sec

The before decontamination leak rates were essentially at the limit of sensitivity of the equipment.
The measured leak rate of the ICC plug of canister S00114 was 7 x 10-5 atmcc/sec. As planned, the nozzle was then heated to drop the ICC plug and sleeve into the canister and a new seal was made using a repair plug. The leak rate of this repair ICC seal was measured both before and after decontamination.

Before:	1.3 x 10-4 atmcc/sec	After:	1.2 x 10-4 atmcc/sec

The results for canisters S00114 and S00145 demonstrated that seals with leakrates less than 2 x 10-4 atmcc/sec for helium can be made. In fact all 12 canisters filled during this campaign met this requirement (Table I). Furthermore, it was demonstrated that aqueous frit blasting did not significantly change the leak rate of the seal.
TABLE I
CANISTER WELD PARAMETERS
The final weld is made by forcing the weld cap into the nozzle opening under a simultaneous application of DC current. The parameters of force, current, and time of application of current used to make the final upset resistance weld of nine of the canisters produced during FA-13 are presented in Table II
TABLE II
The nominal values to be used for making final welds are a force of 80,000 pounds, a current of 248,000 amps, and a time of 1.58 seconds.
The parametric study2 for weld performance determined acceptable windows for force and current of 90,000 15,000 lbs and 248,000 22,000 amps, respectively at 1.58 seconds. Hence all welds were made within the parametric window for acceptable welds.
WEIGHTS OF CANISTERED WASTE FORMS
The weights of the empty canisters were measured in DWPF prior to glass filling. After being filled with glass, the canister weight as measured on the pour turntable (PTT) with the bellows raised was also recorded. After arrival at TNX (a Savannah River Technology Center facility), all canistered waste forms were weighed using a calibrated overhead crane scale. The weights of the canisters were measured at TNX to determine if it would be appropriate to use the DWPF weight system to approximate the fill height. The net glass weight for each canister sent to TNX is given in Table III, along with the corresponding weight measured at DWPF.
TABLE III
At DWPF the weight of the glass was obtained by subtracting the weight of the empty canister from the weight of the glass filled canister as measured on the pour turntable with the bellows raised. At TNX, the weight was obtained using the crane scale measured weight minus the combined weight of the empty canister plus the weights of the canister closure plugs. The weights of the closure plugs are as follows:

Weld plug	4 pounds
ICC plug	10 pounds
ICC repair plug (if used)	12 pounds

In all cases the weights measured at DWPF were greater than those obtained at TNX.

These differences, listed as deltas in Table III, range from 32 to 96 pounds. These results indicate that the pour turntable provided a fairly accurate estimate of the canistered waste form weight with the bellows raised.
The differences between the weights of the filled canisters with the bellows lowered and raised are provided in Table IV. The delta increased with filling such that the average additional weight of the bellows was 278 pounds after filling, an increase of 60 pounds over the average difference of the empty canisters. Hence, the force and weight observed were not constant as the canister was filled with glass. The difference is manageable since 60 pounds corresponds to only 1.5 inches of glass fill height. However, significant scatter existed in the delta from canister to canister. The maximum differential was 120 pounds which corresponded to 3 inches of glass fill height. These results suggest that weight alone as an indicator of fill height has an uncertainty on the order of 2 inches.

TABLE IV

FREE VOLUME AND FILL HEIGHTS

The WAPS requires that the canister must be filled with glass to a height equivalent to at least 80% by volume of the empty canister. For a DWPF canister, 80% corresponds to a fill height of 86 inches.
The glass fill height was measured on S00146 and determined to be 90.2 inches. This corresponds to a canister that has been filled to approximately 84%.
The free volume of canister S00146 was determined to be 119.6 liters as described previously(3). The total volume of an empty canister has been estimated to be ~735 liters. Using this value, the glass occupies 83.7% by volume of this canister. Both free volume and fill height measurements indicate that the acceptance requirement was met.
For a Westinghouse built canister which uses stainless steel plate for the cylinder, the typical wall thickness is 0.43 inches and the diameter averages ~ 23.95 inches. Canister S00146 was representative of these dimensions. Using these dimensions, the volume occupied by a 1 inch thick section of the canister was calculated to be 6.86 liters. The measured density of the glass from canister S00146 was found to be 2.695 g/cc.(4) Therefore, each one inch section of the canister, with no voids, should contain 40.7 pounds of glass.
The DWPF canister has a reverse dished bottom which reduces the volume of glass a canister can hold. In addition, the bottom head has a thickness of 0.5 inches. Since the fill height is measured from the bottom of the canister, the amount of volume excluded by the dished bottom and wall thickness can be estimated to accurately determine the glass volume. The excluded volume for the bottom skim cut was calculated to be approximately 4.1 liters, while the half inch wall thickness causes an additional 3.43 liters to be excluded. Therefore, the total volume excluded is 7.53 liters. This corresponds to a 1.1 inch slice of the canister.
For canister S00146, the fill height was measured at 90.2 inches. Therefore, the amount of glass present should be:

(90.2 - 1.1) 40.7 pounds/inch = 3626 pounds.

The measured weight of the glass at TNX was 3606 pounds. This corresponds well with the calculated value, but it does not take into account two factors. First, a void (shrinkage cavity) was detected in this canister several inches below the top surface of the glass. This void was not spherical, but was approximated to be a sphere of 7 inches in diameter. Therefore, the approximate calculated volume would be 3 liters. This corresponds to ~17 pounds of glass which must be subtracted from TNX measured weight (3606 pounds) and brings the calculated and measured values even closer together. The other factor was the fill height itself, since the top surface was concave. As the canister wall was approached from the center axis, the glass fill height increased slightly. It may have decreased again at the wall, but it was difficult to determine since numerous pieces of glass had broken away from the top surface. This latter effect, although small, has not been accounted for in this analysis.
The fill heights of a total of five canisters were measured at TNX. Measurements were performed using standard measuring devices after the nozzles had been removed from the canisters. The distance to the glass surface was measured four times at 90 degree intervals around the base of the canister nozzle, therefore all measurements were towards the center of the canister (in the concave region). These four

measurements were then averaged and compared to the fill heights calculated from the canister weights using the 40.7 pounds/inch factor, as above. The measured and calculated fill heights are shown in Table V.

TABLE V

The maximum difference between the measured and the calculated fill heights was 1.1 inches which along with the data on free volume, indicates that no significant glass porosity or voids existed in the canisters.

DEW POINT OF THE GAS WITHIN THE FREE VOLUME

The dew point of the gas within the free volume space of canister S00146 was measured as previously described(3). The dew points obtained with the two hygrometers (calibrated the hygrometers within + 2C) were:

Hygrometer #1: 5.1C

Hygrometer #2: 2.6C

Average dew point: 3.9C

The dew point was also monitored as a function of internal gas pressure. This was accomplished by slowly pumping the system and monitoring the dew point as a function of gas pressure. The dew point (hygrometer # 1) fell from 4.9C at 700 Torr to 3.0C at 600 Torr to 0.9C at 500 Torr. The partial pressure (vapor pressure) of water in gas is a linear function of the overall gas pressure. Hence the dew point should fall as the pressure is reduced. The measured dew points as a function of overall pressure followed this expected dependence.

The observed dew point within the canister is evidently dependent on the dew point of the air within the melt cell. The temperature and relative humidity for the melt cell when each canister was sealed was recorded and is shown in Table VI.

TABLE VI

Canister S00146 was sealed at a dew point of 13C in the melt cell. If the dew point in the melt cell at the time of sealing was higher, then the dew point in the canister free volume space is expected to be higher. The dew point in the melt cell at the time of sealing was higher than 13C for all but one of the other canisters. This implies that the other canisters have dew points within the free volume greater than 0C. It is important to control the dew point of the gas within the canister free volume. If the temperature of the canistered waste forms within the Glass Waste Storage Facility at SRS reaches 0C, then dew will form on the inside walls of the canister for those canisters having dew points greater than 0C. The concern here is that liquid water can lead to corrosion of the canisters.

The leak rate from the ICC seal of S00146 was 2 x 10-5 atmcc/sec for helium, a rate which is an order of magnitude less than required for this seal. (See section on ICC Leak Rates before and after Decontamination). Therefore, it has also been demonstrated that no significant inleakage of water occurred during the decontamination process.

INTERNAL PRESSURE OF THE GAS WITHIN THE FREE VOLUME

The internal gas pressure of S00146 was measured as 741 Torr at 31C. Since the waste acceptance criterion limits the internal gas pressure at a temperature of 25C, the measured gas pressure of 741 Torr was converted to a pressure at 25C. This pressure became 726 Torr (0.96 atm or 14.0 psi) at 25C, which readily meets the acceptance requirement of a pressure less than 1.5 atm or 22 psi at 25C immediately after filling and sealing.

COMPOSITION OF THE GAS WITHIN THE FREE VOLUME

Mass spectrometric data obtained on the air within the free volume of canister S00146 did not reveal any compounds, other than air, within the sensitivity of the equipment. The acceptance criterion of the WAPS is: No detectable foreign materials present in the free gas. Therefore this acceptance criterion was met. Scans of the canister free volume gas were obtained using a mass spectrometer from 1 to 200, 1 to 50, 40 to 95, and 90 to 200 mass units. These data were compared to equivalent scans taken from room air, which was considered the standard since the gas within the free volume space of the canistered waste form should contain only air from the melt cell. Consequently, the mass spectrometer was looking for changes between the composition of the gas within the free volume and within the room air. The only difference noted was in the amount of carbon dioxide present. Relative to Argon 40,

approximately 25% less carbon dioxide was present in the canister air than in room air.
Scans using a multiplier to increase the sensitivity were also performed from 90 to 200 and 45 to 90 mass units. These regions were where detection of foreign materials would be expected. These data were again compared to the scans obtained with air, and no differences were noted.
Sensitivity of the Extrel Questor II process mass spectrometer was estimated in two ways. The first method used isotopes of argon as a sensitivity indicator with Ar-38 present at ~ 6 ppm. For organics, benzene concentrations of 1, 10, and 100 ppm in air were used. Both techniques demonstrated sensitivities less than 10 ppm, with an estimate of 5 ppm. Hence, detection of foreign materials was bounded by this sensitivity.
CONCLUSIONS
The results of the testing on canistered waste forms produced during the first campaign of Startup Testing at DWPF have demonstrated that the DWPF is ready to continue on with the next four Waste Qualification campaigns.

ABSTRACT
The Department of Energy's Radioactive Tank Waste Remediation Focus Area is integrating the management of technology development for the remediation of the radioactive waste tanks across the DOE complex. The Focus Area is organized to address the key technology development needs in the areas of Structural Integrity and Waste Analysis; Waste Dislodging and Conveyance; and Waste Pretreatment and Processing. These efforts are directed towards demonstrating innovative technologies which will reduce costs, enhance worker safety, and/or enable the safe remediation where technological solutions are currently unavailable or inadequate. The Tank Waste Focus Area is developing sensors that will minimize the handling of samples for laboratory analysis, alleviating the safety concerns associated with handling. To assist in planning for retrieval of the waste from the tanks, technologies to map the interior of the tanks are being developed. Remotely controlled waste retrieval systems, that are capable of dislodging the sludge and saltcake fractions of the wastes and conveying the dislodged waste out of the tanks are also being demonstrated. The separation technologies under development will separate tank wastes into low-level, TRU and high-level fractions, thereby significantly reducing the volumes of high-level wastes requiring costly treatment and disposal. Low-level waste (LLW) treatment technologies are also being demonstrated to reduce waste

volumes and produce waste forms which are chemically and physically durable. Examples of the technologies in each of these areas will be discussed.

INTRODUCTION

Radioactive and hazardous wastes, generated from the production and processing of nuclear weapon materials, have been stored in more than 330 underground storage tanks (USTs) nationwide across the Department of Energy (DOE) complex beginning in the 1940's. The majority of the waste, over 400,000 m3 (100 million gallons), is stored at five DOE sites: the Hanford site in Richland, Washington; the Fernald site in Ohio; the Idaho National Engineering Laboratory near Idaho Falls, Idaho; the Oak Ridge Reservation in Tennessee, and the Savannah River Site in South Carolina. The remediation of these tanks is specified in compliance agreements for each of the sites. Specific remediation milestones and requirements have been established for each site. At Hanford, for example, recent renegotiations of the Tri-Party Agreement (TPA) (between DOE, the EPA, and the Washington Department of Ecology) have revised the cleanup strategy and timetable.

Two waste storage tank design types are prevalent across the DOE complex: single-shell wall and double-shell wall designs. The tanks are made of stainless steel, concrete, and concrete with carbon steel liners, and their capacities vary from 5,000 gallons (19 m3) to 106 gallons (3,785 m3) (see Fig. 1). The tanks have an overburden layer of soil ranging from a few feet to tens of feet. The physical and chemical compositions of the wastes vary from tank to tank. Tank waste consists of several physical forms: sludge, supernate, and salt cake. Most of the waste is alkaline, and contains the following major chemical constituents: nitrate and nitrite salts (approximately half of the total waste), hydrated metal oxides, phosphate precipitates, and ferrocyanides. The 640 MCi of radionuclides are distributed primarily among the transuranic (TRU) elements and fission products, primarily 90Sr and 137Cs. In-tank atmospheric conditions vary in severity from near ambient to temperatures over 93oC, and tank void-space radiation fields can be as high as 10,000 rad/h.

Fig. 1.

In response to the need for remediating UST waste, the DOE Office of Technology Development created the Underground Storage Tank Integrated Demonstration in 1991. Planning for the remediation of DOE's radioactive waste tanks has also been the responsibility of the DOE Offices of Waste Management and Environmental Restoration. As part of its "New Approach to Technology Development", DOE created the Radioactive Tank Waste Remediation Focus Area in 1994 to integrate and coordinate the tank waste remediation technology development efforts throughout these Offices. The mission of the Focus Area is to develop and apply technology systems, using an integrated approach, to safely and efficiently accomplish tank waste remediation across the DOE complex. The near term goal of the Tank Waste Focus Area is to demonstrate the ability to retrieve and treat liquid tank waste by June, 1997. The ultimate goal is to demonstrate and deliver safe and cost-effective solutions that meet regulatory requirements and are acceptable to the public and other stakeholders. The Tank Waste Focus Area also strives to develop industrial partnerships and to encourage the commercialization of the technologies developed. To meet these goals, DOE has established a Focus Area management team that brings together technology developers (from the Office of Technology Development) and representatives of the organizations that will manage the remediation (the Offices of Waste Management and Environmental Remediation). DOE has also selected an "Implementation Team Lead Organization" to lead the technology development in the Field. For the Tank Waste Focus Area, DOE's Richland Operations Office, in collaboration with other Operations Offices, has been designated as the Lead Organization. Technical leadership is provided by the Pacific Northwest Laboratory, teamed with other National Labs.

The Tank Waste Focus Area has focused its technology development on those fields where currently available technology does not meet the technical and safety requirements for tank waste remediation. Efforts are also being conducted to enhance baseline technologies and develop technologies that may be needed should existing technologies prove inadequate. The Focus Area seeks to integrate the development activities across DOE's EM Offices so that site specific problems are addressed from a national perspective. The fundamental problem areas that are shared by most of the participant sites and have been designated as sub-program elements are: Structural Integrity and Waste Analysis; Waste Dislodging and Conveyance; and Waste Pretreatment and Processing. Characterization of tank wastes has historically been

very expensive, and has failed to obtain representative data for many tanks. The Tank Waste Focus Area is developing sensors that will enable in-situ waste analysis and minimize the handling of samples during laboratory analysis, alleviating the safety concerns associated with handling. To assist in planning for retrieval of the waste from the tanks, technologies to map the interior of the tanks are being developed. In collaboration with the Robotics Crosscutting Program of OTD, the Tank Waste Focus Area is developing remotely controlled waste retrieval systems, that are capable of dislodging the sludge and saltcake fractions of the wastes and conveying the dislodged waste out of the tanks. These devices are designed to fit through access ports as small as 12 inches in diameter, and work in highly radioactive environments. Waste separation techniques will separate tank wastes into low-level, TRU and high-level fractions, thereby significantly reducing the volumes of high-level wastes requiring costly treatment and disposal. Low-level waste (LLW) treatment technologies will reduce waste volumes and produce waste forms which are chemically and physically durable. The following sections will discuss each area in some detail.

STRUCTURAL INTEGRITY AND WASTE ANALYSIS

Safe remediation of high-level waste from tanks is impossible without knowledge of waste's chemical and radioactive composition, and basic physical parameters. A goal is to obtain the majority of this information on an in-situ basis. In addition, information is needed on the physical location of the waste surface, the tank walls, and any obstructions (e.g., risers) within the tank. This requires the development of innovative methods for placement of sensors into the tanks and their subsequent positioning within the tank.

Chemical Speciation

The waste analysis projects are focused on developing technologies which identify the chemical speciation, moisture content, and rheological properties, such as density and viscosity, of the waste. Tank waste characterization currently involves removing core samples from each tank and subsequently evaluating these samples in a hot cell. Retrieval and analysis of a single core sample can take up to six months and cost more than a million dollars. In-situ characterization technologies will significantly decrease the cost and time required for analysis. In addition, in-situ methods will reduce worker exposure and be much safer than any methods which require direct handling and transportation of high-level waste. In-situ analysis is also expected to better measure the characteristics of the waste as it exists in the tanks.

Chemical speciation analysis methods currently being developed include spectrographic methods, such as Laser Raman and infrared. One method analyzes the Raman shifts in scattered light to identify and quantify chemical compounds, while the other utilizes vibrational spectroscopy in the near-infrared (NIR) region to detect moisture levels. While Raman spectroscopy will not replace regulatory approved analytical methods, its development as a screening technique for both ex-situ and in-situ characterization offers a significant reduction in time, cost, and secondary waste generation, minimizes radiation exposure to personnel, and provides a valuable guide to the sampling and analysis of core waste material. Remote measurements in harsh chemical and radioactive environments are made possible with the use of rugged fiber optic cables and probes, which transmit light to the waste and the signal to the spectrograph.

In-situ characterization of core sections will be achieved with the use of a Raman fiber optic probe fitted inside a cone penetrometer. Such a probe is being developed at the Lawrence Livermore National Laboratory. Another potential in-situ use is for chemically profiling the waste surface inside a tank. The feasibility of applying laser Raman spectroscopy to tank waste characterization is being demonstrated with both non-radioactive (cold) and radioactive (hot) tests. Analyses of pure materials and surrogates show that Raman scattering can be used to identify major waste components, including ferrocyanide, ferricyanide, nitrates, and nitrites. In addition, a remote fiber optic probe was installed in a radioactive-test cell (hot cell) at Hanford and is being used to record Raman spectra of real tank waste material. Two hot cell campaigns provided operational experience and spectral data for tank waste materials, some of which have significant fluorescence. Stable, high powered laser diodes (785 nm emission) were ordered as a means to mitigate the fluorescence. A 0.4 watt, high power doubled NdYAG laser was successfully integrated into the cold Raman test system. Probe testing was completed with four fiber optic

probe designs including two commercially available probes. The result indicated that in-line filters were effective in reducing silica Raman noise and that probe field-of-view is a strong sensitivity issue with slurry materials.
A non-contact, imaging Raman spectrometry system for the rapid chemical screening of underground storage tank wastes is also being developed by the Lawrence Livermore National Laboratory. The basis of this system is an optical field-of-view Raman surface scanner coupled to an imaging spectrograph with a two-dimensional array detector that provides spatially resolved chemical information about the tank waste material. The spatial data will be used to provide a chemical map of the waste surface. Fiber optics will be used to provide the remote interface between the tank waste environment (i.e., either hot cell for core samples, or in tank for in-situ waste analysis) and external instrumentation. The non-contact imaging scanner optical head is being designed to be compatible with both existing Raman hot cell systems at Westinghouse Hanford Company and commercially available units. The potential for using the non-contact imaging system with other spectroscopic techniques is being explored.
A prototype, laboratory bench-top model of the non-contact imaging Raman core scanner has been constructed and its utility in the chemical characterization of mock core samples has been demonstrated. The ability of the system to characterize the two-dimensional surface of a sample has been shown. A comparative study between the single point, contact fiber optic Raman probes and the laser scanning, non-contact imaging Raman spectroscopy has been performed. Factors considered in the comparative study were: available laser power at the sample, the effect of distance from the sample surface to the collection, the effect of background lighting, the interference from background Raman scattering, and other method-specific interference. The detection limit of ferrocyanide was established for each technique. The non-contact method proved to be more sensitive by an order of magnitude (resolution of 0.01 weight percent ferrocyanide).
The Westinghouse Savannah River Company at the Savannah River Technology Center has developed a Near-Infrared (NIR) spectroscopy system with a fiber optic probe, to measure the moisture content of the tank waste, an important safety parameter when ferrocyanide is present. The moisture system is being developed for both hot cell and direct in-situ waste applications. NIR spectroscopy is a well established technology, with many commercially available components and modules. Water normally interferes with IR analysis due to its strong optical absorption bands located around key vibrational absorption bands. With the NIR system, the water concentration of the tank waste is determined from the optical spectra back-scattered from the waste surface. The moisture-sensing system uses a calibration model developed with partial least squares fit analysis from standard materials having known moisture content. The spectra from unknown samples are then processed using this mathematical model to produce a water content value.
The initial testing of this moisture sensing method with tank simulant materials has been completed. The calibration model was built and tested with four waste tank simulants that are chemically and physically representative of the tank salt cake and slurry mixtures found in Hanford's underground storage tanks. The NIR system correctly predicted moisture within a 5 wt% error for all four tank materials. The errors were reduced to 2 to 3 wt% when the composition of the samples closely matched those used to build the model. These moisture measurement errors are well within the requirements to establish the safety status of a waste tank containing ferrocyanide materials.
Surface Topography
Knowledge of the topography of the waste in the tanks is needed prior to the deployment of in-situ sensors and during the retrieval operations. Two methods are being developed to address that need. The laser range finder (LRF) will provide rapid but coarse mapping of the tank interior. A structured light technique will be used for detailed mapping of the tank interior. Structured Light and Laser Range Finder technologies are well established and are based on relatively simple concepts. Essentially, the hardware consists of a laser, a receiver (such as a camera), and data processing equipment.
For the structured light system, the position and direction of propagation of the laser beam is known and controlled. The camera shows the two-dimensional projected position of the beam on the surface to be mapped. Simple trigonometric calculations are performed to determine the position of the surface. In comparison to the Laser

Range Finder, the structured light approach is slower, but gives a much finer resolution in all three dimensions. The Structured Light System has been demonstrated to perform with an accuracy and repeatability of better than 0.5 inch in field testing. It can be used to map the interior of the tank, including the surface contour, the condition of the walls and dome, and the location of in-tank hardware. The Structured Light Surface Mapping System will be deployed through either single or multiple risers. In the case of multiple riser deployment, the laser and the camera are inserted in separate risers, giving a very accurate and efficient "pitch and catch" set-up. For those cases where it may be necessary to deploy the entire system through a single penetration, the system will be capable of being deployed through a single 4" riser, albeit with some loss of accuracy and detail. In 1992, a surface mapping system based on the structured light approach was deployed at Fernald to map waste surfaces in the K-65 silos. The system contributed significantly to the successful completion of a CERCLA Removal Action Milestone in December 1993. The successful field deployment of structured light technology at Fernald made it highly desirable to both commercialize the technology and transfer it to the Hanford site.

The Laser Range Finder has a lower resolution than the structured light system, but is capable of providing near real time images. These capabilities qualify it for use in supervisory control and/or periodic surveillance. The laser range finder uses a laser to measure the distance to an object. Given the distance to this object in a known (controlled) direction, the position of the object in space is easily calculated. In each of these cases, from the measurement of multiple points, a three dimensional image of the object and its position can be determined. The Laser Range Finder is based on an existing piece of commercial hardware and appears to be well suited for use in tanks. Data fusion capability is being developed to combine data from the Laser Range Finder and Structured Light systems to provide an integrated map, which will aid in path planning and collision avoidance. Each of these systems will be radiation-hardened to allow for longer in-tank time and therefore, higher resolution. Along with the hardware, software is being developed to aid in data acquisition and control.

Deployment Platform

These characterization and surveillance instruments will be deployed and positioned within the tanks using a remotely operated robotic arm. This Light Duty Utility Arm (LDUA) (Fig. 2) will operate as a versatile platform in a high-level waste environment, and therefore will be hardened against the hostile elements (radiation, caustics, water vapor, etc.) present in the tank surroundings. The LDUA will be an integrated robotic deployment system to perform inspection, surveillance, waste analysis, and small-scale retrieval tasks in underground storage tanks. The LDUA system will provide a mobile multiaxial positioning system that will access the tanks through existing 12 in. diameter riser penetrations located in the tank dome. Other ancillary system equipment will be deployed through existing 4 in. diameter riser penetrations. The system provides the capability to deploy remotely operated end effectors at multiple elevations and positions within the tank using a robotic manipulator arm mounted on a telescoping mast. The arm will provide seven degrees of freedom with a 13.5 foot reach. The LDUA has been designed and is currently being fabricated by SPAR Aerospace, the Toronto-based company known for constructing the Space Shuttle Arm. The support system design has been completed and a trailer is being outfitted for field use. Most of the control and data acquisition systems have also been procured. The trailer instrumentation will be installed and tested, and the first LDUA system completed by the fall of 1995. Currently, in addition to the LDUA demonstration at Hanford planned by the Tank Waste Focus Area, LDUA systems are being obtained for use at Idaho and Oak Ridge.

Fig. 2.

Leak Detection

An acoustic emission method is being developed to detect and locate leaks in underground pipeline systems. This technology will be employed also as a process monitoring tool during the tank waste retrieval campaign. Leaks in underground pipeline systems can be located using the characteristic soundwaves generated by the flow of fluids (either liquids or gases) through a hole. The difference in primary or secondary line pressure and the environment causes flow into the secondary line or the environment (depending upon the location of the leak). Sound-sensitive sensors placed along the entire length of the pipeline transform sound (mechanical)

energy from the leak to electrical energy. These electrical impulses are evaluated by a signal analyzer to determine the distance of the signal source from a known reference point. Various types of acoustic sensors intended for use in the proposed system have been tested to determine their anticipated life expectancy when subjected to radiation fields. This established a service life cycle for sensors attached to radioactive waste piping.

WASTE DISLODGING AND CONVEYANCE

Unlimited sluicing, adding large quantities of water to suspend solids, is the baseline method for sludge removal from DOE's tanks. However, since the consistency of the waste varies from low viscosity liquids to peanut butter-like sludges to hard, concrete-like solids, this process may not be capable of removing all of the material from the tanks. Also, the resulting dilution increases the volume of waste significantly. Most importantly, dilution may increase the risk due to the existing and potential leaks of hazardous and radioactive liquids from corroded and deteriorated tanks into nearby soils and groundwater.

The Waste Dislodging and Conveyance task of the Tank Waste Focus Area is developing tools for the removal of materials from these tanks. The working tools and removal devices being developed include rubblizing devices, cutting and extraction tools, water and air jets, grit blasting devices, waste conditioning devices, transport and conveyance devices, suction devices, monitoring devices, and various mechanical devices for the recovery or repair of waste dislodging and conveyance tools. For some retrieval operations it may be necessary to add small amounts of water to facilitate waste dislodging and removal. However, systems are being optimized to minimize the amount of water added to tanks, and to position the conveyance equipment deployed with the dislodging equipment to remove solid waste and free liquid as promptly as possible. Dislodging and conveyance tools will ultimately be deployed as end effectors on a remotely operated, articulated arm called the Long Reach Arm, being developed by the Office of Technology Development's Robotics Crosscutting Program.

The systems being developed use water jet technology to dislodge the waste while simultaneously conveying the waste and the used water to the surface by pneumatic or air conveyance systems. The deployment of high-energy and low flow-rate tools with concurrent suction will minimize secondary waste. Since no additional stress is placed on the structure of the tanks, these technologies are ideally suited for use in older tanks which may have weakened or damaged structures. Currently, two such tools are being demonstrated. The scarifier uses ultra-high-pressure water jets (40,000 to 50,000 psi) in a dislodging tool coupled with a pneumatic transport system. The miner uses medium pressure water jets (5,000 to 11,000 psi) coupled with jet pump transport. These waterjet technologies have been used to meet compliance milestones in the TPA at Hanford. The program has demonstrated a half-scale high-pressure scarifier at a waste removal rate of 2 ft3/min., half that of the target full-scale retrieval rate of 4 ft3/min.

The Tank Waste Focus Area, in cooperation with the Robotics Crosscutting Program, is developing an Integrated Hydraulics Testbed at Hanford. This system will characterize aspects of waste dislodging and conveyance processes, evaluate process equipment performance, and address integration issues associated with deployment of dislodging and conveyance systems by a manipulator arm. A fundamental understanding of the mechanics of dislodging and mobilizing waste will also be developed . The Testbed will enable longer duration, multiple-pass tests on a large area of simulated waste. The components can be deployed over all three dimensions to facilitate modeling of the behavior and response of various deployment control systems. A final test plan has been completed and the gantry robot for the testbed has been received by Hanford, and mechanics, hydraulics, and simulant testing will begin in 1995.

WASTE PRETREATMENT AND PROCESSING

The treatment and disposal of DOE's high level waste (HLW) is expected to be costly and presents many difficulties due to the high radioactivity, the variability in composition, and the number of different chemical components. A primary objective of DOE's technology development for tanks is to remove radionuclides and minimize the volume of the HLW final waste form (e.g., glass). The remaining LLW will then be eligible for near-surface disposal. Since the radionuclides constitute only a small portion of the waste, separations technologies offer promise to accomplish this goal. Performance of new and improved waste forms for the solidification and

disposal of LLW will also be evaluated.
Separations
In retrieving, processing and disposing of these wastes, separation technologies are the primary means to concentrate the radionuclides so that the volume of high level waste to be vitrified is minimized and the activity of the residual waste is reduced to make it eligible for near surface disposal. It is estimated that the volume of waste to be vitrified can be reduced by a factor of between 10 and 200 using advanced separation technologies. Removal of the radionuclides also reduces shielding requirements and makes further processing of the hazardous components of the waste safer, more efficient, and less expensive. The Tank Waste Focus Area is demonstrating separations systems and utilizes the technologies being developed in the Efficient Separations Crosscutting Program. Technologies will be demonstrated for the treatment of HLW supernate, sludges and acidic wastes.
The presence of radioactive cesium and strontium (e.g., 137Cs) is a major source of beta and gamma activities in high level wastes found in underground storage tanks. Ion exchange is one of the proposed technologies to remove cesium and strontium from these wastes. Due to the somewhat unique chemical characteristics of the tank wastes (i.e., extremes of pH and high ionic strength), most common ion exchangers are not suitable for this processing. The Savannah River Site (SRS) has developed a resorcinol-formaldehyde ion exchange resin for cesium removal. The resin has been demonstrated to have a high capacity for removing Cs and to be compatible with the extreme characteristics found in the Hanford and SRS tank wastes. In particular, the resorcinol-formaldehyde resin is found to have 10 times the capacity of the Duolite CS-100 phenol-formaldehyde resin. Currently, the resorcinol-formaldehyde resin is being demonstrated in column mode with a tank waste simulant. Engineering-scale tests will also be run on the Skid-mounted Ion exchange Demonstration (SKID) unit at the SRS. The resulting data will be critical in determining the optimum processing conditions (e.g., flow rate, elution volume and eluent). The data will also aid in the design of a modular, mobile ion exchange system for the extraction of cesium from alkaline tank waste, such as will be used for a Cesium Removal Demonstration. Recently concluded radiolysis studies on the resin suggest that the resin is stable up to a dosage of 5 x 108 rad, and a higher dosage causes some loss of extraction efficiency in a high pH environment, but not in water.
The Tank Waste Focus Area is planning a Cesium Removal Demonstration in 1996, using the high salt content supernate stored in the Melton Valley Storage Tanks (MVST) at Oak Ridge. The project will demonstrate the use of a modular, mobile, ion exchange system, using existing facilities for secondary containment, the offgas system, and support functions such as utilities. Decontamination for contact maintenance and the ability to transfer of the unit to other DOE facilities will also be demonstrated. The ion exchange material will be chosen based on its effectiveness in laboratory batch tests and small scale column tests using both simulated and actual waste supernates.
If the content of Transuranic elements (TRU) in TRU waste streams can be reduced to below 100 nCi/g, the waste can be classified as non-TRU. The TRUEX process is a solvent extraction process developed to separate the TRU components from aqueous solutions. Use of the TRUEX process may also reduce the volume of high-level waste, resulting in high cost savings during disposal. The Generic TRUEX Model (GTM) is a user-friendly computer software that models and predicts the TRUEX extraction behavior, calculates TRUEX flowsheets, and estimates space and cost requirements for installation. The GTM runs on a personal computer (IBM-compatible or Macintosh) using commercial spreadsheet software. The objective of the current task is to validate and refine the GTM's ability to design flowsheets for specific feeds and process goals and to predict extraction behavior of feed components and potential processing difficulties. This task will also discover and identify R&D needs for preparing TRUEX for broader implementation. The TRUEX processing of actual HLW and TRU wastes at Oak Ridge National Laboratory (ORNL) will validate the GTM.
The Tank Waste Focus Area has initiated a technical interchange between the US DOE and the Commissariat l'Energie Atomique (CEA) in France continues to examine the technical problems associated with the removal of actinides from acidic waste streams. In addition to the acidic wastes at INEL, large volumes of acidic wastes may be produced if Hanford, Savannah River, and Oak Ridge pursue acid dissolution of their sludges. This exchange is focusing on the French DIAMEX process which uses diamides as extractants to remove the actinides. This process will be evaluated

against comparable US extraction technologies, such as the TRUEX process.
Pretreatment
Fine particulates suspended in liquid wastes have a harmful effect on radioactive waste treatment processes such as ion exchange. These effects include ion exchange bed fouling, reduced removal efficiencies, higher shielding requirements, premature breakthrough of radioactive particulates, and interference of downstream waste disposal processes. Treatment processes for aqueous high level wastes are expected to require pretreatment to separate insoluble solids from the liquid. Crossflow filtration has been demonstrated as an efficient method to remove insoluble solids. The Tank Waste Focus Area is integrating laboratory scale filter testing with actual full scale operation to permit correlation between units and comparison between simulant and actual waste. The filtration needs of the proposed pretreatment processes for the underground storage tank wastes at Hanford and Oak Ridge will also be evaluated, to determine the best applicable filtration technologies.
The only tanks at Oak Ridge that comply with the Federal Facility Agreement between DOE, EPA and the Tennessee Department of Environment and Compliance are the double shell tanks. Evaporators offer the possibility of removing water from the waste in the double shell tanks, so waste from noncompliant tanks can be moved to compliant tanks. The alternative to evaporation would be to solidify the waste in noncompliant tanks, which produces a waste form for which there is currently no permitted storage. The Tank Waste Focus Area is developing an evaporator to remove excess water from a 4 to 5 molar sodium nitrate solution contaminated primarily with 137Cs and 90Sr at activity levels of about 8 mCi/l and 0.2 mCi/l, respectively. The project will evaluate the relationship between the performance of pilot scale evaporators processing surrogate solutions, and full scale units processing actual waste. It will also determine processing capabilities (such as decontamination factors), identify potential operating/maintenance problems for remotely operated evaporators, and evaluate the feasibility of decontaminating evaporator systems for hands-on maintenance and the possibility of moving the unit to another site.
An evaporator demonstration will be conducted at ORNL in late 1995 to process 25,000 gal of liquid LLW supernate from the Melton Valley Storage Tanks. The demonstration will return 19,000 gallons of concentrated waste to the tanks, and 6,000 gallons of condensate to the lab's process waste system. Technical specifications for the evaporator system were developed and the contract was awarded to Delta Thermal in October, 1994. Modifications to the System Safety Analysis for the facility that will house the evaporator have begun. The Oak Ridge Engineering Division has begun work on a feasibility study to define requirements for the installation of the evaporator system.
Solidification
The reference waste form for LLW at most sites has been a cement-based grout; however, this increases the volume requiring disposal, does not effectively retain certain contaminants, and has questionable long-term stability. Alternate waste forms must therefore be tested and evaluated. The Tank Waste Focus Area is testing ceramic waste forms for their ability to decrease waste volume, reduce processing and disposal costs, and enhance performance and long-term stability. Hanford has recently changed its reference LLW form from grout to glass.
The Nitrate To Ammonia and Ceramic (NAC) (Fig. 3) process involves chemical reduction of the nitrate contained in the mixed (hazardous and radioactive) tank waste and solidification of the waste. In this process, aluminum metal is used to reduce the nitrate, and silica is added to produce an alumina-silica ceramic. The nitrate-free ceramic product is then calcined, pressed, and sintered into a final waste form that is expected to pass leach tests. The NAC process can achieve concentrations of nitrate below drinking water standards. It is expected that radioactive species such as plutonium and strontium will enter the solid ceramic phase during the reduction of the nitrate anion. Sodium will be retained in a nepheline ceramic phase. In the process, radioactive contaminated scrap aluminum from various DOE sites could be shredded and used as feed to the NAC reactor. An additional advantage of the process is a reduction in the final waste volume of 55 to 75 vol% (as compared to a 30% to 40% volume increase by grouting). Laboratory experiments have demonstrated the feasibility of this process. The process was initially developed by the Oak Ridge National Laboratory, and Florida International University (FIU) is working with ORNL on further development.
Fig. 3.

CONCLUSION

The Tank Waste Focus Area, in collaboration with the National Laboratories and with university and industrial partnerships, is developing, demonstrating, and incorporating innovative technologies into DOE tank remediation baseline planning. Current demonstration activities are designed to meet regulatory milestones and ensure that proven technologies are available to meet the remediation requirements throughout the DOE complex. Where possible, demonstrations are progressing from non-radioactive testing using surrogate wastes to the use of lower radioactivity samples, e.g., at the Oak Ridge site, with eventual demonstration in the harsh, high radioactivity environment of the wastes at Hanford, INEL, and Savannah River. Besides solving DOE underground storage tank problems, the tools and technologies being developed and demonstrated are designed to facilitate their transfer to the private sector. Most of the technologies being evaluated have private sector partnerships and commercial applications of these technologies are being explored. At least four improved technologies/systems will be made available for transfer to industry during FY 1996. By bringing together the technology developers, customer organizations, and stakeholders, the Tank Waste Focus Area is establishing a streamlined development program that will provide cost effective solutions for use throughout DOE and at private facilities.

SEGREGATION OF SOLID LOW LEVEL RADIOACTIVE WASTES AND UNCONDITIONAL RELEASE FROM CHALK RIVER LABORATORIES

Pauline G. Hartwig

Environmental Research Branch

AECL Research

Chalk River Laboratories

Chalk River, Ontario, Canada

ABSTRACT

Currently in Canada, a number of programs have been designed to reduce the volume of Low Level Radioactive Wastes (LLRW) that must by stored in licensed radioactive waste management facilities. These wastes arise from operation of nuclear generating plants and research facilities, medical and industrial uses, and the decommissioning of nuclear facilities. The waste volume reduction programs are based on exempting certain LLRW from further licensing upon transferral for disposal, or on segregating wastes into either "releasable" or LLRW categories based on criteria that have obtained prior regulatory approval.

The design and construction of a pilot-scale study is now underway to demonstrate the cost-effectiveness and technical feasibility of segregation and unconditional release of solid wastes from AECL Research Chalk River Laboratories (CRL). Prior to program design at CRL, a study was conducted to examine three cases of de minimis/LLRW Segregation Programs that have been successfully implemented in Canada. For each case, the release criteria adopted, the procedures and instruments used in segregation or release, and the nature of the regulatory approval process were studied. Based on these cases, waste scanning procedures and a pilot plant layout were proposed for CRL.

REGULATORY POSITION

The nuclear regulatory body for Canada is called the Atomic Energy Control Board (AECB). The current position of the AECB on the exemption of radioactive materials from further licensing upon transferral for disposal is summarized in Regulatory Document R-85. R-85 states that when the circumstances of such disposal are considered to represent a negligible, or de minimis risk, expenditure of additional regulatory resources, or continued licensing of the material, is not justified. The AECB uses a de minimis dose of radiation to individuals of 0.05 millisievert in a year for deciding such exemptions on a case-by-case basis, provided that the radiological impact will be localized and the potential for exposure of large populations is small. (AECB, 1989)

The primary de minimis dose criterion of 0.05 millisievert per year follows from the acceptance of a corresponding de minimis health risk. The choice of a de minimis dose criterion of 0.05 millisievert to an individual per year represents an

extrapolation from a fatality risk from cancer of 10-6. The secondary requirement, that the potential for exposure of large populations be small, is intended to restrict undue reliance on dilution as a means of attaining compliance with the de minimis dose criterion (AECB, 1989).
R-85 is applicable principally to the disposal of solid low-level radioactive wastes. Exemption from further licensing of miscellaneous liquid wastes is determined on a case-by-case basis. R-85 does not apply to liquid or gaseous emissions currently designated as effluent discharges in the operating licences issued by the AECB for various nuclear facilities.

RESULTS OF CASE STUDIES

Case 1: Bruce Nuclear Power Development (BNPD)

In March of 1987, AECB approval was granted for the segregation of active and inactive solid wastes from Bruce Nuclear Generating Station (BNGS) "A" using a waste bag monitor. This approval was granted prior to the issue of R-85, but represents nonetheless a de minimis-type approach to waste disposal in that the application for exemption was based on an assessment of radiological dose calculated from pathways analysis.
The conditions of the approval were:
1. the value of 11 kBq gross gamma activity, as measured with a bag monitor, was to be used to segregate active and inactive waste
2. the inactive waste must remain within the property boundaries of BNPD
3. regular random selection of sample bags and survey of their contents in detail as a quality control check of the process.
Bruce NGS "A" conducted a test operation in 1985/86 to demonstrate the viability of waste categorization using a Waste Bag Monitor. The test operation used National Nuclear Corporation's WCM-11 waste bag monitor, which contains 4 large plastic scintillators. The alarm setpoint used was 11 kBq per waste bag. Over 48,000 waste bags from all station Zones were surveyed. When handfrisked on the exterior of the bag for contamination, none of the bags classified as inactive by the waste bag monitor contained detectable contamination. The volume of waste classified as radioactive was reduced by 27%, or 360 m3/a. A further check on the efficiency of the waste bag monitors was conducted by incinerating all wastes classified as inactive. Just prior to incineration, all wastes were again handfrisked on the exterior surface of the bag and no contamination was found. The incinerator ash was compared to ash from inactive incinerations prior to the startup of the program, and no differences in radionuclide levels were found (Lemkay, 1986).
A modified waste handling procedure was proposed. Waste bags were initially screened with a medium range gamma meter. Bags with dose rates detectable on that meter, or bags that had fields greater than 10 mSv/h, were not put in the waste bag monitor. Waste bags that contained less than 11 kBq/bag according to the waste bag monitor were classified as inactive. Bags of inactive waste were incinerated. Data bases were used to record waste bag data and the inactive incinerator ash data. The data were summarized monthly to ensure that the residual radioactivity of the inactive waste remained at or below a level of 0.3 Bq/g (Lemkay, 1986).
Other data submitted to the AECB prior to approval included a simple public exposure pathways analysis and a method to infer the concentrations of pure beta-emitting isotopes (primarily 3H, 14C, and 90Sr), which would not be detected by the standard screening procedures (Lemkay, 1986). The calculated maximum exposure to a member of the public was 20 mSv/a, which is below the regulatory criterion of 50 mSv/a.
This program for the segregation of active/inactive solid wastes at BNGS "A" was still in place as of December 1, 1994 (J. Hudson, personal communication).

Case 2: Darlington Likely Clean Waste Management Program

Prior to the fall of 1992, all wastes originating in Zone 3 of the Darlington Nuclear Generating Station (DNGS), which consists of areas that contain radioactive systems and material, were treated as contaminated (Ontario Hydro, 1990). This procedure resulted in large volumes of materials, which were in fact at least 75% inactive, being sent to the BNPD Radwaste Site for storage as low level radioactive waste. In the fall of 1992, the Likely Clean Waste Management Program obtained regulatory approval and was initiated to permit free release of Zone 3 Likely Clean Waste to offsite landfill or recycling if it displayed no activity above background.
An important distinction between the Likely Clean program and the AECB criteria for exemption from regulatory control is that AECB R-85 allows for a de minimis dose rate of 0.05 millisievert per year to an individual, while wastes designated as

clean by the Likely Clean program are uncontaminated to the limit of detection of the instruments and procedures in use (Hudson, 1993).
The first action in implementing the program was a source term analysis to establish the radionuclides potentially present in the waste streams. This allowed the selection of correct instrumentation for monitoring, and defined areas of the Station that were excluded from the collection of Likely Clean waste due to a higher risk of generating contaminated wastes. Periodic review of the source term characterization will be conducted.
Workplans, flowsheets, procedures and training materials were prepared for the Program, and staff dedicated to waste collection and processing/monitoring. A waste collection/segregation system for Likely Clean waste was set up in selected areas of Zone 3, and station staff were trained to include only items for which they knew the radiological history and which were expected to be free of contamination. At waste collection stations, waste bags are surveyed with a gamma meter, monitored for tritium and barcoded. A barcode reader/transaction manager is used to record each bag's barcode, including its point of origin, date and time of collection and name of the waste collector. Bags with gamma activity in excess of 10 mSv/h are rejected and enter into the active waste stream, and an investigation is conducted as to their point of origin and reasons for exceeding the criteria for Likely Clean.
A separate room was organized for the handling of Likely Clean waste, with a low background radiation level of approximately 50 nGy/h. All Likely Clean bags are deposited in the Clean Sorting room and stockpiled for 24 hours to allow any tritium in the wastes to reach an equilibrium air concentration inside the bag. The concentration of tritium inside the bag is then checked with a Triton tritium monitor, and any waste bags with tritium levels in excess of 0.5 Maximum Permissible Concentration in air , or MPC(a), are monitored in the bag monitor and then redirected to the active waste stream. Bags with <0.5 MPC(a) tritium are placed in the waste bag monitor to determine eligibility for hand sorting. The monitor reads the barcode, measures total and specific activity, and instructs the operator to redirect the bag to the active waste stream if the specific activity is greater than 74 kBq/kg. Each eligible waste bag is opened on a stainless steel sorting table that is equipped with a HEPA air filtration system. Wastes are handfrisked inside and out with an NE Technology CM7A contamination meter, which can simultaneously monitor alpha and beta/gamma contamination. The alarm setpoint on the CM7A is set at 29.6 Bq/100 cm2 for 137Cs. Any items with internal surfaces not directly measurable, materials displaying a radiation symbol, or items with activity above background levels are treated as active waste. Hand frisking is done at a maximum rate of 3 cm/s in order to ensure a detection capability of 55.6 Bq/100 cm2 at scanning speed. Handfrisking is limited to a maximum of two hours per person per day, and personnel must pass a written examination and practical training before they are qualified to work in the program. Items displaying no activity above background are sorted into recyclable or landfill categories. Landfill wastes are compacted and rebagged. A final quality assurance check is performed using a waste bag monitor with the setpoint at the intsrument's current Minimum Detectable Activity (MDA), which is usually about 240.5 Bq/bag for the 10 kg compacted bags. The landfill wastes are then released to offsite landfill. This program was still in operation as of December 1, 1994 (J. Hudson, Ontario Hydro, personal communication).
Case 3: Unrestricted Release Of Decommissioning Wastes, AECL CANDU Decommissioning Group (CDG)
AECB approval for unrestricted release for wastes arising from the decommissioning of Tunney's Pasture in Ottawa, Ontario, a former radioisotope production facility, was granted in March of 1992. Release criteria were based on unconditionally exempt levels for identified radionuclides extracted from the IAEA Working Document "Exemption from Regulatory Control Recommended Unconditional Exempt Levels for Solid Radioactive Materials"(IAEA, 1991). These levels are indicated in Table I.
TABLE I
The unconditionally exempt levels were established by the IAEA to apply to solid materials irrespective of the use to which they are put or to their destination after control has been relinquished. The levels are based on a review of the results of the exemption studies conducted on landfill disposal and incineration of wastes, and the recycle and reuse of ferrous and non-ferrous metals and concrete. These studies identified limiting radionuclides for detailed consideration in scenarios and exposure pathways. For the purpose of exemption, the level of individual dose

due to the sum of exposures from exempt practices of some tens of microsieverts per year was considered trivial. The dose to an individual from each exempt practice was to be in the order of 10 mSv/a. The general allowable surface contamination levels were 1.0 Bq/cm2 for beta/gamma emitters and 0.2 Bq/cm2 for alpha emitters. The averaging area was 1 m2, or the total surface area for smaller objects. A Ludlum scaler with an HP260 pancake detector was used for measuring small surface areas. A Berthold LB122 with a gas proportional detector was used for measuring large surface areas. As well, a Ludlum 2350 with a gas proportional detector was used. Loose contamination was detected from smears using a scaler with a shielded beta/gamma detector and another scaler with an alpha detector (J. Stapleton, AECL CANDU Decommissioning Group, personal communication).

In January of 1994, AECB approval was granted to the AECL CANDU Decommissioning Group for the segregation of radioactive wastes stored in a number of 28 m3 containers at Gentilly-1 Nuclear Generating Station in Quebec. These wastes were comprised mainly of non-compactible waste, primarily steel pipe, that were wrapped in plastic, and compactible wastes, primarily protective clothing and other consumable material. Wastes cleared for unconditional release according to the contamination limits agreed upon by the AECB underwent compliance inspection by an AECB inspector prior to release to offsite landfill. The compliance inspections involved one or more visits, sometimes unannounced, for verification of monitoring results, and were followed by approval to continue with offsite release without further inspection. However, metals cleared for unconditional release and destined for offsite recycling were to be stockpiled and verified by the AECB prior to all releases. For unidentified radionuclides, the release limits were <1.0 Bq/cm2 for beta-gamma emitters (137Cs equivalent), and <0.2 Bq/cm2 for alpha emitters (241Am equivalent). For identified radionuclides, the release limits were again based on values specified in the IAEA Working Document (IAEA 1991). Identified radionuclides known to be less radiotoxic, such as the pure beta emitters 14C, 63Ni, and 36Cl, were to be released to the approved levels stated in Table I (W. Gutzman, AECL CANDU Decommissioning Group, personal communication).

IMPLICATIONS FOR NEW PROGRAM DESIGN

The examination of these three cases has indicated key considerations for program design and for seeking regulatory approval. The major decision that has to be made prior to program design is whether the preferred strategy is to prove wastes are "clean" to the limit of detection of the instruments and procedures used, or to base waste segregation upon levels of radioactive contamination that meet de minimis risk and dose criteria or recommended unconditional exempt levels.

With the pending enactment of the Canadian Environmental Assessment Act, and a potentially larger role for public input and acceptance, a low-level radioactive waste program based on the "clean" principle may have greater chances of obtaining necessary approvals (Lipsett et. al., in prep). Another advantage of this approach is it's independence of release limits, the values of which may evolve through time and research. However, a disadvantage of this approach is that, as detection equipment and practices improve over time, distinguishing between measurable radiation levels due to radioactive contamination and those due to natural background levels (ie. due to naturally-occurring radionuclides, cosmogenic radionuclides, weapons testing fallout etc.) for some radionuclides in some waste forms may prove to be a major challenge (IAEA, 1993). As well, this approach does not explicitly define limits that may be used as worst-case source term values for performance assessment. One approach to modelling the impact of these practices may be to perform a dose assessment corresponding to the detection limit of the equipment and procedures used.

The advantages of establishing release levels based on the de minimis risk and dose criteria, or recommended unconditional exempt levels, are that the presence of variable background levels of radioactivity in wastes, particularly decommissioning wastes, will rarely pose a problem as background levels are usually far below unconditional exempt levels. The impact of unconditional release will be easier to model given that the levels will define worst-case source term values. Unconditional release of these materials means that they become eligible for offsite recycling/reuse or landfill, which eliminates incurring long-term liability for these wastes within a licensed site. The reduction in long-term liability results in a large cost saving, and resolution of the waste problem by the same generation that generated the waste. Some cost recovery for these programs may be possible through

the reuse/recycle route. However, consideration must be given to removing radiation/prior ownership symbols from reusable materials, and to defacing uniquely nuclear items for offsite landfilling. One disadvantage is that the release level approach may have a more difficult time gaining public acceptance.

Design and construction are currently underway at CRL for a pilot-scale program to segregate and unconditionally release wastes. This pilot program will be jointly undertaken by the AECL CANDU Decommissioning Group, AECL Waste Management Systems, and the CANDU Owner's Group. The goal of the pilot program is to prove that waste segregation is cost effective and technically feasible within the Active Area of the CRL site. The Chalk River site has been in use as a nuclear research and isotope production facility since the mid-1940's, so the possibility of the presence of a full suite of radionuclides, including alpha emitters and low-energy beta emitters, must be planned for. LLRW at Chalk River include active-area office wastes, research laboratory wastes, LLRW generated in reactor buildings, and decommissioning wastes. Careful consideration of the lessons learned in the three cases presented in this document has resulted in the decision to adopt a policy of unconditional release of materials based on criteria with prior regulatory approval. AECB approval has been sought to unconditionally release segregated wastes to Unconditional Clearance Levels consistent with the draft IAEA recommendations (K. Cotnam, AECL Research, personal communication). A program is currently underway to refurbish the CRL site, which will result in a large volume of building-emptying and demolition waste. These buildings have been exposed to up to 50 years of atmospheric fallout of radionuclides from cosmogenic sources and weapons testing, and therefore some of the wastes will have measurable radioactivity levels above the background one would expect from new construction materials. However, these radioactivity levels would be found on any buildings of similar age from this region of Canada because their source is atmospheric deposition. As a result, using the "non-detectable above background" approach would result in unacceptably high volumes of waste being handled as LLRW.

Waste handling procedures have been designed based on a combination of the approaches of the AECL CANDU Decommissioning Group and the Darlington Likely Clean Waste Management Program. A draft floor plan for the pilot can be seen in Fig. 1.

Fig. 1.

Personnel entering the pilot will first use gas-flow proportional hand and foot monitors to ensure that no contamination enters the facility through that route. Airflow into and out of the pilot will pass through HEPA filtration systems. After an education program provided by the pilot staff, waste generators will segregate the wastes at source into "Active" and "Likely Clean" bags. Wastes will be barcoded at their point of collection to allow tracking through the system. Likely clean wastes entering the facility will be stored for a period of time in a "Tritium Laydown Area" to allow any tritium in the wastes to reach an equilibrium concentration in the bag air. Each bag will be checked with a hand-held tritium monitor, and those bags that meet the pilot criterion for tritium, which is currently in the process of being finalized, will be eligible for further processing. The eligible bags will be placed in an initial Waste Curie Monitor with an alarm setpoint designed to ensure that active wastes are not inadvertently entering the facility, and to allow for barcodes to be entered into the pilot database. The wastes will then enter the segregating/monitoring room, which had been constructed with radiation shielding in the walls to ensure as low and as stable a background radiation level as possible. Waste bags will be opened onto an enamel-covered steel sorting table, where a gas-flow proportional hand scanner will be used to make near-contact measurements for alpha, beta and beta-gamma contamination. The alarm setpoints on the hand scanners will be determined to reflect the unconditional release criteria. Wastes will be sorted into two categories: wastes that meet the criteria for unconditional release, and wastes that will be handled as LLRW. Wastes suitable for unconditional release will be rebagged and barcoded, and a final check of radioactivity levels will be made in a second Waste Curie Monitor, which will also enter the new barcode into the pilot database to facilitate tracking and/or retrieval of the releasable wastes for compliance monitoring.

Pending AECB approval, the Waste Segregation Pilot will become operational in the first quarter of 1995.

CONCLUSIONS

A review of the Canadian case studies has indicated that LLRW waste segregation programs can result in significant reduction in the volumes of LLRW. The results of the pilot waste segregation program at Chalk River Laboratories will indicate whether a segregation program will be technically feasible and cost effective for the Active Area of the CRL site.

AN ALTERNATIVE APPROACH TO THE RCRA "CONTAINED-IN" RULE FOR THE CHARACTERIZATION OF INVESTIGATION DERIVED WASTES

Kirsten L. Derr

Golden, Colorado

ABSTRACT

Since 1990, the DOE/RFFO and EG&G have been discussing the management of IDW with EPA and CDPHE. These discussions have centered on the development of a comprehensive management program that would characterize IDW in accordance with regulatory guidelines and risk assessment methodologies, rather than using the RCRA "contained-in" rule.

The definition of RCRA hazardous waste is codified in Title 40 Code of Federal Regulations (CFR) 261. Under RCRA, the definition of hazardous waste focuses mainly on process wastes from a variety of chemical processes. However, in the strictest sense under RCRA, any material that is mixed with, derived from, or that contains any amount of RCRA listed contaminants also becomes a RCRA hazardous waste. Therefore, environmental media such as soil or groundwater that receives spilled, discharged or abandoned hazardous waste also becomes hazardous waste by definition, as long as the media contains hazardous constituents in detectable concentrations. The regulation of hazardous waste is primarily intended to prevent contamination of groundwater by regulating the storage, treatment and disposal of process waste and focusses on the prevention of using dilution as a form of treatment. Therefore, it is difficult to apply the definition of hazardous waste to environmental media that has received historical contamination, especially if the event occurred prior to the promulgation of RCRA regulations defining hazardous waste.

At RFETS, approval was obtained from the Region VIII EPA and CDPHE to characterize soil and sediment IDW using a risk-based determination, rather than using the Resource Conservation and Recovery Act (RCRA) "contained-in" rule, to determine if the IDW were hazardous waste. The impact of requiring IDW generated at RFETS to be classified as RCRA hazardous waste under the "contained-in" rule would result in the treatment, storage and disposal of a large volume of assumed hazardous waste. Specifically, over 4000 drums of IDW at RFETS had been generated from remedial investigations by the late spring of 1994, with additional investigations ongoing. The risk-based methodology developed for the characterization of IDW at RFETS is a

unique combinations of the traditional RCRA waste characterization process and an innovative risk assessment evaluation processes. This methodology allows IDW to be evaluated based on a review of associated chemical analytical data obtained during field investigations instead of assuming that all IDW contains process hazardous waste. Through the application of the risk-based methodology 79% of the drums evaluated were determined to be chemically non-hazardous (i.e, uncontaminated or containing very low concentrations of contaminants). Therefore, the material is exempt from RCRA waste management requirements and may be returned to the point of generation or disposed of as a non-hazardous waste.

INTRODUCTION

The Rocky Flats Environmental Technology Site is a DOE facility managed and operated by EG&G Rocky Flats, Inc. The primary mission of the Site, from its inception until the early 1990s, was to produce metal components for nuclear weapons. Both radioactive and non-radioactive wastes were generated during the research and production processes, and past waste handling procedures involved both on-site storage and disposal of wastes. In 1992, the primary mission of RFETS changed from weapons production to stabilization of the radioactive material remaining on site and environmental restoration.

In the late 1980's, the DOE/Rocky Flats Field Office (RFFO) began environmental investigations to determine the extent of site contamination. As a result of these investigations, by 1993 a backlog of over 4,000 drums of IDW had accumulated on site. Originally, the IDW generated during environmental investigations was to be stored of generation and disposed of in accordance with each Record of Decision (ROD) for the individual Operable Units (OUs). However, due to lengthy investigation period leading to each ROD, alternative means of handling the IDW were required. The alternative selected was to package the IDW and manage the drums according to appropriate waste handling requirements.

In March, 1994, DOE/RFFO received a warning letter from the CDPHE. The correspondence was a follow-up to an inspection that was performed of the soil and sediment IDW drums and subsequent review of the management protocol which had been established for the drums (CDPHE letter to DOE/RFFO, March 1994). Among the concerns expressed by CDPHE was that waste characterization had not been fully completed for IDW drums in 90 day storage areas. Many of the drums had also been stored in the 90 day areas more than the allowable time frame. The State specifically cited violations of 6 CCR 1007-3, Section 262, which requires a generator of a solid waste to determine if the material is a hazardous waste. The DOE/RFFO was advised by CDPHE to "take actions that will bring characterization, labeling, management, and storage of the soil and sediment IDW drums into compliance with Sections 262.11 and 262.34 and Part 100 of the Colorado Hazardous Waste Regulations." Inclusive to this effort was the preparation of "additional standard operating procedures that ensure completion of a properly conducted hazardous waste characterization for IDW containers that contain solid waste." To this end, the DOE/RFFO directed EG&G to initiate development of a procedure which could be used to properly characterize the soil and sediment IDW.

Purpose

This paper presents a procedure developed in 1994 by Woodward-Clyde Federal Services (WCFS) and EG&G to chemically characterize IDW using regulatory guidelines and risk assessment methodologies. The procedure is currently used to characterize chemical constituents of IDW only. A risk-based methodology for the characterization of radioactive constituents of IDW is under development.

Background

Since 1990, the DOE/RFFO and EG&G have been discussing the management of IDW with EPA and CDPHE. These discussions have centered on the development of a comprehensive management program that would characterize IDW in accordance with regulatory guidelines and risk assessment methodologies, rather than using the RCRA "contained-in" rule.

In December 1993, WCFS and EG&G began developing an operating procedure that would address the final regulatory disposition of IDW generated during environmental investigations at RFETS. EPA delegated their approval authority for this procedure to CDPHE. In April 1994, the operating procedure was approved by the State.

Investigation Derived Wastes

Environmental field investigations result in the generation of waste materials. These investigation derived wastes may include drilling muds, soil drill cuttings,

well development purge water, contaminated personal protective equipment (PPE), and solutions used to decontaminate non-disposable protective clothing and equipment. According to the EPA, "the management of investigation derived wastes must ensure the protection of human health and the environment and comply with certain regulatory requirements that are applicable or relevant and appropriate"(EPA 1991).

State and Federal Guidance Concerning IDW

The RCRA contamination assessment process requires that facilities with historical contamination perform investigations to thoroughly evaluate the nature and extent of the release of hazardous waste and constituents to the environment. These investigations, known as RCRA Facility Investigations (RFIs) include sampling of groundwater, soil, and any other potentially contaminated media. The RFI process generates drill cuttings and excess soil from sampling. Since the soil comes from a potentially contaminated area it must be contained and eventually disposed of.

The definition of RCRA hazardous waste is codified in Title 40 Code of Federal Regulations (CFR) 261 and 6 Colorado Code of Regulations (CCR) 1007-3. Under RCRA, the definition of hazardous waste focuses mainly on process wastes from a variety of chemical processes. However, in the strictest sense under RCRA, any material that is mixed with, derived from, or that contains any amount of RCRA listed contaminants also becomes a RCRA hazardous waste. Therefore, environmental media such as soil or groundwater that receives spilled, discharged or abandoned hazardous waste also becomes hazardous waste by definition, as long as the media contains hazardous constituents in detectable concentrations.

The regulation of hazardous waste is primarily intended to prevent contamination of groundwater by regulating the storage, treatment and disposal of process waste and focusses on the prevention of using dilution as a form of treatment. Therefore, it is difficult to apply the definition of hazardous waste to environmental media that has received historical contamination, especially if the event occurred prior to the promulgation of RCRA regulations defining hazardous waste.

During an environmental investigation, soil is displaced by sampling efforts, especially drilling, and the total volume may not be used for analytical samples. This soil, if removed from a potentially contaminated area, using a strict interpretation of the definition of hazardous waste, contains hazardous waste and cannot be returned to the location of origin and therefore must be contained. The impact of this interpretation of the regulations may result in a large volume of waste soil, known as investigation derived waste, that must be characterized and disposed. Waste characterization requires either using process knowledge or analytical results to determine the concentration of hazardous constituents. It may be difficult to use process knowledge to characterize potentially contaminated soil. It is also difficult to use process knowledge to confirm that soil is not contaminated. Regulating agencies will generally not accept process knowledge to characterize environmental media as uncontaminated. On the other hand, taking and analyzing samples from every container of soil can be extremely time consuming and costly. Therefore, alternatives to sampling every container and using only process knowledge needed to be explored and negotiated with regulating agencies.

State and Federal Guidance Concerning IDW

Guidance for the management of IDW issued by the EPA and the State of Colorado are based on different assumptions about the origin of the IDW. The EPA's guidance is based on IDW generated from a CERCLA field investigation. It states that "site managers should not assume that a waste considered to pose a potential risk at a CERCLA site is a listed or characteristic RCRA hazardous waste" unless there is positive evidence that the IDW contains a such waste (EPA 1991). However, the guidance also states that for proper protectiveness, or if RCRA requirements are considered relevant and appropriate to the site, IDW may best be managed as a hazardous waste. One of the management options for soil IDW allowed by the EPA is to return it to the boring location immediately upon generation. Other management options include consolidation within an area of concern, sending the IDW to an on-site or off-site treatment and disposal unit, or storage of the IDW for future treatment or disposal. Use of these management options are based on site-specific information and must be protective of human health and the environment.

Individual states are not given authority to implement CERCLA, but can be given authority for RCRA. A state's guidance for management of IDW may assume the material is the result of a RCRA corrective action or RFI and potentially contains RCRA hazardous waste. The State of Colorado's guidance states that environmental media is

not a solid waste. Therefore, by definition the media itself cannot be a hazardous waste. However, environmental media may contain hazardous waste and must be managed as such. To determine if the environmental media contains a hazardous waste, state guidance suggests that the media be analyzed for a suite of analytes based on available site knowledge. If no site knowledge is available, a complete Appendix VIII (40 CFR 261 and 6 CCR 1007-3, Section 261) analytical suite is required. Once the analytical results are validated, the results are compared to the following criteria:
1. non-detect for organic compounds except for those that are naturally occurring and/or
2. less than or equal to background level for inorganic and naturally occurring organic compounds.
If the IDW does not contain constituents above detection limits or above background and does not exhibit one of the hazardous waste characteristics (ignitability, corrosivity or reactivity) the State of Colorado no longer regulates the IDW and it may be returned to the location of origin or disposed of in the manner of choice. As an alternative to the State characterization scheme previously discussed, if the IDW contains constituents that are either detected organic compounds or inorganic compounds detected above background, then the concentrations of contaminants may by compared to site-specific risk based criteria.
If the IDW "passes" the risk assessment criteria, even though it failed the analytical criteria, and does not exhibit a hazardous waste characteristic, then the IDW is considered to not contain a hazardous waste. However, the IDW may still need to be managed in accordance with the state's Solid Waste Regulations because of the low levels of contaminants present.
If the IDW fails the risk-based criteria, it contains hazardous waste and must be managed as such.
The State's Interim Final Policy and Guidance for Corrective Action at RCRA Facilities (CDPHE 1993) provides guidance for performing risk assessment for IDW and will be discussed in more detail in the following paragraphs.
When a site is both a RCRA and CERCLA site, the more conservative guidance will generally prevail. State-specific RCRA guidance is usually more conservative then EPA's CERCLA guidance for the management of IDW.
Colorado's Risk Assessment Guidance
The State of Colorado allows the use of risk assessments to determine allowable levels of contaminants in IDW. This is an alternative to assuming that any detectable level of a contaminant makes the IDW hazardous. However,the risk methodology is based on extremely conservative assumptions. First, the level of acceptable risk for chemical carcinogens is any concentration below 1x10-6 risk level. This risk level is more conservative then the range allowed by the EPA of 1x10-4 to 1x10-6 for CERCLA investigations. Second, a long-term resident must be assumed to be the exposed individual, regardless of the planned or proposed future use of the site. Third, multiple exposure pathway must be evaluated including: soil ingestion, dermal contact with soil, inhalation of particulates, inhalation of VOCs, and ingestion of homegrown produce grown in contaminated soil. Fourth, there is no provision for source depletion or attenuation even though the source may only a be 55 gallon container of soil. Finally, although modelling is not required, the corrective action must take in to account migration and leaching potential of contaminates in soil.
Pros and Cons of IDW Management Options
Returning IDW to its location of origin is the most cost effective management option allowed by the EPA, but often is not considered protective of human health and the environment. Of the other waste management options, site-specific factors need to be taken into consideration to determine which management option is most cost effective. Assuming that IDW from potentially contaminated areas is hazardous without analysis may be cost-effective if the area is heavily contaminated with known contaminants. Characterization by process knowledge in this case will save analytical and data evaluation costs. However, if the IDW will ultimately be treated and disposed of off-site, the receiving Temporary Storage and Disposal (TSD) facility will likely require a thorough analysis of the IDW.
Most states will require analysis of the IDW. It may be possible to group drums by sampling location and composite the drum samples. At RFETS, the State allowed borehole samples to be used to characterize the drill cuttings in each drum. This

approach may be possible as long as there are records to correlate each container with the corresponding sampling location and is cost-effective since drum sampling may not be necessary in most cases.
Performing a site specific risk assessment may also be time-consuming and expensive, especially if toxicology information must be researched for a large number of chemicals but there is only a small volume of IDW to be characterized. The State of Colorado allows the establishment of alternative action levels below which a waste is no longer considered a threat to human health and the environment. These alternative action levels include Colorado Water Quality Standards, federal drinking water standards, and federal Water Quality Criteria. These standards are likely to be more conservative than risk-based levels for soil, but may be more cost effective than developing a site-specific risk assessment.

IDW CHARACTERIZATION AT RFETS

Data Availability

As mentioned previously, the State allowed the use of borehole data in lieu of drum samples. This was because detailed records of the sampling location, sample numbers and depth of samples were recorded for the drill cuttings in each container. However, in some cases, samples were not taken in the interval represented by the drum, certain types of analysis were not requested for that interval, or the sample results were never recorded for a variety of reasons. In those cases, other corresponding samples were used to characterize the drum. These samples were from

- An interval above the drummed interval in the same location,
- An interval at or above the drummed interval in a nearby location,
- An interval at or above the drummed interval in a location within the same individual hazardous substance site (IHSS, also known as a solid waste management unit (SWMU)), and/or
- An interval below the drummed interval in the same location

When more than one sample was used to characterize a drum, the results were averaged by analyte in accordance with the approved standard operating procedure.
If no data were available for the drum and no appropriate associations could be made, the drum was sampled.

Risk Assessment Methodology

The State of Colorado required RFETS to use the conservative risk assessment methodology described in its Policy and Guidance on Risk Assessment for Corrective Action at RCRA Facilities The guidance assumes a long-term residential multiple pathway exposure to a non-depleting source.
Most of the intake parameters used in the risk assessment methodology developed by RFETS for IDW are standard default values prescribed by the EPA for long-term residents. In addition, the state required that time-weighted averages be used for all pathways to account for the sensitive subpopulation of children under age 6. The intake parameters that apply to all pathways include:

- Exposure Frequency = 350 days or events per year
- Exposure Duration = 24 years for adults and 6 years for children
- Body Weight = 70 kg for adults and 15 kg for children
- Noncarcinogenic Averaging Time = 8760 days for adults and 2190 days for children
- Carcinogenic Averaging Time = 25550 days for adults and children

The pathway specific intake parameters are outlined below:

Soil Ingestion

- Ingestion Rate = 100 mg for adults and 200 mg for children

Dermal Contact with Soil

- Exposed surface area = 7100 cm2 for adults and 4600 cm2 for children
- Absorption Factor = 0.5 for adults and children
- Adherence Factor = 1 mg/cm2/event

Inhalation of Particulates (inorganics only)

- Inhalation Rate = 0.83 m3/hr for adults and 0.73 m3/hr for children
- Particulate Emission Factor = 4630 m3/mg

Ingestion of Homegrown Produce (metals only)

- Ingestion rate = 122,000 mg/day for adults and children
- Fraction from contaminated source = 0.36
- Soil-to-produce partitioning factor = chemical-specific

RFETS was not required to evaluate the exposure due to inhalation of Volatile Organic Compounds (VOCs) because models for calculating their concentrations in air had not been approved when the waste characterization was performed.

Performance of the Risk Evaluation for RFETS IDW
At the time the original risk evaluation was performed, over 4000 drums of IDW had accumulated at RFETS. To streamline the waste characterization process, some global assumptions were made, and part of waste characterization the process was automated by writing a computer program to perform the calculations and comparisons required by the procedure.
The basic steps of the waste characterization procedure performed by RFETS are as follows;
Step 1:
Determine which samples can be used to evaluate each drum.
Step 2:
Perform an evaluation of the analytical data including data useability, review of B-qualified data, and flagging or discarding any unusable or unnecessary data. A step was included to determine if any of the available flashpoint or pH data exceeded the regulatory standards for the hazardous waste characteristics of ignitability or corrosivity. If either of these standards is exceeded, the waste is a characteristic hazardous waste and must be managed accordingly. The risk assessment is still required to be performed for those drums
Step 3:
Determine background values to be used in the comparison of detected values to background. Data and statistical tests to determine background were dictated by the state. For RFETS, a chemical was determined to be above background if it exceeded the background mean plus two standard deviations value.
Steps 5 through 9 were performed by a computer program written specifically for RFETS data and the approved characterization methodology. The computer program processed the data on a drum-by-drum basis and provided as output a form for each drum. The form showed the drum and sample number, detected analytes and their average concentrations, risk and regulatory computations and comparisons, and the final disposition (i.e. RCRA hazardous, non-hazardous, etc).
Step 4:
Determine which chemicals were detected and calculate the average concentration of those chemicals in each drum.
Step 5:
Compare the average concentration of the inorganics to background values. If the chemical exceeds background, continue with the risk assessment. Inorganics not exceeding background values need not be evaluated further.
Step 6:
Compare the average concentrations of detected chemicals to corresponding RCRA Toxicity Characteristic (TC) values. The TC values in 40 CFR 261.24 are maximum allowed concentrations that leach from a solid medium. However, since the toxicity characteristic leaching procedure (TCLP) analysis was not performed on most of the samples and the values are expressed as liquid concentrations, the TC values were multiplied by an approximation value of 20 to be compared to total concentrations in soil. The TC list includes only 40 chemicals. Consequently, not all chemicals in the IDW had a corresponding TC value.
If any of the chemical concentrations exceed their corresponding TC value, the drum contains RCRA hazardous waste and must be managed accordingly. The remainder of the risk assessment must still be done to determine the appropriate waste codes for the IDW. If all of the chemical concentrations were below the modified the TC value, continue with the risk assessment.
Step 7:
Calculate risk-based concentrations (RBCs) for each chemical using given intake parameters and toxicity. Such information is available from the EPA on the Integrated Risk Information System (IRIS) and the Health Effects Assessment Summary Tables (HEAST). For the RFETS characterization the chemical list included all those that appeared in the environmental database. The list was then split into a RCRA and Inclusive. The State of Colorado required that the risk from all detected chemicals that appeared on the RCRA Appendix VIII list be summed to determine the risk due to RCRA constituents. If the drum passed the RCRA test all additional detected chemicals would be added to the RCRA risk to determine if the drum passed the Inclusive test. These tests will be described in more detail later.
Step 8:
Determine which chemicals are on the RCRA Appendix VIII list. For these chemicals

divide the average detected concentration by the corresponding RBC values (there may be a carcinogenic RBC and a noncarcinogenic RBC for each chemical). Sum the carcinogenic concentration to RBC ratios and noncarcinogenic concentration to RBC ratios separately. If either the carcinogenic or noncarcinogenic ratio sums exceed one, the drum contains RCRA hazardous waste and must be managed accordingly. At this point the risk assessment is completed. If neither of the ratio sums exceed one, continue with the risk assessment.

Step 9:

Calculate the carcinogenic and noncarcinogenic ratios for the remaining chemicals and add these ratios to the previously calculated ratio sums for each RCRA constituent. This step is known as the Inclusive risk analysis. If either the carcinogenic or noncarcinogenic ratio sum exceeds one, the waste must be managed until the proper disposition can be determined. At RFETS, the IDW that fails this Inclusive risk analysis test is being managed similarly to the RCRA waste until the CERCLA ROD, at which time, the treatment and/or disposal options will be determined. If neither the carcinogenic ratio sum nor the noncarcinogenic ratio sum exceed one, the IDW is deemed nonhazardous and disposal is not unrestricted at the site. At RFETS, this IDW will likely be used as clean fill on the plant site.

Since RFETS is a nuclear facility, a risk evaluation for radionuclides also needs to be performed before any of the IDW is truly considered non-hazardous. An extension to the above procedure is currently being developed that will characterize the radiological risk from each drum of IDW.

COST COMPARISON

In order to demonstrate the value of the chemical risk-assessment methodology, a cost comparison has been conducted. The comparison is limited to funding expenditures that were or may have been required for the chemical characterization of the IDW drums. Specifically, the costs of performing the risk-assessment methodology was compared to an estimate of the cost for obtaining RCRA characterization samples for each drum. The costs for the sampling project are best estimates of efforts required to obtain the samples and laboratory analytical results. The costs for the risk-assessment methodology are based upon actual costs incurred and are limited to the characterization of the IDW.

The cost estimate for the IDW drum characterization by direct sampling for contaminants of concern, is based upon the actual field sampling efforts. The scenario assumes a 14 week period in which to sample all 4200 IDW drums, using two field crews. Field crew members would be typical of those required to obtain samples, provide health and safety monitoring, package and ship all samples, and accurately document all activities. It is assumed that each field crew samples 30 drums per day, five days per week, for 14 weeks. Labor rates are $85.00 per hour for each field crew member. Laboratory analysis performed for each sample is 1) Contract Laboratory Procedures (CLP) for total metals, 2) Volatile Organic Analysis (VOAs), 2) Method 80/80 for drums suspect of pesticides or Polychlorinated Biphenyls (PCBs), 3) and radiological screens for 10% of the samples. The total estimated cost for the drum sampling and laboratory analysis would be $4.68 million dollars. The cost estimate is summarized in Table I, Cost Estimate for IDW Drum Characterization by Direct Sampling for Contaminants of Concern.

TABLE I

The cost incurred for the Risk-Assessment methodology for the characterization of the IDW drums was roughly $1.9 million dollars. This figure includes an accelerated sampling effort of 300 drums in a 72 hour period with rush charges an all samples sent to contractor labs. The remaining $600,000.00 was used for the procedure development, writing the computer code, and performing the risk-assessments of the 4200 IDW drums. Another benefit from the expenditure of the funds in the development of the program, is its continued usefulness. The same method is available for application to soil and sediment IDW which has been or will be generated from future field activities. Therefore, RI characterization samples may continued to be used for the dual purpose of site and waste characterization.

When these costs are compared, an estimated savings of $2,780,000.00 is indicated. This represents a substantial cost savings. Actual cost savings may be greater since costs of data management and final waste characterization were not included in the estimate. These additional costs would be expended for data management and validation, data review, and a final waste determination. Such activities require detailed review and can result in significant costs. Economic savings are not the

only benefit of the approved method. By not requiring RCRA sampling of the IDW drums, a substantial decrease in the potential exposure to personnel to chemical and/or radiological contaminants was achieved. This results in compliance to As Low As Reasonable Achievable (ALARA) requirements for occupational chemical and radiological exposures.

CONCLUSIONS

The Risk Assessment Methodology was applied to the characterization of 4200 soil and sediment IDW drums in the spring of 1994. The method complied with the EPA's and CDPHE's requirements to ensure protection of human health and the environment while complying with regulatory requirements that were applicable or relevant and appropriate. By carefully reviewing federal and state regulations that address IDW and risk assessment criteria, WCFS and EG&G were able to cultivate an innovative and technical process for characterization of the waste. By the application of the methodology, a reduction in waste and cost were realized. Based upon the result of the work, 79% of the drums were determined to be chemically nonhazardous and 4% of the drums were determined to contain CERCLA hazardous substances or other hazardous constituents in levels high enough to present a risk to the human health and the environment. Only 17% of the drums were determined to contain RCRA hazardous waste in levels high enough to present a risk to human health and the environment or in excess of RCRA regulatory levels.

A comparison of the waste characterization alone has indicated cost savings of at least $2.78 million dollars. This does not include cost savings based upon long term storage and or treatment of the soil and sediment IDW. Estimates show that an additional $4 to $8 million dollars were saved by performing the risk-based determination and not being required to respond to the strict requirements of the RCRA "contained in" rule. The cooperative efforts of WCFS and EG&G with CDPHE resulted in a characterization program for the IDW which resulted in cost saving and waste minimization. Most importantly, this was accomplished while maintaining the appropriate approved level of protection to human health and the environment.

SAIC
D.F.Gehr
WSRC

ABSTRACT

The startup process for the Defense Waste Processing Facility (DWPF) at the Savannah River Site (SRS) is a phased effort that includes three startup test phases prior to radioactive operations: Cold Chemical Runs (CCRs), Melter Heatup, and Waste Qualification Runs. While these three pre-radioactive test phases do not introduce radiological hazards to the facility, each does introduce chemicals in addition to the normal industrial hazards that pose potential risks to onsite personnel. The DWPF Final Safety Analysis Report (FSAR) scheduled to be completed in CY 1995, will define the safety basis for DWPF radioactive operations but will not address the specific hazards presented by the pre-radioactive startup tests. The FSAR will evaluate both radioactive and chemical hazards present during radioactive operations. It will not address the specific chemical hazards present during the test phases nor the configuration of the DWPF and operations during the test phases. These scope and schedule mismatches were recognized by the DWPF project team and addressed by the preparation of the CCR Safety Envelope Strategy. A review of the safety-related DOE Orders and Notices directed at facility operations found little guidance in the area of preparing an interim safety basis for facility pre-radioactive testing with significant chemical hazards. It became apparent that an interim safety basis was needed for the DWPF during the three test phases. A committee of DOE-HQ, DOE-SR and contractor representatives was formed, to draft a strategy for establishing an interim safety basis.

Development of a strategy was necessary to allow "buy-in" by the DOE line management

and interested parties, including the various oversight groups within the Department of Energy, since such an approach had not been used for other facility startups. Some of the more salient elements contained in the Strategy include:

Pre-radioactive Operation Authorization Basis Process - provides a description of the purpose, scope and roles of the CCR Safety Envelope (SE) Document, Safety Programs, and the Operational Readiness Reviews by the Contractor and DOE.

Safety Envelope Boundaries - defines the elements and boundaries (limits) of the SE to assure safety of onsite personnel and the public.

Operational Safety Requirements (OSRs) Significance Criteria - defines the thresholds for onsite and offsite chemical dose for determining the need for (Preliminary) Operational Safety Requirements.

Safety Envelope Acceptance Strategy - outlines the plan for preparation, review, approval and revision process for the CCR SE. It defines the roles for numerous DOE Oversight Groups.

Unreviewed Safety Question Process- requires the development and use of an Unreviewed Safety Question process to assure the limits of the CCR SE are not exceeded.

Graded Application of DOE Orders for CCR - defines the objectives of the Orders and Notices that are applicable during CCR.

The Strategy was approved by the SRS Manager, the Assistant Secretary for Environmental Restoration and Waste Management (EM-1) with concurrence by the Assistant for Environment, Safety and Health (EH-1) in December 1992. Since the Strategy's approval, it has been used to establish each test phase's safety basis within the DWPF SE and has become an essential element in gaining DOE's (both program and oversight organizations) authorization to begin each test phase. To date, two of the three test phases have been successfully completed at DWPF, and the last nonradioactive tests, Waste Qualification Runs, have started. The DWPF CCR Safety Envelope Strategy has been a significant contributor to their success. Acceptance of the Strategy by the DOE community as an approach to establishing the safety basis for pre-radioactive testing with chemical hazards as well as the Strategy's use and reliance on the project's Safety Programs (e.g., fire protection, industrial hygiene, emergency preparedness) are considered unique in the DOE.

Background

The Defense Waste Processing Facility (DWPF) is designed to accept the high level radioactive waste (insoluble solids and processed supernate (i.e., sludge & precipitate)) from the tank farms at the Savannah River Site, mix it with glass formers (frit), melt the slurry to form a borosilicate glass, and pour the molten glass into a canister which is subsequently decontaminated and seal welded. These canisters will be temporarily stored at DWPF and will be transferred to a permanent geologic repository. DWPF is being tested at various design parameters to assure product quality and safety. Simulated sludge and precipitate feeds are prepared and processed in lieu of radioactive waste for startup testing. A simplified process overview sketch is provided in Fig. 1, DWPF Process/Hazard Overview. This sketch also identifies the chemical hazards associated with the pre-radioactive simulant testing.

Fig. 1.

The startup process for the DWPF is a phased effort that includes three test phases prior to radioactive operations: Cold Chemical Runs (CCRs), Melter Heatup, and Waste Qualification Runs. While these three pre-radioactive test phases do not introduce radiological hazards to the facility, each does introduce chemicals in addition to the normal industrial hazards that pose potential risks to onsite personnel. The DWPF Final Safety Analysis Report (FSAR) scheduled to be completed in CY 1995, will define the safety basis for DWPF radioactive operations but will not address the specific hazards presented by the pre-radioactive tests. The FSAR will evaluate both radioactive and chemical hazards present during radioactive operations. It will not address the specific chemical hazards presented by the test phases nor the configuration of the DWPF and operations during the test phases. These scope and schedule mismatches were recognized by the DWPF project team and were addressed by the preparation of the CCR Safety Envelope Strategy (1). A review of safety-related DOE Orders and Notices directed at facility operations found little guidance in the area of preparing an interim safety basis for facility pre-radioactive testing with significant chemical hazards It became apparent that an interim safety basis was needed for the DWPF during the three test phases.

A committee of contractor, DOE-HQ and DOE-SR personnel developed a strategy paper which included contractor, DOE-SR and DOE-HQ activities. The committee prepared an action memo, approved by EM-1, which outlined the SE Strategy and sought DOE oversight concurrence from the Office of Environmental Safety & Health (EH). DOE-HQ also reviewed and accepted the SE through a contracted, independent Technical Review Group (TRG). The Strategy also required Operational Readiness Review (ORR) assessments by the contractor and DOE to assure effective implementation of the Safety Programs. Approval of the Strategy at the EM-1 level was appropriate to commit all affected groups to the program.

The Strategy was approved by the SRS Manager, the Assistant Secretary for Environmental Restoration and Waste Management (EM-1) with concurrence by the Assistant for Environment, Safety and Health (EH-1) in December 1992. Since the Strategy's approval, it has been used to establish each test phase's safety basis within the DWPF Safety Envelope and has become an essential element in gaining DOE'S (both program and oversight organizations) authorization to begin each test phase. To date, two of the three test phases have been successfully completed at DWPF and the last nonradioactive tests, Waste Qualification Runs, have started. The DWPF CCR Safety Envelope Strategy has been a significant contributor to their success. Acceptance of the Strategy by the DOE community as an approach to establishing the safety basis for pre-radioactive testing with chemical hazards as well as the Strategy's use and reliance on the project's Safety Programs (e.g., fire protection, industrial hygiene, emergency preparedness) are considered unique in the DOE.

Discussion

Some of the more salient elements of the Strategy follow:

The Pre-radioactive Operation Authorization Basis process establishes two distinct elements.

The first element is the preparation of a CCR Safety Envelope (CCR SE) (2) which is reviewed and accepted by the contractor, DOE-SR and the DOE-HQ. The CCR SE defines the safety basis and bounds the chemical hazards for DWPF nonradioactive testing.

The second element is the establishment of safety programs at DWPF. The safety programs include Fire Protection, Industrial Hygiene, OSHA, Operating Procedures, Training and Process Hazards Reviews, and Emergency Preparedness Programs. The safety programs were assessed by the contractor and DOE Operational Readiness Reviews prior to authorization to start testing and are not elements of the CCR SE.

Safety Envelope Boundaries - The two safety basis program elements define the program limits. The combined, but distinct elements assure effective safety controls to provide protection for the worker (i.e., Safety Programs) via Process Requirements (PR), and onsite personnel/public via the Safety Envelope which includes the Preliminary Operational Safety Requirements (POSRs). A schematic is provided in Fig. 2, DWPF CCR Authorization Basis Flowchart, to show the process and relationship between the two Authorization Basis elements.

Fig. 2.

CCR Safety Envelope - The Safety Envelope is established by assessing and using existing safety documents (e.g., Preliminary Safety Analysis Report, Hazards Analysis and Process Hazards Reviews). Where chemical consequences exceed the Operational Safety Requirements Significance Criteria (defined in the Strategy), the hazard is documented and controls are established as Preliminary Operational Safety Requirements (POSRs). These controls include Safety Limits, Limiting Conditions of Operation, and Administrative Controls The POSR term is established to distinguish it from radioactive OSR, or Technical Safety Requirements (TSRs) that will be required for radioactive operations.

POSRs are an integral part of the SE. Structures, Systems and Components (SSCs) used to prevent or mitigate the hazard are designated SSCs Important to Safety and listed in the SE accordingly.

Principal Design Criteria, Process Descriptions and Facility Design also form part of the SE. POSRs unique to the testing phases include locking out or limiting selected hazardous inventories that will not be required during radioactive operations and controlling simulant feed specifications to limit hazards.

The Safety Envelope includes the following sections:

a. Identification and description of the Chemical Hazards
b. The Safety Analysis associated with the Hazards
c. Administrative Controls appropriate to the Hazards (i.e. POSRs)
d. List of Structures, Systems and Components Important to Safety

e. Principal Design Criteria
f. Facility Design
g. Process Description
Operational Safety Requirements (OSRs) Significance Criteria - are provided in the following
TABLE I
These criteria were chosen based on Westinghouse Savannah River Company policy and good industrial safety practice. DOE-SR and DOE-HQ line management concurred with the criteria.
Unreviewed Safety Question (USQ) Process - The Strategy prescribes a USQ process, per DOE Order 5480.21, that includes a contractor review process to assure that design, operational or chemical process changes are reviewed against an approved Safety Basis (the SE) and that the Safety Basis limits are not exceeded without review by the DOE. The process assures that design or process changes do not increase accident frequencies or consequences that exceed the previously accepted SE or introduce new accidents which may exceed the OSR Significance Criteria. The USQ program is applicable to all plant modifications, temporary modifications, operating procedures and test procedures. From a contractor perspective, it is important to bound the accidents with conservative analysis and perform a careful review of the intended testing to assure the test activities are enveloped the SE. This review avoids review time of USQs for unanticipated events and the potential delay in aggressive testing schedules.
Graded Application of DOE Orders for CCR - The Strategy requires review of Orders and Notices to determine applicable requirements for the pre-radioactive testing program. The following orders and notices were recommended for consideration in this process. SEN-16B, Start or Restart of Nuclear Facilities, SEN-6E, Dept. Organization & Mgmt. Arrangements, Order 5481.1B, Safety Analysis & Review System, Order 5480.23, Safety Analysis Reports, Order 5480.22 including the implementation standard DOE STD. 3009, Technical Safety Requirements, Order 5480.21 Unreviewed Safety Questions. The DWPF Safety Envelope Acceptance Strategy and the Safety Envelope document have been invaluable tools during nonradioactive testing of DWPF. These documents defined the hazards unique to testing DWPF and allowed the operating contractor, DOE-SR, and DOE-HQ personnel to focus on the actions necessary to protect DWPF and Savannah River Site workers from those hazards. Employing a similar approach during the startup of new, large, and complex facilities like DWPF is highly recommended.

REPOSITORY DISPOSAL CRITERIA FOR DOE SPENT FUEL
L. L. Taylor
H. H. Loo
R. D. Klingler
Idaho National Engineering Laboratory
1955 Fremont Ave.
Idaho Falls, Idaho 83415-3422
ABSTRACT
A decision by the U.S. Department of Energy (DOE) in April, 1992, discontinued reprocessing and recovery of highly enriched U-235 (HEU) from irradiated fuels stored by the Idaho Chemical Processing Plant at the Idaho National Engineering Laboratory. The new mission of monitoring waste storage from previous reprocessing campaigns and of dealing with continued receipt and storage of irradiated fuels has prompted court actions by the State of Idaho requiring DOE to demonstrate efforts for preparing, packaging and shipping existing wastes out of the state to a national repository. These actions resulted in the formation of a multidisciplinary effort to evaluate options and approaches necessary for these wastes to qualify for geologic disposal. While the options being studied cover both high-level wastes (HLW) and spent nuclear fuels (SNF), dealing with a variety of HEU-type fuels presents special problems beyond those encountered with the commercial spent fuels now being studied for disposal in the proposed repository at Yucca Mountain, Nevada.

INTRODUCTION

The U. S. Department of Energy (DOE) has received irradiated nuclear fuel at the Idaho Chemical Processing Plant (ICPP) for interim storage since 1951, and for reprocessing to recover highly-enriched uranium-235 (HEU) since 1953. With the changes in world events, a decision by DOE in April, 1992 shutdown fuel reprocessing operations. At that time, efforts at ICPP were redirected toward evaluating options for safe interim storage and permanent disposal of both spent nuclear fuels (SNF) and the high-level waste (HLW) resulting from past reprocessing operations. With the characteristics and variety (over ninety types) of unprocessed irradiated DOE-owned fuels in storage at the ICPP and other DOE sites, development of treatment and packing criteria within the current regulatory guidelines is vital for defining interim storage and disposal options.

At Yucca Mountain (YMP), Nevada, the designated nuclear waste study site that may become the eventual geologic repository, the Office of Civilian Radioactive Waste Management (DOE-RW) has studied commercial fuels and some vitrified HLW generated by defense contractors. This paper reviews the current disposal criteria as it might affect disposal of DOE-owned SNF in a geologic repository.

HISTORY OF REPOSITORY DISPOSAL CRITERIA

Several regulatory standards identified disposal requirements for SNF and HLW. The primary regulations are 10 CFR 60 (NRC standard) and 40 CFR 191 (EPA standard). In addition, based on the Energy Policy Act of 1992, EPA contracted the National Academy of Sciences (NAS) to conduct a study to provide, no later than December 31, 1993, " . . . the (EPA) Administrator shall, based upon and consistent with the findings and recommendations of the National Academy of Sciences, promulgate, by rule, public health and safety standards for protection of the public from releases from radioactive materials stored or disposed of in the repository at the Yucca Mountain site." The EPA is to promulgate the standards not later than one year after the Administrator receives the findings and recommendations of the NAS. No later than one year after the EPA Administrator promulgates the standards, the NRC shall, by rule, modify its technical requirements and criteria, as necessary, to be consistent with the Administrator promulgated standards.

At the writing of this summary, the NAS had held seven meetings on various topics and had completed a draft of the findings and recommendations; the draft report is currently undergoing review by the National Research Council. The plan was to issue the final report by March, 1995; thus, the earliest EPA standard promulgation date would be March, 1996. So, the current technical requirements are used as the basis to determine the repository disposal criteria.

The development of the criteria for disposal of nuclear wastes in a geologic repository focuses on both the waste packaging (size, weight, package materials, etc.) as well as the individual waste form(s) themselves. Inclusion of DOE-owned spent fuels into a national repository engenders certain other considerations in developing specific disposal criteria that will be somewhat different from the commercial fuels under the auspices of DOE-RW. Certain DOE SNF (and HLW) materials may be classified as hazardous wastes under the Resource Conservation and Recovery Act (RCRA). Depending on the final determination as to the applicability of RCRA on these materials, 40 CFR 268 Land Disposal Restrictions (LDR) may have to be considered and implemented into the disposal criteria.

Unanswered questions arise with respect to criticality safety and fissile material accountability in a storage/disposal environment. Regulations, such as 10 CFR 60.131(b)7, are very specific governing conditions of criticality safety for operating facilities, including geologic repository operations. Additional work may well be needed to clarify implementation of criticality safety requirements in a post-closure repository environment. Similarly, 10 CFR 70.51 identifies certain requirements relative to accountability and safeguards associated with the handling, storage, and disposal of HEU and other weapons-grade, fissile materials.

Finally, DOE-RW has in the past two years focused on the development of a multi-purpose canister (MPC) for the storage, transportation, and disposal of commercial spent fuel. This standardized design should be used when ever possible for the disposal of DOE-owned SNF. Such an approach would provide significant savings through the use of common container design, handling, and transportation equipments. However, due to the variety of DOE-owned SNF, certain modifications of the MPC (design of internal features) may be required and must be resolved with the DOE-RW organization prior to defense waste acceptance into a national repository.

The following material references the Preliminary Waste Acceptance Criteria for the ICPP Spent Fuel and Waste Management Technology Development Program (WINCO-1157, September 1993) and its replacement, Waste Form Product Characteristics (draft-November 1994). These documents detail the basic waste criteria that, through computer simulations done in support of the performance assessment, identify waste forms and packaging needed to meet existing regulatory requirements for defense waste and DOE-owned SNF disposed of in a geologic repository.

ACCEPTABLE WASTE PACKAGING AND FORM CRITERIA

At the time much of the disposal criteria was being established for high-level wastes (HLW) generated as the result of fuel reprocessing activities, lesser efforts seem to be directed toward intact, spent fuel disposal. As a result, many of the attributes identified in federal regulations for HLW waste form/packaging and performance were not originally intended for direct application to spent fuels. A list of both waste package and waste form criteria as they are expected to apply to DOE-owned spent fuels is shown below.

Waste Package Criteria
Waste Package Materials Temperature Limits
Package Weight Allowable Void Space
Dimensions Package Labeling
Heat Generation Waste Package Handling Features

Waste Form Criteria
Solids Leach Rates
Liquids Corrosion
Explosiveness, Pyrophoricity, Combustibility Gas Generation
Chemically Reactive Mechanical Properties
Neutron Absorbers Radiolysis
Criticality Safety Surface Dose Limits
Safeguards and Material Accountability Radionuclide Inventory
Solubilities Organics
Inert Gases

As an example, liquid exclusion from waste packages is identified in 10 CFR 60.135(b)2: "The waste package shall not contain free liquids in an amount that could compromise the ability of the waste packages to achieve the performance objectives relating to containment of HLW . . . " However, given an argument that there is a potential for free liquids in some packages, can some free liquid be allowed if it can be demonstrated that it won't compromise the package? What amount of free liquid might compromise the package? On what basis might liquids be allowed without concern toward package damage? Should an absolute or quantitative value of allowable liquid be identified, without which there will always be a case for arguing against any package disposal?

Waste Package Materials

The selection of 304L stainless steel is suggested as a basic material for nuclear waste packages (1,2), although various combinations of both common and exotic materials may be used in conjunction with the overall containment. Series 300 (austenitic) stainless steels offer a good combination of corrosion resistance, fabrication, weldability (304L), availability, and favorable costs. Other barriers such as overpacks (Incoloy 825, carbon steel) and the geology/hydrology characteristics of the repository, should allow designed waste packages to meet the retrievability requirements - and allow the waste forms to meet the release limits - for the prescribed 10,000 year containment in the repository.

Package Weight

Selection of either the Multi-Purpose Canister (MPC) [125-ton] or Legal-Weight Truck (LWT) canister [25-ton] for DOE SNF will be dictated by the handling facilities of the producer responsible for fuel packaging. In most cases, the LWT would be used for shipment to and repackaging in an MPC prior to final disposal in the repository. It is conceivable that a small number of LWTs could end up as a final disposal package in a repository

Dimensions

Dimensional information for both MPCs and LWTs planned for storage/disposal containers of DOE-owned fuels is available in various documents (3,4). Overall

external configuration of the package will copy the design used for commercial fuel. There will necessarily be changes to the package internals to accommodate the variety of different fuels types, both in terms of packing density and the lengths of the fuel elements. External dimensional standards adopted for containers used in disposal of DOE-owned spent fuels will adhere to the criteria established for commercial fuels by the DOE Office of Civilian Radioactive Waste Management (OCRWM).

Heat Generation

Heat generation rates are currently quoted at ~800 watts for individual HLW canisters (1) (a Multi- Barrier Waste Package [MBWP] would contain four canisters). Current design for YMP (if a 'hot' repository concept is approved) will allow ~14kW/MPC with a commercial nuclear fuel load. The limitation on allowable heat generation for any MBWP or MPC in the repository will be a function of the ability of the geologic media to dissipate the heat, specifically, heat transfer away from any canister will be a function of the repository conditions (5).

MPC/MBWP configuration will affect heat retention within the canister, which in turn affects centerline or skin temperatures of HLW glass and spent fuels, respectively. In all cases, the controlling item will be the internal heat generation of either the fuel or glass waste form itself. Design will necessarily require an iterative approach to identify allowable heat generation based on known characteristics of the waste form, the package for the waste form, and the ambient conditions found in a specific repository.

Temperature Limits on Waste Forms

There are three basic concerns that potentially impact the temperature or thermal limits imposed on the waste packages destined for storage/disposal. They are: 1) fuel cladding temperature limitations, 2) phase changes in HLW borosilicate glass, and 3) collective temperature effects of the individual waste package on the repository media itself.

Originally, fuel cladding design was based on temperatures in operating, water-moderated reactors. The ability to quickly carry heat away from the fuels thereby allowed higher power levels in the controlled environment of the reactor without concern for overheating. Ambient conditions expected for fuels stored in dry conditions associated with MPC/geologic disposal will generally be more restrictive because of the thermal resistances encountered in the canister design and implied conservatism needed to establish or meet waste acceptance criteria. Of the typical fuel cladding materials encountered in DOE-owned fuels, zirconium and aluminum predominate. Burnup and cooling time (time-out-of-reactor) for each of the individual fuel types, along with criticality safety concerns, will determine the allowable fuel loading in each canister to avoid over-temperature conditions for the cladding or repository limits. Current limits for the aluminum clad fuels have been established at 150C, while zirconium and stainless steel clad fuels will allow for temperatures up to 340C (6).

Collectively, each waste package destined for the repository will have a calculated rate of thermal output. Any given waste package, when combined with the repository environment, will result in a steady state or equilibrium temperature both inside the package and within the geologic medium. Hence, the thermal output limits imposed on any package destined for the repository will be determined by the conditions in the repository itself, namely host rock temperature, predominant mechanism(s) of heat transport, 'thermal' package density within the repository, thermal output of each waste package, and individual waste package backfilling. Not until the actual, detailed characteristics of the repository are identified can the waste package loadings (both thermal and fissile) be finalized.

Allowable Void Space

The void space limitation was intended to encourage producers to maximize packing efficiency in canisters. However, this may be in direct conflict with the packaging required to assure criticality safety when multiple, HEU fuels are contained in a single package. Costs associated with 'excess quantities' of canisters (both production and storage/disposal) created by inefficient packing should ensure optimal packing. At least in the case of spent fuels to be disposed of in salt, void volumes should be filled with inert materials so that the canister emulates a solid body that might better withstand the crushing pressures experienced with salt creep over time. Other considerations favoring addition of other inert materials to a fuel cask with its significant void space might be: 1) enhanced heat transfer, 2) in situ stabilization of fuels, 3) added moderator displacement, and/or 4)

retardation of fuel 'reconfiguration' inside the MPC over time.

Package Labeling

Issues relative to waste package placement within the repository may be dependent on the content of the package (SNF or HLW) and/or the thermal considerations in terms of balancing or even concentrating heat loads for a 'hot' repository configuration. The ability to stage/position waste packages within the repository will be dependent on traceability of data back to the original packages and knowledge of their contents (source term inventories). Any subsequent need for retrieval within the 50-year time frame, should that prove necessary, would also rely heavily on traceability back to a data package and the linkage with any given waste package.

Waste Package Handling Features

Adoption of MPCs as a standard package will allow utilization of the developed technology and standardized equipment design without a large investment in design and qualification of a new canister.

Solids

Prohibition of particulate solids (7) is intended to minimize the spread of contamination, either through a handling accident (canister rupture), or subsequent leaching of materials due to the much greater surface area exposed to leachate upon waste package failure. The need to consolidate particulate material is also dictated by the adoption of best demonstrated available technology (BDAT) as a treatment path for nuclear wastes. Ultimately, the Department of Transportation (DOT) is expected to invoke standards governing the nature of the transported solids.

Consolidation of scrap materials such as TMI fuel debris, may not justify treatment beyond the canisterization already done. Similarly, fuels with known, damaged cladding (whether through destructive testing or corrosion failure induced by wet storage) will likely be 'canned' prior to packaging in an MPC.

Liquids

Free-standing liquids are prohibited from wastes packages destined for geological repositories for several reasons. The combination of internal corrosion (an overriding concern), gas generation, and leaching of the waste form(s) prior to canister breach can all contribute to an accelerated failure of the waste package. Current requirements are ill-defined and totally subjective at this time, with no quantitative technical basis identified (8). Assumptions made for HLW 'glass logs' may be totally inappropriate for spent fuels because of either the nature of packaging, processing, or preceding storage conditions. HLW canisters will experience temperatures in excess of 400C during production, and it is difficult to postulate under these conditions or events any accumulation of any liquids (free or otherwise) in an HLW package.

There is a greater likelihood of liquid availability in waste packages associated with spent fuels than with HLW waste forms. Fuels formerly stored wet and then dried while in interim 'dry' storage have a chance to dry out due to self- heating; canned fuels (formerly stored wet) may or may not dry out while in dry storage, depending on both the can and storage conditions. Fuels stored wet and loaded wet into an MPC offer the greatest chance of water introduction and retention in an MPC. Treatment under these loading conditions is expected to rely on both (self)heating and vacuum dryout after underwater SNF loading into the waste package.

One approach to establish the 'allowable liquid' limits may center on an allowable weight % based on the waste mass, and that in turn may be dependent on the type of waste under consideration. As an example, the Waste Isolation Pilot Plant WAC standards are based on certain assumptions associated with essentially undocumented packaging of materials in 55-gallon drums; these assumptions relative to typical residues that could remain in containers led to a 1% by volume limit. The method of developing a quantifiable acceptance criteria must be technically based, perhaps an allowable wt% (liquid) of waste loading that might result in: 1) canister overpressurization [steam generation?], 2) internal corrosion [allowable mils thickness degradation of the canister inner walls], 3) gas generation [H2 formation], or 4) some other definable value.

Fuels being loaded directly from 'wet storage' into an MPC may require a drying step that invokes some form of testing. Testing may consist of a combination of vacuum with water vapor sampling, dip-tube suctioning, etc. One approach (for purposes of calculation) may assume/allow the equivalent of a 100% saturated volume of any empty MPC in the form of water vapor. As condensed moisture (~385 gm), it would likely be visible were physical inspection possible. With this amount selected as an upper

limit, it would be possible to calculate: 1) maximum pressurization that could occur, given limiting conditions inside the waste package for temperature and pressure, 2) estimates of total metal mass reaction and gas production (M + H2O--->MO + H2), 3) estimates of uniform or perhaps localized corrosion amounts. Most of the conceivable events involving water in an enclosed MPC should be scalar over the time frame of interest.

Explosiveness, Pyrophoricity, Combustibility

Restriction on pyrophorics is to minimize potential for creating 'combustion', given an ignition source in a waste package. Studies at the Rocky Flats Plant (9) have shown that small quantities of pyrophoric plutonium can be accommodated in other nonpyrophoric materials without generating an unacceptable hazard. A 1% limit has been established in the criteria for the WIPP as an acceptable level of pyrophoric material in a transuranic waste package. The 1% is used instead of 3% (demonstrated acceptable at Rocky Flats) since TRU waste forms may not be as uniform or homogeneous as the materials in the Rocky Flats Plant study. Analysis as to the applicability of this limit to SNF will have to be further addressed. The presence of pyrophorics actually does not present a problem in most packages, where the amount of free oxygen would be limited. At best, exposed pyrophoric material at elevated temperatures might act as an oxygen scavenger in the repository environment, with perhaps a fast but controlled rate of oxidation and a limit on the extent of reaction.

Explosives, if contained in a waste package, present a potential hazard to operating personnel during shipment and handling and provide a source for failure of the waste container. Explosive materials would consist primarily of gaseous species (hydrogen) and/or nitrated organics. Through the exclusion of organics and chemically reactive species (nitric acid), and nitrated organics themselves, the issue of explosives should be adequately addressed. In the case of HLW treatment, much of the treatment occurs at temperatures which would destroy any explosive materials or components which might recombine over time. Credit should be allowed for any process that thermally treats material with explosive potential. Hydrogen generation, whether through corrosion reactions with metal in a package or by radiolysis, becomes the single, most significant source of a potentially explosive condition over extended time. However, this situation would also require an ignition source and a source of oxygen. Carbon in the graphite fuels is in itself combustible, but in a monolithic form, limited oxygen, and lack of a significant ignition source would qualify it as non-combustible.

Chemically Reactive Species

Intentionally excluding chemically reactive materials from any waste package is to: 1) prevent formation or development of new reactive materials in the package over time, and 2) avoid reactions that lead to accelerated degradation of the waste form or the containment package.

Reactive materials could generate new compounds or species within waste form or package that were not considered or analyzed in the performance assessment. These new species might alter the characteristics of the waste package in terms of solubilities or breakdown of the form itself, leading to accelerated leaching. Abnormal gas generation rates due to elemental sodium/water or uranium carbide/water reactions could accelerate transport away from the package. Packaging requirements might adopt a two phased approach. Oxygen displacement using an inert atmosphere within the waste package will initially promote decreased reactivity of untreated metallic fuels. Additionally, it may be possible to take credit for limited oxygen entry into a waste package such that 'controlled' oxidation occurs without concern for combustion, and where leachability of the metal oxide is less than that of the pure metal. For spent fuels with special concerns brought about by failed cladding or special, chemically reactive materials, such fuels may require treatment beyond mere canning.

Most wastes, to stand a chance of being acceptable in a geologic repository, will have a predominant amount of oxides or robust, non-reactive metals associated with them. In almost all conditions, the oxides themselves are stable; however, the leachability of technetium and neptunium are both highly dependent on their valence state in the final waste form. Although subject to some leaching, in general low solubilities of the oxide waste forms provide retardation against transport in a groundwater environment.

Neutron Absorbers

Use of neutron absorbers is applicable only to the tuff media. Earlier studies ('93 PA) addressed the use of either fissile mass limits (granite: 0.7 kg U-235/package) and spacing, or water exclusion (salt:10.0 kg U-235/package) and spacing as the two contingencies required for criticality safety in repositories containing fissile materials (10). In a tuff environment, neutron absorbers were considered as one of the contingencies for packages with high fissile loading where credit was not taken for water exclusion (4).
Reference to boron (in its natural isotopic occurrence) as a suitable neutron absorber is not intended to exclude other materials from consideration; it is merely illustrative. Allowance for other materials, such as cadmium, gadolinium, europium, would be based on an ability to have some assurance that the absorber would remain in proximity to the fissile material it is intended to 'poison'. Many factors need to be considered relative to neutron absorbers that might be used in a waste package containing SNF: differential separation of materials, method of fixation inside a waste package, cost, availability, environmental regulations. The same considerations apply whether they are associated with high-enriched uranium (HEU) or low-enriched uranium (LEU) packages.
Criticality Safety
In general, fissile material loadings in individual canisters will be dictated by the geological medium surrounding the canister at the time of placement in the repository. The canister contents need to remain subcritical under all credible conditions likely to be encountered at the Producer's site, including any interim storage array (11). The calculated effective neutron multiplication factor, keff, must be shown to be less than or equal to 0.95 (at initial package loading) after allowing for bias in the method of calculation and uncertainty in the experiments used to validate the method of calculation. The Producer needs to describe the method of compliance in the Waste Form Compliance Plan (WCP) and provide supporting documentation in a Waste Form Qualification Report (WQR). The WQR should also include sufficient information on nuclear characteristics, such as fissile material density and enrichment, of the canistered waste form to enable subcriticality to be confirmed under the repository storage and disposal conditions found in the repository. Where mixed fissile species are present, fissile gram equivalents (FGE) U-235 will be used to determine allowable fissile loadings in the canisters.
Application and enforcement of double contingency barriers to criticality safety beyond the post-closure phase of the repository is unclear. Under current regulations, providing continued assurance as to the presence and adequacy of these barriers in a post-closure environment will require both monitoring and/or periodic inspections to verify the continued adequacy of said contingencies, and remedial action if one or more of the barriers is compromised.
The issue of criticality safety in any repository is more likely a political issue than a technical one. In the PA for the salt and granite repositories, waste packages containing 0.7 to 10.0 kgs U-235 equivalent loadings, respectively, are intended to make a near-field (single package) criticality impossible. The adoption of this approach, while assuring against criticality, created an inordinate number of waste packages to deal with all the spent fuels throughout the DOE complex. Subsequent studies (12) associated with tuff media were to allow for a criticality at some small probability and evaluate the consequences in the repository if it did occur. At issue in this case study is the initial condition of the repository as a 'dry' location. Given water exclusion and fixed neutron absorbers as the two contingencies in place at the time of repository closure, double contingency protection would be in effect. However, without installed monitoring, there will be no convenient way to determine if one or more of the contingencies remained in place, nor would any remediation effort to correct failed barriers likely be possible.
Safeguards and Material Accountability
In accordance with International Atomic Energy Agency (IAEA) policies and treaties to which the United States government is a signatory, the United States has a compliance responsibility regarding materials contained in many of the DOE-owned SNF packages intended for repository disposal. Interpretation of current documents suggest there will be reporting requirements at least up to the time the material is disposed of in a geologic repository, if not beyond that point unless modifications or reinterpretation of controlling documents are made. Regulatory guidance (13) indicates that SNF materials with greater than 20% U-235 enrichment that are

packaged for disposal in a geologic repository must include documented accountability of fissile materials. Such controls establish the guidelines for material balance areas (MBA), security issues, and inventory and other record requirements. The impact of these requirements on geologic disposal of DOE spent fuels has yet to be evaluated in any detail.

Solubilities

With no more detail than found in the statement "the design shall include consideration of solubility", 10 CFR 60.135(a)2 prescribes actions that should be considered without identifying a quantified measure of compliance. Waste treatment issues relative to HLW should in most cases either fix materials of interest in an essentially non-leachable form, or the treatment process (conversion from a nitrate to an oxide or perhaps a change of valence) significantly reduces the solubility of the material. Selection and qualification of chemical species found within the HLW matrix is intended to minimize solubilities. Except in cases where a product form would be chemically more reactive, soluble, or corrosive, oxide forms of the radionuclides are the preferred species.

Spent fuels (intended for geologic disposal under the same regulatory constraints) need not typically be packaged or treated before insertion into the multi-purpose canister unless it is a designed portion of the packaging because of material concerns, such as failed cladding, sodium bonding, or reactive metals. Performance assessment analyses take into account the solubilities of the various constituents comprising the waste package. The materials selected for analysis in the PA are based on their predominance in the waste, their 'mobility' under normal conditions, and the expected effects on the biosphere should they transport past the repository boundary.

Leach Rates

Specific leach rates for radionuclides from SNF are based on the combined barriers provided by the fuel element matrix itself, cladding, and any canister(s) containing the material. Allowable leach rates for packaged SNF will have to be qualified under the regulatory release limits for the geologic repository(ies) as determined by performance assessment modeling efforts. In an analogous situation, an HLW borosilicate glass inside a 304L stainless steel canister would equate to the fissile material (UO2 , UAlx , etc.) inside cladding (Al, stainless steel, zirconium), both of which end up in an MBWP. A great deal of effort has been expended to develop a qualified HLW borosilicate glass form with high resistance to leaching. Emphasis for fuels has been directed toward SNF 'package' criteria, since the SNF materials will have to qualify to the same regulatory release limits prescribed for HLW waste forms without any treatment or conditioning of the fuels.

Corrosion

Corrosion performance of any waste package will be pure conjecture until the actual repository is identified, along with the characteristic makeup of the ground water in that area. Once ground water characteristics associated with a given repository are identified, then there will need to be a development program to predict material behavior in that ground water environment. Predicting corrosion behavior of materials after some 3-5 years of studies, and then extrapolating that information to performance for 50, 300, 1000 or 10,000 years into the future is pure speculation. The performance assessment models use extrapolation techniques and statistical sampling for corrosion rate ranges to estimate probable times to package failure, given current knowledge about failure mechanisms.

Gas Generation

Gas generated by any waste package located in a geologic repository may be of concern either from its behavior while in the repository or its effect on material transport through and beyond the repository boundary (14). Gas generation from external corrosion of the waste package will be a design condition associated with the metal barrier(s) of the MPC/LWT and any overpacks.

However, greater variability is expected within the SNF waste packages (both in type and amount) because of the wider variety of materials encountered with the mix of fuels of differing compositions. Initial loading of canistered waste forms (HLW or SNF) will likely be governed by the requirement for an inert cover gas in the waste package at the time it is seal-welded. Any delays in oxidation within the waste package should translate to increased longevity of metal components within that package, providing additional barriers to liquid transport once the outer package breaches.

Gas generation within any 'intact' canister is basically limited to: 1) the amount of hydrogen that might be formed due to the corrosion reaction caused by the residual water in the MPC/LWT, and 2) the buildup of helium from the alpha decay of any transuranics. In either case, a 'puff' off-gas release might be a concern at a canister breach. In case 1, hydrogen offers a potential flammable mixture, given the presence of both oxygen and an ignition source.

Mechanical Properties

Variability associated with the various components expected in the waste forms themselves suggests the requirements to consider mechanical properties (14) is focused on the packaging materials for the waste forms themselves. Mechanical properties of the waste package should address the issue of package deformation due to creep in the salt repository. For geologic disposal in a tuff repository, thermal effects may govern package design depending on the concept selected for allowable thermal heat loading.

Radiolysis

Consideration of radiolysis in a repository (14) was intended to focus on how water chemistries external to the waste package might be affected by the radiation fields created in a repository.

Surface Dose Limits

Stringent standards will be imposed on the shipment of any waste package containing SNF or HLW. The greatest concern will focus on the measured, external levels (< 200 mrem/hr) (15) that would impact workers involved in canister handling during all phases of transport between the producer site and the geologic repository. Lesser levels (<2 mrem/hr) will be permitted in the cab of transport vehicles. The shielding requirements for virtually any container with high level wastes suggest almost exclusive use of rail transport.

Radionuclide Inventory

Knowledge of the curie inventories of the radionuclides contained within the various waste packages serves several purposes. The average and maximum values for any package allow determination of heat loading, surface dose limits, and calculating materials available for release upon package breach (at any point in the future) in the post-closure repository environment. Additionally, curie inventories of transuranics (and especially fissile materials) are needed for the calculations necessary to assure criticality safety in the various SNF packages.

Reporting requirements are generally stated in a fractional percentage (>0.05%) of the total curie inventory in a package, and for those radionuclides with half-lives greater than 20 or (in some cases) 10 years (16,17). The regulatory guidance found in 40 CFR 191 gives reporting requirements, using a 20 year cutoff for any radionuclide without regard to a fractional percentage. Invoking a requirement for reporting radionuclides down to 10 year half-lives appears to have no basis other than to demonstrate the producer can 'do better' than what the current regulations stipulate. The self-imposed fractional percentage for reporting concentrations is totally arbitrary. As an example, 54 of the 63 radionuclides/transuranics listed with Shippingport (HEU) fuels fall below the >0.05% cutoff (18). Yet several of the radioisotopes, including Tc-99 and Np-237 which are considered very mobile once released into groundwater, fall below the threshold of the Producer imposed reporting requirements.

Organics

The presence of organics associated with SNF and HLW materials is much less likely based on the known properties of both types of waste. Much of the processing HLW experiences is at conditions that virtually precludes the presence of anything more than negligible concentrations of organics. The intention in writing the exclusion requirement was to prevent the addition of any organics in the treatment or preparation of the waste packages. The exclusion of organics simplifies package qualification from the standpoint of minimizing moderator in SNF packages, a potential gas generator in all packages, and elimination of reactive materials such as residual nitrates that might combine with the organics to form explosive materials within the waste packages.

Inert Gases

The allowable use of inert gases is to facilitate the welding procedure(s) that may be used to close the various waste canisters as they are produced. Of some concern may be the ambient temperature of the waste canister at the time of closure, and whether trapped gases may increase in pressure. While in a remote cell with a

controlled temperature environment, pressures inside the canister might well be less than in a repository environment where heat retention in the surrounding geological structure can increase the canister temperature above what was experienced in the remote cell at canister closure.

CONCLUSIONS

Although waste acceptance is the responsibility of the repository, disposal criteria based on existing regulations are examined here to provide an initial indication as to the technical, regulatory, and programmatic issues that remain to be resolved prior to acceptance of DOE-owned SNF in a repository. Furthermore, in the near term, these efforts will provide guidance in the development work and facility requirements needed to provide a waste package suitable for geologic disposal.

DISPOSAL OF CLASSIFIED WASTES FROM NUCLEAR WEAPONS DISMANTLEMENT

Cindy Longenbaugh
U.S. Department of Energy
Albuquerque Operations Office
Ellen L. Watson
Roy F. Weston, Inc.

ABSTRACT

The DOE Nuclear Weapons Complex (NWC) has a policy for disposition of weapons components, but there is not currently any established policy or defined process for management of classified waste generated from weapons dismantlement. The Atomic Energy Act (AEA) governs classified material management, but does not contain specific requirements for the disposal of hazardous or mixed wastes. The Resource Conservation and Recovery Act (RCRA) governs disposal of hazardous and mixed waste but does not specifically address disposal of hazardous and mixed classified wastes. Further, DOE Orders do not currently provide guidance on disposal of classified wastes. Each NWC site presently has its own approach to management of classified wastes.

There are several significant issues associated with disposal of classified waste:
1. Long-term capacity restrictions and costs of classified waste disposal;
2. Obstacles to demilitarization and sanitization (processes which render the waste free from military value and unclassified);
3. Dual requirements between the AEA and RCRA;
4. Inconsistent terminology and procedures between sites; and
5. Stakeholder and security concerns.

Concern about these issues has led to informal discussions among several organizations in the Albuquerque Operations Office (AL) regarding management of classified waste. As a result of these discussions, DOE is evaluating current classified waste management practices at NWC sites. The primary goal is to examine the generation and ultimate disposal of classified wastes and to develop a DOE waste disposal policy or defined process for classified wastes generated from nuclear weapons dismantlement.

The AL group is encouraging the NWC to minimize classified waste generation and disposal and to develop formal practices and procedures to effectively manage the classified wastes that are generated.

Any policy or procedures implemented by DOE should:

Ensure that ultimate disposal of classified waste is protective of public health and the environment.

Ensure that hazardous, mixed, and/or radioactive classified wastes are disposed of in full compliance with all applicable regulatory requirements;

Define practices and procedures to effectively manage classified wastes destined for ultimate disposal, while ensuring site-specific flexibility;

Further mitigate the problem by generating classified waste only as a last resort; and

Be consistent with DOE's Disposition Policy.

INTRODUCTION

As part of its defense mission, the Nuclear Weapons Complex (NWC) within the U.S. Department of Energy (DOE), generates classified materials from dismantlement of nuclear weapons. These materials may be hazardous, radioactive, or non-hazardous and non-radioactive. Ideally, these materials should undergo demilitarization* and sanitization.* There are cases, however, when sanitization has not been a viable option and generation of classified waste results. This classified waste requires secure disposal.* Currently, DOE does not have a policy or formal process for management and ultimate disposal of classified waste. This has been complicated by the fact that classified waste is regulated by the Atomic Energy Act (AEA), which governs radioactive and classified materials, and, if hazardous, may be regulated by the Resource Conservation and Recovery Act (RCRA). The complexity of the management of classified waste and compliance with both the AEA and RCRA are of great importance to DOE, and as a result, the Albuquerque Operations Office has initiated action to address this issue.

The DOE Disposition Policy, issued in May 1993, provides guidance for disposition of classified materials prior to being considered waste. This policy lays the foundation for management of nuclear weapons, subassemblies, components, hardware, or ancillary equipment once they have no further use. This policy requires sites to work with approved practices and procedures for managing these components in accordance with the AEA and RCRA and other authorities as appropriate. Demilitarization and sanitization must be addressed per AEA requirements prior to declaring the components mentioned above as waste.

If the decision is made at the site not to sanitize, and instead to dispose of disassembled parts as classified waste, a policy or, at a minimum, defined processes consistent with the Disposition Policy must be developed to justify that the site has addressed the need for sanitization and determined that it is not feasible, and that disposal plans for the resulting waste do not violate any regulatory or DOE requirements. It is DOE's intent to integrate such a "classified waste policy" with the already existing DOE Disposition Policy.

For the purposes of this paper, the term classified waste is defined as classified material that will not be sanitized based on technical, Environmental Safety and Health (ES&H), or economic justifications. Classified waste is ultimately disposed of at DOE approved disposal sites which meet AEA and disposal site requirements to include RCRA and low-level waste requirements, as appropriate. The term ultimate disposal is defined as the fate of a classified material once all programmatic and

statutory concerns have been addressed and the dismantlement program is no longer concerned with it.
This paper does not attempt to establish a DOE policy or procedures regarding management of classified wastes from dismantlement activities. The contents of this paper reflect the opinions of the authors and do not necessarily reflect the position of DOE.
SIGNIFICANT ISSUES
The following sections discuss the significant issues associated with classified waste management and ultimate disposal resulting from dismantlement.
Long-Term Capacity and Costs
Classified waste must be disposed of in secure classified waste landfills. These landfills must be guarded in perpetuity, or until the waste is declassified* or unearthed and sanitized. Continued generation of classified waste will require DOE to evaluate long-term landfill capacity and security. As part of DOE waste minimization objectives and as a result of diminishing budgets, DOE should reevaluate disposal of classified waste as a preferred option. With capacities for all waste disposal within DOE slowly being absorbed, classified waste disposal should be reviewed as part of a site's waste minimization program, as well as part of a DOE-wide waste minimization effort.
The two primary DOE facilities to which most NWC sites send classified wastes for disposal are the Nevada Test Site (NTS) and Savannah River Site (SRS). However, several other sites have on-site classified disposal capabilities.
A potential problem arises if it becomes necessary to close and remediate a classified waste landfill. In that situation, all of the classified waste would have to be retrieved and sanitized or re-disposed of in another secure classified landfill. The potential costs of this process must be reviewed when analyzing trade-offs of sanitization versus disposal.
Although at an individual site, disposal of classified waste may appear to be more cost-effective than sanitization in the short-term, DOE should weigh those costs against the cost of infinite protection of the classification of the waste at the disposal site and any future disposal site to which the waste may be transferred. By including waste minimization into the budget equation, DOE will likely be able to effectively justify sanitization versus disposal in most cases. If classified waste generation is not minimized, DOE budgets must begin to project for outyear classified waste capacity requirements.
Demilitarization and Sanitization
Ideally, demilitarization and sanitization of nuclear weapons components should occur prior to ultimate disposal. Once a classified component has been demilitarized and sanitized, it is no longer classified and can be disposed of with other unclassified wastes, as appropriate. Currently, however, sanitization of classified components is often not determined to be the best option. At present, disposal of these materials as classified wastes is the option chosen at most NWC sites.
declassification is an administrative determination that a component is no longer classified.
Within the NWC, various obstacles exist associated with sanitization of classified materials. These obstacles include:
- Lack of on-site technical capability to perform sanitization;
- Lack of available financial or personnel resources to support sanitization activities;
- Lack of an appropriate facility in which to sanitize classified materials; and
- Difficulties and expenses associated with ensuring worker safety and protecting the environment during the sanitization process.

DOE sites must consider these potential obstacles when deciding whether or not to sanitize classified material prior to disposal. As noted above, the near-term versus long-term cost to dispose of waste generally has been the deciding factor to dispose of parts as classified waste instead of demilitarizing and sanitizing. Budget cuts are becoming commonplace throughout the NWC and it is often difficult to be visionary and consider the long-term DOE budget picture while attempting to manage the current fiscal year budget at one site. DOE must play a balancing act by strategically planning for the future while concurrently managing the complex on a day-to-day basis.
Statutory RequirementsManagement and control of nuclear weapons components, including dismantlement operations, fall under the authority of the AEA. The AEA

limits control of nuclear weapons, components, and materials; and the dissemination of "restricted data," and specifies that:

"It shall be unlawful, except as provided in Section 91, for any person to transfer or receive in interstate or foreign commerce, manufacture, produce, transfer, acquire, possess, import, or export any atomic weapon" (42 U.S.C 2122).

"It shall be the policy of the Commission to control the dissemination and declassification of Restricted Data in such a manner as to assure the common defense and security" (42 U.S.C 2161).

As a result of these AEA provisions, any classified material destined for ultimate disposal must be guarded in perpetuity or until such time that it is declassified or sanitized.

Disposal of solid and hazardous wastes are subject to the provisions of RCRA and respective state waste management regulations.

With regard to the AEA, RCRA provides that:

"Nothing in (RCRA) shall be construed to apply to (or to authorize any state, interstate, or local authority to regulate) any activity or substance which is subject to the Atomic Energy Act of 1954 except to the extent that such application (or regulation) is not inconsistent with the requirements of such (Act)" (42 U.S.C 6905(a)).

Interpretation of this clause of RCRA varies to the extent that many states that administer RCRA have determined that RCRA applies to any classified wastes that are hazardous or are considered mixed wastes (contaminated with both hazardous and radioactive constituents), while at least one state has determined that this provision of RCRA exempts classified waste from RCRA requirements. This inconsistency in interpretation will likely continue until such time that EPA or the courts issue an interpretation on RCRA applicability to classified waste. While the current interpretation may vary from site-to-site, the NWC general interpretation has been that RCRA does, in fact, apply to hazardous and mixed classified wastes and that an inconsistency need not necessarily exist.

Another area subject to interpretation is whether classified materials should be considered waste. RCRA contains statutory requirements that apply to solid waste and includes definitions of solid waste. It has become apparent that within DOE there are varied interpretations of terminology associated with classified material destined for ultimate disposal. For example, one site may not consider a classified hazardous material that is sent for burial in a classified landfill a waste because it still requires protection and cannot be considered discarded. Another site may consider the material to be waste because it has no future use and consider its burial in a landfill as discarding. DOE is working to develop definitions associated with the term "ultimate disposal" as it relates to classified material for which the NWC has no further use.

Stakeholder and Security Concerns

As DOE and states further cultivate their partnerships to evaluate and prioritize site issues, the states and other stakeholders have become increasingly involved in DOE decision-making processes. If classified waste is determined to be subject to RCRA by a state that has received authorization from EPA to implement RCRA, DOE is then required to comply with the law regardless of the fact that the waste is classified. It is DOE's responsibility to manage classified waste at each site in compliance with all applicable regulations, including AEA and RCRA. Although states may not have access to the classified waste, it is DOE's responsibility to assure the states that classified waste is managed safely and compliantly and not to withhold RCRA characterization or disposal information from the states due to waste classification.

Inconsistent Procedures

The decision process regarding disposal of classified wastes versus sanitization is different from site to site within the NWC. Factors such as funding, technical capability, worker safety and protection of the environment are all considered in disposition decisions. There is not, however, a consistent manner across NWC sites to assess whether the site's justification for ultimate disposal versus sanitization is the best option, or whether classified waste destined for ultimate disposal is managed effectively.

CURRENT PRACTICES AT NWC SITES

The NWC sites currently have a variety of approaches to management of their classified waste. The classified waste generated encompasses the following waste

types:
  hazardous;
  non-hazardous and non-radioactive; and
  low-level radioactive.
Current classified waste disposition activities at NWC sites include disposal of hazardous; radioactive; and non-hazardous and non-radioactive classified waste, including sanitary waste at on-site disposal facilities; as well as disposal of low-level radioactive classified waste off-site at approved DOE facilities.
General obstacles to sanitization were discussed previously in this paper. Specific obstacles being encountered at NWC sites at this time include:
  Lack of equipment to sanitize radioactive contaminated components.
  Lack of facilities in which to sanitize radioactive contaminated components.
  Costs of sanitization, in particular for certain small quantities of classified wastes.
  Lack of available personnel to perform sanitization activities.
  Potential worker hazards.
  Lack of awareness of sanitization options.

AVENUES FOR RESOLUTION

Efforts have been initiated within the NWC to develop a policy statement that will minimize the generation and disposal of classified waste while providing guidance for development of practices and procedures to effectively manage the classified wastes that are generated.
The Albuquerque Operations Office (AL), as the lead NWC office, has selected representatives with experience in weapons programs, environmental regulations, waste management, and the AEA to develop a draft policy statement, or at a minimum defined procedures, which will be forwarded to DOE/HQ for consideration. It is not the intent of this group to prohibit NWC sites from generating any classified waste, but rather to provide a comprehensive review of current classified waste management practices and how they reflect DOE's strategic goals of waste minimization and effective management of classified waste while meeting all regulatory requirements.
The AL group is working toward developing a policy or procedures that will both encourage the minimization of classified waste generated and disposed, and develop practices and procedures to effectively manage the classified wastes that are generated.
Any policy or procedures that are implemented by DOE should:
  Ensure that hazardous, mixed, and radioactive classified wastes are disposed of in full compliance with all applicable regulatory requirements;
  Define practices and procedures for NWC sites to effectively manage classified wastes destined for ultimate disposal, while ensuring site-specific flexibility;
  Further mitigate the problem by generating classified waste only as a last resort; and
  Be consistent with DOE's Disposition Policy.
A flow diagram illustrating a potential site decision-making process regarding sanitization versus generation of classified waste is shown in Fig. 1. This diagram emphasizes DOE involvement in site decisions to sanitize or dispose as classified waste. Criteria to review each site's classified waste management practices will not merely be based on economics, but will also include factors such as schedule, capability, health and safety concerns, regulatory requirements, and available disposal capacity.
Fig. 1.
The AL team approach has been beneficial in ensuring that both the environmental and weapons program concerns are objectively addressed to the benefit of DOE. It is envisioned that this team approach will overlap at the DOE/HQ and site level to effectively integrate all stakeholders.
In developing a classified waste management policy, DOE is faced with making potentially difficult decisions that affect long-term versus short-term goals by encouraging sanitization as the first option, and classified waste generation and disposal as a last resort.

APPROACH FOR ADDRESSING ENVIRONMENTAL JUSTICE IN ENVIRONMENTAL STUDIES

John W. Williams
Ibrahim H. Zeitoun
Science Applications International Corp.

Patrick J. Wells
United States Department of Energy

ABSTRACT

This paper discusses the inclusion of environmental justice in environmental documents that are prepared in compliance with the National Environmental Policy Act (NEPA). Environmental assessments (EAs) and environmental impact statements (EIS) contain sections which describe the affected environment and impacts on the affected environment. This paper discusses an approach that would be used to incorporate environmental justice in these standard sections of environmental documents. It also addresses basic concepts such as "disproportionately high and adverse," and the relationship to the traditional concept of significant. Some practical examples are given of the types of data and analyses which can be included in the description of the affected environment and in the evaluation of environmental impacts.

DISCLAIMER

Opinions and conclusions expressed in this paper are those of the authors only. Unless so stated in writing in other documents, these opinions and conclusions should not be construed to represent the positions or policies of any organization or government agency.

INTRODUCTION

Environmental justice has assumed an increasingly prominent role in the environmental movement over the past decade. In general, the term "environmental justice" refers to fair treatment of all races, cultures, and income levels with respect to environmental laws, policies, and government actions. In February 1994, Executive Order 12898 titled Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations, was released to Federal agencies. This order requires each Federal agency to incorporate environmental justice as part of its mission. Federal agencies are specifically ordered to identify and address disproportionately high and adverse environmental effects of its programs, policies, and activities on minority and low-income populations. In a related memorandum to heads of all Federal departments and agencies, released concurrently with Executive Order 12898, the President underscores provisions of existing laws that are intended to help ensure the environmental quality of communities throughout the nation. This memorandum further states that mitigation measures identified in environmental documentation should address significant and adverse environmental effects on minority communities and low-income communities.

In addition to describing environmental goals, Executive Order 12898 directs the Administrator of the Environmental Protection Agency to convene an Interagency Federal Working Group on Environmental Justice (referred to below as the Working Group). The Working Group provides guidance to Federal agencies for identifying disproportionately high and adverse human health or environmental effects on minority and low-income populations. The Working Group also coordinates with each Federal agency during development of an environmental justice strategy. Since definitions developed by the Working Group are not finalized, draft definitions are used in the analysis below. In coordination with the Working Group, the Department of Energy and other Federal agencies are developing guidance on implementation of the executive order.

CONCEPTS AND DEFINITIONS

This paper deals with the inclusion of environmental justice in EAs and EISs prepared in compliance with NEPA. The executive order which advocates this inclusion does not explicitly define key terminology. Rather, the development of definitions for terms such as "disproportionately high and adverse," "minority," and "low-income" are delegated to the Working Group. As of this date (January 1995), the development of definitions by the working group is not complete. In this paper we will present and discuss draft definitions, and discuss applications of these definitions to the preparation of environmental documentation.

The concept of "disproportionately high and adverse" effects is central to the implementation of the President's Executive Order. Attempts to define "disproportionately high and adverse" can be controversial because the terminology

is subject to individual perceptions of fairness, and it is difficult to define these terms in a meaningful and unambiguous manner. Analyses presented in this paper use the following definitions:

Disproportionately high and adverse human health effects - Human health effects, including cumulative or synergistic effects, on minority or low-income populations which exceed generally accepted levels of risk.

Disproportionately high and adverse environmental effects - Deleterious effects on biological and other resources within low-income or minority communities significantly exceeding those within the community at large.

Substantially affect human health - To impact human health such that there is a measurable incidence of any specific physical illness, disease, or disorder significantly higher than the national average.

Substantially affect the environment - To impair air quality, ground or surface water quality, animal or plant life, real property values, or other socioeconomic factors, such that there is a measurable impact significantly greater than that for the nation as a whole.

Regulations issued by the Council on Environmental Quality (CEQ) focus environmental documents on effects which are environmentally significant. These regulations specifically require that "Impacts shall be discussed in proportion to their significance. There shall be only brief discussion of other than significant issues." (40 CFR Section 1502.2b). The CEQ Regulations provide a rather detailed description of "significant" in terms of context and intensity (40 CFR Section 1508.27). However, the benefits or burdens of insignificant effects can be disproportionate. For example, if an action results in an insignificant risk of adverse health effects in an area with predominantly low-income households, the action may be perceived as inherently unjust, regardless of the magnitude of the risk. Both the letter and spirit of the CEQ Regulations discourage detailed discussion or mitigation of insignificant environmental effects. In such cases, treatments of environmental justice require a balance between reasonable allocation of resources devoted to effects which are not environmentally significant but which concern basic concepts of fairness. In this paper, it is assumed that in the preparation of NEPA documentation, an environmental effect must be found to be significant prior to any detailed evaluation of disproportionately high and adverse effects. A further discussion of "significant" verses "disproportionate" is given in Section 4 below.

Two other terms are of central importance because the subject executive order addresses environmental justice for two specific groups. One is "minority population" and the other is "low-income population." In this paper, we adopt the following definitions:

Minority - Individuals classified by the U.S. Bureau of the Census as Negro/Black/African American; Hispanic, Asian or Pacific Islander; American Indian, Eskimo, or Aleut; and "Other Races." The minority population in a potentially affected area is the number of individuals residing in the area who are members of a minority group.

Low-Income Household - A Household for which the median household income is 80 percent or below the median household income for the metropolitan statistical area (urban) or county (rural). The low-income population in a potentially affected area is the number of low-income households residing in the area.

We use the Office of Management and Budget Directive No. 15 as a basis for presentation of racial and ethnic data. This directive advocates the collection and reporting of the following minimum designations:

Race:	American Indian or Alaskan Native
	Asian or Pacific Islander
	Black
	White
Ethnicity:	Hispanic Origin
	Not of Hispanic Origin

Data of this format are available from the U.S. Bureau of the Census. In this paper, we specifically used Table P-12 of the Census Bureau's Standard Tape File 3A (STF3A) to describe the racial and ethnic composition of minorities (1).

Executive Order 12898 specifically identifies low-income populations as one of the

two populations designated for consideration of environmental justice. Using the above definition for low-income households, Table P-80 of STF3A can be used to identify low-income populations. One alternative is to use Table P-121 of STF3A which provides data for individuals who are below the poverty level. Both sets of data are indicators of low-income status. We use the definition above and Table P-80 of STF3A because the executive order specifically cites low-income rather than poverty status.

METHODOLOGY

Description of the Affected Environment

A description of the affected environment is standard for EISs and EAs (40 CFR Section 1502.15). As a consequence of Executive Order 12898, the affected environment sections of EAs and EISs now include a characterization of the potentially affected minority populations and low-income populations. For example, if the proposed action were to potentially affect urban seaports in the United States, the minority populations residing near the ports could be described as illustrated in Fig. 1. Estimates of the minority populations residing within 16 km of the port were obtained from a Geographical Information System (GIS) and 1990 census data extracted from STF3A. For comparison, Fig. 1 also includes a similar description for the U.S. population. In this figure, the ethnic designation "Hispanic" includes Hispanics of all races. Populations shown for American Indian, Eskimo, or Aleut; Asian or Pacific Islander; Black; and Other Races include only individuals who are not of Hispanic origin. For this particular example, the east and west coast ports differ noticeably in the racial and ethnic composition of minority populations residing near the ports. In terms of racial and ethnic percentages of the total population, both ports differ noticeably in composition from that for the total U.S. population.

Figure 2 shows a comparison of low-income households as a percentage of total households surrounding the ports and for the total U.S. This information was also extracted from 1990 census data contained on STF3A. These graphs show the percentage of low-income households residing within 16 km of the urban ports of Philadelphia and Long Beach, respectively. Data for surrounding counties refer to the percentages of low-income households residing in all counties which lie at least partially within a circle of 16 km radius centered at the port. The graphs also show percentages of low-income households for the states which contain the ports and for the U.S. For the port of Philadelphia, the percentage of low-income households residing within 16 km of the port exceeds those for surrounding counties, the state, and the nation. The opposite is true for the port of Long Beach. Data such as that shown in Fig. 2 provides a perspective for comparison of low-income households at the local, state, and national levels.

Fig. 1.

Fig. 2.

In summary, GIS software and U.S. Census Bureau data can provide a useful description of the minority populations and low-income populations residing in geographical areas within the U.S. and its territories. The racial/ethnic composition and income characteristics of the population can be described in some detail. This type of description is useful in the preparation of documents which comply with both NEPA and Executive Order 12898.

ENVIRONMENTAL IMPACTS

Descriptions of the environmental impacts of a government action are central to EAs and EISs (40 CFR Section 1502.16). This section discusses the inclusion of environmental justice in the impacts section for cases in which there are no significant impacts and for cases in which there are significant impacts.

We first consider the case in which there are no significant environmental impacts. As discussed in Section 2, CEQ regulations advocate detailed treatment only of those effects which are environmentally significant. Exhaustive treatment of effects which are not significant is specifically discouraged by the CEQ Regulations. When discussing negligible environmental effects, portions of the impacts section which deal with environmental justice should summarize the evidence that the effects are not significant and cite specific parts of the environmental document that support the findings.

If the government action results in significant environmental effects, then the executive order requires analyses to determine if the action results in disproportionately high and adverse effects on minority populations or low-income

populations. This evaluation in turn requires the identification of minority and low-income populations residing in the affected area. Use of census data combined with block group or census tract boundaries in the Census Bureau's TIGER LINE files can be an especially powerful tool in this evaluation (2).

The approach used in the evaluation depends on whether or not the environmental effects are quantified. In past studies of environmental equity in the siting of hazardous waste or other unwanted facilities, analyses often do not quantify adverse effects on the surrounding populace. Instead the burden of unwanted effects is assumed to fall equally on all residents in an affected area (3,4). Such studies have been concerned with disproportionate burdens rather than disproportionately high and adverse impacts. In order to determine whether or not an effect is disproportionate, it is necessary to answer the question: Disproportionate relative to what? A common approach is to define benefitted and burdened populations and compare statistics such as the percentages of minority residents or mean incomes between the populations (3,4). For example, in a study of sites for Waste-to-Energy Facilities, burdens of the facility were assumed to fall on all residents of the town in which the facility is located (3). The benefitted population was defined to be all persons residing within the service area of the facility - usually the entire county. If the adverse effects are not quantified, then the definition of benefitted and burdened population are imprecise, and presence alone in a given area is assumed to result in a burden. Such studies necessarily focus on disproportionate results, because the lack of quantification permits no comparison of minority and non-minority effects or low-income and non-low-income effects within the burdened population. The use of census data and GIS technology can still provide a useful tool for such studies in cases where the geographical distribution of unwanted facilities relative to low-income or minority populations is of central interest (2).

On the other hand, if the health, social, or other environmental effects are quantified, there is no need to define distinct benefitted and burdened populations in the evaluation of environmental justice. Rather, one can estimate the disproportionality between minority and non-minority or low-income and non-low-income populations within the burdened population. For example, radiological health effects are usually a central concern in the preparation of environmental documentation for actions involving radioactive materials. Models for health effects due to the transportation or storage of radioactive materials allow the quantification of impacts on the population. When combined with census data, these models allow a detailed evaluation of the impacts on minority and low-income populations. Figure 3 shows the low-income population residing within 16 km of the Military Ocean Terminal at Sunny Point, North Carolina. This port recently received urgent-relief shipments of spent nuclear fuel from foreign research reactors (5). Figure 3 was obtained from GIS software and U.S. Census Bureau data. The GIS provides a quantitative display of demographic data within a spatial context. Although estimates of radiological health effects were found to be negligible (5), this type of data could be used to estimate the health effects on populations residing near the port. As illustrated in Fig. 3, GIS processing of census data provides a technique for the spatial resolution of demographic data.

Fig. 3.

CONCLUSIONS

Disproportionately high and adverse effects on burdened populations are the central concern in evaluations of environmental justice. In NEPA documentation, significant environmental effects, if any exist, receive the primary consideration. This paper addresses the position that only those environmental effects that satisfy the requirements for significance given in the CEQ Regulations are appropriate candidates for detailed analysis under environmental justice concerns. Implementation of the analyses with GIS software and Census Bureau data provides a useful tool for characterization of minority and low-income populations, as well as quantification of environmental effects on minority and low-income populations.

STREAMLINING THE NATIONAL ENVIRONMENTAL POLICY ACT COMPLIANCE PROCESS

Miriam E. Whatley

Waste Isolation Division
P. O. Box 2078 MS-170
Carlsbad, NM 88221

ABSTRACT

In June 1994 Secretary of Energy Hazel O'Leary issued the Secretarial Policy on the National Environmental Policy Act. In the introductory memorandum, she stated, "I am directing a number of actions to streamline the NEPA process, minimize the cost and time for document preparation and review, emphasize teamwork, and make the process more useful to decision makers and the public." This paper evaluates the streamlining strategies that several DOE sites are using to meet the challenges presented in the Secretary's policy. Emphasis is on time- and cost-saving measures, quality improvement, and stakeholder involvement. Several NEPA compliance personnel from various DOE sites were interviewed to gain a better understanding of present conditions and goals for the future.

INTRODUCTION

In June 1994, Secretary of Energy Hazel O'Leary issued the Secretarial Policy on the National Environmental Policy Act (NEPA). In the introductory memorandum, she stated, "I am directing a number of actions to streamline the NEPA process, minimize the cost and time for document preparation and review, emphasize teamwork, and make the process more useful to decision makers and the public." Her policy statement instructed the U.S. Department of Energy (DOE) to seek out and implement innovative strategies to streamline the NEPA compliance process and called for the completion of each DOE environmental impact statement (EIS) in just 15 months (1). This new time allotment is an ambitious goal. The average time needed for the preparation of a DOE environmental assessment, a much less detailed NEPA document than an EIS, has been 15 months (2).

In reviewing the DOE's EIS process, it is evident that improvement is needed. At the November 1992 meeting of the Weapons Production Complex Area Managers, plant managers, and design laboratory managers, the plant and laboratory managers identified the need to reduce the review and approval time for documents prepared under NEPA as one of their top five issues (2). In response to their concerns, a Total Quality Process Management Team was formed to address problems in the NEPA process. Their main focus was to improve the process for preparing environmental assessments; however, the recommendations contained in the Report of the Environmental Assessment Process Improvement Team also apply to the preparation of EISs.

In November and December of 1994, a survey was circulated among six DOE organizations that are responsible for NEPA document preparation. These organizations consisted of the Rocky Flats, Hanford, Oak Ridge, Savannah River, Waste Isolation Pilot Plant, and West Valley sites. Responses were received from five of the six organizations. In addition, some of the surveys were followed up by personal interviews for clarification.

Survey and interview results indicated that the DOE has welcomed the challenges proposed by the Secretary of Energy and the process improvement team to " ... make NEPA work better and cost less." DOE organizations are striving to implement and share creative strategies for streamlining the NEPA compliance process.

The survey participants are from organizations with varied missions, but they all have similar expectations from the NEPA documentation process--initiating projects on schedule; getting the maximum value added in return for time and money spent; making informed, environmentally sound decisions; and having stakeholder support for decisions made. EIS document managers are tired of unnecessary project delays, "midstream" change in scopes, waste of time and money expended, "truck-load" volume EISs, and dissatisfied stakeholders.

To date, studies have been done, groundwork established, and a new NEPA policy issued; however, system-wide changes are not easily achieved. The following discussion examines some of the methods being implemented by the DOE to make the transition from an era of slow-moving and costly environmental analyses to a better, faster, less expensive approach to the NEPA process. Changes being initiated include reducing the average length of EISs, increasing reliance on reference documents, getting the most out of EIS contracts, creating EIS management teams, and maximizing stakeholder involvement. Lessons learned at the various facilities are being shared so that the DOE may make fundamental, positive changes to the way its NEPA business is conducted.

EIS TIME AND COST REDUCTION

One of the ways the DOE intends to meet the 15-month EIS schedule and reduce document preparation costs is to reduce the volume of the documents. If documents are smaller, it logically follows that they will cost less and will take less time to produce. Brief EISs have always had the approval of the Council on Environmental Quality (CEQ). Their regulations state that "Environmental Impact Statements shall be analytical rather than encyclopedic." The CEQ also recommends that the text of final EISs " ... shall normally be less than 150 pages and for proposals of unusual scope or complexity shall normally be less than 300 pages." (3)

The DOE is getting back to basics, carefully prioritizing those issues that require analyses. Sometimes this involves a re-evaluation of traditional EIS formulas. The Savannah River
Site's F-Canyon Plutonium Solution Environmental Impact Statement provides only a limited discussion of the following:

Geologic resources	Noise impacts
Aesthetics/scenic resources	Socioeconomics
Ecological systems	Cultural resources

The Environment Impacts Section justifies the narrow discussion of these topics by indicating that minimal impacts would be expected to impact these resources. This section then focuses analyses on areas deemed worthy of closer attention such as health effects, air and water resources, utilities, waste management, land use, and transportation (4). By omitting sections of "boiler plate" information from the Environmental Impacts Section, the preparers have succeeded in reserving comprehensive analysis for legitimate issues (5). Readers wanting more information are directed to several other site environmental documents that are available in public reading rooms.

DOE is currently planning the preparation of their second supplemental EIS (SEIS-II) for the Waste Isolation Pilot Plant (WIPP). To reduce cost and document preparation time, the DOE plans to curtail the use of new and original environmental analyses that are not needed (6). This will be accomplished by incorporating, by reference, pertinent analyses contained in other WIPP compliance documents such as the WIPP No-Migration Variance Petition, the WIPP RCRA Part B Permit Application, and the WIPP Safety Analysis Report.

The DOE also hopes to reduce costs for the WIPP SEIS-II by providing the contractor with an annotated outline (7). Use of the annotated outline should reduce contract costs and ensure a better quality product by providing clear objectives to the contractor for each section that will be included in the document.

NEPA personnel at the Hanford Site state that they have reduced EIS preparation costs by dividing the project into several small pieces. For their Safe Interim Storage of Hanford Tank Wastes Environmental Impact Statement (8), NEPA contractors carefully evaluated staff assignments and utilized lower cost staff for less important aspects of the EIS. Furthermore, no staff members were assigned full-time to the EIS, so only productive hours were billed to the EIS budget (9). The DOE plans to take a similar approach for the WIPP SEIS-II, contracting out distinct analytical sections to the contractor so that only productive hours are billed (6).

Another strategy now being employed by the DOE to slash months from EIS schedules is the creation of project-specific management teams that are responsible, start to finish, for the collective preparation of EISs and for cooperative comment resolution. These management teams, with participants from all of the required organizational units, hold interactive internal review meetings, sometimes resolving comments for an entire EIS in just two weeks (5).

QUALITY IMPROVEMENT AND STAKEHOLDER PARTICIPATION

Quality improvement and stakeholder involvement go hand-in-hand for an EIS. DOE sites nationwide are making a greater effort to seek out stakeholder views prior to making EIS decisions. Increased up-front communication with the public results in EISs that display a more balanced range of alternatives. Another benefit is that the scope of the EISs is being agreed upon early in document development; fewer changes are occurring midstream in the process.

Savannah River Site NEPA personnel are finding that changing the format of their public meetings has made a significant improvement in the quality of the communication between DOE and the interested public. Savannah representatives stated that the public has been very receptive towards informal meetings. DOE representatives are leaving the platform and lectern behind and meeting face-to-face with the public for one-on-one question-and-answer sessions. For the F-Canyon Plutonium Solutions Environmental Impact Statement, even the draft hearings had a large informal component. For the first few hours of the meeting, stakeholders were asked if they had any questions or concerns that they would like to submit to the DOE representatives "off the record." At the conclusion of this informal comment period, the participants were given the opportunity to provide formal statements to a court recorder. Many of the attendees were so pleased with the informal discussion that they no longer felt their issues required formal response and resolution (5).

The WIPP has prepared a draft Stakeholder Involvement Plan which outlines the public outreach efforts that are planned for the SEIS-II. The SEIS-II preparation formula will include conducting intensive public participation meetings and will focus on individuals who have historically held interest in the WIPP project (10). By obtaining key stakeholder input at the beginning of the EIS process, the DOE expects to reduce later changes to the document's scope and to have greater public support for the alternatives that are chosen for evaluation. The DOE also plans to increase public accessibility to the SEIS-II development by using people instead of machines to answer the comment phone lines during business hours and by accepting comments via fax line and electronic bulletin board. These steps will reduce costs associated with the SEIS-II while enhancing opportunities for public involvement.

While the DOE plans to enhance opportunities for public involvement with the SEIS-II, it wants to ensure that time and money are expended only in response to genuine public interest. DOE representatives will hold fewer formal meetings at fewer locations for the SEIS-II. This approach responds to the lessons learned during the last SEIS preparation process. Attendance was low at some of the locations where previous hearings were held (DOE representatives outnumbered the attendees five to one), and few of those that did attend had a genuine interest in the WIPP project. Accordingly, the draft and final SEIS-II will also be provided to fewer public reading rooms than the previous SEIS.

CONCLUSION

The DOE has begun a journey that will lead to a streamlined NEPA process. However, no single strategy will result in the needed improvements, and the solutions now being attempted will not result in overnight success. Some of those interviewed felt that changes are not occurring quickly enough and that the DOE needs to make an even greater commitment to internal cooperation. The DOE should ensure that EIS management teams are composed of those with decision-making authority, that the EIS scope is agreed upon, and that contractors are provided with clear performance expectations.

The 15-month EIS envisioned by the Secretary is within the grasp of the DOE. The DOE is beginning to " ... make NEPA work better and cost less," finding success in reducing review cycle time, focussing environmental analysis on worthy issues, and strengthening communication with stakeholders. Improvements being made in one area of the NEPA process are triggering positive changes to other areas, and lessons learned with each EIS are being shared for the benefit of future preparers.

The DOE has taken the Secretary's challenge to heart, restructuring the way its NEPA business is conducted. Creativity, perseverance, and shared responsibility will ensure that the new approaches succeed.

COMPUTER-AIDED WASTE MANAGEMENT STRATEGIC PLANNING AND ANALYSIS*

H.I. Avci

Argonne, Illinois

ABSTRACT

A computational model called WASTE_MGMT has been developed to assist in the evaluation of alternative waste management approaches in a complex setting involving multiple sites, waste streams, and processing options. The model provides the quantities and characteristics of wastes processed at any facility or shipped between any two sites as well as environmental emissions at any facility within the waste management system. The model input is defined by three types of fundamental waste management data: 1) waste inventories and characteristics at the point of generation; 2) treatment, storage, and disposal facility characteristics; and 3) definitions of alternative management approaches. The model has been successfully used in the preparation of the U.S. Department of Energy (DOE) Environmental Management Programmatic Environmental Impact Statement (EM PEIS). Certain improvements are either being implemented or planned that would extend the usefulness and applicability of the WASTE_MGMT model beyond the EM PEIS and into the strategic planning for management of wastes under the responsibility of DOE or other agencies.

INTRODUCTION

The process of "waste management" can be as simple a task as packaging and properly disposing of a single waste stream at a single site, or it can be a very complex undertaking involving many sites with multiple waste streams subject to a variety of pretreatment, treatment, storage, packaging, transportation, and disposal options. Such complex waste management issues are being faced by the U.S. Department of Energy (DOE) and other federal agencies such as the U.S. Department of Defense. To provide an overall management strategy for all radioactive and hazardous waste generated or stored at its many installations around the country, the Office of Environmental Management (EM) of DOE is preparing a Programmatic Environmental Impact Statement (PEIS), often referred to as the EM PEIS. An internal review draft of the EM PEIS was issued in late November 1994. After being reviewed by the various DOE headquarters and field offices, the EM PEIS will be revised in response to comments and will be distributed for public and other agency (other than DOE) review. The current schedule calls for this distribution to take place in late March 1995.

The EM PEIS evaluates alternative management strategies for DOE wastes at approximately 50 sites and for five types of waste: high-level (HLW), low-level (LLW), transuranic (TRUW), low-level mixed (LLMW), and hazardous (HW). For each waste type, up to several thousand waste streams can exist at a given site. The number of alternative strategies evaluated varies by waste type from a few to more than 10. Wastes generated as part of on-going operations, wastes in storage from

past operations, and wastes that will be generated as part of environmental restoration activities are considered.

In such complex cases involving multiple sites, waste streams, and processing options, a computer model can be invaluable in analyzing the various waste management strategies and selecting the alternatives that meet certain predefined criteria. Argonne National Laboratory (ANL) scientists have developed a computational model called WASTE_MGMT for use in assessing the impacts associated with alternative strategies for management of the wide array of wastes being considered in the EM PEIS. The model has been used successfully for the EM PEIS and has the potential to be a valuable strategic planning tool for future management of DOE wastes. The model can also be adapted for similar use by other agencies.

This paper provides a brief description of the WASTE_MGMT computational model, explains how the model was used in the EM PEIS project, and discusses the ongoing and planned improvements to the model. The sources of data used as input to the model for the EM PEIS application are listed. Potential future uses of the model are discussed. More information about the WASTE_MGMT computational model can be found in Refs. 1 and 2.

DESCRIPTION OF WASTE_MGMT COMPUTATIONAL MODEL

In its current state of development, the WASTE_MGMT computational model calculates the following quantities for a given waste management strategy:

Annual quantities and characteristics of the wastes processed by each treatment, storage, and disposal (TSD) module (A module is a facility that houses one or more processes for TSD of a certain type of waste and can be characterized by material and/or energy flow into and out of it.);

Annual quantities and characteristics of the wastes shipped among sites;

Annual emissions of radionuclides and hazardous chemicals to air and water resulting from the operation of the TSD modules; and

Annual generation rates and characteristics of secondary waste streams resulting from the operation of the TSD modules.

To estimate the above, the WASTE_MGMT model requires three types of input data: 1) waste inventory and characteristics at each site; 2) characteristics of the technology modules used to sort, package, treat, store, and dispose of the waste; and 3) definitions of alternative management approaches. Waste inventory and characteristics data include the inventory in storage, estimates of future generation rates, radionuclide and hazardous chemical concentrations in the waste, and physical form of the waste. For the EM PEIS application, these data were collected for each waste type, site, and treatability group. Treatability groups were defined in such a way that they would encompass the large number of waste streams at a given site and so that the wastes within each group would be subject to the same kinds of TSD options. For example, 10 treatability groups were defined for LLW, 8 for TRUW, 23 for LLMW, and 9 for HW.

The TSD modules are characterized by parameters that relate the output quantities and resource requirements to unit quantity of waste processed by each module. Parameters are developed not only for the bulk waste quantities (such as volume and mass), but also for the contaminants (radionuclides and hazardous chemicals) in the waste.

Alternative waste management approaches are defined by specifying the processing paths followed by wastes in each treatability group from site of origin to disposal site, including the identity and location of TSD modules. The fate of the secondary waste streams generated during treatment operations is also defined.

The model is implemented in Microsoft FoxPro 2.5 for MS-DOS, extended version, and consists of approximately 4,200 lines of FoxPro code with comments. An additional 2,800 lines of code were written for preparation of the model's base tables. The processing time required to obtain results for a given strategy is strongly dependent on the complexity of the strategy and the processing speed of the computer used. Using a 90 Mhz INTEL Pentium processor, the computation times vary from less than a minute for a simple case up to 15 minutes for a very complex case.

APPLICATION OF WASTE_MGMT COMPUTATIONAL MODEL IN THE EM PEIS

The WASTE_MGMT model was used for evaluating alternative strategies for the management of three of the waste types considered in the EM PEIS: LLW, LLMW, and TRUW. Because of the unique features of HLW and HW, the alternatives for these two waste types were evaluated with approaches that were specifically designed for them.

The application of the WASTE_MGMT model for the evaluation of LLW, LLMW, and TRUW alternatives is discussed below.

Input Data and Sources

As discussed above, three types of input data were needed for the EM PEIS application. The nature and sources of these data items are discussed below.

Waste Inventory and Characterization: The waste inventory and characteristics data were collected by ANL from the best available sources within the DOE system. Data bases such as the Integrated Data Base (IDB) (3), the Waste Management Information System (WMIS) database (4), and Mixed Waste Inventory Reports (MWIRs) (5,6) were used. When the available data were not sufficient for the needs of the EM PEIS, the DOE sites were contacted to obtain additional data. In the event that the needed data could not be obtained, engineering judgment and approximations were used as necessary.

The waste inventory and characteristics data used for the analysis of LLW alternatives in the EM PEIS are described in Reference 7. The LLMW data were processed from the MWIR data bases with the help of Byron Palmer at Los Alamos National Laboratory (8) and Burdon Musgrave (9). The LLMW data used for the EM PEIS are provided in Refs. 8, 9, 10, 11, and 12. The TRUW data are available in Hong et al. (13). All these data will also be discussed in the EM PEIS.

TSD Module Characterization: The characterization parameters for the TSD modules considered in the EM PEIS were obtained primarily from the available literature. The material reviewed included documentation such as reference design reports, the Functional and Operational Requirements Report prepared by the Mixed Waste Treatment Project (14), trial burn test results from facilities permitted under the Resource Conservation and Recovery Act (RCRA), and various reports and publications in the open literature. The DOE or commercial sites operating the various facilities were contacted as needed to obtain additional information. Engineering judgment was used when the needed information was not available. Reference 7 provides the TSD characterization parameters used for LLW alternative evaluation in the EM PEIS. The parameters for LLMW and TRUW are provided in Refs. 8, 9, 10, 13, and 15.

The technologies employed for the TSD wastes in the EM PEIS are those that are either currently available or will soon be available. The characterizations of these technologies are conducted in a generic sense, and the same parameters are used for any site where the technology is located.

Definition of Alternative Strategies: The alternative strategies for managing each waste type were developed by META/Berger in consultation with DOE. The strategies were developed in terms of defining the treatment and disposal options and the names of the installations where the TSD facilities are located. The specific locations of the facilities at a given installation were not defined. The EM PEIS will provide descriptions of these alternative strategies.

Output Data and Uses

The output data currently calculated by the WASTE_MGMT computational model are listed above. For the EM PEIS, these results were subsequently used to calculate the human health risks due to facility operations (by Oak Ridge National Laboratory [ORNL]), human health risks due to transportation (by ANL), costs (by EG&G, Idaho and MK Corporation), ecological risks (by ORNL), facility accident source terms (by ANL), and air and water quality impacts (by META/Berger). These impacts were calculated outside of the WASTE_MGMT model by manual transmission of the output data from the WASTE_MGMT model to other models or spreadsheet applications. For example, the data obtained from WASTE_MGMT on air emissions of radionuclides were used to calculate the radiological risks to on-site workers and the off-site public by multiplying the released quantity of each radionuclide by an appropriate unit-risk factor for that radionuclide. The unit-risk factors, which were developed by ORNL, take into account site-specific conditions such as meteorology, population distribution, and site terrain. A separate factor was calculated for each radionuclide and receptor by assuming that a unit quantity of the radionuclide was released from a certain point at a site. Similarly, the transportation risks were calculated from 1) the WASTE_MGMT model output data on quantities and characteristics of the wastes shipped among sites and 2) transportation unit-risk factors (risk per unit distance traveled) developed by ANL.

FUTURE USE OF WASTE_MGMT COMPUTATIONAL MODEL

The fragmentation of analyses for the EM PEIS was necessitated by the division of labor among the organizations participating in preparation of the document and by

the tight schedules involved. Under different conditions, this fragmentation could be avoided, and WASTE_MGMT could be expanded into an integrated model that could calculate costs and environmental impacts associated with a given waste management strategy. For example, site-specific and radionuclide-specific unit-risk factors (risk per unit release) could be incorporated into the WASTE_MGMT model as a data file. The risks resulting from facility operations could then be calculated within the model by simple multiplication of the released quantities and the unit-risk factors.

Cost curves could be developed for the generic TSD facilities using the EM PEIS cost estimating methodology. These curves would define the costs of constructing and operating a facility as a function of the size of the facility (i.e., the quantity of waste processed at the facility). Such cost curves could be incorporated into the WASTE_MGMT computational model, and the model could then be used to estimate the facility costs associated with a given strategy. This process would be accomplished by interpolating on the cost curves for facility waste loads that correspond to the given strategy. Such curves could also be developed and used in the model for estimating facility resource requirements (e.g., staffing, energy, materials, and land).

In its fully developed form, the WASTE_MGMT model could be used to estimate the costs, risks, and resource requirements for a given waste management strategy at DOE installations. The model would be useful for DOE strategic planning efforts beyond the EM PEIS. In addition, the model was designed such that, given the waste inventory and characterizations data, it can also be used for installations other than those owned and operated by DOE.

Finally, the model could be equipped with a user-friendly graphical interface to facilitate its use by individuals who are not familiar with the design of the model. Alternatively, the results of complex cases from prior runs could be cataloged, and these could be used, through the user interface, to provide quick responses to questions frequently asked by the public or DOE strategic planners. Such improvements would greatly increase the usefulness of the model to future EM PEIS work, as well as to DOE waste management strategic planners. These improvements are either currently being worked on or will be initiated in the near future.

B.M. Biwer
M.A. Lazaro
H.M. Hartmann
A.J. Policastro
Argonne National Laboratory
Argonne, Illinois

ABSTRACT

In its Programmatic Environmental Impact Statement (PEIS), the Office of Environmental Management (EM) of the U.S. Department of Energy (DOE) is considering a broad range of alternatives for the future management of radioactive and hazardous waste at the facilities of the DOE complex. The alternatives involve facilities to be used for treatment, storage, and disposal of various wastes generated from DOE environmental restoration activities and waste management operations. The evaluation includes five types of waste (four types of radioactive waste plus hazardous waste), 49 sites, and numerous cases associated with each alternative for waste management. In general, the alternatives are evaluated independently for each type of waste and reflect decentralized, regionalized, and centralized approaches. Transportation of waste materials is an integral component of the EM PEIS alternatives for waste management. The estimated impact on human health that is associated with various waste transportation activities is an important component of a complete appraisal of the alternatives. The transportation risk assessment performed for the EM PEIS is designed to ensure through uniform and judicious selection of models, data, and assumptions that relative comparisons of risk among the various alternatives are meaningful and consistent. Among other tasks, Argonne National Laboratory is providing technical assistance to the EM PEIS on transportation risk assessment. The objective is to perform a human health risk assessment for each type of waste relative to the EM PEIS alternatives for waste management. The transportation risk assessed is part of the overall impacts being analyzed for the EM PEIS to determine the safest, most environmentally and economically sound manner in which to satisfy requirements for waste management in the coming decades.

INTRODUCTION

The U.S. Department of Energy (DOE) Office of Environmental Management (EM) is responsible for the treatment, storage, and disposal (TSD) of various wastes generated within the facilities of the DOE complex from environmental restoration activities and waste management operations. For the EM PEIS that is being prepared (1), alternatives are considered relative to the decentralized, regionalized, and centralized approaches. The types of radioactive waste being evaluated include high-level, transuranic, low-level, and low-level mixed. Hazardous waste is also being evaluated. The magnitude of the transportation activities varies with the alternative and ranges from minimal transportation for the decentralized alternative to significant transportation for the centralized alternative. Various aspects of the impact of transportation are radiological versus hazardous, rail versus truck, routine versus accident, worker versus public, population versus individual, and aggregate risk (i.e., probability times consequence) versus consequence. Because of

complex-wide considerations, large amounts of waste in some alternatives are expected to result in unprecedented large-scale transportation activities for DOE or other federal agencies; the potential cumulative impacts of these activities may warrant special attention.

The magnitude and complexity of the scope of the EM PEIS present the following unique features regarding transportation risk assessment: 1) large amounts of waste requiring shipment result from programmatic considerations that are unprecedented for DOE and other federal agencies, 2) consistency exists between the radiological and hazardous risks, and 3) the magnitude and complexity of the routes for shipment require an integrated and expedient computational approach. The EM PEIS method represents a comprehensive and integrated approach to assessing risk regarding the transportation of radioactive, hazardous, and mixed waste.

TECHNICAL APPROACH

The technical approach for conducting the transportation risk assessment was developed following a thorough and critical review of the literature and existing documentation prepared for major federal actions under the National Environmental Policy Act (NEPA). Consideration was also given to recent commitments arising from public awareness and litigation. The approach has also received DOE internal review and external review outside of DOE.

The transportation of radioactive and hazardous wastes involves risk to both crew members and members of the public. Part of the risk results from the nature of the transportation operation itself, which is independent of the waste contents or characteristics of the cargo; for instance, traffic accidents during transportation may cause direct injuries or fatalities. Similarly, pollution from vehicle exhaust emissions may also affect human health. These risks are characterized as "vehicle-related." On the other hand, the transportation of waste may pose an additional risk because of the characteristics and potential hazards of the cargo (i.e., waste) itself. These risks are therefore considered "cargo-related."

The technical approach is conceptualized in Fig. 1 for the EM PEIS transportation risk assessment. A more detailed description of the method has been provided by Monette et al. (2) for transportation of radioactive waste and by Hartmann et al. (3) for transportation of hazardous waste. Potential risks were estimated for the collective population, as well as for the maximally exposed individual, during routine transportation and accidents. For radioactive wastes, the cargo-related risks include exposure to external radiation from the waste package during routine operation and potential exposure to dispersed waste contents in accidents. The RADTRAN 4 (4) computer code was used to estimate the collective population risk. The approach of RADTRAN has been used extensively in previous NEPA assessments and has received wide acceptance. The collective population risk is a measure of the radiological risk posed to the society as a whole by the alternative being considered. As such, the collective population risk is a reasonable primary measure for comparing different alternatives. Supplemental analyses were provided by using the RISKIND (5) computer code to address areas of specific concern to individuals or population subgroups. The supplemental analyses are primarily meant to address the "what if" scenarios frequently raised in public comments. Examples of such scenarios are "What if an accident happens near my community?" or "What is the risk to me if I live adjacent to the access road?"

Fig. 1.

The general methodology for characterizing risk from exposure to hazardous chemicals has many parallels to the methodology for characterizing risk for radioactive waste transportation; however, no standard computer code exists in the chemical area that is a direct counterpart to RADTRAN. One of the major tasks of the EM PEIS transportation risk analysis is to develop the details and coding of the general chemical risk methodology that parallels the steps in the RADTRAN method. Included in such details are a realistic treatment of the chemical accident itself, as well as development of a variety of appropriate chemical risk end points. The treatment of fires (leading to toxic gas releases) and water immersion is also to be included in the implementation of the general chemical risk methodology. Unique to this approach is the assessment of the impacts of water immersion.

Another unique feature of chemical risk assessment is that routine operations of hazardous chemical transportation do not lead to cargo-related risks. Chemical risks occur only from accident conditions because small spills or seepages of hazardous or chemical waste during routine operations are kept to a minimum by existing

regulations and packaging of that waste. Consequence modeling of chemical spills during accidents is performed by using the Areal Locations of Hazardous Atmosphere (ALOHA) (6) air dispersion code in conjunction with several end points for human health effects (discussed in the following paragraphs). The ALOHA code has been used extensively by the U.S. Environmental Protection Agency (EPA) for assisting emergency field personnel in planning for accident release consequences and in implementing emergency response measures.

DEVELOPMENT OF END POINTS FOR HEALTH EFFECTS

The potential exposures from transportation of radioactive materials, either from routine operations or from postulated accidents, are usually at a low dose, such that the primary adverse effect is the induction of latent cancer. The correlation of the radiation dose and human health effects for low doses has been traditionally based on what is termed the "linear, no-threshold hypothesis," as described by the International Commission on Radiological Protection (7).

In addition to latent cancer (which is assumed to be a linear, no-threshold effect), exposure to toxic chemicals may also cause threshold, nonlinear effects. These effects are often of an immediate nature (i.e., acute). The severity of the immediate health effects therefore depends strongly on the toxicity and exposure concentration of the specific chemical(s) released and can range from slight irritation to potential fatality for the exposed individuals. Thus, for the EM PEIS human health risk assessment, three end points were assessed: 1) potential for life-threatening effects, 2) potential for other adverse effects, and 3) increased cancer risk. The first two end points are acute. The potential life-threatening effects are specific only to toxic chemicals identified as "poison inhalation hazards" by the U.S. Department of Transportation (DOT) (Title 49, Parts 173.115 and 173.132-133 of the Code of Federal Regulations [CFR]). Estimates of these effects are derived from the 50% lethal concentration (LC50) or other appropriate toxicity values. The toxicity values have been derived from the following sources: 1) the Registry of Toxic Effects of Chemical Substances (RTECS) database (8), and 2) Dangerous Properties of Industrial Materials (9). Estimates of other adverse effects are based on the inhalation reference dose values developed by the EPA, when available. Such data are derived from the EPA Integrated Risk Information System (IRIS) (10) database and the Health Effects Assessment Summary Tables (HEAST) (11). For the effects of latent cancer, assessment is performed for a carcinogenic risk of one in one million (10-6) or higher. The concentration values corresponding to this risk level have also been derived from the IRIS and HEAST databases. A description of the derivation of the concentration values for these end points for health effects is provided in Hartmann et al (3).

PARAMETERS AND ASSUMPTIONS

Major input parameters and assumptions used in the EM PEIS transportation risk assessment are discussed in the following paragraphs.

Waste Inventory and Characterization

A radioactive waste inventory computational model (WASTE_MGMT) (12,13) has been developed by Argonne National Laboratory to support the EM PEIS analysis of risk and cost. The model combines information on the waste inventory and characterization of waste across the DOE complex, on characterization of the TSD modules, and on definitions of the EM PEIS alternatives. Waste properties are provided in terms of isotope- or chemical-specific concentrations. Physical forms of waste are generally classified into a small number of categories such as vitrified waste, liquid waste, metal waste, and heterogeneous solid waste. Hazardous waste is inventoried and characterized with a separate database of shipping manifests collected from the entire DOE complex for the year 1992. From those manifests and associated data, physical and chemical characterizations were obtained, from which data on treatment and disposal could be obtained or estimated.

Packaging And Shipping Configurations

For the transportation of radioactive materials, the basic types of packaging required by the regulations are designated as Type A, Type B, or "strong and tight." The regulatory requirements are those specified by the DOT and the U.S. Nuclear Regulatory Commission (NRC) (49 CFR 173 and 10 CFR 71). For the EM PEIS, all transportation of radioactive waste has been assumed to take place in certified containers and exclusive-use vehicles. Low-level waste and low-level mixed waste are assumed to be transported in Type A packages. The high-level and transuranic wastes require the use of Type B packaging. The transuranic waste will essentially consist

of Type A waste containers within reusable, certified Type B shipping containers, such as TRUPACT-II for contact-handled waste and NuPac 72B for remote-handled waste. For hazardous waste, packaging is assumed to follow the DOT specifications for containers (49 CFR 173).

Shipping Routes

Representative shipping routes have been determined for all possible pairs of DOE sites that generate or store wastes. For each origin-destination pair, representative highway and rail routes were generated and analyzed by using the routing models HIGHWAY (14) and INTERLINE (15), respectively. The routing models are updated periodically to reflect current road and track conditions and have been benchmarked against the reported shipping distances and the observations of commercial truck and rail firms. The routes calculated conform to current routing practices and all applicable routing regulations and guidelines; however, the routes do not necessarily represent the actual routes that will be used to transport waste in the future. For risk analysis, the important routing characteristics include total shipping distance and the fractions of travel in rural, suburban, and urban zones of population density. The hazardous waste methodology uses only HIGHWAY because no such waste is currently or is planned to be sent by rail.

External Dose Rate

Because all shipments are assumed to take place on exclusive-use vehicles, the maximum external dose rate from a radioactive waste package is limited by the regulatory value of 10 mrem/h measured at 2 m from the lateral surfaces of the conveyance. Because of the complex nature of the EM PEIS alternatives and the different types of waste, a representative external dose rate appropriate for each type of waste was determined for the EM PEIS analysis. This dose rate was based on the average of the entire waste inventory appropriate for the EM PEIS analysis and, therefore, was not intended to represent site-specific values. External dose rate concepts are not applicable to hazardous waste.

Traffic Accident Rates

For calculation of the accident-related risk, accident rates for truck and rail transportation were taken from a compilation by Saricks and Kvitek (16). Data include the accident rate, injury rate, and fatality rate. State-specific accident rates for truck shipment were based on statistics compiled by the DOT Office of Motor Carriers for 1986-1988, specifically for heavy combination trucks involved in interstate commerce. These data were benchmarked against the existing nuclear commercial carriers. State-specific rates for rail accidents were based on statistics compiled by the Federal Railroad Administration for 1985-1988. Rail accident rates include both accidents on main lines and those occurring in rail yards. For hazardous materials, data on accidents were based on 1979-1983 California highway accident data for shipment of hazardous waste.

Accident Severity Categories

A range of potential severities for radioactive waste transportation-related accidents has been described by the NRC (17). The NRC scheme for classifying accidents categorizes accidents as a function of the magnitudes of the mechanical forces (impact) and thermal forces (fire) to which transported packages may be subjected. For each category of severity, a conditional probability is also assigned. The RADTRAN accident risk assessment considers the entire range of accident categories as defined by the NRC, including accidents with low probability but high consequences and those with high probability but low consequences. On the other hand, for consequences to maximally exposed individuals and to population subgroups, scenarios analyzed by the RISKIND code include those representing the accident scenarios with the highest release of waste. Hazardous waste accident scenarios were based on accident release data compiled from the DOT Hazardous Materials Incident Reporting System (HMIRS) (18) database. The contents of each DOE shipment were assumed to have a "breach fraction" (expected fraction of containers ruptured) and a "release fraction" (expected amount of each chemical released from those breached containers) during a transportation-related accident. The amounts of the chemicals released were used in the consequence modeling.

Accident Release Fractions

The release fractions relevant to the risk assessment include three major components: the fraction of the waste contents that could be released to the environment for a given severity of accident, the fraction of the released material that can be dispersed to the atmosphere, and the fraction of the dispersed portion

that is respirable. Most solid materials are difficult to release in particulate form and, therefore, are nondispersible even if they are released. Gaseous materials, on the other hand, are relatively easy to release when the container is breached. Release fractions under accident conditions have been estimated by the NRC (17) for Type A and Type B containers under various categories of accident severity. The dispersible fractions and respirable fractions have been suggested by RADTRAN (4) for various forms of materials. Breach and release fractions for hazardous waste are based on analysis of thousands of accidents in the HMIRS database (18).

Atmospheric Conditions

Because predicting the specific location of a transportation-related accident is impossible, generic weather conditions were used for transportation risk assessment. For accident risk analysis, neutral weather conditions (represented by Pasquill stability class D) were assumed. Because neutral meteorologic conditions constitute the most frequently occurring atmospheric stability conditions in the United States, these conditions are most likely to be present during an accident. For maximally exposed individuals, however, both neutral (represented by Pasquill stability class D) and stable (represented by class F) conditions were considered; the stable condition was used to represent a conservative condition intended to maximize the consequence.

Scenarios For Maximally Exposed Individuals

For routine transportation, risks to maximally exposed individuals were estimated for a number of hypothetical exposure scenarios. The receptors include transportation crew members, inspectors, and members of the public exposed during traffic delays, while working at a service station, or while living near a waste site. Parameters typical of such scenarios have been described in previous DOE documents (19,20). For accidents, the maximally exposed individuals are assumed to be downwind. The accident severity category with the highest release was used to represent "worst-case" scenarios for the accident analysis.

For hazardous waste, worst-case accidents were evaluated in a similar manner and were chosen on the basis of the shipments with the maximum quantity, toxicity, and volatility of the hazardous waste within those shipments.

DEVELOPMENT OF AUTOMATED COMPUTATIONAL SYSTEM

Because of the magnitude and complexity of the EM PEIS transportation risk analysis, an automated computational system was developed by Biwer et al. (21) to facilitate the computation of risk for radioactive waste. The system uses the unit-risk factor concept; that is, unit-risk factors derived from the RADTRAN 4 calculations form the basis of the system. Key parameters providing a foundation for the unit-risk factors include transport mode, external dose rates from waste packages, transport speeds, and radionuclide-specific information. Shipment risks are estimated by the combination of the unit-risk factors with state-specific population zone distances and accident rates, package release characteristics, and other relevant factors. For the purpose of the EM PEIS analysis for DOE facilities, the system also incorporated routing information derived from HIGHWAY (14) and INTERLINE (15). The system is designed to incorporate such routing information and unit-risk factors to produce risks for a particular alternative. The system is now equipped with a menu-driven feature for analyzing transportation-related risks for large and complex shipping campaigns required by the EM PEIS. For hazardous waste, a semiautomated system has been set up that links the hazardous waste database, the ALOHA model, and a spreadsheet program that computes risk.

ASSESSMENT OF ALTERNATIVES

On the basis of the technical approach and the assumptions discussed previously, the transportation risk assessment was performed for the EM PEIS. Potential transportation-related health risks were calculated for both all-truck transportation (radioactive and hazardous wastes) and all-rail transportation (radioactive wastes only). For shipments between each origin-destination pair, the collective risks to workers and the public for incident-free conditions and for accidents were assessed. For each alternative, the total collective risks represent the aggregate of risks from the set of origin-destination pairs. For comparison, the vehicle-related impacts (i.e., the total number of traffic accident fatalities) from collisions were also estimated and are presented along with the cargo-related (waste-related) impacts.

CONCLUSIONS

The transportation risk assessment conducted for the EM PEIS is a comprehensive and

integrated approach that can be applied to all types of radioactive waste, as well as to hazardous waste, generated within the DOE complex. By combining a traditional method (for radiological risk assessment) with some developmental components (for hazardous risk assessment), the magnitude and complexity of the analysis are addressed. The results of the assessment constitute an important component of the overall evaluation of waste management alternatives of the EM PEIS.

ABSTRACT

Human health risks as a consequence of potential radiological releases resulting from plausible accident scenarios constitute an important consideration in the U.S. Department of Energy (DOE) national program to manage the treatment, storage, and disposal of wastes. As part of this program, the Office of Environmental Management (EM) is currently preparing a Programmatic Environmental Impact Statement (PEIS) that evaluates the risks that could result from managing five different waste types. This paper 1) briefly reviews the overall approach used to assess process and facility accidents for the EM PEIS; 2) summarizes the key inventory, storage, and treatment characteristics of the various DOE waste types important to the selection of accidents; 3) discusses in detail the key assumptions in modeling risk-dominant accidents; and 4) relates comparative source term results and sensitivities.

OVERVIEW OF APPROACH

The objectives, scope, and various aspects of the approach to accident analysis in the U.S. Department of Energy (DOE) Environmental Management Programmatic Environmental Impact Statement (EM PEIS) have been reported earlier (1,2,3). As a consequence of evolving directions in the EM PEIS, these considerations have been somewhat refined and are briefly reviewed here. The EM PEIS currently calls for separate evaluations of the risks that could result from managing five different waste types: hazardous (HW), high-level (HLW), low-level mixed (LLMW), low-level (LLW), and transuranic (TRUW). The last four wastes present radiological risk and are addressed in the paper. Since the process details of final disposal alternatives are not being addressed in the EM PEIS, waste disposal or repository accidents are not addressed here.

The most recent guidance (4) from the Office of National Environmental Policy Act (NEPA) Oversight within DOE calls for consideration of the spectrum of accident scenarios that could occur in activities encompassed by the actions evaluated in the EM PEIS. This guidance also calls for a graded approach in which the risk-dominant scenarios are emphasized. Determination of risk dominance requires assessment of both the likelihood and the severity of plausible accident scenarios that could present a significant health hazard to either the workforce or the public. The spectrum of accident scenarios includes all accidents important to risk, from low frequency events with potentially high consequences (as typified by accident sequences associated with natural phenomena such as earthquakes) to relatively high-frequency events with very low consequences (as typified by routine industrial accidents).

To address the broad scope of the EM PEIS and to comply with the recent NEPA guidance, a phased approach was developed that includes the following interrelated elements: 1) selection of potentially risk-dominant storage and treatment operations and related facility configurations across the DOE complex; 2) selection, development, and probabilistic evaluation of a uniform set of risk-dominant sequences of accidents; and 3) determination of the evolution and final compositions of source terms predicted to be released from these sequences. This paper focuses on accidents important to risk, as determined by elements 1 and 2 above, and discusses the major source term modeling assumptions used in element 3. A personal-computer-based computational framework and database (5) have been developed to automate these elements and provide source terms. The source terms were subsequently used by Oak Ridge National Laboratory in the EM PEIS to assess the radiological health affects and risks to the general public and to the workforces.

RADIOACTIVE WASTE TYPES

The inventories and salient storage and treatment characteristics of the radioactive waste types considered in the EM PEIS are summarized below. The waste management alternatives discussed in the EM PEIS include the identification of siting options for storing and treating each waste type before disposal. Storage inventories and treatment throughout for each site affected by a given alternative are then defined by the current inventories, existing and projected waste generation rates, and then disposition of the waste. The volume and radio nuclide composition of each waste are tracked in a relational database (6) as the waste is processed to final disposal.

Low-level Waste

Several million cubic meters of LLW currently exist in the DOE complex. This waste ranges from low-activity waste that can be disposed of without treatment by engineered, shallow land disposal techniques to higher activity waste requiring the use of treatment and disposal techniques that provide greater confinement. LLW includes contaminated equipment and maintenance waste from operations; dry solids and solidified sludges from processing; and miscellaneous wastes, including neutron-activated reactor vessels and surface-contaminated concrete walls from decommissioning and decontamination (D&D). The waste is generally packaged in drums or containers and stored on outdoor concrete pads or in weather-protective sheds awaiting shallow land disposal or treatment. LLW is generated at more than 30 sites; 5 sites generate more than 80%: Hanford, Idaho National Engineering Laboratory (INEL), Los Alamos National Laboratory (LANL), Oak Ridge National Laboratory (ORNL), and the Savannah River Site (SRS).

Two representative treatment philosophies are assumed in the EM PEIS: minimum treatment (stabilization of liquids and fines) and maximum volume reduction. The treatment technologies the depend on the physical characteristics of the waste and the final waste form as defined by the site-specific waste acceptance criteria (WAC) are 1) incineration, 2) solidification, 3) vitrification, 4) compaction and supercompaction, 5) size reduction (e.g., shredding, metal cutting, and shearing), 6) evaporation, 7) general aqueous treatment, and 8) various waste packaging techniques.

Low-level Mixed Waste

About 180,000 m3 of LLMW is currently stored at approximately 50 DOE sites. Generally, LLMW results from the same processes that generate LLW and includes aqueous liquids, organic liquids, sludge and particulates, soils, debris, special wastes, and inherently hazardous materials. LLMW is generally packaged in drums or containers and stored in Resource Conservation and Recovery Act (RCRA)-compliant weather-protective sheds before treatment. Another 250,000 m3 of LLMW is expected to be generated over the next 20 years, excluding that derived from environmental restoration activities. More than 99% of this waste has been or will be generated at 11 sites; sites generating the largest amounts are Hanford, ORNL, Rocky Flats Environmental Technology Site (RFETS), and SRS. The EM PEIS treatment technologies are 1) organic destruction, 2) aqueous liquids (wastewater) treatment, 3) metal (wastewater metal) removal, 4) neutralization (acid or base additions to neutralize waste streams), 5) stabilization, 6) metal recovery, 7) mercury recovery, 8) decontamination, and 9) deactivation of reactives.

Transuranic Waste

At the end of 1991, there was approximately 70,000 m3 of retrievably stored TRUW; about 96% of this waste is stored at Hanford, INEL, LANL, ORNL, and SRS. The TRUW

includes solid materials, such as contaminated clothing and equipment, and liquids and sludges resulting from chemical processing. A significant fraction contains hazardous components. TRUW is generally packaged in drums or containers and stored in concrete structures, in weather protective sheds, in earthen berms, or, in the case of remote-handled TRUW, in below-grade caissons. Most contact-handled TRUW, which dominates the total TRUW inventory, is stored in facilities with minimal containment, although DOE sites are increasingly moving toward qualified TRUW storage.

EM PEIS alternatives consider 1) minimal treatment (liquid absorption, compaction, immobilization, and repackaging) to meet the current Waste Isolation Pilot Plant (WIPP) WAC; 2) intermediate treatment (shredding, grouting, and changing containers) to reduce gas generation by waste in the repository; and 3) treatment to meet RCRA land disposal restrictions, which involves thermal destruction technologies similar to those for LLMW. For all alternatives, aqueous liquid is treated on-site before shipping. The treatment technologies are the same as those identified for LLMW.

High-Level Waste

HLW includes 1) liquid waste produced directly in reprocessing spent nuclear fuel and weapons production targets and any solid material derived from this waste that contains fission products in sufficient concentrations and 2) other material from the power reactor fuel cycle as determined by the U.S. Nuclear Regulatory Commission. HLW contains transuranic elements an fission products that are highly radioactive, heat generating, and long-lived. DOE HLW management follows six implementation phases: current storage in underground tanks, retrieval, pretreatment, treatment (generally high-temperature vitrification to produce glass logs to be sealed canisters), interim canister storage, and geologic repository disposal. However, the EM PEIS alternatives only address expanded interim canister storage at Hanford, SRS, and West Valley where the facilities will be sized to accommodate a production rate on the order of several hundred canisters per year.

SELECTION AND MODELING OF RISK-DOMINANT ACCIDENTS

Review of the operations and facilities discussed in the EM PEIS for the various waste types led to the establishment of three broad classes of accidents according to release characteristics and the facilities and populations affected. These classes include 1) general handling accidents involving a breach of waste packaging, 2) severe accidents at storage facilities, and 3) severe accidents involving treatment (or pretreatment) processes and facilities. Risk dominant operations, facility configurations, dominant accident sequences, and associated frequencies within each broad class of accidents are described further below.

Radiological source term = MAR x DF x RARF x LPF, Eq. (1)

where

MAR = the quantity of material at risk,

DF = The damage fraction or fraction of MAR exposed to accident stresses capable of rendering the MAR airborne,

RARF = the respirable airborne release fraction or fraction of material subjected to accident stresses actually rendered airborne and respirable, and

LPF = The leak path factor or fraction of the respirable airborne inventory that escapes any containment or confinement barriers to reach the ambient atmosphere.

The development of the MAR and DF parameters for the selected accidents is described below. The RARF is a function of the various accident stresses (pressurized release, fire, explosion, etc.) That affect the waste and the physical form of the MAR (liquid, sludge, solid, ash by-product, etc.), which varies by waste type, storage site, stage of treatment, and type of treatment technology. Values for the RARF were adapted from Mishima (7) to account for this functionality in the identified sequences. The LPF is a function of the response of the confinement was assumed to be breached and an LPF of 1.0 was assumed.

General Handling Accidents: LLW, LLMW, and TRUW

For EM PEIS alternatives addressing these waste types, general handling accidents involving waste package breach are expected to dominate the radiological risks to workers because of the relatively high frequency of such accidents and the proximity

of the workers to any release. Operations considered include handling in storage and staging areas, packaging and unpackaging, movement of waste within treatment facilities, and some treatment operations. Handling accidents include container breaches caused by package drops, by forklift or other vehicular impacts, by crane drops or crushing, and by overpressurization. The risk from exposure to radiation from operational incidents, such as puncture wounds during waste sorting, minor contamination from glove failures, and minor spreads of contamination from treatment equipment overpressurization, were judged to be enveloped by this class of accidents.

In the majority of handling accidents or hands-on pressure incidents, the MAR would be limited to a single package. Although more severe sequences involving an array of several containers are plausible, the releases of greatest overall risk to the workforce were judged to involve a worker in contact with or very near to a single breached package. Thus, a MAR of 55 gal (208 L) corresponding to the contents of a standard plastic-lined, carbon-steel drum was specified for all contact-handled waste types. The physical and chemical composition of the MAR was defined by weighting the relative treatability category inventories at each site. The DF would depend on the location of the breach, the physical form of the MAR, and the severity of the accident stress. Liquids and volatiles would be free to flow out of breached container, whereas most solid material would remain inside. Breached containers were assigned a DF of 0.25 for solid waste or a DF of 1.0 for liquid waste.

On the basis of a review of recent safety analysis reports, a probability of 1.0 x 10-4 per operation for package breaches, which is consistent with the aforementioned estimates of source term parameters, were assigned. Since most areas are simply staging areas for treatment or disposal operations, two handling operations were assumed, one for receiving and one for removal. Thus, the expected annual frequency (fmb) of a container breach for waste product x caused by a handling accident is as follows:

$$fmb = 0.0002 \times nx \,, \qquad \text{Eq. (2)}$$

where nx is the number of waste containers of waste product x received annually. To convert this value to a throughput number, it was conservatively assumed that the complete inventory turns over each year. Then the expected annual frequency of significant mechanical breaches would be given by the following equation:

$$fmb = 0.0002 \times N \,,$$

Eq. (3)

where N is the capacity of the facility in number of drums.

General Handling Accidents: HLW

Review of available safety documentation suggests that the risk-dominant accident during interim glass canister storage is the breaching of a canister during handling operations or transfer. It was conservatively assumed that the breach was so severe that the entire contents of a canister were dispersed into the surrounding vault (MAR = 1 canister, DF = 1.0). Partially degraded facility filtration was assumed (LPF = 0.001). The frequency for a canister drop with the above release was estimated to be 1.0 x 10-5/canister/year, with facility frequencies derived from the throughput.

Severe Storage Facility Accidents: LLW, LLMW, and TRUW

Radiation releases from severe accidents in a storage area are expected to dominate the risk of releases to on-site personnel and the general public for many DOE sites. Numerous storage facilities with large quantities of waste provide little or no formal containment or provide containment that would likely be breached in the event of severe thermal or structural challenges. This analysis focused on releases from severe operational accidents and external events involving fires in centralized storage pads and facilities judged vulnerable to large-scale releases. Other accidents were also considered but generally dismissed as being clearly enveloped in importance to risk by the fire sequences.

Accidents for storage facilities having solidified, vitrified, or otherwise highly stable wastes awaiting disposal were generally not analyzed. Landfills or other underground burial areas were also excluded from analysis. Finally, the volume of

solid wastes and the number of handling operations associated with drum, box, or crate storage exceed those associated with liquids stored in tanks for all waste types except HLW. Consequently, tank storage of liquids was judged to have a low relative risk and no related source term analyses were performed.

Fires can be categorized as either being local and involving limited inventories of wastes or, at the other end of the spectrum, as major facility fores induced by events that provide a source of fuel (such as heating gas, vehicle gasoline, or aviation fuel) and that also disable or overpower any available safeguards. Design and operational safeguards are in place to prevent fire propagation from a localized source, such as a single package or drum or a rubbish pile, to a much larger inventory. Packages for combustible materials include steel drums, fire-resistant boxes, and fire-protected shipping containers and are generally required by RCRA to be segregated. Finally, most centralized facilities have fire detection and suppression capabilities, including normal operator surveillance, automatic sprinkler systems, fire barriers, and on-site fire department response (or some combination of these types of protection).

The MAR in all storage fire scenarios depends on the storage configuration. The DF is a strong function of the packaging, the physical form (and combustibility) of the MAR, and the detection of and response to the fires. Two categories of fires were considered: waste-container fores and facility fires. Because of the relative infrequency of a single-container fire and the much greater consequences of fully developed facility fires, only the latter were analyzed. The representative fire was assumed to encompass the spectrum of undetected or unsuppressed fires, and the entire facility inventory of combustible waste was assumed to constitute the MAR. A DF of 0.1 was assumed as a generic value to account for the segregation and separation of waste packages in the facility and for the nature of the waste packaging as described previously. The estimated annual frequency for a fully developed facility fire with these source term parameters is 1.0 x 10-4/yr, the product of a generic facility fire frequency of 1.0 x 10-2/yr and a conditional fire suppression system failure probability of 1.0 x 10-2 . This value is consistent with existing documentation and is judged to be reasonable in light of the existing preventative and mitigative safeguards discussed previously. External event sequence frequencies depend on the location of the sites.

Although the inventories, physical forms, and radiological compositions of waste stored at each site are characterized in the EM PEIS and stored in the waste management database (6), compilation of analogous information for individual facilities on each site is beyond the scope of the EM PEIS. Accordingly, a unit inventory approach was used to develop radiological source terms with radiological and physical compositions derived by volume-weighing the inventories of the treatability categories within each waste type at each site. Because of the minimal containment properties of most facilities storing packaged LLW, LLMW, and contact-handled TRUW, a generic confinement configuration was assumed that did not consider containment or filtration (LPF = 1.0).

Severe Storage Facility Accidents: HLW

Because of the scope of the EM PEIS, ruptures, fires, and explosions of current storage tanks, which probably dominate the health risk of overall HLW management, were excluded. Radiological releases from severe fires, explosions, or natural phenomena-induced events were considered for interim storage facilities. However, the relevant safety reports for the various HLW interim storage facilities do not elevate the risk of fire, in part, because there is no significant accumulation of combustibles to support fire propagation. Given this, the low frequency of severe external events, and the lack of plausible airborne release mechanisms in light of the high integrity of the HLW canisters, severe interim HLW storage facility releases were judged unimportant to risk and not analyzed any further.

Severe Accidents Involving Treatment Processes and Facilities

The focus here is on possible fires or process explosions from operational or external causes. Many treatment operations were excluded from detailed investigation of large-scale releases on the basis of either the lack of a sufficiently radiologically concentrated MAR or the lack of an energy source capable of creating a risk-dominant airborne release. These operations include evaporative processes and solidification operations, such as grouting and cementation. In general, benign operations, such as packaging and nonthermal size-reduction activities, were excluded from consideration for large-scale accidents.

Technologies for mercury separation were excluded because of their relatively low-energy operating characteristics. Thermal desorption of residues, sludges, and resins, or of debris wastes, involves combustible material. This process was excluded, however, because (1) it operates at lower temperatures and pressures then incineration, a competing technology, and (2) the output product is much less dispersible then the ash from incineration.

Other processes involving high temperatures or pressures were more closely reviewed in light of the potential energy source for dispersing airborne radioactive or toxic material, as well as for challenging the facility's integrity and capability for filtration. Similarly, operations involving or being performed in the presence of combustible materials or involving feed lines of natural gas or fuel were reviewed in light of the potential for ignition and subsequent fire or explosions. On the basis of these considerations, as well as consideration of the alternative-dependent volume of waste to be treated by each process, incineration, wet-air oxidation, and vitrification were identified for their potential for major airborne release. A final comparative review of the characteristics of the identified treatment processes, augmented by scoping source term calculations, led to the selection of incineration as the technology most likely to dominate risk to the staff of the facility and the site, as well as to the surrounding general populations, for LLW, LLMW, and TRUW. (Risks of HLW treatment technologies are not considered in the EM PEIS).

Detailed modeling of facilities is beyond the scope of the EM PEIS. Accordingly, a treatment facility with generic confinement characteristics was used to assess accidents to envelop the releases from accidents in the treatment process. A DOE Hazard Category of 2 and the associated performance requirements for its systems were assumed. Double high-efficiency particulate air filtration was assumed. The MAR at the time of the accident was based on the facility throughput at each site, which varies by alternative. The DF was based on the location of the Mar, which varied by accident sequence. The dominant sequences were generally unconfined operational facility fires that were assigned an annual frequency of 1.0 x 10-3 and external event driven fires, the frequencies of which are site-dependent.

COMPARATIVE RESULTS AND SENSITIVITIES

Cross comparisons of airborne source term releases from similar postulated accidents for comparably sized inventories of LLW, LLMW, and TRUW at risk at various DOE sites were made. LLW accidents would generally result in the smallest releases of radioactivity (as measured in curies) with analogous LLMW accidents producing somewhat greater releases of radioactivity, and, because of the higher concentration of heavy metals, would be expected to result in considerably more significant exposures than LLW or LLMW.

Primarily because of their high atmospheric dispersion potential, fire-related accident sequences initiated by either internal or external events produced the most significant radiological source terms for both storage and treatment facilities. Comparisons of internally and externally driven fires reflected tradeoffs between the lower expected frequencies of external event sequences and their higher expected Dfs of material at risk. The relative importance of fire (as well as other types of source term dispersion mechanisms in accident sequences) is, of course, sensitive to the process, facility, and site characteristics identified above and to the affected waste type combustibility characteristics and initiating accident.

Because of the broad scope of the EM PEIS and the spectrum sites, waste types, and facilities considered, generic accidents with representative source term parameters were used for analysis. The results were sensitive to two categories of uncertainty: (1) that occurring from the application of generic models to a range of real facilities, waste materials, and processes with somewhat different characteristics and (2) that from the modeling per se. One of the biggest sources of uncertainty in the results follows from the uncertainties in the physical and chemical compositions of the inventories. The uncertainties not only affect the MAR factor in the source term equation, but propagate through all the source term factors. Resulting differences in source term evolution could be reflected in threshold failure effects on accident mitigation or containment systems. Consequently, significantly different atmospheric releases would be expected.

ABSTRACT

The Department of Energy (DOE) is preparing a Draft Environmental Impact Statement (DEIS) to evaluate the impacts of a proposed policy for the management of foreign research reactor (FRR) spent nuclear fuel (SNF). Among the policy alternatives being evaluated is United States acceptance of FRR SNF for storage and/or processing. The DEIS will address only FRR SNF that contains uranium enriched in the United States This paper discusses the DOE methodology being developed to identify potential ports of entry in the United States that would satisfy National Environmental Policy Act (NEPA) requirements and other requirements resulting from District Court decisions, Congressional guidance, recommendations of a U.S. Merchant Marine Academy (USMMA) Workshop, and suggestions from public scoping meetings. From these various sources, DOE was able to develop a list of basic screening criteria which all acceptable ports must satisfy. These included: 1) appropriate experience handling containerized cargo, 2) favorable transits from the open ocean to the port facility, 3) appropriate facilities for receipt, handling and transhipment of FRR SNF, 4) ready access to truck and rail transport, and 5) lowest human population around the port facility. These criteria are being used in the DEIS to screen a large number of possible candidate ports to narrow the search to a reasonable range of potential ports on the Atlantic, Gulf, and Pacific Coasts. In addition to commercial ports,

several military ports are being considered from which a few will be identified in the DEIS for transporting FRR SNF to the United States using chartered vessels. After the screening criteria applied to each of port beginning with those initially selected for screening, DOE will consider the potential usefulness of each remaining port relative to other ports for receipt and shipment of the FRR SNF to any of the five potential DOE storage sites [i.e., the ease of shipping FRR SNF to each port from numerous foreign nations, and whether or not the low population criterion will permit shipment to storage facilities at the Savannah River Site (SRS), the Idaho National Engineering Laboratory, the Oak Ridge Reservation, the Hanford Site, and the Nevada Test Site]. Next, DOE will use a series of desirable attributes that individually are not adequate to reject an otherwise acceptable port, but collectively will permit DOE to select the most desirable group of low population ports for the proposed action. These port attributes include emergency response planning, secure short-term storage, good separation from high populations, berthing options that permit avoidance of conflicting activities, and ports that do not present severe environmental concerns (including the likelihood of severe natural phenomena). Use of these attributes will enable DOE to select the most acceptable commercial and military ports for acceptance of FRR SNF shipments to the United States if such a policy alternative is adopted.

INTRODUCTION

The United States Department of Energy (DOE) and Department of State are jointly proposing an action to adopt a new policy for management of FRR SNF. Only SNF containing uranium enriched in the United States would be covered by the proposed alternative. The purpose of the policy is to support United States nuclear weapons nonproliferation policy objectives, specifically by reducing the amount of highly-enriched uranium used in international commerce. Among the alternatives being analyzed are: 1) acceptance of the FRR SNF by DOE for storage and eventual disposition in the United States, 2) chemical separation of a portion of the SNF in existing DOE facilities in the United States, or through development of a new technology followed by storage and disposition of the resulting products and waste in the United States, and 3) reprocessing of the FRR SNF at overseas facilities. A no action alternative is also being analyzed.

DOE is preparing a DEIS to evaluate the impacts of the proposed policy and alternatives. As part of the implementation of one proposed policy alternative, DOE is developing criteria for evaluation of candidate United States ports against certain requirements. This paper discusses the methodology being developed for identification of potential United States ports that are well-qualified for receipt, handling and transhipment of FRR SNF to DOE storage facilities.

BACKGROUND

The U.S. Nuclear Regulatory Commission (NRC) has the authority under the Atomic Energy Act of 1954, as amended, to regulate certain aspects of SNF transportation within the United States Of the thousands of shipments completed over the last 30 years in the United States and abroad, none has resulted in an injury due to the radioactive nature of the cargo (1). For the same period, about 1,200 overland SNF shipments (924 domestic and 293 foreign) took place without any injury attributable to accidents or incident-free transport.

Since 1979, when the NRC first began approving shipments of SNF in the United States, there have been 317 SNF shipments in robust "Type B" shipping casks transported safely into and out of several United States ports of entry (under a previous policy). These ports included Newport News, Norfolk and Portsmouth, Virginia (Port of Hampton Roads); Savannah, Georgia; Portland, Oregon; and Oakland, California (1). However, prior to the fall of 1993, DOE did not have any generally applicable criteria for identifying desirable ports of entry for receipt of FRR SNF. As a result, DOE is developing appropriate criteria for identification of qualified ports of entry for the potential receipt of FRR SNF. The port selection process for the Draft EIS will be based on a set of criteria being developed by DOE to identify those ports which are most capable of providing for the safe receipt, handling and transhipment of FRR SNF during the period of the proposed action. The final methodology to be used in identifying capable ports will be based on criteria that has evolved from several events:

1. A 1991 Federal Circuit Court ruling on a draft environmental assessment which requires DOE to consider a reasonable range of alternative ports, including low population ports that are near SRS (2).

2. The 1993 Notice of Intent for the proposed action listed a series of preliminary criteria which might be applied to identify capable ports, including: a) "adequacy of harbor and dock characteristics to satisfy the cask carrying ship requirements; b) availability of safe and secure short-term storage; c) adequacy of overland transportation systems from the ports to the storage site(s); d) experience in safe and secure handling of hazardous cargo; e) emergency preparedness status at the port and nearby communities; and f) proximity to the proposed storage sites" (3).
3. A DOE-sponsored workshop on port selection criteria for SNF was held at the USMMA at Kings Point, New York, on November 15-16, 1993. Participants included independent experts from the maritime industry in the areas of marine transportation, intermodal systems, marine insurance, admiralty las, U.S. Coast Guard Operations, U.S. Navy Operations, Military Sealift Command Operations, and national cargo, pilotage, and ships operations (4). The workshop resulted in the development of specific recommended criteria.
4. On November 30, 1993, the National Defense Authorization Act (NDAA) of 1994 was signed into law, requiring the use of specific criteria to be used if "economically feasible," and "to the maximum extent practicable" in selecting ports for both emergency and non-emergency receipt of FRR SNF at SRS (5).
5. Nine public scoping meetings were held in November and December, 1993 to elicit public comments related to the proposed scope of the EIS. As a result, DOE received numerous comments related to the port selection process, including recommendations for avoiding use of high population ports and using low population ports, including military ports (6). Other comments focused on use of the safest and most experienced ports that are closest to storage sites.

PORT IDENTIFICATION PROCESS

It was the opinion of independent maritime experts that any modern port could safely receive, handle, and tranship FRR SNF to any of the potential storage sites (4). Nevertheless, DOE concluded that by careful selection, superior ports for FRR SNF receipt could be identified. The proposed candidate port identification process involves several steps that are related to the recommendations, requirements, and events discussed above. First, DOE has identified several required (i.e., mandatory) criteria which are being used to screen all potential ports in the contiguous states. In general, failure to satisfy any one of these criteria would result in disqualification. The proposed criteria are:

The ports must have appropriate (routine) experience handling containerized cargo, since all FRR SNF is expected to be shipped in this configuration

The ports must offer favorable transits from the open ocean to the selected terminal(s)

The ports must have appropriate facilities for safe receipt, handling and transhipment of FRR SNF

The ports must have ready access to intermodal transport (i.e., truck or rail facilities at or near the selected terminal)

The combined human population surrounding each port and the transportation routes to each potential storage site must be low (compared to other ports) to the extent economically feasible and the maximum extent practicable

These criteria are being applied to an initial list of a large number of potential commercial and military candidate ports in the contiguous United States which were identified from several commercial publications (7-12), and military references (13-16). Through the initial screening process, the number of capable ports can be narrowed down to a reasonable range of potential ports of entry. A more detailed discussion of the screening criteria is provided below.

Criterion 1: Appropriate Experience

Appropriate experience, a requirement of the NDAA, was defined as that which results from routine handling of containerized cargo equivalent to unloading or loading a small container vessel at every week or two [on the order of 20,000 twenty-foot-equivalent units (TEUs) per year; a TEU is an International Standards Organization container size of about 2.4 m x 2.4 m x 6.1 m (8 ft x 8 ft x 20 ft]. This experience could derive from any mix of breakbulk/container vessels or self-contained ships, and assure a core of experienced, trained stevedores who are readily available (i.e., avoids use of less experienced, part-time workers). It effectively discriminates against ports which are used for handling bulk cargoes (oil, grain, coal, etc) or cruise ships, since these operations do not involve routine handling of containerized cargoes (e.g., everything from TV sets and machine

parts to toxic materials, flammable, or explosive cargos). As noted earlier, containerized cargo experience is considered a major factor in experience because most or all FRR SNF is expected to be shipped in containers [specially designed to safely hold FRR SNF casks in the range of about 10 to 25 mt (17)], and container handling is the same regardless of the cargo inside the container.

Screening of commercial ports under this criterion will permit DOE to identify ports that are considered to be reasonably representative of United States ports which might be used for FRR SNF shipments. Many of these ports will not meet this criterion because they are associated with bulk cargo shipping (oil, chemicals, grain, ore, etc) that uses specialized cargo handling equipment (e.g., conveyer or pumping systems) totally unrelated to container handling equipment.

This criterion will also permit rejection of all naval bases and shipyards in the contiguous United States that do not regularly handle containerized cargoes (almost all breakbulk cargoes). In general, most military ports experience great variations in annual cargo throughput that reflect periodic changes in military missions. As long as military ports have periodic annual experience comparable to qualified commercial ports, they will be accepted under this criterion.

Criterion 2: Favorable Transit from Open Sea

This criterion is based on a recommendation of the USMMA workshop participants who found that a short transit from the open ocean to port was necessary to maximize the safety of SNF shipments. However, it was clear that since this criterion focuses on ship safety, it is essentially synonymous with the requirement for a favorable ship transit. Thus, while a port might be within a few miles of the open sea, if the channel exposed ships to numerous hard shoals, ship wrecks, or reefs, transits might be more risky than longer but less difficult transits. Thus, DOE determined that ports meeting the intent of the Workshop recommendation would have relatively short trips from large, deep bodies of water that were oceans, seas, or extensions thereof, such as bays or sounds (e.g., the Chesapeake Bay, San Francisco Bay, or the Puget Sound), and present no special navigational hazards to ships. Long transits along narrow, winding, or crowded ship channels (e.g, the St. Lawrence seaway to a Great Lakes port, or far up the Mississippi River) were not considered to be consistent with the USMMA recommendation. In addition, it was concluded that a minimum channel depth of 7.6 m (25 ft) would be required for use by at least small to intermediate size vessels (7-12). Information on channel depth and navigational problems were identified in the U.S. Coast Pilot series (18-23).

Criterion 3: Appropriate Port Facilities

The NDAA of 1994 requires the use of ports with "appropriate port facilities" that allow safe handling of FRR SNF (5). The USMMA Workshop recommended as "necessary for safe shipment" that an acceptable port have "adequate port cargo facilities," including berthing options (i.e., to avoid conflicting activities at an adjacent berth or onshore if necessary) and onsite cranes with trained operators (4). To meet these requirements, DOE has determined that the ports should have the following minimum physical attributes: 1) adequate water depth alongside pier (at least 7.6 m [25 ft] for small to intermediate size vessels (7-12); 2) adequate piers with berthing options (4); and 3) at least one adequate crane for offloading containerized casks of FRR SNF on to ground transport (at least 30 mt (33.1 ton) capacity for the largest FRR SNF casks which weigh on the order of 10 to 25 mt). While the USMMA Workshop preferred purpose-built container cranes for handling containerized FRR SNF in ports, it did not conclude that such cranes were necessary to satisfy the criterion. Thus, acceptable alternatives include use of other types of shore cranes with adequate lifting capacity, or the use of shipboard cranes.

The DOE also examined the possibility that ports currently found unqualified might meet all requirements during the period of the proposed action. In general, many important port improvements were identified during the next five or ten years. However, in most cases, the improvements will occur in ports already found acceptable, or in ports which were rejected for other reasons. Therefore, future port improvements are not expected to significantly change the list of ports which currently are found acceptable under all the DOE port identification criteria.

Criterion 4: Ready Access to Intermodal Transportation

The USMMA Workshop found that it was necessary for SNF safety that a port have ready access to intermodal transportation (i.e., easy access to truck or rail transport). It is common practice for some ports to move containers from shipside to a nearby marshalling yard for loading onto trucks or railcars. Such moves are increasingly

done quickly using purpose-built container handling equipment which minimizes congestion in the offloading area and avoids additional occupational exposures (since the special systems in use do not require additional handling by other personnel). Therefore, DOE has concluded that lack of an intermodal rail facility immediately at the port is not sufficient basis for rejecting an otherwise acceptable port (all ports have truck access) as long as the rail facility is within a few miles of the port. Such additional transport risk is small compared to that which would result from normal overland transport of FRR SNF for hundreds or thousands of miles to a storage facility. No additional ports were screened out from application of this criterion.

Criterion 5: Low Human Populations

This criterion reflects a number of factors which were identified by DOE for consideration. First, a 1991 District Court decision on return of Taiwanese SNF indicates that the courts consider port populations to be an important part of the NEPA process for assessing the range of reasonable port alternatives (2). Second, the NDAA of 1994 requires that, if economically feasible and to the maximum extent practicable, ports of entry for FRR SNF bound for SRS have the lowest human populations in the area surrounding the port (5). While the NDAA of 1994 was written specifically for FRR SNF shipments to SRS, DOE elected to apply this criterion to identifying ports of entry for all five potential DOE storage sites, to the maximum extent practicable.

However, DOE found in its analyses of total impacts associated with receipt, handling, and transhipment of FRR SNF that public risk is driven not only by port populations, but by the populations within the immediate proximity of overland truck and rail shipments from the port of entry to each of the five potential storage sites (24). Since DOE considers the affected populations along the overland transportation route as important for protection of the public health and safety as those in the immediate vicinity of each port, the total unique population associated with the receipt of FRR SNF at a specific port and overland transport to a specific storage site is being treated as the affected population for each port. Since the NDAA did not define what was meant by populations surrounding ports, DOE examined three sets of populations circumscribed by the 1.6 km (1 mi) radius, the 8 km (5 mi) radius, and the 16 km (10 mi) radius. The 1.6 km radius would include members of the public in the immediate vicinity of the selected port terminal, including those members of the public outside the port boundary who would be expected to be most impacted by most accidents and incident-free transport from the port to the nearest interstate highway. However, for the most severe accidents (involving engulfment of SNF casks in fires beyond the design basis for Type B casks), plume rise would loft released activity high into the air, and peak ground concentrations would not occur until well outside the 1.6 km radius. In addition, the census figures do not include workers within the port boundaries whose numbers may be larger than the 1.6 km population outside the boundary for remotely located terminals. Therefore, the 1.6 km population was not considered adequate to reflect the intent of the criterion. The 8 km radius population was also found not to reflect the majority of the potential public impacts from severe accidents, and was determined to be inadequate. The potential impacts of severe accidents on the 16 km radius population, however, was found to include most of the total radiological impacts on the public for typical (mean) meteorology, and typical dry deposition and fallout patterns.

In addition, analyses of the potential impacts of severe accidents on a range of port populations indicated that the average per capita dose within 16 km, while small, was higher than any of the averages for more distant populations. As a result, DOE selected the 16 km radius population to represent the port populations most likely to be impacted by the entire range of potential port accidents (including severe accidents) and incident-free transport from the port to major interstates or rail systems.

The distributions for the combined populations of candidate ports and populations within 0.8 km of the transportation routes for each of the five potential storage sites for both truck and rail overland transport are somewhat skewed due to a few very high population ports. However, given the large uncertainty and variances for the small sample sizes for port/site combined populations, DOE assumes that the populations are normally distributed.

Very early in the EIS project, DOE realized that any proposed methodology imposed in the NEPA process would be suspect unless the methodology could be shown to be fair

and impartial. Therefore, DOE elected to apply a standard statistical model to these populations to assist in the selection of the lowest population ports practicable, so as to preclude any way to manipulate the data to reach a predetermined outcome. For normally distributed populations half of the combined port/site populations will be above the average, and half will be below. For purposes of selecting ports whose combined port/site populations (truck and rail) are as low as practicable, DOE will select all those populations that are below the average of the combined populations for further analysis.

USE OF DESIRABLE PORT ATTRIBUTES IN FINAL PORT SELECTIONS

For the ports remaining after the above screening criteria were applied, a number of desirable attributes were included in the port identification process which were not important enough individually to reject an otherwise acceptable port from further consideration. However, collectively, these attributes were useful in identifying a final group of ports which will be included in the DEIS. These desirable attributes included the following:

Relative usefulness by each storage site based on using low port/site populations,
Relative usefulness by FRR SNF owners based on available shipping lines serving each United States port,
Lack of significant conflicting uses at port terminal(s),
Adequate emergency preparedness capability,
Secure short-term storage,
Well-separated from high density populations,
No environmentally sensitive areas in ports,
FRR SNF handling experience, and
No severe natural phenomena of concern.

Another desirable port selection factor recommended by the USMMA Workshop (4) is the absence of local regulatory restrictions on receipt and handling of SNF. DOE elected not to use this factor for port selection, but will provide that information in the EIS for consideration by decision-makers. There were two reasons for doing so. First, it is well established that local restrictions on international or interstate commerce are void under the U.S. Constitution, and challenges have been rejected by the Federal courts. Second, if DOE were to avoid selection of ports with local restrictions, every port wishing to close its doors to receipt of SNF (or any other type of cargo) would simply promulgate an ordinance, defeating the port selection process.

"Usefulness," as used here, is a term in which the relative numbers of scheduled shipping lines and types of vessels that use a port, and the countries or regions that are served by those lines are compared for two or more otherwise acceptable ports for purposes of selecting the best of that group of ports. Also, using only those combined port/site populations which meet the low population criterion means that some ports will not be able to receive and transhipSNF either by truck or rail to one or more of the sites. This will also limit the usefulness of some ports.

The status of the low population ports for the remaining desirable attributes cannot be addressed at this time. However, some general observations are possible. Some conflicting uses at an otherwise acceptable port, such as loading or unloading explosive cargoes, can be avoided by judicious planning so that they do not occur when FRR SNF would be present. Other conflicting activities can also be avoided by judicious selection of berths which are well-separated from port areas where potentially dangerous and conflicting activities are underway (e.g., liquified natural gas or petroleum transfers, and loading or unloading of explosives or military munitions). Some severe natural phenomena, such as hurricanes, can also be avoided by careful planning. The Draft EIS will provide a final accounting of these attributes and, along with potential usefulness, will provide the basis for the selection of a final group of ports.

CONCLUSION

DOE has developed an impartial methodology for objectively screening and evaluating potential ports of entry for potential shipments of FRR SNF into the contiguous United States These criteria will be included in a DEIS to evaluate a policy for managing FRR SNF. Application of these criteria will assure that well-qualified ports of entry will be used if a policy is adopted for the United States to accept FRR SNF.

ENVIRONMENTAL ASSESSMENT OF THE SINKING OF THE NUCLEAR-POWERED SUBMARINES THRESHER AND SCORPION
Richard B. Sheldon, Ph.D.

GE-Corporate Research and Development
Bldg. K-1, Room 3B35
P.O. Box 8
Schenectady, NY 12301
ABSTRACT
Comprehensive deep ocean radiological environmental monitoring operations were conducted in 1983 and 1986 at the site of the sunken nuclear-powered submarine THRESHER and in 1986 at the site of the sunken nuclear-powered submarine SCORPION. Numerous sediment, water, and marine life samples were obtained from the sites. In addition, many in situ gamma radiation measurements were collected using sensitive gamma spectrometry techniques. None of the samples collected from the sites showed any evidence of release of radioactivity from the reactor fuel elements. Very low concentrations of radioactivity in the form of activated corrosion products (cobalt-60 and nickel 63) from the primary piping systems were detected in the sediments at both sites. Fission products were not detected above concentrations of world-wide fallout levels in sediment, water, or marine life samples. No cobalt-60 or nickel-63 was detected in the large number of fish and other marine life specimens or in undisturbed water samples at the sites. Samples of sediment, water, and marine life from the SCORPION site were analyzed for plutonium isotopes using very sensitive mass spectrometry techniques. Total plutonium radioactivity concentrations and the relative concentration of plutonium isotopes were typical of background concentrations due to fallout from nuclear weapons testing. Thus there is no evidence of leakage of plutonium from nuclear weapons that were on the SCORPION when it sank. The 1983 and 1986 survey results confirm that the THRESHER and the SCORPION have not had a significant effect on the radioactivity in the environment.
INTRODUCTION
Comprehensive deep ocean radiological environmental monitoring operations were conducted in 1983 and 1986 at the site where the U. S. Navy nuclear-powered submarine THRESHER sank in 1963 and in 1986 at the site where the U. S. Navy nuclear-powered submarine SCORPION sank in 1968. Both surface-ship-deployed and submersible-operated monitoring equipment were utilized during the course of these expeditions to obtain measurements and samples from the vicinity of the THRESHER and SCORPION sites. The objectives of these operations were:

To provide valuable follow-up radiological environmental monitoring data to that obtained from previous missions to the THRESHER and SCORPION sites.

To test and evaluate improved technology for conducting oceanographic radiological monitoring in the deep ocean.

The results obtained from the 1977 expedition to the THRESHER site and the 1979 expedition to the SCORPION site both utilizing the U. S. Navy's deep submersible TRIESTE, and the results obtained from the 1983 expedition to the THRESHER site utilizing DSV ALVIN, it's former support ship the R/V LULU, and the ORV CAPE FLORIDA, were useful in evaluating the potential sea disposal of obsolete submarines as described in the Final Environmental Impact Statement on the Disposal of Decommissioned, Defueled Naval Submarine Reactor Plants (U.S. Navy 1984). The 1986 expedition to both the THRESHER and SCORPION sites utilized DSV ALVIN with its support ship R/V ATLANTIS II. The enhanced capabilities of R/V ATLANTIS II compared with R/V LULU for conducting deep sea oceanographic operations precluded the need for an additional oceanographic research vessel during the 1986 expedition.

Background

The U. S. Navy nuclear-powered submarine THRESHER sank on April 10, 1963, 100 miles from land in water 8500 ft deep off the coast of Nova Scotia. Radiation measurements, water samples, bottom sediment samples, and debris collected from the area where THRESHER sank were analyzed for radioactivity with highly sensitive equipment shortly after the sinking and again in 1965 by various laboratories. None of these samples showed radioactivity above naturally occurring background levels or evidence of radioactivity released from the THRESHER. In 1977, follow-up samples of water, sediment, marine life, and debris were collected from the immediate THRESHER area by the submersible TRIESTE. None of these samples showed any evidence of release of radioactivity from the THRESHER'S reactor fuel elements. However, cobalt-60 released from the coolant system was detectable at low levels in sediment samples from localized areas that were not sampled during the original surveys. The cobalt-60 radioactivity in these sediment samples was small compared with naturally occurring radioactivity. Cobalt-60 was not detectable in the samples of water,

marine life, or debris. Nickel-63 was not detectable in any of the samples analyzed except by magnetically concentrating the radioactive corrosion products from a composite sample of sediments containing the highest concentrations of cobalt-60.
The U. S. Navy nuclear-powered submarine SCORPION sank on May 22, 1968 several hundred miles southwest of the Azores in more than 10,000 feet of water. The SCORPION carried two MARK 45 ASTOR torpedoes with nuclear warheads when it sank. The warheads were low-yield tactical nuclear weapons containing plutonium and highly-enriched uranium. Seawater and bottom sediment samples taken near SCORPION'S hull were analyzed for radioactivity with highly sensitive equipment shortly after the sinking. None of these samples showed radioactivity above naturally occurring background levels or evidence of radioactivity released from the SCORPION. In 1979, follow-up samples of water, sediment, marine life, and debris were collected from the immediate SCORPION area by the submersible TRIESTE. None of these samples showed any evidence of release of radioactivity from the SCORPION'S reactor fuel elements. However, cobalt-60 released from the coolant system was detectable at low levels in sediment samples from localized areas that were not sampled during the original surveys. The cobalt-60 radioactivity in these sediment samples was small compared with naturally occurring radioactivity. Cobalt-60 was not detectable in the samples of water, marine life, or debris. Nickel-63 was not detectable in any of the samples analyzed except by magnetically concentrating the radioactive corrosion products from samples of sediments containing the highest concentrations of cobalt-60.
It was the low concentrations of radioactivity present in the sediment near the THRESHER and SCORPION that provided a means to assist in the evaluation of improved deep ocean monitoring devices. The monitoring program conducted at both sites included the following elements:

In situ gamma spectrometry measurements of sediment and submarine debris.

Measurement of currents and temperature in the bottom water adjacent to the submarine debris.

Collection of representative bottom water and sediment samples for radionuclide analysis.

Collection of disturbed sediment for chemical and radionuclide analysis.

Collection of bottom-dwelling fish and marine life for radionuclide analysis.

Operation of an acoustic transponder navigation network to ensure proper placement of oceanographic sampling and monitoring devices.

MONITORING EQUIPMENT

A number of sampling devices were utilized to obtain samples of seawater, sediment, and marine life, and to make in situ gamma spectrometry measurements. This included instrumentation specifically developed for this purpose and modifications to existing oceanographic sampling equipment. A detailed description of this equipment is contained in Table I and is described in detail in Sheldon and Michne 1993a and b.
Equipment operated from DSV ALVIN included sediment core tubes and box corers used to obtain samples of sediments and interfacial seawater; Niskin bottles, pumping systems, and passive chemical monitors used to obtain large samples of seawater for subsequent analysis; and several types of in situ gamma spectrometers to make direct measurements of gamma-emitting radionuclides.
Surface-deployed equipment operated from R/V ATLANTIS II during the 1986 expeditions to both the SCORPION and THRESHER sites and from ORV CAPE FLORIDA during the 1983 expedition to the THRESHER site included various biological samplers including tetrahedral marine life traps and a two-chambered fish trap; water samplers including Niskin bottles, GO-FLO samplers, and a pumping system (Winget et. al. 1982); sediment and interfacial water samplers including box corers, a tripod sphincter corer (Burke 1968), and a quadropod sampler; two types of wire-deployed or free vehicle in situ gamma spectrometers; current meters; and acoustic transponder navigation equipment to precisely identify the locations of samples obtained from the sites.

METHODS

As indicated previously, the expedition to the THRESHER site in 1983 utilized the DSV ALVIN with it's support ship R/V LULU, both operated by the Woods Hole Oceanographic Institution, and the oceanographic research vessel ORV CAPE FLORIDA, operated at the time by the University of Miami. The 1986 expedition to both the THRESHER and SCORPION sites utilized the Research Vessel (R/V) ATLANTIS II, with ALVIN, both operated by Woods Hole Oceanographic Institution. ATLANTIS II is 210

feet long, displaces 2300 long tons, and is driven by two 1100 horsepower diesel engines with a twin screw configuration. She is outfitted with a stern mounted A frame utilized for the efficient launch and recovery of ALVIN. Scientific facilities aboard the ship included a deep submersible control and monitoring station equipped with a UQC underwater telephone and electronic equipment. This station includes computers to permit tracking of ALVIN and other equipment outfitted with acoustic transponders on the ocean floor.

The basic navigational network consisted of setting three transponders in a triangular configuration with the main target near the center of the triangle. The transponders were anchored approximately 100 meters above the ocean bottom. One acoustic signal was periodically transmitted from the ship to the three transponders, which replied at different frequencies. The time for this round trip signal was measured at the ship using an acoustic processor controlled by an IBM computer. After all transponder anchors had settled to the ocean bottom, a survey was conducted using Loran C navigation. The ship was driven around the network transmitting to and receiving from the transponders. These signals were then processed in the computer to give XYZ coordinates of each transponder and the exact distance between them. These numbers were then put into the computer's acoustic navigation program.

The navigation program was then used to control the ship's position relative to the transponder network in XY coordinates. The navigation program could locate other packages within the network besides the ship. This was the basic method used to deploy monitoring equipment on the bottom at predetermined targets from the surface ship. The ship was maneuvered as the monitoring equipment was tracked to hit the bottom at the specified target. The equipment was released at the desired location from a depth of approximately 50 to 100 meters off the bottom and the exact position of the instrument in relation to the target was determined. A description of this underwater acoustic navigation system is contained in Loud and Scheer 1984.

Six ALVIN dives were conducted at the THRESHER site in 1983, in which various monitoring devices were utilized. Thirteen deployments of various oceanographic monitoring devices were conducted from CAPE FLORIDA. These included the current meter, fish traps, box corer, sphincter corer, quadropod sampler, gamma spectrometer, and the water sampling pump described previously.

Two ALVIN dives were conducted at the THRESHER site in 1986 utilizing the submersible-operated and deployed instrumentation discussed previously. Monitoring efforts were concentrated near those areas of the THRESHER that were not heavily sampled in 1983. Two deployments of oceanographic monitoring devices were conducted from R/V ATLANTIS II, including the wire-deployed gamma spectrometer and the water sampling pump. Numerous core tubes and in situ gamma spectrometry measurements were collected by ALVIN.

Ten ALVIN dives were conducted at the SCORPION site in 1986, in which various monitoring devices were utilized. These devices included the gamma spectrometer, water pump sampler, sediment core tubes, and GO-FLO water samplers described previously. ALVIN operations were conducted during the daytime with precision navigation by the computer system aboard ATLANTIS II. Nighttime operations aboard ATLANTIS II included the surface-deployment of monitoring devices, the recharging of ALVIN's batteries, sample processing, and dive preparations for the next day. ALVIN's principle objectives were to survey and sample the SCORPION area, locate and provide coordinates for the target to be used by ATLANTIS II for nighttime deployment of monitoring devices, and to verify the positions of monitoring devices the day after they were deployed. Twenty seven deployments of various monitoring devices were conducted from the surface. These included the current meter, fish traps, box corer, gamma spectrometer, and the water sampling pump described previously. Numerous samples were collected and measurements obtained.

At each site, a current meter was deployed as a free vehicle during the first full day on station and was moored approximately 2 m off the bottom in the vicinity of the submarine. Current direction, velocity, and temperature were recorded continuously. The meter was successfully recovered after it was released from the bottom by an explosive type timer.

Shipboard Gamma Spectrometry

Selected samples of sediment, seawater and marine life were analyzed with shipboard intrinsic germanium detectors each coupled to a Canberra Series 10 multichannel pulse height analyzer. The detector systems were shielded inside lead forts to

reduce background radiation levels and to improve the sensitivity of detection. A sufficient supply of liquid nitrogen was stored aboard ship to keep the detectors operating around-the-clock during the course of the expedition. Results from these analyses were used to make preliminary assessments and to determine the locations for future samples. The same samples were later analyzed using more sophisticated laboratory analytical equipment and the results reported in Sheldon and Michne 1993a and b.

Radiological Precautions

Various radiological control procedures were implemented to minimize personnel radiation exposure and the potential for radioactive contamination in the event that excessive radiation or contamination was encountered. Previous radiological monitoring data were reviewed. Based on this review, the major longlived radionuclides of concern during submergence and surface recovery operations were identified as the activation product cobalt-60, the fission product cesium-137, uranium-235, and the transuranic plutonium-239. The detection of either cobalt-60 or cesium-137 would also imply the presence of other long-lived activation and fission products or core materials such as nickel-63, strontium-90, uranium-235 and plutonium-239.

Radiological control procedures were in compliance with the Woods Hole Oceanographic Institution (WHOI) Isotope User's Manual, which is based on Nuclear Regulatory Commission (NRC) regulations imposed by WHOI's NRC license. The control of personnel exposure during diving operations consisted of using personnel monitoring devices including thermoluminescent dosimeters (TLD's) and pocket dosimeters along with radiation survey instrumentation aboard ALVIN. Each dive crew carried two portable gamma radiation survey instruments for use in high and low radiation fields. On each dive ALVIN also carried an externally mounted radiation detector connected to a multichannel analyzer inside ALVIN. At least one person on each dive was instructed in the use of the radiation survey meters. All diving personnel were assigned and instructed in the use of a 0-200 MR self-reading pocket dosimeter for monitoring real time exposure, and an accompanying TLD to provide a permanent record of external exposure. It was also recognized that based on previous deep submergence operations involving radioactive sources that considerable shielding would be afforded by benthic sediment, seawater, and the 4.5 cm thick titanium sphere of ALVIN. No measurable radiation exposure above natural background was measured by any of the instrumentation or TLDs.

The potential spread of radioactive contamination was controlled by strict adherence to radiological survey and contamination control procedures for all equipment, including ALVIN, which returned to the ship after coming in contact with the THRESHER or SCORPION debris or surrounding areas. Access to all equipment returning to support ships was restricted until radiologically trained personnel had completed beta-gamma surface contamination surveys, radiation surveys, and swipe surveys which were immediately dried and checked for alpha as well as beta-gamma surface contamination. Oceanographic monitoring devices, ALVIN, and the swimmers used to aid in ALVIN recovery operations were all surveyed prior to being released to unrestricted areas. All survey instruments were calibrated by GE-KAPL personnel prior to departure. Each instrument was also source checked daily during shipboard use. None of the personnel monitoring devices or radiological survey instruments measured any detectable radiation or radioactive contamination in or on ALVIN, support vessels or any of the recovered oceanographic equipment. Only very low levels of radioactivity as measured by the in situ gamma spectrometers or sensitive laboratory instrumentation were detectable in any samples obtained from the THRESHER or SCORPION sites.

Analytical Techniques

Samples of sediment, unfiltered seawater and marine life were placed in 500 cc Marinelli beakers or 250 ml plastic containers, as appropriate, for counting using intrinsic germanium detectors coupled to multichannel analyzers. Mass spectrometry analysis was conducted on samples found by gamma spectroscopy to contain detectable levels of uranium-235, and on selected samples obtained from the SCORPION area. Samples of seawater, sediment, and marine life tissues underwent chemical separation procedures for subsequent analysis for uranium and plutonium by isotope dilution mass spectrometry.

Prior to radiochemical analysis of seawater samples, salinity measurements were made on the discrete water samples to verify that they were truly bottom samples and had

not been compromised in any way by malfunction or handling. The samples were then analyzed radiochemically for strontium-90, cesium-137, and plutonium-239 and 240 by the standard procedure contained in Wong et. al. 1970 and Suprenant et. al. 1983. Nickel-63 is the predominant beta-emitter present in the corrosion products inside reactor coolant systems and contained in the activated metal structures inside the reactor vessel. Nickel-63 analyses were conducted on those sediment samples that contained detectable concentrations of cobalt-60, and on seawater, selected marine life samples, and corrosion products magnetically removed and concentrated from a sediment slurry. Corrosion products were magnetically separated from those sediment samples having detectable concentrations of cobalt-60.

Biological samples of fish and other marine life were preserved for subsequent enumeration and identification to the lowest taxonomic levels possible. All of the fish were initially frozen. Crustaceans and other organisms were fixed in 8% formalin and later transferred to 70% ethanol.

Thirty-three of the rattails (Coryphaenoides armatus), three codlings (Antimora rostrada), and the eel pout (Zoarcidae sp.) from the THRESHER site and the twenty rattails (Coryphaenoides armatus), five Ophidiids (Barathrites iris), and the two eels (Histiobranchus bathybius) from the SCORPION site were thawed and dissected on a clean bench for subsequent trace metal analysis. Triplicate samples of various tissues including muscle, skin, kidney, bone, gonads and liver from each fish were analyzed.

Samples of stomachs, intestines, and anal sacs of the twelve fish from the THRESHER site and the twenty-seven fish from the SCORPION site were selected for gut content analysis to determine food web interactions. The primary advantage of the immunological analysis method is its ability to qualitatively characterize the soluble proteins present in an otherwise unidentifiable mass of gut contents or fluids.

RESULTS

Radiological and Environmental Evaluation

The radioactivity concentrations measured in the sediment samples agree with expected results when compared with decay-corrected values for previous samples, including spacial variations in radioactivity levels. When compared with 1977 and 1979 results (U.S. Navy 1984), a smaller percentage of the core samples exhibited detectable concentrations of cobalt-60 in the surface (0 to 5 cm) sediment segment. Similarly, a larger percentage of the cores exhibited detectable concentrations of cobalt-60 in the deeper segment. This indicates a dilution of radioactivity in the surface sediments that cannot be accounted for by radioactive decay alone. This dilution may be due to mixing of the sediments caused by benthic storms, sedimentation, and bioturbation resulting in the movement of radioactivity to greater depths. The main source of the radioactivity was determined to be the corrosion products released from the reactor coolant at the time of the accidents. Subsequent corrosion of activated structural material has not resulted in a significant increase in the radioactivity present in the sediment. The cobalt-60 concentrations measured in the sediment are small compared with the potassium-40 and other naturally occurring radionuclides present. Cobalt-60 was not detectable in any of the seawater samples or marine life including the 63 fish. By gamma counting samples for a nominal 1000 min, it was possible to achieve typical detection sensitivities of 0.01 pCi/gm for sediment and marine life and 0.005 pCi/liter for seawater samples using solid-state intrinsic germanium and Ge(Li) detectors coupled to multichannel analyzers. Levels as low as 0.001 pCi/liter were obtained for seawater samples using radiochemical extraction. Cesium-137 concentrations in excess of fallout levels were not measured in any of the seawater, sediment, or marine life samples analyzed. This indicates that the integrity of the reactor fuel inside the core has been maintained.

The highest concentrations of cobalt-60 in the sediment (< 0.3 pCi/gm at the THRESHER site and < 0.5 pCi/gm at the SCORPION site) were found in the upper 5 cm. Cobalt-60 was detectable in sixteen of the thirty core tubes collected by DSV ALVIN at the THRESHER site and in seventeen of the fifty-three core tubes collected at the SCORPION site. At both sites, the absence of cesium-137 concentrations in excess of those attributable to fallout indicates that the integrity of the reactor fuel inside the cores has been maintained and confirms the results from previous samples obtained by KAPL.

Results from the analysis of marine life samples indicated that the species

composition and abundances were within the range of variation expected for the depth and location of the sampling area. It is evident from these results that there are no significant ecological changes attributed to the sunken submarines and that there has been no significant "reef" effect although some colonization of the debris was observed. The immunological assay of the fish stomach contents indicates the apparent predation on deep sea invertebrates, including benthic gastropods, sea anemones, holothurians, and tanaids. Although little is known about the feeding habits and range of deep sea fish, the fact that none of the fish contained any radioactivity attributable to the THRESHER or the SCORPION and that the organisms found in the fish guts were predominantly benthic indicates that there has been no significant bioaccumulation or concentration of the radioactivity released at the time of the submarine sinkings. Marine animals could theoretically accumulate radioactivity by ingestion of contaminated sediments or prey organisms, by absorption from the seawater, or by the adsorption onto external tissues. Any bioaccumulation of the refractory radioactive corrosion products found in the sediment at the THRESHER or SCORPION sites was not observed. If one considers the nonradioactive cobalt and nickel present in the seawater and sediments combined with the inventory of nonradioactive cobalt and nickel in the fish, there exists a great dilution potential of stable elements to reduce the likelihood of any potential bioaccumulation of radioactive isotopes of these elements.

This monitoring program provided the necessary samples and information to evaluate the environmental impact of the loss of the THRESHER and SCORPION. The collection of seawater, sediment, and marine life samples and their subsequent analysis for radioactive corrosion products and fission products provided a check on the various environmental exposure pathways. Since most of the corrosion products, including those formed during previous reactor operations, released from corrosion resistant material are insoluble (Schmidt 1982), they are likely to have deposited on the sediment when they were released from the submarine debris. Some of these corrosion products may have been adsorbed into sediment particles or complexed by organic materials. The soluble corrosion products which were shown (Schmidt 1982) to represent only a small fraction of the chemical forms in deep ocean sediments, could have been transported through pore water to different locations within the sediment. By taking core samples, both sediment particles and pore water were available for quantitative radiochemical analysis. In situ gamma radiation measurements were useful to obtain immediate indications of any abnormal radioactivity concentrations but were unable to find any areas with contamination levels in excess of 3.6 pCi/g at the THRESHER site or 2.08 pCi/gm at the SCORPION site. If localized areas of higher contamination were found, the information would have been useful to direct subsequent core sampling locations. Because of the small quantities of radioactivity released to the environment, and the great amount of available seawater dilution, it was necessary to use the in situ pumping systems to concentrate and remove the radioactivity from the seawater in the immediate vicinity of the THRESHER and SCORPION. In spite of the highly sensitive detection capability achieved, no radioactivity attributable to either submarine was found in any of the seawater samples analyzed except for small quantities of particulate cobalt-60 resuspended from the sediment by ALVIN operations and two soluble phase cobalt-60 signals near the detection limit attributed to "bleed through" of particles from the prefilter. Elevated concentrations of plutonium were not detected and confirmed in sediment, water, and fish samples. Los Alamos National Laboratory reports that the plutonium in the nuclear weapons at the SCORPION site would have been exposed to seawater either immediately upon sinking or shortly afterward. Plutonium metal corrodes quickly in seawater to form a heavy insoluble material. Since any chemical or physical changes of the plutonium occurred shortly after the sinking and no elevated plutonium was found in the environment during this survey 18 years after the sinking, there is no reason to believe that the plutonium will be subject to accelerated release or dispersion in the foreseeable future.

Evaluation of Monitoring Devices

The radiological environmental monitoring conducted from the ATLANTIS II, ALVIN, LULU and CAPE FLORIDA yielded very useful information on the suitability of various types of equipment for this type of operation. In general, surface-deployed devices such as the box corer, which are heavier and more streamlined, are easier to deploy at a given target than those devices such as the fish trap that are more apt to drift on their way to the bottom. With careful maneuvering of the surface ship, it

was possible to place monitoring devices close to the target area.
These demonstrations of surface-ship and submersible-conducted radiological environmental monitoring involved two semi-independent means of accomplishing the required objectives. The selection of either method for use is dependent upon the specific requirements for the given site. For example, use of the submersible ALVIN at depths in excess of its maximum operating depth of 4500 m is not permitted. The surface-ship-deployed monitoring devices have depth capabilities in excess of 6700 m. Submersible-conducted operations are more appropriate where "close in" sampling from precise locations are required. Surface ships are more appropriate for general area monitoring.
Future deep-ocean radiological environmental monitoring expeditions should concentrate on utilizing those devices that proved to be the most productive during these expeditions. This would include the surface-deployed box corer, water pump, fish traps, current meter, and the submersible-operated sediment core tubes, box corers, water pump, water bottles, marine life samplers, and gamma spectrometer. If sediment samples with undisturbed surfaces are desired, then samplers such as the box corers, or submersible-operated core tubes should be utilized. The other types of sediment samplers either penetrate the bottom too rapidly or otherwise disturb the surface sediment. If high sensitivity is required for analysis of the radioactivity content of seawater, the water sampling pump can provide detection limits better than 100 times greater than that obtainable from collection and analysis of water samples by traditional means. The specific equipment used should be tailored to the objectives of the monitoring expedition. For surface operations, the oceanographic vessel should be equipped with a bow thruster to assist in the proper positioning of the ship and equipment within the acoustic transponder navigation network.
DISCUSSION
The radiological environmental monitoring conducted with the ATLANTIS II, CAPE FLORIDA, LULU and ALVIN demonstrated the capability to conduct deep-ocean monitoring with the equipment discussed above. ATLANTIS II and CAPE FLORIDA were able to place surface-deployed samplers and monitoring devices in close proximity to major pieces of the THRESHER and SCORPION by the use of an acoustic transponder navigation network. The relative positions of these instruments were determined by computer and confirmed by ALVIN to be satisfactory. The exceptional maneuverability of ALVIN, supplemented by the use of the remotely operated vehicle JASON, Jr. provided the most complete environmental monitoring of the THRESHER and SCORPION yet conducted. ALVIN was able to make in situ gamma measurements and obtain sediment, seawater and marine life samples. These expeditions demonstrated that comprehensive radiological environmental monitoring of localized deep ocean areas could be achieved at reasonable cost using existing oceanographic technology.
The samples of water, sediment, and marine life obtained from the THRESHER and SCORPION sites were analyzed for radioactivity. None of these samples showed any evidence of release of radioactivity from the THRESHER or SCORPION reactor fuel elements. Cobalt-60 in magnetic high temperature corrosion products released from the THRESHER and SCORPION coolant systems or internal surfaces of piping or components during the sinkings was detectable at concentrations lower than those measured in 1977 and 1979. Nickel-63 was detectable at low concentrations in corrosion products magnetically separated from sediment samples. The cobalt-60 and nickel-63 radioactivity present in the sediments is small compared with naturally occurring radioactivity. Cobalt-60 and nickel-63 were not detected at significant concentrations in samples of seawater or marine life. Cesium-137, strontium-90, plutonium-239, 240 and americium-241 concentrations in seawater were consistent with deep water concentrations expected at this location and depth from nuclear weapons testing sources rather than THRESHER or SCORPION debris. Thus, the loss of the THRESHER and SCORPION has not had any significant environmental impact.
The reactors and materials used in all U.S. Naval submarines and surface ships are designed to minimize potential hazards to the environment even under the most severe conditions such as the accidental sinking of a ship. The reactor fuel elements are made of materials that are extremely corrosion resistant, even in sea water. Based on deep sea corrosion data from submarine structural materials reported in Barth and Sheldon (1989), the reactor core could remain submerged in seawater for centuries without releases of fission products, while the radioactivity decays. Since the protective cladding on the fuel elements corrodes only a few millionths of an inch

per year, most of the fission product radioactivity (primarily cesium-137 and strontium-90, with nominal half-lives of 30 years) will be gone by the time the cladding is penetrated by corrosion. Since the corrosion rates of these materials at the bottom of the sea are so low, the maximum rate of release and dispersal of the radioactivity would be so low as to be non-detectable and would have no future adverse impact on the deep-sea environment.

ACKNOWLEDGEMENTS
The author wishes to express his gratitude to the scientific personnel aboard R/V LULU, DSV ALVIN, R/V ATLANTIS II, and ORV CAPE FLORIDA, for their assistance in the design, fabrication, and testing of the various deep ocean radiological monitoring devices. The advice and experience of Dr. Robert D. Ballard, Dr. Charles D. Hollister, Dr. Jon Losee, and of the late Sherman L. Williams were particularly invaluable in coordinating oceanographic operations. The assistance afforded by Dr. Josef Parrington, Clyde H. Barth, Carl E. Johnson, John D. Michne, and Keith R. Earnshaw in the collecting and processing of oceanographic samples is greatly appreciated. John D. Michne also assisted in radiochemical analysis of the samples in conjunction with Thomas A. DeVito, Deam M. Van Natten, Dr. Charles W. Boylen, and Gabriela August. Helen C. Hendrickson and Chester F. Pachucki performed mass spectrometry analyses of selected samples while Dr. Jih-Jen J. Cheung and Jon F. Stevens performed chemical analyses of selected samples. Camilla Ingram and Dr. David Stein contributed immensely in the identification of marine invertebrates and fish. Dr. Robert Feller performed the immunological assay of the fish stomach contents and Dr. Herbert Windom determined the trace metal concentrations in the fish tissues. Dr. James A. McHugh and Jack W. Youngblood reviewed the manuscript for this report and provided shoreside logistical support of oceanographic operations. Deborah A. Maione provided drawings of the various types of oceanographic equipment. Lorraine Miskinis provided editorial assistance in the preparation of reports. David Delonga, Earl Young, Thomas Cook, Emile Bergeron, Martin Bowen, and Chis Van Alt of the Deep Submergence Laboratory provided excellent deep sea navigation to permit the collection of samples. I also appreciate the efforts put forth by the Masters and crews of R/V ATLANTIS II, ORV CAPE FLORIDA, RV LULU, and DSV ALVIN and especially the ALVIN pilots for their courage and expertise in maneuvering the submersible under adverse conditions.

Session 61 -- Pollution Prevention/Waste Minimization

Materials Engineering

ABSTRACT
Waste costs, liabilities, and regulations have been and are today growing concerns for government and industry. Pollution prevention opportunity assessments (PPOAs), formerly known in the Department of Energy as process waste assessments (PWAs), are tools which assist a site in achieving pollution prevention benefits. A PPOA is an important tool in a site's Waste Minimization / Pollution Prevention (WMin/P2) Program which can lead to the identification of pollution prevention opportunities, prioritization of pollution prevention activities, implementation of cost-effective pollution prevention practices and technologies, and creation of a baseline from which to set waste reduction goals and measure progress. PPOAs are applicable to any process or planned activity which has the possibility of generating waste -- this includes activities or projects that handle and manage waste after it has already been generated.
This presentation will provide an overview of PPOAs and their role in WMin/P2. It will describe the importance of bringing WMin/P2 into the planning stages of any

process or project and how PPOAs can be used in Decontamination and Decommissioning and Environmental Restoration activities.

INTRODUCTION

Waste costs, liabilities, and regulations continue to be growing concerns for government and industry. Pollution prevention opportunity assessments (PPOAs) are a tool which proactively manages these concerns. The Department of Energy (DOE) has recognized the benefits of PPOAs in the DOE Waste Minimization Pollution Prevention Crosscut Plan (1) which states that the completion of opportunity assessments is of critical importance to DOE because they are an essential management decision-making tool that tell DOE:

1. how much waste and environmental releases can be avoided,
2. through what activity/process changes waste reduction can be achieved,
3. what it will cost to implement a pollution prevention opportunity, and
4. what will be the long-term savings in avoided waste management costs.

Before exploring what a PPOA is, a brief discussion of pollution prevention is necessary. Pollution prevention (P2) may also be referred to as waste minimization, source reduction, and/or recycling. The definition used in the DOE-sponsored PPOA training class is: "Pollution prevention reduces or eliminates material releases to air, water, and/or land." The benefits of pollution prevention include a proactive approach to waste management, compliance issues, and liability concerns; economic incentives; improved employee and public health; and environmental stewardship. Basically it all boils down to the phrase, "It's the right thing to do."

What is a Pollution Prevention Opportunity Assessment?

A PPOA is a tool with the objective of identifying opportunities and methods to reduce or eliminate all wastes (2). A material balance is performed around a specific process, project, or activity to qualify and quantify the materials entering and exiting. The exiting materials are separated into product, by-product, recycled, waste management (liquid and/or solid), and air release streams. Next, opportunities are identified and evaluated for their ability to eliminate or minimize the non-value-added output streams exiting the process. Therefore, the PPOA provides the basic tool for the identification of opportunities to eliminate/minimize the release of hazardous, nonhazardous, and radioactive wastes. This also provides a comprehensive baseline from which to measure P2 progress. The assessments also identify those processes, activities, and procedures that need to be improved or replaced to promote pollution prevention. Simply stated, PPOAs can be the foundation upon which comprehensive and effective pollution prevention rests.

Application of PPOAs to Nonroutine Activities

Opportunity assessments have commonly been completed on routine processes -- those which occur in a manufacturing plant. However, they can also be useful on nonroutine waste streams and at nonmanufacturing sites such as laboratories. By changing one's point of view, PPOAs can also be conducted on non-routine activities.

Some facilities or groups conduct activities on a project-oriented basis (3). This means that only one waste-generating activity is done once. Two examples are an engineering laboratory that builds prototypes and a research laboratory conducting experiments. In each case the projects have unique chemical inputs, a defined length of time, and very specific activities.

Project-oriented activities can be assessed in two ways. First, a macro-level view, looking for consistent, general activities that occur from project to project or experiment to experiment, can be taken. Such activities can include material procurement, cleaning techniques, or personal protective clothing use. Common waste streams can be reviewed using a standard PPOA, resulting in facility-wide waste reduction ideas, such as implementation of procurement controls or procedure changes.

The second way to approach pollution prevention is to include it in the planning phase of the project, experiment, or activity. The project scope and plan would be reviewed in the same way an on-going activity would be reviewed, except on paper in PPOA form. The steps of the project can be mapped, inputs and outputs identified, and brainstorming done to identify options with the potential for waste minimization. Applicable, cost-effective methods to reduce waste can then be written into the project plan. In addition, it is helpful to make sure that at least one member of the planning team is an advocate of pollution prevention.

The waste streams from Decontamination and Decommissioning (D&D) and Environmental Restoration (ER) are also often considered "nonroutine" and project oriented. Even

when these processes are performed on waste, they generate additional, so-called secondary, waste and there are opportunities to minimize this waste. Decontamination and Decommissioning operations usually involve removal of buildings and equipment, while ER usually includes treating or removing soil and returning the land to its natural state. Therefore, these activities can be addressed on a macro level or in the planning phases. The common waste streams such as personal protective equipment, deactivation, decontamination debris from surface cleaning, and material inputs can be assessed or PPOAs can be completed during the planning phase.
An alternate way to consider D&D and ER waste streams is to view them as part of a long series of routine processes.(See Table I)
TABLE I
An example is the D&D of buildings. If there are many buildings at a site selected for demolition, then the entire schedule can be viewed as a regular activity to be conducted multiple times. This perspective permits the consideration of equipment and initiatives which may only be cost effective when used on multiple projects, as well as develop lessons learned from one to another. Therefore, PPOAs should be applied to the entire site restoration program to determine common pollution prevention opportunities, since some opportunities may be economically feasible only when multiple projects are considered. By performing PPOAs on the routine sub-tasks within a D&D or ER project and revising these assessments as knowledge is gained, it is possible to continuously improve waste minimization activities.
Decontamination and decommissioning and ER projects are unique in that a large portion of the waste, commonly referred to as legacy waste, already exists. Since these activities involve the tearing down of structures or cleaning up of existing waste or structures, some people claim that no pollution prevention can be accomplished. However, extensive recycling opportunities with concrete and steel and other building materials are present. The key is to prevent as much secondary waste as possible (source reduction) and embrace recycling as an excellent and viable method for successful P2.
PPOA Methodology
The major steps involved in a PPOA are:
- Planning and Organization,
- Project / Activity Assessment,
- Project Description,
- Flow Diagram,
- Input/Output Summary,
- Option Generation,
- Option Evaluation, and
- Final Report.

In order to perform a successful PPOA, all employees involved in the project must participate, most importantly the operators and workers with the operation and/or program experience. Employee activities can significantly affect the amount of waste generated, and therefore, they can contribute greatly to the assessment. Successful pollution prevention requires actions and ideas from everyone.
After organization, the project needs to be assessed or evaluated. The end result is baseline knowledge of the activity and both qualitative and quantitative measures of the inputs and the outputs associated with it. In order to develop this knowledge, a detailed understanding of the wastes generated and operations performed is required. The assessment should begin by examining information about the process, operations, and waste management practices. Tools such as flow diagrams and material balances are used to achieve this baseline knowledge.
Once the project steps and sources of waste generation are understood, the PPOA enters the creative phase. Following the collection of data and site inspections, the members of the team will have begun to identify possible ways to minimize waste or prevent pollution. Identifying potential options relies both on the expertise and creativity of the team members. Much of the requisite knowledge may come from their education and on-the-job experience; however, the use of technical literature, contacts, and other sources may also be pursued.
Many pollution prevention options will be identified in a successful assessment. At this point, it is necessary to identify those options that offer real potential to minimize waste and reduce costs. Since detailed evaluation of technical and economic feasibility is usually costly, the proposed options should be screened to identify those that deserve further evaluation. Screening followed by detailed evaluation

serves to eliminate suggested options that appear marginal, impractical, non-cost effective, or inferior.
After the option evaluation is complete, a final report is required to document the team's suggested implementation plan. The final report for a PPOA is a compilation of essential facts characterizing the project or activity, identifying pollution prevention options, analyzing option feasibility, and projecting option implementation costs. The purpose of this report is to document the project baseline and pollution prevention options and to provide information to management on the funding requirements necessary to implement the feasible pollution prevention options.
Pollution prevention opportunity assessments have proven to be useful tools to evaluate input materials, identify sources of waste, and generate pollution prevention options for D&D and ER processes. Two techniques have been successfully used to break these processes down into management chunks. Assessments can be performed on common tasks such as equipment decontamination or sampling. Alternatively, assessments can be performed on subelements such as site characterization or screening of alternatives. Regardless of the method chosen, performing a PPOA results in a fuller understanding of the sources of waste and identification of options for pollution prevention.

IMPLEMENTING WASTE MINIMIZATION
USING ROI PROJECTS
Oren Critchfield
Department of Energy
Albuquerque Operations Office
Debbie J. Finfrock
Roy F. Weston, Inc.
ABSTRACT
The implementation of process changes for source reduction and recycling opportunities typically falls to a lower priority when compared to activities for environmental risk management, regulatory compliance, and Department of Energy (DOE) Order compliance. However, source reduction is still the best practice. How can waste minimization (WMin) facilitators convince waste generators to implement WMin projects? DOE has discovered that identifying high return-on-investment (ROI) projects provides an incentive for waste generators to implement WMin because the savings realized can be used to pay for compliance requirements. Initial projects implemented at several DOE sites have proved that WMin projects can achieve the cost savings expected. These cost savings result from avoided waste disposal costs, reduced waste handling costs, and reduced material and energy costs. There is currently an excess of commercial hazardous waste treatment capacity because WMin has been so successful in the private sector. Intangible savings may also be realized from improved safety and work environments, delay or avoidance of capital expenditure for storage and disposal facilities, and avoidance of waste storage and disposal liability.
WHY USE ROI PROJECTS FOR WASTE MINIMIZATION?
The Department of Energy (DOE) is becoming more aggressive in its implementation of waste minimization/pollution prevention (WMin/P2). While DOE sites have operating funds for training employees and tracking and reporting waste, few sites have the capital funds necessary to implement WMin/P2 projects, even for changes as simple as installing a bypass wastewater disposal system. Although some procedural and administrative improvements can be implemented using operating funds, it is usually small capital projects that have the biggest impact on waste reduction. Waste minimization is recognized as the best waste management program for the future due to increasing costs and potential liability, but most waste management programs at DOE sites must focus limited resources on regulatory compliance and risk avoidance.

Return-on-investment (ROI) projects that implement waste minimization can compete for waste management dollars if they offer an ROI that provides a high return on those waste management dollars in a short period of time. This facilitates making capital improvements that increase process efficiency, or recycling and reusing materials, consequently reducing waste. The waste management funds invested in WMin/P2 ROI projects generates savings within a year or two; those savings can be used for compliance activities.

Cost-effective WMin/P2 projects are needed so WMin programs can compete with other regulatory compliance activities. All large quantity waste generators are required by the Resource Conservation and Recovery Act (RCRA) to certify that they have a waste minimization program on each hazardous waste manifest (40 CFR 262, Appendix). The United States Environmental Protection Agency (EPA) issued interim final guidance on the elements of a waste minimization program in 1993 (EPA, 1993), but this guidance is extremely flexible compared to the more explicit rules governing waste management. As a result, waste minimization programs are the first to lose funding during periods of diminishing resources. The EPA is becoming stricter about auditing WMin programs for their effectiveness, but this program will probably not impact waste generating sites for some time.

WHAT ARE ROI PROJECTS?

ROI is a comparison measure used by private industry to evaluate whether to implement capital projects or invest profits in financial opportunities. The return rate is calculated as a percentage of profit earned from the implemented project divided by the capital invested. This return rate corresponds to an interest rate that would be earned on financial investments. If a company can earn a 10% return on a bond or other financial tool, why should it invest in a capital project that only returns 6%? ROI measurements ensure that a company earns the greatest possible profit on funds invested. It also can be used to prioritize projects. In a non-profit government environment, savings realized in a few years from investments creates a sense of urgency for making improvements.

Capital ROI projects involve purchase and installation of equipment to improve a process and reduce waste. An example is installing a pH meter on wastewater outlet piping and a bypass valve that routes the wastewater directly to an effluent point if the pH is within permitted range and requires no treatment (Fig. 1 illustrates existing and proposed effluent treatment systems). Some capital projects may completely replace a process with new technology. Many sites are purchasing digital printers to replace hazardous photochemical processes, so no chemical waste is generated. Other WMin/P2 projects include installing a distillation column to recover acid and recycle it back into a process, installing bulk oil storage tanks so individual oil containers are not needed, and recovering lead from soil for recycling.

Fig. 1.

ROI evaluation for capital projects measures the expected improvement in a process after the project is implemented. The profit earned is determined by deducting the expected operating costs and equipment amortization costs from the expected savings. This profit term is divided by the cost of implementing the project. This ROI calculation takes the following form:

Eq.

where

S - annual operating cost savings
A - annual operating costs
C - capital equipment costs
I - labor and material costs
L - useful equipment life

Annual operating cost savings (S) can be measured in materials and energy saved, waste service costs avoided, and waste handling labor eliminated. Expected annual operating costs (A) include additional labor, increased energy, new materials, and new waste disposal services required to operate the new process. The equipment amortization term (C+I/L) divides the project installation costs (C+I) by the useful life of the equipment. The project installation costs include capital, labor, and material costs. Capital equipment costs (C) include the funds needed to purchase pumps, valves, piping, or other items needed to complete the process change. Labor and material costs (I) are required for the initial installation of the capital equipment. These savings and cost terms are used to measure the performance of the

implemented projects.
ROI PROGRAM AT DOE/AL
DOE/AL based its WMin/P2 ROI program on a successful energy and waste reduction program at Dow Chemical (Nelson, 1993). Dow held a contest to solicit energy and waste reduction projects, implemented those with ROI values greater than 100%, and achieved audited savings of over $110 million per year for 575 projects. The Deputy Secretary of Energy was so impressed by these results that he decided to adopt the program. The DOE Pollution Prevention Executive Board identified high ROI WMin/P2 projects at the DOE sites. Twenty ROI projects have been funded by headquarters and will be audited in FY95 to determine if projected waste reductions and cost savings were achieved.
The Albuquerque Operations Office (DOE/AL) decided to accelerate the ROI program by using waste management funds that had been held back for productivity improvements to implement eight ROI projects during late 1994. DOE/AL developed an ROI program guide to assist sites in identifying projects, calculating the savings and costs associated with implementing the projects, preparing a project proposal package, and locating funding sources. The WMin/P2 projects submitted competed very successfully against other productivity projects. Three projects are now complete and operational, and five other projects are being implemented. Table I summarizes the ROI and the waste reduction expected from each project, estimated using the ROI calculation presented above.
TABLE I
INITIAL PROJECTS
These initial projects are not large or glamorous investments, but the annual savings is significant. Simple process changes can greatly impact the amount of waste generated. DOE/AL has found that the following elements lead to a competitive ROI project:
  use of existing and proposed process flow diagrams;
  preparation of background calculations identifying the savings and costs used in the ROI calculation;
  a thorough understanding of the waste generating process; and
  identification of potential funding sources.
A process flow diagram clearly defines the existing conditions by showing inputs, outputs, waste streams, labor and energy required, and process flow rates. Preparing the proposed flow diagram forces the project champion to consider any additional costs associated with the proposed process -- increased maintenance of equipment, increased energy use, new materials and waste disposal services required. Careful evaluation of a process flow diagram eliminates projects that convert one form of waste into another, which is not waste minimization. The background calculations provide a reality check on the basis for project costs and savings that are easily inflated by eager project champions. Although the WMin/P2 program is currently providing funding for these ROI projects, sites are encouraged to identify other funding sources for ongoing projects.
The following project descriptions give a brief synopsis of the simple and effective process changes implemented or proposed, as well as the basis for the annual savings.
Empty Paint Cans Press
An oil filter press was installed in a paint shop to crush empty and partially empty four-liter and twenty-liter paint cans. The press crushes the cans to one-eighth of their original size and the paint is collected separately. The volume of empty containers requiring disposal is decreased by 11 m3 per year, so the savings result from waste disposal costs avoided.
Portable Oil Analyzer
A portable oil analyzer was purchased for use on all vehicles and installed equipment to determine if an oil change is required. Previously, oil samples were sent off-site for analysis or oil was changed according to a conservative maintenance schedule. Use of the new analyzer saves oil because it is changed less frequently. Elimination of oil incineration costs and off-site laboratory costs are the basis of the savings. This new change-only-when-needed procedure is estimated to extend the life of all lubricants about 400%.
Lead Recovery
Lead-contaminated soil was formerly excavated, put in drums, and shipped as hazardous waste. A soil sifter was purchased to remove the lead, which can be

recycled, and the soil can be returned to its original location. The savings result from waste disposal costs avoided and recycled material sold.

Booster Water Heater

Currently, disposable styrofoam dishes and plastic utensils are used in cafeterias and create large volumes of waste annually. A booster water heater will be purchased at one site so the dishwasher can be used on reusable dishes and silverware. The savings are expected to come from eliminating the need to purchase plastic products and avoided waste disposal costs.

Bulk Oil Storage Tanks

The vehicle maintenance facility currently purchases motor oil in plastic liter and four-liter containers. Bulk oil storage tanks will be installed so oil can be purchased in bulk at a lower unit cost. It also eliminates the containers and saves their disposal costs.

Stainless Steel Rack

A stainless steel vacuum gas rack will be installed to replace the mercury glass rack in a laboratory. This eliminates mercury-contaminated oil and solid waste, so disposal costs are avoided.

Reject Water Bypass

This project will install conductivity and pH meters in an effluent pipeline in order to determine if the wastewater meets city discharge limits (see Fig. 1). If so, wastewater will be diverted through a new pipeline that bypasses the industrial wastewater pretreatment facility so it can flow directly to the discharge point. This saves money on the chemicals and energy needed to run a pretreatment facility, and disposal costs for the sludge generated by the facility on about 15% (80,000 m3) of the process outflow.

SUMMARY

These projects all achieve most of their savings through avoided waste disposal costs. This proves one of the basic tenets of waste minimization -- avoiding waste generation saves both present and future costs. The metrics to measure project performance are built into the ROI formula -- waste volume reduced, actual costs incurred, and material and disposal costs saved. The intangible savings associated with WMin/P2 projects are more difficult to quantify, but include reduced worker exposure due to improved safety and work environments, delay or avoidance of capital expenditure for storage and disposal facilities, and avoidance of waste storage and disposal liability. As process managers learn how WMin/P2 can improve their operations, they are more receptive to other WMin/P2 initiatives. DOE will continue to identify and develop ROI projects to implement WMin/P2 at DOE sites. Many off-the-shelf, short duration, quick turnaround projects are already being implemented. DOE is using other ways to promote projects that require technology development, longer installation periods, and larger capital investments.

MIXED WASTE MINIMIZATION IN THE BIOMEDICAL COMMUNITY

Nancy P. Kirner
David T. Johnson
George T. Faison
Foster Wheeler Environmental Corporation
Bellevue, WA

ABSTRACT

Research-related biomedical mixed waste is one of the major sources of commercially generated mixed waste. Data from the National Institutes of Health (NIH) were evaluated to characterize typical research-related mixed wastes and to determine which of these mixed wastes are difficult to manage. Two such waste streams include

fixes and wastes from electrophoresis gels and wastes from protein blotting procedures. Interviews with individual researchers were conducted to determine reasons for generating mixed waste and methods of minimizing or eliminating such generation. Treatment alternatives were also identified to improve management of biomedical mixed waste. Possible alternatives to generation of mixed waste include automated techniques using chemiluminescence. It is apparent, however, that mixed waste generation from biomedical research can be reduced but not entirely eliminated. The more difficult-to-manage mixed wastes tend to be those having radionuclides with relatively long half-lives and relatively low heat content. One treatment option for facilities having large volumes of such liquid mixed waste is treatment by phase separation, pH adjustment, and chemical oxidation, with subsequent release to a sanitary sewerage system regulated under the Clean Water Act.

BACKGROUND

According to recent surveys conducted by the U.S. Environmental Protection Agency (EPA) and the U.S. Nuclear Regulatory Commission, there is a large number of biomedical research facilities that generate low-level mixed waste (1). Much of these wastes, which are not liquid scintillation counting fluids, are difficult to dispose of. As a result, these wastes are being accumulated on site at research institutions until disposal options become available. Because of the difficulty that research institutions are having in finding adequate storage capacity and disposing of these wastes, they have been the target of increasing scrutiny. Described below are the results of a waste minimization program directed at the low-level mixed wastes (LLMW) produced at one of the largest biomedical research facilities in the United States, the main campus of the National Institutes of Health (NIH).

The NIH main campus is a sprawling site located in Bethesda, Maryland. At this site, basic and applied biomedical research is carried out by over 20,000 researchers using most of the methods, techniques, and procedures that are typical for work in this area. In recent years, these activities have produced a significant volume of LLMW which is in long-term storage on site. It is this volume of LLMW which has served as the impetus for the ongoing mixed waste minimization program.

Low-level and mixed waste is managed at the NIH by a centralized waste management group which is responsible for collecting, characterizing, storing, treating, tracking, and disposing of all LLMW produced at the NIH. This group maintains a sophisticated computer database tracking system which is used to manage information about the LLMW from the time of generation until it is treated, disposed of, and/or placed in long-term storage.

The Waste Minimization Program that Foster Wheeler Environmental Corporation identified for NIH was based on EPA's Waste Minimization Opportunity Assessment Manual (2) which defines waste minimization as "source reduction to reduce or eliminate waste generation, followed by recycling or reuse where wastes are unavoidable, and finally, minimization of the volume, toxicity, and mobility of waste generated through treatment and stabilization." The first step in a program such as this is to obtain management commitment to waste minimization, develop written program objectives, allocate resources, and establish goals. The second step is to assess the available data on the sources and types of waste being generated and identify options for waste minimization. The third step is to develop and evaluate the feasibility of alternatives for accomplishing waste minimization, as defined above. The final step is to implement alternatives that achieve the waste minimization goals and to document and communicate the results.

Foster Wheeler Environmental Corporation conducted the second and third steps of this program for the NIH. Thus, we assessed the quantity and types of LLMW that were being generated and the waste-generating processes. The NIH waste tracking database was used to develop profiles of the typical LLMW streams, their waste designations, and the treatment and disposal options that were being used for the waste. This database contained approximately 3,800 records in a dBASE II format describing LLMW generated between 1989 and June 1993. Each record contained 187 fields that were used to indicate such parameters as the type of waste-generating process, the radionuclides present, the chemical constituents present, the waste volume, the waste designation, and the treatment and disposal options which were used for managing the waste. This information was used to sort the waste streams into groups according to the waste-generating process, to characterize the volume and composition of the wastes produced by each of the process groups, and to determine

which process groups were producing the largest amounts of LLMW which had no disposal options. The Department of Energy's National Low-Level Radioactive Waste Management Program recently published the results of this data investigation in a report (3).
The significant findings from the initial database analysis were 1) relatively few waste-generating processes produced the large majority of LLMW; 2) wastes produced by these processes have similar properties and compositions; and 3) the large majority of the difficult-to-manage LLMW is produced by even fewer processes. Difficult-to-manage LLMW was assumed to be LLMW in storage for more than one year. These results suggested that a successful waste minimization approach might be to investigate in detail the processes that were generating most of the difficult-to-manage LLMW and look for options in these processes which would meet waste minimization objectives.

APPROACH

The approach for investigating the waste-generating processes at NIH was a two-part process. The first step was to use the database information to identify laboratory facilities and researchers that were generating the difficult-to-manage LLMW. The second step was to interview each of these generators regarding the biomedical research procedures they were using and the LLMW that they were generating as a result. During the interviews, each generator was asked to identify alternatives which would achieve LLMW minimization objectives. When the interviews were completed, comparisons were made between researchers using the same procedures to determine if the LLMW generation was comparable. The information obtained from the generators showed that substantial LLMW minimization was achievable for several procedures and that many researchers were already using techniques and procedures that reduced LLMW generation.

RESULTS

Of the difficult-to-manage waste streams identified, two waste streams represent most of the waste in storage for more than one year. These waste streams include fixes and wastes from electrophoresis gels and wastes from protein blotting procedures.

Electrophoresis Gel Fixing/Washing

The biomedical research process which generates the largest volume of LLMW in storage for more than one year is the fixing and washing of electrophoresis gels. This process is a valuable biomedical research tool for making separations of proteins or deoxyribonucleic acid/ribonucleic acid (DNA/RNA) fragments. The electrophoresis gel technique, used by researchers to separate, identify, and purify fragments, is often used to determine the sequence of bases in nucleic acids. A mixed waste is generated with this process when the DNA, RNA, or protein molecule is labeled with a radioisotope such as 32P or 35S for autoradiography or subsequent processing.
The gels used for electrophoresis are typically constructed of polyacrylamide or agarose. These chemicals act as porous media that behave like sieves by retarding or obstructing the movement of the protein or DNA/RNA molecules while allowing smaller molecules to migrate freely. The size of the gel pore determines the extent of the molecular sieving. The mobility of molecules through gels is sensitive to pH which, therefore, must be controlled. To control pH, the molecules being evaluated are dissolved in an aqueous buffer system that maintains the pH required for the separation. The molecules migrate through the gel media when subjected to an electric field. The mobility of the molecules through the electrophoresis gel is determined by the strength of the electrical field applied to the gel and the charge, size, and shape of the molecule.
After the molecule separation step, the gels are typically fixed and washed by soaking them in a bath of 10% methanol and 10% acetic acid in water. Another bath solution which is frequently used is 7% trichloracetic acid. These bath solutions become mixed wastes after their contact with the gels containing the radioactively labeled DNA, RNA, or proteins. Fixing and washing the gels is considered necessary to prevent tearing the gel and to remove contaminants in the gels such as urea that might otherwise prevent the gels from drying or cause them to stick to the photographic film. The fixed and washed gel is then placed in contact with photographic film and radiation emitted from the labeled DNA, RNA, or protein fragments exposes a characteristic pattern on the film. This technique is called autoradiography.

Several alternatives were identified for achieving waste minimization for the gel fixing/washing process. All of these are currently being used, to some extent, and all have advantages and disadvantages as compared with the standard approach described above. An obvious approach is to eliminate the use of radioisotopes for identifying the DNA and protein molecules being separated with gels. Other options include using fluorescent dyes such as ethidium bromide or visible dyes such as Coomassie Blue or silver-based staining. Several manufacturers supply kits and procedures using materials such as these as substitutes. While the use of fluorescent dyes such as ethidium bromide may avoid generation of a mixed waste regulated under the Resource Conservation and Recovery Act, ethidium bromide is considered to be a toxic chemical. Thus, overall risk minimization should also be considered in evaluating substitute processes.

A variation on these materials is the use of automated DNA sequencing equipment in which fluorescent dyes are laser activated, scanned, and analyzed by computers in real-time as the molecules migrate through the gels. This type of equipment is expensive (>$100,000) and is more efficient in high volume, standardized applications that can tolerate the required time needed for the initial setup, calibration, and standardization.

If autoradiography cannot be eliminated, the volume of gel fixing and washing bath solutions (mixed waste) may be eliminated by using gels whose manufacturers' claim do not require fixing. However, if the research question cannot be answered using these substitute gels, mixed waste can be minimized by using smaller volumes of solutions for the fixing step, or by recycling the bath solutions several times before discarding them. Volume reduction of as much as 90% has been achieved by some researchers. In other situations, the fixing volume can be reduced by obtaining more effective gel dryers which can quickly dry gels even though they have not been extensively washed prior to drying and would otherwise require lengthy drying times.

The generation of a LLMW during gel fixing/washing can also be prevented in some cases if ethanol is substituted for methanol. However, the effectiveness of such a substitution is case-specific and not always feasible.

Blotting Techniques

Another significant biomedical research LLMW generating process is called "blotting." In this process, radioactively labeled protein residues, which have been previously separated using gel electrophoresis, are transferred, using an applied electric field, from the gel to a membrane such as a glass fiber filter coated with a thin layer of noncovalently adsorbed polybase or other media such as sheets of polyvinylidene difluoride (PVDF). This is done because, typically, after electrophoresis, the protein molecule is trapped within the gel matrix and is relatively inaccessible. However, if the protein molecule is transferred to a membrane surface, it becomes easily accessible to many detection and analysis techniques. After the protein is transferred to the filter paper, it is washed using reagents such as methanol or ethanol to improve retention on the membrane and to remove impurities prior to further analysis. These washings can produce a LLMW if the proteins are labeled with radioisotopes and if reagents such as trichloroacetic acid or methanol are used.

The use of radioisotopes for protein identification and the generation of a LLMW may be avoided if chemiluminescent reagents are used. Most of these use the horseradish peroxidase (HRP)-mediated luminol oxidation reaction in which the oxidation of luminol is catalyzed by peroxidase to produce light that can be photographically recorded. Vendors claim that chemiluminescence offers advantages over radioactive methods due to its speed, sensitivity, and convenience. Another possibility for waste minimization is the substitution of ethanol for methanol for final membrane washing. This technique can avoid the generation of a LLMW provided that the ethanol concentration is sufficiently low that an ignitability-characteristic waste is not generated.

Another waste minimization possibility is to use a transfer procedure with an electrophoresis buffer consisting of tris-glycine buffer at a pH of approximately 8.3. While this procedure requires approximately 12 hours to complete, it does not generate a LLMW. A more recent procedure using a concentration of 20% methanol in the transfer buffer results in the generation of a LLMW. The advantage of this procedure, however, is that it is much more rapid and uses a smaller amount of electric current.

Equipment substitutions can also reduce the LLMW volume generated from blotting. One vendor supplies a multi-purpose fluorescence scanner for gels and membranes that can be used as a substitute for radiolabeling techniques. The vendor claims that the system can be used to detect and quantify a variety of complex protein separations by using fluorescent dye kits specific to the test being performed. The system uses an argon scanning laser with a 50-micron scanning width that is combined with a photomultiplier tube and computer analysis system. The time required for analysis is reduced from a total time of 72 hours for film autoradiography to as little as 2 hours with fluorescence. A drawback to this system is that the cost is approximately $57,000.

Other Mixed Wastes

A number of other LLMW-generating processes used in biomedical research were evaluated for waste minimization options. Other processes included high-pressure liquid chromatography (HPLC) scintillation counting wastes and cell culture/harvesting wastes. HPLC waste is generated when high-pressure liquid chromatography is coupled with liquid scintillation counting with output from both analyses assessed by computer. HPLC systems can identify and quantify specific molecular species with high speed and accuracy. HPLC liquid scintillation waste generation rates can be as high as 10 milliliters per minute, 24 hours per day. Another mixed waste that appeared to be difficult to manage was generated from cell culture/harvesting. LLMW is generated when radiolabeled cell cultures are lysed with trichloroacetic acid, followed by cell fragment washing using methanol. Mixed waste is generated from the lysing solutions as well as the washes and liquid scintillation counting.

Effective options were found to be available for most of these processes. Similar to the options described above, the alternatives usually required that generators make some compromises with respect to sensitivity, procedural time, equipment costs, and/or broadness of application.

LLMW Waste Treatment Options

Much of the LLMW produced by the procedures described above does not currently have a disposal option, although some options may become available in the future. These wastes typically contain methanol, acetic acid, or trichloroacetic acid at a concentration of approximately 10%. Other compounds that could be present at lower concentrations include phosphoric acid, chloroform, and ethanol. The pH of the wastes is typically in the range of 1-4 and the radioisotopes typically present are 35S, 32P, 3H, and 14C in relatively low concentrations. Disposal of such a waste stream to the sanitary sewer system would be possible in some areas if it is pretreated. The pretreatment objectives would be to remove compounds from the waste stream that would prevent it from being discharged, increase the pH to acceptable discharge limits, and create a smaller secondary waste stream that could be transferred to an incineration facility or other disposal outlet.

With the exception of chloroform, the reagents present in the LLMW are miscible in water. With the exception of phosphoric acid, they are also organic compounds that are potentially subject to further oxidation. The 32P and 35S radionuclides have relatively short physical half-lives (14.3 days and 87.9 days, respectively) and can be impounded for decay prior to disposal. Treatment technologies for this waste stream are, therefore, focused on removal or destruction of the organics and adjustment of the pH to acceptable discharge levels. Several technologies are available to accomplish these objectives including phase separation, chemical oxidation, biological degradation, carbon adsorption, solvent extraction, and pH adjustment.

One possible treatment system was evaluated by combining phase separation, pH adjustment, and chemical oxidation together in a sequential treatment train. The treatment process would begin with phase separation of immiscible organics, followed by pH adjustment using sodium hydroxide. Then the waste stream would pass through a chemical oxidation reactor where the organic compounds would be oxidized to carbon dioxide. This process would be followed by another pH adjustment and discharge to the sanitary sewer system. If significant quantities of 14C, or other radionuclides, are present, it is likely that an emissions control system would be required for carbon dioxide gas released from the chemical oxidation reactor.

One of the most commonly used chemical oxidation processes for wastewater uses ultraviolet (UV) light and hydrogen peroxide to oxidize organic compounds to carbon dioxide. The UV light activates organic molecules making them more amenable to

oxidation and assists in the creation of hydroxyl radicals from the hydrogen peroxide. The hydroxyl radicals are powerful oxidants that then act on the organic molecules present to produce carbon dioxide and water. Chlorinated compounds will contribute some acidity to the water that would require adjustment of the pH following the oxidation step. The hydrogen peroxide is added to the influent stream and the mixture is passed through a closed vessel equipped with powerful lamps that generate light energy in the UV spectrum. Typically, versions of this technology that use high-intensity lamps operate continuously at ambient temperature and require residence times of 1 to 5 minutes to effect near-complete oxidation of organic compounds.

An advantage of chemical oxidation is that no secondary waste is produced because organics are completely oxidized. The high concentration of the organics (100,000 ppm) in the anticipated waste stream would require a recirculating water stream of treated water to which the concentrated waste stream would be slowly added to maintain an influent organics concentration at a desired concentration of about 1,000 ppm. A 30-kW system is estimated to have the capacity to process 30,000 liters of concentrated LLMW per year at an initial capital cost of approximately $100,000. The annual operating costs for such a system are estimated to be approximately $35,000 for electrical power, chemicals, and UV bulbs. Operating labor would be an additional expense.

CONCLUSIONS

The results from this study indicate that waste minimization options are available for the typical procedures used in biomedical research. These management options have the potential, however, to require more time to perform each analysis, to increase capital expenditures for equipment, to change the quality of the final results compared to a standard published protocol, or to be useful in a more narrow application than traditional procedures. Because of these potential limitations, the individual preferences of researchers need to be both respected and challenged. Institutional conditions such as the availability of funds for new equipment, the costs for disposal services, and institutional tolerance toward the generation of LLMW can affect the LLMW generation. Vendors and equipment manufacturers have the resources to invest in the development of improved protocols and procedures for biomedical research. The development of these alternatives is currently a very active area.

Onsite waste treatment for some types of LLMW is an option for some facilities. This treatment is site-specific due to widely varying permit conditions, permit status, and the ability of an institution to support the operation and maintenance of waste treatment equipment. Providing aqueous mixed waste treatment services to several small generators may be feasible, however, for waste brokers.

ACKNOWLEDGEMENTS

This work was supported by the U.S. Department of Energy (DOE) through the National Low-Level Waste Management Program operated for DOE by Lockheed Idaho Technologies Company. Assistance from the NIH is greatly appreciated.

WASTE MINIMIZATION DURING TRANSITION AT THE SAVANNAH RIVER SITE REACTOR FACILITIES

Joel A. Miller
Westinghouse Savannah River Company

ABSTRACT

The Reactor Division at the Savannah River Site is actively pursuing deactivation from an operating mode to a cold shutdown condition with minimum surveillance and maintenance. In addition, the Reactor Division is conducting several transition activities to prepare its five separate reactor facilities for their eventual decontamination and decommissioning. During the planning of this transition, increases in waste generation, both in the types and quantities, was forecasted. The

Reactor Division, therefore, initiated several activities to minimize the waste generated during the transition. This paper addresses the many activities pursued and their effectiveness.

INTRODUCTION

The Savannah River Site (SRS) is a 815.8 square kilometer (315 square miles) Department of Energy (DOE) production facility located in western South Carolina. This facility has multiple operational areas which generate a variety of waste materials. Located on the site are five reactor facilities (K, L, P, R, C) in various stages of deactivation and transition.

In March 1993, the Reactor Division (RD) at STS received guidance from the DOE to halt operation of the K-Reactor and deactivate all reactor facilities to a cold shutdown condition. During FY-94, the RD aggressively pursued this objective by performing the transition activities listed below. Each activity presented a unique waste management challenge, in particular in the area of waste minimization.

- Discharge reactor tank components into the spent fuel pools, including cadmium control rods (mixed waste) from four of the five reactor tanks
- Drain all operational reactor systems, consolidate and clean-up heavy water moderator, and vacuum dry all reactor heat exchangers
- Remove all excess equipment and materials (clean and contaminated) from all five reactor facilities
- Consolidate nearly 40 years of chemical inventory in all five reactor facilities and their disposition
- Clean-up spent fuel pools and consolidate domestic and foreign fuel
- Demolish and remove reactor facility support buildings ranging from clean administrative buildings to a contaminated hot shop
- Remove underground fuel oil storage tanks
- Remove installed lead shielding (clean and contaminated) in four of the five reactor facilities

The activities described below address the minimization of waste generated from the above items. The waste minimization activities are divided into four categories (source reduction, recycling, treatment, disposal) corresponding to the four aspects of the Department of Energy pollution prevention strategy.

SOURCE REDUCTION

Source reduction activities are those which will prevent the generation of waste altogether, and therefore is the most important aspect of any waste minimization effort. Three separate activities established by the Reactor Division will be discussed. They are the formation of the Reactor Waste Management group, the review of work packages using a comprehensive checklist, and the inclusion of waste minimization into ALARA reviews.

Reactor Waste Management

The Reactor Waste Management (RWM) group was formed in June 1991 to respond to the growing difficulties of properly handling waste in K-Reactor (operating) and L and P-Reactors (standby). The group originally consisted of one manager, three supervisors and about seven non-exempt operators. Their charter was to coordinate the packaging and shipment of the vast quantity of operational waste being generated in the K, L, and P-Reactors. At the start of the deactivation/transition, the group had grown to one manager, 10 professionals/supervisors, and 24 non-exempt operators. Their revised charter included coordinating the package and shipment of all reactor facility transition waste in accordance with new and more stringent disposal facility requirements, all environmental field operations (sampling, closure of USTs, etc.), the design and operation of a state-of-art decontamination facility, and completion of transitional and decontamination projects.

Because of the dedicated waste handling group within the Reactor Division, waste minimization has not only enjoyed increased success, but the average education level of the Division regarding waste minimization has greatly increased. The latter effect was accomplished by formal classroom training for all members of the Division, but probably more importantly through the availability of expert help from the RWM group.

Work Package Review

Each work package developed in the Reactor Division is reviewed specifically for waste minimization using a checklist. The checklist asks the following questions (abridged) concerning the generation of waste.

- Will the activity use a hazardous chemical?

Will the activity involve the disposal of waste that is constructed of or comes in contact with hazardous constituents?

Will the activity result in generating greater than 1 B-25 (90 ft3) of radioactive waste?

Will the activity involve a new waste stream or the modification of an existing waste stream?

If any of the above predetermined amounts of waste generation are triggered, the work package must be reviewed by the RWM group. During the RWM review, a specialist works with the actual workgroup on how to effectively minimize the waste being generated. In addition, the RWM group is alerted to any generation of hazardous/mixed waste so that substitutes can be identified or if generation is unavoidable, the proper collection areas can be set up. It is important to note that the work group, not just the RWM group, is actively participating in waste minimization planning.

ALARA Reviews

Many jobs conducted during the transition have required formal As Low As Reasonably Achievable (ALARA) reviews because of significant exposure or contamination levels. As a part of these reviews, waste minimization is formally discussed and planned. Experience shows that jobs with these higher exposure and contamination levels generate more waste than jobs with lesser exposure and contamination. Once again the work group is actively participating in waste minimization planning.

RECYCLING

Recycling is the pollution prevention aspect where most waste minimization activity has taken place in the RD. Within the reactor facilities there are large quantities of recyclable metals and reusable equipment and materials. The recyclable metals include stainless steel from process piping and spent fuel pool components, carbon steel equipment and piping, and copper cable and piping. The stainless steel represents the most cost effective candidate for immediate recycling, therefore, was pursued as a part of the SRS's beneficial reuse program.

Much of the equipment and material left in the radiological areas of the five reactor facilities have the potential for reuse or to become clean salvage if it were decontaminated. Therefore, the RWM group is pursuing the design and start-up of a Central Decontamination Facility not only for excess RD equipment and materials, but also for the site's excess equipment and materials. In addition to the Central Decontamination Facility, the RWM group met the challenge of consolidating the excess chemicals of all five reactor facilities and centralizing them into a single computerized storage facility. The chemicals are then advertised for reuse throughout SRS.

Each one of the above recycling activities (stainless steel, Central Decon Facility, excess chemicals) are discussed in more detail below.

Stainless Steel Recycling

Within the reactor facilities, the process piping is constructed of 304 stainless steel. Also, several smaller items such as slug buckets within the spent fuel pools, filter frames within building filter compartments are also made of 304 stainless steel. SRS is pursuing the cost effective recycling of these stainless steel materials. The general idea is to deliver contaminated stainless steel to subcontractor's melter for recycling into stainless steel burial boxes and drums. As of today, three subcontractor's melter have been awarded a contract to demonstrate their capabilities on approximately 60 tons of contaminated stainless steel. Stainless steel has been collected in L-Reactor (process piping), and in R-Reactor (slug buckets). The L-Reactor piping was cut up into pieces suitable for feeding into the contractor's melter using plasma-arc torches. This process was costly as well as time consuming and served as additional emphasis to build the Central Decontamination Facility which will include a containment for the purpose of size reducing material. The Central Decontamination Facility is discussed in the next section of the paper. Each piece of process piping was bagged/tagged and loaded into B-25 containers controlled by the RWM Waste Inventory and Management Program (WIMP). The WIMP is a computerized program utilizing barcode technology to positively track the contents and disposition of every container of waste/material in the RD. The WIMP is discussed in detail in the "Disposal" section of this paper. The full B-25s were sealed and placed into "sea-train" type containers specifically procured to meet transportation requirements to the subcontractor's melter. The R-Reactor slug buckets turned out to be a perfect candidate for stainless steel recycling. They

required no size reduction and the buckets selected for initial recycling were contaminated to the point that decontamination for clean recycling was questionable. The slug buckets were directly loaded into the "sea-train" containers. At the writing of this paper several loads of stainless steel were being readied for shipment to the subcontractor's melter.

Central Decontamination Facility

The objective of the Central Decon Facility (CDF) is to operate a state-of-the-art decontamination facility using portable equipment in a building modified to handle a variety of changing decontamination equipment and techniques. The facility will offer a central location to stage salvageable contaminated materials, perform decon, and release them for uncontrolled use. Additionally, by utilizing portable to semi-portable equipment, the separate units can be moved to support local large scale decon work such as that resulting from the decontamination and decommissioning of a SRS facility.

The CDF is located in C-Reactor (see Fig. 1) and the Central Shops area of SRS. Within the C-Reactor building, there is a staging and sorting area, a large decon/size reduction hut and the decon area itself.

Fig. 1.

The staging and sorting area is located in the assembly area of the C-Reactor. It offers a large square footage area to stage contaminated materials for decon and also for deconned/clean materials awaiting salvage or reuse. A large "permacon" hut will be erected in the stack area for large item decon or size reduction/packaging of items deemed not cost effective to decon. The actual decon booths/units are located in the drum storage area and crane maintenance area of the C-Reactor building. Within this area a service ring header will be installed consisting of a ventilation exhaust trunk, 480V/120V power, service and breathing air, and radioactive liquid drain lines. The ring header will service portable decontamination booths/systems located around the service ring header. The concept of the service ring header allows for quick addition of new and effective decontamination equipment and techniques.

Also located within the C-Reactor complex is the CO2 blasting enclosure. CO2 blasting equipment is housed in a portable enclosure specifically designed to effectively contain all contaminates and particulate emissions in a fast moving HEPA exhaust stream. The CO2 pellets sublime into gas and therefore do not contribute to any secondary waste streams. The CO2 blast enclosure and equipment consists of the following items:

1. Two "sea-train" type containers modified to house a stainless steel lined blasting booth, a glovebox room, a counting/change room, a blast equipment room (CO2 pelletizer and air dryer), and a ventilation room. (See Fig. 2).
2. A portable (on wheels) CO2 tanker with refrigeration unit.
3. A portable (on wheels) air compressor.

Fig. 2.

The pelletizer, within the blast equipment room, produces solid carbon dioxide pellets from liquid CO2 from the portable tanker. These pellets are propelled using dry compressed air from the portable air compressor/air dryer and delivered to the blast booth of the enclosure. There they are trained onto the surface to be decontaminated. The pellets sublime causing a large local pressure change on the surface which removes contaminates, paint, and any other surface particulates. The contaminates are immediately entrained into a fast moving HEPA exhaust stream. All the entrained contaminates are then deposited onto a HEPA pre-filter or the HEPA filter itself. The CO2 enclosure is currently being procured with expected delivery in June 1995. Feed material for the CO2 enclosure include: 170 tons of contaminated lead collected from the removal of installed shielding in the reactor facilities, stainless steel slug buckets, carbon steel shielding, etc.

Located in Central Shops is the 728-N Vacuum Blasting Facility. This is a HEPA exhausted building used to perform decon via the LTC Vacuum Blaster. The LTC Vacuum Blaster is an all pneumatic operated grit blaster with a grit recycling capability to significantly reduce the amount of secondary waste generated. The LTC Vacuum Blaster is supported by a 750 cfm air compressor and a combination air cooler/air dryer. The vacuum blaster is a very aggressive technique suitable for work on "hard to decon" fixed contamination. The facility recently was put into operation. Feed material will mostly consist of contaminated tools and contaminated stainless steel requiring an aggressive means of decontamination. At the writing of this paper, the

Vacuum Blasting Facility has proven highly successful in the decontamination of tools and stainless steel slug buckets. Approximately 11.5 tons of stainless steel has been cost effectively released as clean salvageable 304 stainless steel.
To support decision making at the Central Decontamination Facility a computer database is being developed which will take information concerning a candidate item to be decontaminated, and using history developed through operation, make a decision if the candidate can be cost effectively decontaminated.
For each decontamination candidate the data base must either contain or calculate the following information.
Unique identification number (barcode)
Determine salvage metal price based on the material the item is made of and its weight
Determine the disposal cost avoided if the item is not handled as radioactive waste, but reused or recycled
Determine the cost to decontaminate the item
Determine if it is cost feasible to perform the decontamination
The data flow diagram (Fig. 3) describes the flow and general connection of data for the Decon vs. Disposal database. The flow of data starts with a candidate and the capture of pertinent information concerning the candidate. The following table describes the information needed on the candidate.
Fig. 3.
TABLE I
If the candidate is cost feasible to decontaminate, other information must be captured, including a storage location, cost data, and decontamination history. If the candidate is not cost feasible to decontaminate, then it is disposed of.
Several reports are necessary to be generated from the Decon vs. Disposal database. First, there is the Decon item file. This is a history report on each candidate that also serves as an input form. It is a convenient form to accumulate costs and other information while the item is being decontaminated.
In addition several other reports such as Decon Method Cost Reports, Time to Decon Reports, and Cost Benefit Reports are required on an as needed basis.
Excess Chemical Reuse
The large quantities of surplus chemicals collected over 40 years of operation in the five separate reactor facilities had to be properly handled. Many of these chemicals were hazardous and would have to be disposed of as hazardous or mixed waste which has high storage and disposal costs. The RWM group implemented a chemical excess program which has significantly reduced not only the hazardous and mixed waste generated, but also has saved other SRS Divisions new chemical purchase costs.
More than $200,000 in hard dollar waste disposal costs and new chemical purchase costs have been avoided since the start-up of the Reactor Division Excess Chemical Program. The program, which includes a building converted for storage of excess chemicals, barcoding computer database equipment for management, and use of the site all-in-one network as advertisement, was started-up for less than $1,000 by utilizing surplus equipment and buildings. Excess chemicals were collected in each reactor facility and centrally stored. Each chemical was barcoded and entered into a data base file which is periodically downloaded to the site-wide all-in-one network for reuse advertisement. Customers utilizing RD excess chemicals include the Department of Energy (DOE), all other SRS Divisions, and the SRS Environmental Protection Department. SRS is currently reviewing the program as a model for a new initiative to handle excess chemicals on a sitewide basis. In this way the lessons we have learned can benefit the site program.
TREATMENT
The RD is a generator of waste at SRS and does not necessarily treat waste. However, in one case, it has proved beneficial for the RD to take on the waste treatment role. Currently there is only one centralized waste compactor (253-H compactor) used for treatment of compactable waste at SRS. The 253-H compactor is not capable of receiving tritiated waste, which is generated in all five reactor facilities as well as at the heavy water processing facility. The tritiated compactable waste historically was disposed of in B-25s which were directly buried in the disposal facility without treatment in a compactor. Because of the draining of the process systems in the five reactor facilities, a large amount of tritiated compactable waste was generated. The RWM group responded to this by installing and starting-up a

small compactor in the L-Reactor for the express purpose of compacting this tritiated compactable waste stream. Installation into a reactor facility, which is permitted to release tritium, simplified the start-up requirements. Substantial waste minimization has been realized; however, the actual cost savings are minimal because of the health protection requirements to operate the compactor. In order to compact tritiated waste, operators must wear plastic suits with supplied air which drives costs up. Although the operation of the compactor has proved successful and cost effective, it failed to produce the promise of substantial cost savings.
A small compactor located in close proximity to a compactable waste stream can prove very cost effective if costs to operate are minimal (i.e., minimal HP requirements) and no other large treatment facility is available (economies of scale).

DISPOSAL

Two activities are worthy of mention in the area of disposal. Although disposal activities are not directly associated with waste minimization, the following activities prove that when faced with the final option, disposal, there are still ways to minimize the waste actually shipped for disposal. The two activities described below are the Waste Inventory and Management Program and the RWM Self Monitoring Program.

WASTE INVENTORY AND MANAGEMENT PROGRAM (WIMP)

The WIMP system is a relational database with integrated barcode technology to track and inventory radioactive, hazardous, and clean waste. WIMP is currently configured to track and inventory radioactive waste with future plans to track and inventory hazardous and clean waste. WIMP is made up of three major functions with several minor support functions. The three major functions are: Issue Container, Waste Tag Entry, and Return Container. Each function is explained below.

Issue container

The issue function is used to issue a B-25, B-12, 55 gal. drum, etc. to a responsible individual within a work group. The individual must have completed and passed a four hour training session with exam in order to take custody of a container. WIMP is loaded with the individuals allowed to take custody of containers and will not allow a container to be issued to non-authorized personnel. WIMP will generate an issue form which captures all the pertinent information about the individual and the job being worked. The container is issued with a unique barcoded ID number. If greater than 3 B-25s are issued to one individual or to one particular work package, WIMP will automatically request a waste minimization surveillance be conducted. The issue form is generated with the rules associated with use of a B-25 and requires the signature of the individual accepting custody. One of the rules is that only non-compactable waste can be placed in a B-25. Since the institution of the WIMP system, compactable waste generation has doubled while non-compactable waste has reduced leading to a significant minimization of waste.

Waste Tag Entry

As waste is generated and bagged, the individual sealing the bag fills out and attaches a Radioactive Waste Tag on the bag. The waste tag captures all the pertinent information concerning the bagged waste including: type of waste (non-compactable, compactable), contents, location generate, packager, waste stream number, ID number (barcode) of container waste is placed in, etc. The waste tag is signed by the packager ensuring no hazardous or other prohibited items are present in the waste. The bottom of the waste tag is separated and collected to be entered into the WIMP system. Each waste tag is entered into WIMP to form the contents, "waste cuts," of each B-25 container.

Return Container

After the B-25 container is full, custody is returned to the RWM group for storage and shipment. The individual returning the container must review a return container form, which lists the complete contents of the container, and signs that no hazardous or other prohibited items were placed in the container. Operators inspect the container for fullness and then seal and store the container. Periodic inventory is conducted using a portable barcode reader as well as setting up the shipment of containers.

Other minor functions include manifesting, sorting capability, report generations, and querying.

RWM Self Monitoring Program

The RWM Self Monitoring program allows trained RWM Operators to perform Health Protection (HP) coverage of most RWM jobs including monitoring for other personnel

and writing up official HP surveys. The program has been more successful than originally anticipated and is credited with not only increasing the productivity of the RWM group, but also alleviating some of the work load constantly facing HP. Waste minimization has also been increased by combining the waste minimization knowledge of the RWM Operator with the freedom gained from having HP knowledge and radiological control at your fingertips.
Currently our memorandum of agreement with HP concerning the RWM Self Monitoring program allows monitoring up to the following limits.

Transferrable Surface Contamination: 100,000dpm/100cm2 beta-gamma
or
1 x 106 dpm/0.1m2 beta-gamma
2,000 dpm/100cm2 alpha
Radiation: 5 mrem/hr
Airborne Tritium: 25 microcuries/hr (confirmed activity)

The memorandum of agreement lists the following low risk general activities where a HP trained RWM Self Monitor can perform the surveys necessary to conduct the activity.
- In-process Decontamination
- Waste Removal From the Contamination Areas
- Low Level Waste Trailer (LLWT) Activities (liquid waste removal)
- Sampling Known Drums, Tanks, etc.
- L-Area Compactor Operations

CONCLUSIONS
The effective management of radioactive waste, and especially the minimization of that waste, is largely contingent on the dedication of each worker within the organization. This idea holds true in many situations and is not particularly eye opening, but the way the RD has accomplished this dedication is unique and proved effective in the span of just one year.
The formation of the RWM group not only allowed waste issue to be centrally controlled, but provided every worker with the RD ready access to correct information concerning waste. No longer are workgroups "hiding" hard to handle materials or even disposing of the material because it is easier, or they lacked information on how to properly handle the material. The programs established by the RWM group (Excess Chemical Reuse, Central Decontamination Facility, and WIMP) provides an easy mechanism for the handling of excess chemicals, equipment, scrap material, and waste.
A new mentality has developed. The average worker actively looks for opportunities to reduce waste at its source, recycle metals, or minimize waste by segregation. Workers now plan for waste minimization during the creation of work packages and ALARA reviews. They understand what can and cannot go into waste containers and maximize their waste going to the compactors. Through the institution of the WIMP, ownership of waste containers is transferred to individuals who now take pride in effectively controlling the contents of their containers.
The formation of the RWM group has resulted in turning a whole division of personnel into active champions of waste minimization.

POLLUTION PREVENTION AND WASTE MINIMIZATION IN ENVIRONMENTAL RESTORATION
Robert C. Fleming
U.S. Department of Energy
David L. Erne
Booz Allen & Hamilton
ABSTRACT
In recent years, increasing attention has been given to pollution prevention and waste minimization (PP/WMin) within the Federal government as a result of the Pollution Prevention Act of 1990 and Executive Order 12856, Federal Compliance With Right-to-Know Laws and Pollution Prevention Requirements. During the same time, one of the Department of Energy's (DOE) main missions has changed from weapons production to environmental restoration which includes decommissioning of facilities. Restoration activities, by their nature, will result in the removal of a large quantity of waste requiring treatment and disposal. It is anticipated that

waste resulting from restoration activities will become DOE's largest waste source. No Federal or State guidance exists to assist environmental restoration program and project managers in preventing or reducing waste resulting from environmental restoration activities. Therefore, DOE Office of Environmental Restoration has developed program guidance to incorporate PP/WMin principles into the restoration process. This paper discusses the program guidance for environmental restoration.

INTRODUCTION

DOE's primary mission has changed from weapons production activities to environmental restoration. Environmental restoration includes remediation and decommissioning (formerly referred to as decontamination and decommissioning). As a result of environmental restoration activities, DOE is producing a greater quantity of material requiring treatment and disposal. However, treatment capacity is not always available, and disposal is becoming more difficult and costly as a result of increasing regulatory requirements and limited disposal capacity. Therefore, there is a greater need to prevent or minimize waste generation. Pollution prevention and waste minimization (PP/WMin) activities reduce the demand for treatment and disposal capacity resulting in less regulatory involvement and reduced costs. It is important for PP/WMin principles to be incorporated in environmental restoration activities to ensure the greatest environmental and financial benefits.

Much of the waste to be processed by environmental restoration activities (e.g., contaminated soil, water, building materials) was generated as a result of past production activities. This waste is referred to as primary waste. In the course of performing restoration activities, new waste (e.g., drilling cuttings, solvents used in cleaning equipment or treating waste) is generated. This waste is referred to as secondary waste. PP/WMin can be applied to both types of waste. For primary waste, recycling and reuse are the most significant PP/WMin opportunities (particularly for decommissioning activities). For secondary waste, source reduction results in the greatest benefits. For both types of waste, segregation of hazardous from nonhazardous or radioactive from nonradioactive can result in substantial benefits.

The 1994 Waste Minimization/Pollution Prevention Crosscut Plan (1), DOE's principal PP/WMin program planning document, requires each site to develop and maintain site-wide and generator-specific PP/WMin programs. In addition, the Crosscut Plan identifies the key elements which sites must include in their PP/WMin programs. The purpose of this environmental restoration guidance document is to provide supplementary information for sites to utilize when developing PP/WMin programs for environmental restoration activities. This document provides:

- a summary of regulatory requirements for applying PP/WMin principles to waste generating activities;
- supplementary guidance to the Crosscut Plan addressing several key elements of an environmental restoration PP/WMin program;
- a summary of various phases of environmental restoration work and target PP/WMin opportunities for each activity; and
- a brief description of several PP/WMin tools which can be applied generically throughout the restoration process.

Many of the PP/WMin principles discussed in this guidance are engineering and administrative practices commonly applicable to any type of work. This guidance is intended to briefly describe these practices and provide examples of the application of these practices as they relate to environmental restoration activities. The document is not intended to provide detailed guidance for conducting PP/WMin activities. For broader, general guidance on site pollution prevention programs, sites should refer to the 1994 Waste Minimization/Pollution Prevention Crosscut Plan, or guidance prepared by the Environmental Protection Agency (EPA) or State regulators.

REQUIREMENTS

A variety of requirements exist for establishing and implementing a PP/WMin program. The most extensive requirements exist in the Pollution Prevention Act of 1990. These requirements, as well as other requirements applicable to DOE sites, are discussed below. It should be noted that no requirement excludes restoration activities from the application of PP/WMin.

Federal and State Laws and Regulations

All significant environmental laws and regulations have requirements for pollution prevention and/or waste minimization to be incorporated into compliance activities. The following is a summary of some of the more significant requirements:

Pollution Prevention Act (PPA) of 1990 - established a national policy that waste generators implement a program which emphasizes, in decreasing order of preference: a) source reduction, b) recycling, c) treatment, and d) disposal. The PPA also requires facilities which must report toxic releases under Section 313 of the Emergency Planning and Community Right-to-Know Act (EPCRA) of 1986 to identify and implement source reduction and recycling activities for those toxic chemicals reported. Pollution prevention is defined in the PPA as "source reduction." Source reduction includes: a) reducing the amount of hazardous substances, pollutants, or contaminants entering a waste stream or otherwise released into the environment; and b) reducing hazards to public health and the environment from the release of such substances, pollutants, or contaminants. Pollution prevention does not include most recycling or waste volume reduction (e.g., evaporation or other waste concentrating activities which do not reduce the quantity of hazardous substances, pollutants, or contaminants in a waste). These activities are typically considered waste minimization by EPA.

Resource Conservation and Recovery Act (RCRA) of 1976 - requires hazardous waste generators to have a program in place to reduce the volume and toxicity of hazardous waste and report PP/WMin efforts undertaken to EPA annually. RCRA amended the Solid Waste Disposal Act of 1965.

Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) of 1980 -includes as one of the nine criteria for evaluating the acceptability of an action the reduction in the toxicity, mobility, or volume of a waste through treatment. CERCLA was substantially amended and expanded by the Superfund Amendment and Reauthorization Act of 1986.

Requirements also exist in the Clean Water Act of 1972 and the Clean Air Act of 1963 (most recently amended in 1990), and state laws and regulations. In addition, states and EPA incorporate PP/WMin on a site-by-site basis into permits and compliance agreements.

Executive Order

While a variety of Executive Orders require pollution prevention, the most significant to restoration activities is Executive Order 12856, Federal Compliance With Right-to-Know Laws and Pollution Prevention Requirements (2). This Executive Order requires Federal agencies to comply with the reporting requirements of EPCRA and PPA. The Executive Order also requires Federal agencies to establish a goal of reducing the release or off-site transfer of toxic chemicals by 50% by the end of 1999 and requires sites to develop a pollution prevention plan.

DOE Orders

DOE has several Orders requiring PP/WMin to be incorporated into all Departmental activities. DOE Order 5400.1, General Environmental Protection, requires sites to establish programs for the minimization of all types of waste, including hazardous and mixed waste and to develop pollution prevention plans. DOE Order 5820.2A, Radioactive Waste Management, requires sites to develop waste reduction programs for radioactive and mixed wastes.

To assist sites in meeting these requirements, the 1994 Waste Minimization/Pollution Prevention Crosscut Plan, issued by Secretary O'Leary on February 25, 1994, provides guidance on the development of site-wide and generator-specific PP/WMin programs. In addition, a variety of other Federal and State guidance is available (e.g., EPA's Facility Pollution Prevention Guide (EPA/600/R-92/088) (3), Texas Natural Resources and Conservation Commission's Pollution Prevention Assessment Manual for Texas Businesses (4)).

PP/WMIN PROGRAM FOR ENVIRONMENTAL RESTORATION

As previously noted, each site should have site-wide and generator-specific PP/WMin programs as outlined in the 1994 Crosscut Plan. Seven program components, which are key to a successful environmental restoration PP/WMin program, are discussed below. Although the discussions are not prescriptive in nature they are useful to environmental restoration managers as a guide to developing a PP/WMin program for environmental restoration work.

Goals/Objectives

Establishing goals/objectives is key to ensuring that a PP/WMin program is successful, and where the goals are quantifiable, success is measurable. However, as noted in the 1994 Waste Minimization/Pollution Prevention Crosscut Plan, developing quantitative PP/WMin goals for environmental restoration activities is difficult because the nature of environmental restoration work, in most cases, is to remediate

as much contaminated media as necessary to protect human health and the environment. Therefore, unless specific activities lend themselves to quantitative goal setting, sites should, as a minimum, establish qualitative goals for eliminating or reducing waste during environmental restoration activities. A goal may be a simple statement of the site's intent to identify and implement activities which eliminate or reduce the generation of waste in all phases of environmental restoration work.

In addition to setting goals, sites should develop PP/WMin objectives. Objectives are specific actions which assist project managers and/or workers in understanding and meeting PP/WMin goals. For example, an objective for pollution prevention would be to require environmental restoration project managers to seek alternative non-hazardous chemicals as substitutes for chemicals which result in the generation of hazardous waste.

Resources/Budgets

To meet goals and objectives, adequate resources and funding must be available. The 1994 Waste Minimization/Pollution Prevention Crosscut Plan discusses the PP/WMin activities for which budgets should be established. The EM Budget Formulation and Activity Data Sheet (ADS) Development Field Guidance for the Fiscal Year 1997 Planning and Budget Cycle (5) describes how the funding should be identified in ADSs. Beginning with the FY 1997 budget cycle, EM-40 will meet the WMin/PP reporting requirements of Executive Order 12856 and Office of Management and Budget Circular A-106 (Federal Agency Pollution Abatement and Prevention Planning) by incorporating PP/WMin budget information in the section of the ADS designed for pollution abatement or prevention projects. These projects include all PP/WMin activities with the exception of pollution prevention opportunity assessments (see section below), or research, development, and demonstration projects.

PP/WMin Expertise/Training

Each DOE Operations Office has a WMin Coordinator. The Coordinator is responsible for developing and implementing the site PP/WMin program and providing expertise to all site organizations to develop generator-specific PP/WMin programs. Environmental restoration managers should seek assistance from the WMin Coordinator in establishing a restoration PP/WMin program and identifying opportunities to eliminate or reduce waste generation.

Each site should have a PP/WMin training program available to all site personnel. At most sites, this training will be geared to production processes and not restoration activities. The environmental restoration organization should work with the site WMin Coordinator to develop training specific to restoration activities. Training should target environmental restoration project managers, design engineers, and field workers.

Additional general training is available through the Kansas City Plant (KCP). KCP conducts training in Pollution Prevention Opportunity Assessments (see next section). KCP is developing a PPOA process for restoration activities (expected to be complete in 1995). Training is conducted periodically at KCP or arrangements can be made for training at another location.

Pollution Prevention Opportunity Assessments (PPOA)

A Pollution Prevention Opportunity Assessment (previously referred to as Process Waste Assessment) is an analysis of a process or activity to identify opportunities to eliminate or reduce the generation of waste (including air and water emissions) or consumption of raw materials, water, or energy. Once identified, the opportunities are evaluated and compared to determine the most efficient and cost effective option to implement.

A variety of PPOA processes exist. The Environmental Protection Agency has outlined a PPOA process in the Facility Pollution Prevention Guide (EPA/600/R-92/088) (3). Kansas City Plant has developed a separate process sponsored by DOE's Waste Minimization Division (EM-334). In addition, individual state regulatory agencies may provide guidance on PPOA processes. These methods emphasize source reduction as the primary activity and recycling/reuse as secondary activities. While the general concepts of these processes can be applied to restoration activities, it should be noted that the greatest PP/WMin benefits in environmental restoration activities will result from emphasizing recycling/reuse for primary waste and source reduction for secondary waste. Sites should choose a particular PPOA process and apply it consistently to all activities on site. This will result in consistent site-wide data on waste prevented and cost savings.

PPOAs should be included as a routine aspect of restoration activities, as

appropriate. The level of effort associated with a PPOA will be dependent on the environmental restoration project/activity to be implemented. For example, a PPOA for sampling operations will require a less detailed analysis than a PPOA for the implementation of a remedial alternative. Project managers should determine the depth of assessment appropriate for each activity. In addition, all PPOAs should be well documented (documentation is discussed later in this paper). In general, the following points should be considered relative to applying PPOAs to environmental restoration activities:

A PPOA should be applied to the entire site restoration program to determine common pollution prevention opportunities.

PPOAs should be applied as early in the planning process as possible and throughout each step of an individual restoration project including execution. For example, in the CERCLA remedial action process, PPOAs should be applied during the Preliminary Assessment/Site Inspection (PA/SI) when gathering historical data, before the Remedial Investigation when characterizing the site, before the Feasibility Study for evaluating alternatives, and before the Remedial Design and Remedial Action for designing and implementing the preferred remedial alternative. Likewise, PPOA's should be applied through all stages of a CERCLA removal.

Teams should be established for conducting PPOA's. The teams should include personnel with expertise in conducting PPOA's (e.g., site WMin Coordinator) and personnel with direct responsibility for, and knowledge of, the activity (e.g., design engineer, construction coordinator).

All media (e.g., air, water, soil) potentially impacted by the activity should be included in the PPOA.

An economic analysis of alternatives should be conducted. The analysis is essential to comparing the alternatives and justifying actions taken.

As a result of conducting a PPOA, it is possible that a process which produces a large quantity of waste, or a waste that is difficult to treat, is identified as a pollution prevention opportunity, although no substitute process is readily available. In these instances, information on the process in need of technology change should be identified to EM's Office of Technology Development (EM-50). EM-50 collects and prioritizes the pollution prevention technology development needs identified throughout the EM organization and targets its pollution prevention technology development efforts in the areas of identified needs.

Prioritization of Opportunities

Since funding and resources are limited, sites must develop a method to prioritize PP/WMin activities. A variety of systems exist and are usually included as part of a PPOA process. However, it is essential that a site choose a method and consistently apply that method to all activities. Factors usually considered in prioritizing activities are listed below. All factors are tied to waste reduction or prevention.

Regulatory drivers: Regulatory drivers such as Land Disposal Restrictions (LDR), Emergency Planning and Community Right-to-Know Act (EPCRA) Section 313(c) toxic chemical reduction requirements, or compliance agreement obligations are all relevant to restoration activities.

Financial considerations: Sites should analyze the lifecycle costs associated with PP/WMin projects and utilize the analysis to compare different projects for prioritization.

Risk: Utilizing such factors as permissible exposure limit or threshold limit value as a ranking of risk posed to worker or public safety and health could be considered for prioritization.

Documentation/Information Exchange

It is important that all PP/WMin activities (including PPOAs) be documented and the information made available to other DOE sites. Documentation should include information such as a brief description of the PP/WMin activity and its applicability to environmental restoration, approximate amount of pollution avoided or the amount of waste minimized, any obstacles overcome to implement the activity, cost information, if available, and a site contact. Documentation should be consistent across all projects on a site. The information for PPOAs should be recorded in appropriate documents (e.g., Remedial Investigation/Feasibility Study (RI/FS) work plan, Record of Decision (ROD), etc.) and should be combined for a site-wide report of all PP/WMin activities performed during a year.

To ensure that information is available throughout the DOE complex, documentation should be provided to DOE's Pollution Prevention Information Clearinghouse (EPIC).

The system provides a single source of DOE PP/WMin activities and provides access to EPA's Pollution Prevention Information Exchange System (PIES). EPIC and PIES provide technical information on PP/WMin and information on PP/WMin conferences, workshops, etc.

Identification of PP/WMin Issues

In the process of conducting environmental restoration activities, sites will identify issues which prevent PP/WMin. This may include DOE policies which inhibit activities that may result in PP/WMin or situations where adequate technologies have not been developed to treat a restoration activity waste. These issues, upon being identified, should be discussed with the site WMin Coordinator. For DOE-wide policy issues, the site PP/WMin coordinator will interact with the Waste Minimization Division (EM-334). EM-334 will address this issue through appropriate channels (e.g., the Waste Reduction Steering Committee or the Pollution Prevention Executive Board). For issues which are limited to EM-40 activities only, sites may wish to discuss the issue with the appropriate EM-40 program manager. The program manager will interact with the EM-40 Pollution Prevention Core Group for resolution. For technology issues, the site WMin Coordinator will interact with the Site Technology Coordination Group (STCG). It is the function of the STCG to identify programmatic needs to the Office of Technology Development (EM-50).

ENVIRONMENTAL RESTORATION ACTIVITIES

The basic steps in environmental restoration are similar whether the activity is remedial or decommissioning. The following is a brief description of the stages of environmental restoration, and some PP/WMin opportunities associated with each stage.

Negotiations

In most cases, sites will meet with regulators to discuss the requirements for conducting restoration activities prior to beginning the activity and periodically during the activity. EPA has established a policy to include PP/WMin in all Agency activities including restoration. Therefore, site representatives should take advantage of negotiations to incorporate PP/WMin in initiatives related to restoration activities. Example PP/WMin opportunities include obtaining agreement that historical data is acceptable to limit sampling, thereby limiting sampling waste; establishing future land use as other than the most conservative assumption of residential; testing innovative technologies which will result in less waste; and limiting monitoring requirements after closure. Though these are difficult measures on which to obtain regulator agreement, several successes have been realized within the DOE complex.

Interim Action

These are actions taken to ensure that there is no imminent threat of hazards to the environment, public, or workers. Interim actions include many or all of the following stages (i.e., preliminary assessment, characterization, evaluation of cleanup alternatives, etc). However, in an interim action, the time and effort spent on each individual stage is less than for a full remediation or decommissioning.

Preliminary Assessment and Inspection

This is the process of beginning to identify potential areas of concern by reviewing historical information and inspecting the site. Sites should collect as much historical information as possible to preclude extensive sampling in later stages and should use this pre-planning stage to begin identification of PP/WMin opportunities.

Characterization

Based on information obtained in the preliminary assessment and inspection, sampling is conducted to determine the extent of hazardous or radioactive contamination. PP/WMin opportunities should be identified and incorporated in the workplan and any appendices. For example, sites should target the large waste producing activities associated with characterization such as borehole drilling and sampling.

Under CERCLA, the process of adequately determining the type and extent of contamination at a site and identifying and evaluating cleanup alternatives is an iterative process. To make this process more efficient, and thereby reduce the cost and potential for waste generation, DOE and EPA have developed more efficient approaches to the RI/FS process. DOE has developed the Streamlined Approach for Environmental Restoration (SAFER), and EPA has developed the Superfund Accelerated Cleanup Model (SACM). Sites should consider applying a streamlining approach to the RI/FS process to facilitate PP/WMin.

Evaluation of Cleanup Alternatives
Alternative cleanup options are identified and screened. This process requires PP/WMin to be incorporated in the selection of an alternative since the quantity of waste generated is a factor considered in the evaluation of alternatives. In addition, project managers should ensure that PP/WMin principles are incorporated in treatability studies.
Documentation of Preferred Alternative
For each restoration process, a document is produced which formally discusses the actions to be taken to complete the remedial process or decommissioning. While no PP/WMin actions are taken during this stage of the restoration process, the documentation of the preferred alternative should discuss PP/WMin actions taken and considerations made in this area during the process of selecting an alternative.
Design of Cleanup Action
Engineering and planning are conducted to implement the approved alternative. A PPOA of all activities in the cleanup process should be conducted to identify all PP/WMin opportunities. This is an important stage to identify all opportunities, since PP/WMin activities can be included in workplans and contracts. PP/WMin concepts should be applied to the design of structures or equipment to be used in the restoration activity to reduce or eliminate waste generation when the structures or equipment are decommissioned at the end of the restoration activity.
Implementation of Cleanup Action
The approved alternative is executed. PP/WMin opportunities identified in the design stage should be implemented. In addition, cleanup activities should be reviewed periodically to identify additional PP/WMin opportunities not identified in the design stage or opportunities which may be appropriate as a result of changes which may occur in the implementation of the cleanup action. Once identified, these new PP/WMin activities should be incorporated into the cleanup activity. Sites should ensure that contractor/subcontractor personnel have been trained properly in PP/WMin principles.
Closure
Upon completion of the cleanup action, final administrative steps are taken to ensure that the action has been completed successfully and documented fully. Depending upon the action taken, some ongoing activities may be necessary (e.g., continued sampling or maintenance). PP/WMin opportunities identified for sampling or maintenance during the characterization stage can be implemented during the closure stage.
POLLUTION PREVENTION/WASTE MINIMIZATION TOOLS
There are a variety of standard PP/WMin activities which can be applied throughout the environmental restoration process. Several of these activities are discussed below. It should be noted that, in some cases, there is no difference between applying these concepts to production processes or restoration activities (e.g., the operation of a treatment technology).
Operating Practices
Changes to operating practices may yield a significant reduction or elimination of waste. In addition, these changes are usually very easy and inexpensive to implement.
Housekeeping: Work areas should be kept clean and equipment properly maintained to reduce the chance of breakage or leaking. Spill response plans should consider cleanup methods which reduce the generation of spill cleanup waste. Equipment should receive regular preventive maintenance to ensure efficient operation.
Material segregation: All materials should be handled or stored to prevent commingling. Commingling of materials can result in larger quantities of waste being produced. In addition, recycling may be reduced or precluded if contaminants are not segregated from recyclable materials, since recycling value decreases with decreasing purity. Materials which should be segregated include: hazardous and nonhazardous wastes, radioactive and nonradioactive wastes, liquids and solids, chemically incompatible substances, and recyclable materials and nonrecyclable materials.
Administrative changes: In some cases, administrative criteria result in the increase in waste generation. For example, the location of boundary lines established for radiologically controlled areas may result in unnecessary classification of materials as radiologically controlled waste.
Process Changes

Process changes can include changes to equipment or changes to materials used in the process. More efficient equipment may result in less use of resources or less waste generation. Substituting non-hazardous materials for hazardous inputs (e.g., solvent substitution) will result in the reduction or elimination of hazardous waste. Utilizing nonhazardous or less hazardous materials also results in reducing the potential for worker exposure.

Recovery/Recycling/Reuse

Although these activities are not considered pollution prevention, they will result in minimizing waste. This activity will probably result in the greatest benefits for decommissioning activities. Recycling building materials such as scrap metal, timber, and concrete can result in significant waste reduction and cost savings. Recycling is easier if the materials are not radiologically contaminated. However, if there is surface contamination, sites should use the release criteria provided in DOE Order 5400.5, Radiation Protection of the Public and the Environment, and Nuclear Regulatory Commission Regulatory Guide 1.86 (6) to facilitate recycling. Volumetric release criteria are not available currently. In addition to building materials from decommissioning, consideration should be given to recycling, reusing, or reclaiming unspent cleaning solvents or lubricants used in all activities.

CONCLUSIONS

By incorporating the concepts of pollution prevention and waste minimization into environmental restoration activities, DOE can significantly reduce the amount of waste which must be treated and disposed. This will reduce risks to the environment, workers, and the public; lower waste management costs; and assist in maintaining compliance. Sites should develop environmental restoration PP/WMin programs as defined in the 1994 Waste Minimization/Pollution Prevention Crosscut Plan. The programs should include qualitative and quantitative (where possible) reduction goals and ensure that adequate resources are available to meet these goals. PPOAs should be applied in all stages of environmental restoration activities. Budget information for environmental restoration PP/WMin activities should be trackable and retrievable for inclusion in the A-106 reporting process. Program offices requiring assistance in establishing an environmental restoration PP/WMin program should contact the site WMin Coordinator or the program manager at DOE Headquarters.

ABSTRACT

Under the 1994 Waste Minimization/Pollution Prevention Crosscut Plan, the Department of Energy (DOE) has set a goal of 50% reduction in waste at its facilities by the

end of 1999. Each DOE site is required to set site-specific goals to reduce generation of all types of waste including hazardous, radioactive, and mixed. To meet these goals, Argonne National Laboratory (ANL), Argonne, IL, has developed and implemented a comprehensive Pollution Prevention/Waste Minimization (PP/WMin) Program.

The facilities and activities at the site vary from research into basic sciences and research into nuclear fuel cycle to high energy physics and decontamination and decommissioning projects. As a multidisciplinary R&D facility and a multiactivity site, ANL generates waste streams that are varied, in physical form as well as in chemical constituents. This in turn presents a significant challenge to put a cohesive site-wide PP/WMin Program into action.

In this paper, we will describe ANL's key activities and waste streams, the regulatory drivers for waste minimization, and the DOE goals in this area, and we will discuss ANL's strategy for waste minimization and it's implementation across the site.

INTRODUCTION

Pollution Prevention and Waste Minimization implementation at a large research and development facility can be a difficult process. The key steps to implementation are pollution prevention awareness and training, knowledge of waste streams and practices, and a judicious approach to committing resources. Cultural change and buy-in on the part of the user community are critical steps in program implementation. Argonne has developed an approach that has begun with employee awareness and training and source reduction and recycling. A Waste Minimization Advisory Committee selected from a cross section of internal stakeholders has also been formed. The next step in the process is the development of interlinks between ANL's data management systems to identify areas of concern. All of these steps have demonstrated success in their initial phase.

ARGONNE R&D AND WASTE GENERATION

Argonne National Laboratory (ANL) is a multiprogram national laboratory with sites near Chicago, Illinois, (ANL-East) and Idaho Falls, Idaho, (ANL-West). ANL was established by the Atomic Energy Act of 1946 as the successor to the Metallurgical Laboratory of the Manhattan Project. Its initial mission was the development of fission reactor technology for power generation and the supporting science and technology; Argonne conceived most of the reactor systems in use today. The Laboratory's focus expanded to include high-energy physics research in the mid-1960s and environmental R&D in the 1970s.

ANL's major national research facilities include: Advanced Photon Source, Structural Biology Center, Intense Pulsed Neutron Source, Argonne Tandem Beam Linear Accelerator System (ATLAS), and High-Voltage Microscope/Tandem Accelerator. In addition, there are a host of other facilities such as the Fuel Cycle Facility, Hot Fuel Examination Facility, Transient Reactor Test Facility, and the National Battery Test Laboratory. The Integral Fast Reactor (IFR) Program, including the Experimental Breeder Reactor-II, are based at Argonne West (ANL-W) near Idaho Falls.

ANL's areas of supporting and basic research include: materials science, chemical sciences, computing and information sciences, mechanistic biology, environmental research, nuclear physics, and high energy physics. Technology development activities are focused in the areas of energy and industrial technologies and advanced reactors. Even though in January 1994 the DOE announced the termination of the IFR program, the DOE is proposing to redirect Argonne's advanced technology capabilities to the areas of nonproliferation, spent nuclear fuel and waste treatment, reactor and fuel cycle safety, and decontamination and decommissioning programs. The Laboratory's Institutional Plan (FY1995-FY2000) recognizes the major mission areas to be energy and environmental technologies, national research facilities, basic research, industrial and manufacturing technologies, technical evaluation, and education. ANL's core competencies include fission and other advanced energy systems; accelerator-based research, facilities, and technologies; industrial and transportation technologies; modeling, simulation, and advanced computing, environmental R&D, partnership R&D with industries and universities; education and training. ANL has a total staff of 5,210 over 1,100 of which represent the scientific and engineering staff. The Laboratory budget for FY94 was in excess of 450 million dollars.

The diversity of mission activities, the facilities, the R&D programs, and D&D projects generates a wide variety of radioactive and hazardous waste streams. Table

I summarizes the recent ANL waste generation data (in this paper, we focus on ANL-E, referred to as ANL, unless otherwise noted, and the data presented are for ANL-E, even though a similar waste minimization program is in place at ANL-W). The R&D waste generation accounts for approximately 40-60% of the low level, hazardous, and special waste streams. This waste is generated by many different projects and the quantities may vary from negligible to liters or drums per year. Approximately 90% of the radioactive waste generated at ANL
can be classified as low level. Hazardous wastes represent the largest segment of the waste inventory. In Table I, the increases from 1992 to 1993 reflect increased project activities particularly in the D&D area and an increased knowledge of the waste in the legacy waste area. The 1994 data are currently being compiled and are likely to reflect mild increases in the two areas mentioned above.

REGULATORY DRIVERS AND DOE DIRECTIVES

Waste Minimization and Pollution Prevention are driven by a complex set of regulatory drivers, in ANL's case, administered by the EPA, state laws, disposal site criteria, Presidential Executive Orders, and the DOE Orders. The list of regulatory drivers is summarized in Table II.

By far, the PPA and the FFCA had the most impact on DOE facilities including ANL. The FFCA waived the sovereign immunity for federal facilities, and it also amends the RCRA by requiring DOE to prepare facility plans that provide for the development of treatment capacities for mixed wastes. The PPA establishes a hierarchy of pollution prevention activities that must be followed.

The Department of Energy (DOE) is committed to waste minimization and pollution prevention at its facilities. The first Waste Minimization/Pollution Prevention Crosscut Plan, published in 1992, introduced waste minimization strategies and key objectives. Under its 1994 Waste Minimization/Pollution Prevention Crosscut Plan, the DOE has set a goal of 50% reduction in waste by the end of 1999, and each DOE site is required to set site-specific goals to reduce generation of all types of waste including hazardous, radioactive, and mixed. To meet these goals, ANL has developed a comprehensive PP/WMin Program Plan that is applicable to all activities and all waste generators at the site.

WASTE MINIMIZATION PLANNING AND IMPLEMENTATION

In compliance with the Pollution Prevention Act hierarchy, waste source reduction is a main element of waste minimization strategy at Argonne. The pollution prevention hierarchy can be briefly summarized as the following order: source reduction, recycling, waste treatment, and disposal.

A PP/WMin Program Plan and a PP/WMin Awareness Plan have been prepared. The purpose of the two ANL plans is to attain for this site the goals of the DOE's 1994 Crosscut Plan and to ensure compliance with the federal and DOE requirements discussed earlier. The strategies outlined in these plans are now being implemented.

To meet the challenge of PP/WMin at Argonne, several major initiatives have been taken:

1. Implementation of source reduction and recycling practices.
2. Employee awareness and training programs.
3. Tracking of waste through Waste Management Data System (WMDS)
4. Implementation of a Chemical Management Systems (CMS).

The program is being expanded to include: 1) linking the CMS with the WMDS to provide information and reporting capability, 2) development of training videos, and 3) implementation of site-wide waste reduction goals.

ANL has also formed a Waste Minimization Advisory Committee that includes representatives of the research and development areas, operations, and compliance. It also includes representatives of DOE's Argonne Area Office as well as the DOE Chicago Operations Office. A representative of the New Brunswick Laboratory, which is also located at the ANL site, is also on the committee. The purpose of the committee is to review pollution prevention program implementation, waste generation practices, and provide direction and integration of the program into the laboratory culture.

Waste source reduction and recycling have become the principal elements of waste minimization strategy at ANL. The Laboratory has committed to specific waste reduction goals of 50 % for Toxic Release Inventory (TRI) wastes and 25% for other waste streams over a five-year period. The baseline for these reductions is the 1993. Concerted efforts are being made for source reduction through materials exchange and recycle of excess materials such as metals. Initiatives in this area

include the use of nonhazardous scintillation fluors, alternative solvents, and chemicals. A Chemical Exchange Program is also in effect at ANL to exchange chemicals not being used by generators. Technical expertise is provided to waste generators and several technologies are being evaluated to further reduce the volumes of waste generated.

Separation technologies developed by ANL researchers have allowed the extraction of radionuclides such as Pu, Am, Np, and U out of certain waste solutions. For stored and operational liquid waste from site-wide activities, another ANL-developed ion-exchange process can allow the separation of actinides.

ANL's waste minimization strategy features awareness and training of the employees as a first step. The waste generators are also being trained on proper techniques for readying waste for pick up by waste handling specialists. A bar code computer system allows waste management personnel to retrieve information about individual waste containers from a central data base with a hand-held, battery-operated bar code reader. This information determines the waste handling requirements. After employee awareness and training, the next important step is the general waste stream analysis and review and identification of priority areas. The final step is to work directly with D&D and environmental restoration projects to identify opportunities at the outset. The D&D and restoration projects are the single largest generator of hazardous and radioactive waste.

The ANL Awareness Program began in 1993 with a poster program similar to the safety posters presented in many locations. The program started with developing a character that people could identify with the recycling program, individuals could suggest a name for the character, and receive a recycling container for their work place. They voluntarily emptied this into common collection bins. As an immediate result of this program, white paper recycling increased by 62% (over 1993), which represents approximately 40% of the available paper on site. In 1994, ANL recycled 190 tons of white paper, which as standard sheets laid end to end could stretch 6,500 miles. This program achieved a plateau of recycling that was limited by the number of people willing to bring their paper to a central receptacle. This hurdle is being overcome by instigating a custodial collection once per week in lieu of garbage collection. This is being tried in several buildings to identify problems before going laboratory wide. The principal problems identified so far include inadequate collection equipment and the need for a container that can be transported up and down stairways. One building generates so much general trash that a trash pick-up cannot be avoided. The problem is being addressed by conducting a second sort of facility waste to identify particular problems. The awareness program is being expanded to feature metal recycling and sharing of materials in the near future.

Training efforts are starting with a simple video to be used in all employee training sessions. The theme will be to identify the problem and focus on simple solutions that individuals can use every day to impact pollution prevention. Topics will feature housekeeping, documentation, control of quantities, and sharing of materials. Specific training of waste generators is also planned.

Awareness and training will only take the program to a certain stage. The next major hurdle is to identify specific waste streams for review and action. The collection of data is the first major step. With over 1100 technical staff generating very small to large quantities of waste, the problem is in identifying priority targets. For instance, methylene chloride may be a very high priority pollutant, but if it is generated in very small quantities, scarce review resources may be dedicated elsewhere.

ANL currently has three data bases that are relevant to the pollution prevention effort. The procurement system processes purchase requests and is currently based on the military code system. It is relatively easy to review purchase orders for cost or quantity but not for specific material or user. Fortunately, this system is currently being phased out. The new system is ORACLE-based and will have capabilities more friendly to the pollution prevention effort. The second data base is the Chemical Management System (CMS). This system was created in 1992 to serve as a repository for material safety data sheets (MSDSs)and inventory control. It is ORACLE-based and also contains all of the regulatory tables plus a capability to identify surplus material for exchange. The final data base is the Waste Management Data System (WMDS). This system is currently CLIPPER-Based and manipulates all of the waste data from the time of documentation. The present data system interlinks are shown in Fig. 1.

The initial steps in the data management process occurred in FY93 when data were developed for the DOE Annual Waste Reduction report and the (TRI) Report. This process was only partially effective because the first data only reflected waste as shipped. A second review of data was necessary to identify specific sources and quantities of TRI chemicals. This effort brought several problems to the forefront: 1) the data did not necessarily reflect material entering the system; 2) data quality was unreliable; for instance some data did not reflect concentrations but only the absolute container size; 3) access to the data was extremely limited, and 4) the waste management data base did not directly access either the regulatory lists or the MSDSs contained in the CMS data base; and 5) units of measure were not always consistent.

The need to link pollution prevention to WMDS was immediately apparent. The limited data available from the 1993 TRI report indicated that the largest H_2SO_4 generator contributed 1000 L of waste. A review with the generator indicated that half of this was dilute rinse water that could be neutralized.

Fig. 1.

The planned data linkages will provide for real-time data availability to the pollution prevention staff. Because waste data can provide a powerful driver for managers to incorporate pollution prevention in their programs, the second step in the data management process will be to generate two reports for laboratory managers to use. The first will be a simple report summarizing individual division waste generation. This report will be provided to division management. The second will be a detailed report of specific waste generation practices and will be available electronically to the researchers. Linking of the data bases is currently underway. The user community, requests chemicals through the procurement chain. The original systems had the user independently ordering materials. With the establishment of the CMS, the first step was for an individual to prepare a purchase requisition and a data sheet for chemical management and inventory control. Procurement is developing new software for its system and as a part of that effort, the link between the user, purchaser and the inventory control by chemical management will be electronic and automatic. The next step in this process will be to prompt a user to determine if they can use materials from inventory and provide them with the link to inventory. A user that cannot use inventory will not be required to do so. Finally, quantity approval limits will be applied to limit excess purchase.

The final links will be between the waste management system, chemical management system, and the pollution prevention group. The final data management configuration will resemble Fig. 2.

Fig. 2.

The advantages offered by the linked system are many:

Users will have access to CMS including MSDS and regulatory information at the outset of a project or experiment.

Procurement and inventory information will be fed to CMS and subsequently to pollution prevention and waste management in a real time frame resulting in knowledge of future activities.

Users will be able to generate waste requisitions electronically and transmit the information to waste management resulting in a more detailed knowledge of waste and its timely disposal.

This planned linkage will provide use of regulatory tables, inventory trends, procurement and waste documentation. This information will be used by pollution prevention group to determine target waste generators, waste generation trends, and documentation of successful source reduction efforts. The current schedule calls for the initial links between waste management and pollution prevention to be completed the spring of 1995. The final links will, however, be determined by the budget availability
for these activities.

CONCLUSION

Argonne has implemented a comprehensive waste minimization program with significant initial success. We have found that institutional buy-in at a complex R&D site, such as Argonne, is essential to implementation of a consistent waste minimization effort. Awareness and training are also essential components and are in fact responsible for source reduction in major part but they have limitations that are impacted by buy-in and commitment on the part of the user community as well as, both the physical and financial commitment. Awareness and training have been effective at

identifying and capturing the "low hanging fruit" but have limitations at prioritizing waste streams. A detailed knowledge of waste generating practices is essential at a large research facility because of the varied nature of the materials. Overall, it is anticipated that Argonne will be able to meet its waste minimization goals through a multi-faceted but consistent approach applied to all facilities and activities at the site.

WASTE MINIMIZATION APPLICATIONS AT A REMEDIATION SITE

Lisa Allmon
FERMCO
Dave Rast
U. S. Department of Energy
Fernald

ABSTRACT

Applying waste minimization principles at a remediation site is a challenge for many companies. We are required to practice waste minimization and pollution prevention (WM/PP), but how is it achieved at a site where waste generation is thought to be a key product?

The real challenge is to shift the waste minimization paradigm from focusing efforts on source reduction to focusing on recycle/reuse by inverting the EPA waste management hierarchy. A fundamental difference at remediation sites is that source reduction has limited applicability to legacy wastes but can be applied successfully on secondary waste generation. The bulk of measurable waste reduction will be achieved by the recycle/reuse of primary wastes and by segregation and decontamination of other wastestreams. Each effort must be carefully measured in terms of being economically and ecologically beneficial.

Structuring a successful, dynamic WM/PP program produces a mechanism to set the paradigm shift in motion. The program must be comprehensive, integrated, and proactive in order to capture opportunities early in the CERCLA/RCRA process.

The structure of a successful WM/PP Program will be illustrated by a case study of a Decontamination and Decommissioning (D&D) project (Plant 7) which was completed at the Fernald Environmental Management Project during the summer of 1994.

Key elements of the program were successfully integrated into the remediation project by including waste minimization personnel in all phases of the project to coordinate, promote, identify, plan, and implement in the field all waste minimization opportunities. Design, Engineer, Construction (DEC) Teams offered invaluable access to all aspects of the remediation project.

Source reduction opportunities were identified for secondary wastes generated from decontamination activities, radiological area access control, waste packaging activities, and procurement of materials/chemicals. Implementation of these actions dramatically reduced the amount of wastes generated during the D & D activities.

Recycle/reuse opportunities were identified for the majority of primary wastes including structural steel, lead flashing, transite, and concrete. The decision to recycle and based on the life-cycle cost of the waste including disposal costs and on the decision to be responsible, ecologically, for waste management.

Segregation techniques were essential for dispositioning wastes as sanitary, low-level, mixed, or recyclable and greatly reduced costs for waste disposal. Segregation also allowed for the responsible management of wastes. Volume reduction in conjunction with segregation techniques accomplished a further reduction in disposal costs.

Management personnel of the Plant 7 D & D project effectively utilized the shifting focus from source reduction to recycle/reuse to accomplish a measurable reduction in primary wastes shipped for disposal and to reduce the amount of secondary wastes which were generated during the project.

The success of this benchmark effort communicates to other facilities gearing-up for remediation that waste minimization can be practiced at a remediation site and can be accomplished in an ecological and economical fashion with stakeholder acceptance.

INTRODUCTION

The Fernald Environmental Management Project (FEMP) is owned by the Department of Energy and was used for the processing of uranium. The facility is a 1,050 acre site in southwestern Ohio. In 1989 Fernald suspended production of uranium metals and was

placed on the National Priorities List (NPL). Since production at Fernald formally ceased in 1991, the site's mission has changed from one of production to environmental restoration. A Remedial Investigation and Feasibility Study (RI/FS) is being conducted, along with other response actions under the 1990 CERCLA Consent Agreement with the EPA. This change in the mission led to many changes in Management's operating philosophy. Many groups which were necessary for producing a product were deemed irrelevant for remediation work, including Waste Minimization. At first sight, Waste Minimization does not readily appear to be applicable to remediation work. Environmental remediation is designed to correct adverse impacts to the environment from past operations and generates significant amounts of waste requiring management. The premise of pollution prevention is to avoid waste generation, thus remediation is in direct conflict with this premise. Although greater amounts of waste will be generated during environmental remediation, treatment capacities are not always available and disposal is becoming more difficult and costly. This creates the need for pollution prevention and waste minimization.

Applying waste minimization principles at a remediation site is an enormous challenge. If the remediation site is also radiologically contaminated it is even a bigger challenge. Innovative techniques and ideas must be utilized to achieve reductions in the amount of waste that must be managed or dispositioned.

One concept utilized at Fernald was to shift the waste minimization paradigm from focusing efforts on source reduction to focusing efforts on recycle/ reuse by inverting the EPA waste management hierarchy. A fundamental difference at DOE remediation sites is that source reduction has limited applicability to legacy wastes but can be applied successfully on secondary waste generation. The bulk of measurable waste reduction will be achieved by the recycle/reuse of primary wastes and by segregation and decontamination of secondary wastestreams. Each effort must be measured in terms of being economically and ecologically beneficial.

In Operable Unit 3, which consists of all the facilities and structures on the site, nearly 87% of the material to be dispositioned can be recycled. This includes heavy and light gauge metal such as equipment, lead flashing, ductwork, steel structures etc. The remaining waste will be disposed at either a designated DOE disposal facility, commercial disposal facility or in an on-site disposal cell. The exact amount to be disposed is driven by effective project management.

During the decontamination and decommissioning (D&D) of these facilities, secondary wastes will be generated. These secondary wastes include such things as anti-contamination clothing, wastewater, compactible trash, packaging materials, used equipment, tools, used chemicals, and a variety of other materials. The amount of secondary waste generated is dependent on how efficiently the project is planned and managed. Segregation techniques must be employed by project personnel in order to take materials and equipment into radiologically controlled areas and survey the materials back out as radiologically clean. By utilizing these techniques, materials are driven to the least-cost disposition, such as sanitary waste. Practicing segregation and practical decontamination will greatly reduce the amount of waste to be disposed, realizing a substantial cost savings.

Another effective concept employed at Fernald is the structuring of a dynamic Waste Minimization Program in order to set the paradigm shift in motion. The program must be comprehensive, integrated, and proactive in order to capture opportunities early in the CERCLA process. Waste Minimization opportunities must be identified during each phase of the CERCLA process by integrating waste minimization/waste management personnel into the project teams. Project and design engineers must also be trained in the application of waste minimization techniques.

Starting at the Remedial Investigation, waste minimization opportunities exist during sampling activities, lab analysis, and treatability studies. Waste characteristics, waste quantities and potential dispositioning options are identified during this phase. Waste minimization plays a key role in defining the number and types of options available for conducting these activities.

During the Feasibility Study phase, additional analysis are performed to identify waste treatment and disposition options. Secondary waste generation becomes important during this phase and must be properly quantified.

The more tangible opportunities for waste minimization occur during the Remedial Design/Remedial Action phase. Design/Engineer/Construction (DEC) teams should be formed which include waste minimization personnel. This allows involvement up front

in the design phase in order to coordinate, promote, identify, plan and implement all waste minimization opportunities. DEC teams offer invaluable access to all aspects of the remediation project.
The Waste Dispositioning Plan provided to the D&D contractor is another area where waste minimization opportunities can be identified. Segregation, decontamination, volume reduction and efficient packaging should all be discussed in the plan.
Finally, actual field presence of waste minimization/waste management personnel during project implementation is essential in order to assure all possible waste reduction techniques are utilized. This includes monitoring waste minimization boundaries, packaging activities, chemical usage, and segregation activities.
Effective project management has proven to be the most essential element in assuring waste minimization is applied to all remediation projects. Fernald has also determined that quantifying the actual amounts of wastes avoided or recycled/reused per project enables the effectiveness of the waste minimization program to be assessed. Quantifying these amounts was accomplished by developing specific performance measures for remediation activities. Typical waste minimization performance measures are based upon reductions in the amount of waste generated at a facility. At a remediation site this measure of effectiveness does not ensure proper accounting for reductions in secondary waste generation or recycle/reuse initiatives.
As an alternative to waste generation data, Fernald is tracking the initial (in situ) quantities of materials requiring management to the final quantities disposed, recycled, or reused from each remediation project. These three indices quantify the success of waste minimization applications and provide a benchmark for waste minimization in remediation activities. Remediation activities are tracked as nonroutine waste generating processes instead of as routine, on-going processes. Since each remediation activity is projectized, specific waste information is available. Activities are initiated with the approximate known quantities and types of waste in situ. This known quantity is used to calculate the following indices:
1. Recycle Index - This is calculated by taking the amount (volume or density) of the waste recycled over the amount of waste in situ.
2. Reuse Index - This is calculated by taking the amount (volume or density) of materials which are reused over the amount of waste in situ. This includes the reuse of equipment, supplies, and materials which can be quantified.
3. Disposal Index - This is calculated by taking the amount (volume or density) of waste that is disposed over the amount of waste in situ. This is tracked per waste type, such as demolition debris, metal, transite, and soil. This index enables the tracking of secondary waste generation, as well as packaging efficiencies and bulking factors.
Understanding what causes an increase or decrease in the amount of waste disposed leads to better project management. Tracking these three indices over time gives an accurate, graphical display for management to use in evaluating the waste management program. These indices should show a trend of more efficient management and cost savings as each project is completed and the lessons learned are applied to the next activity.
In conclusion Fernald has realized the importance of applying waste minimization principles to remediation activities. Shifting the focus from source reduction to recycle/reuse of primary wastes and minimizing secondary waste generation has accomplished measurable reductions in wastes shipped for disposal. The success of this effort communicates to other facilities gearing-up for remediation and D&D activities that waste minimization is relevant during remediation and can be applied through effective project management.

ABSTRACT
Radwaste system optimization efforts are intensifying as nuclear utilities are barred from low level waste (LLW) disposal sites and environmental and ALARA programs encourage a reduction in the curies discharged to the environment. The three nuclear units at Millstone station, GE BWR (unit 1), C-E PWR (unit 2) and Westinghouse PWR (unit 3), have completed a series of bench top and side stream pilot scale tests of Eichrom's Diphonix resin, a novel gel type ion exchange resin. This testing was part of an overall optimization of their radwaste systems including use of coagulants and cesium specific zeolite materials. By installing Diphonix resin, Millstone is addressing the goals of minimizing the spent resin generated from their liquid radwaste systems and minimizing the activity discharged into the environment from these systems while continuing to use existing capital equipment. Millstone Station's effluent summaries for 1993 show that greater than 50% of the activity discharged from each unit was from cobalt isotopes. Discharge of Zn-65 from unit 1 was the site's highest contributor to whole body dose. Each liquid radwaste system at Millstone station consists of a particulate removing filtration component and an ion removing ion exchange component. The ion removing component relies primarily on standard mixed hydrogen form cation and hydroxide form anion exchange resin beds and, in some cases, a synthetic cesium specific zeolite. The liquid radwaste processed by these systems contains sodium, calcium, chloride and sulfate ions at concentrations approximately one billion times those of the radioactive components in these systems*(1). The standard mixed bed resins are exhausted by exchanging the sodium, calcium, chloride and sulfate ions. The resin exchange capacity is overwhelmed by the common ions causing the radioactive components to pass through. The result is the need to replace resin beds at a much higher frequency than desirable.
Diphonix resin differs from typical cation exchange resin through its unique combination of diphosphonic acid and sulfonic acid functional groups which exhibit selectivity for Co, Zn and other transition metals over sodium and calcium*(2). Samples of radwaste liquids from each Millstone unit were passed through laboratory scale columns of Diphonix resin. These tests demonstrated that Diphonix resin was capable of removing all detectable cationic Co-58, Co-60 and Zn-65. In another test, a side stream was taken from the discharge of unit 1's radwaste system carbon bed effluent and passed through a column of Diphonix resin over a period of weeks. This test
is designed to measure throughput to cobalt or zinc activity breakthrough. Although the test is continuing, breakthrough has not been reached after passing in excess of 45,000 gallons per cubic foot of Diphonix resin. It is typical for standard cation resin to have cobalt or zinc activity breakthrough after passing 5000-10000 gallons per cubic foot. This significant increase in throughput for Diphonix resin over typical cation resin throughputs makes the use of Diphonix resin a preferred technology. Other key reasons Millstone has installed Diphonix resin are the reduction in curies discharged to the environment and the lower personnel exposure resulting from less frequent resin replacements and handling.
RADWASTE OVERVIEW
An increasingly important cost affecting domestic nuclear power plants is the handling and storage/disposal of low level radioactive waste, LLW. These increasing costs are triggering a conversion to products capable of processing greater radwaste liquid volumes per unit spent waste generated. Any change in processing technology should also reduce the curies discharged to the environment and the resulting personal exposure dose. Eichrom's Diphonix resin has these capabilities. Northeast Utilities Millstone Station has evaluated this resin for its radwaste systems using bench top and side stream pilot scale tests. The success of these tests led to the installation of Diphonix resin to process liquid radwaste at Millstone. Details of Millstone's evaluation are reported here.
LLW Disposal
As of June 30, 1994 thirty one states lost their access to the Barnwell repository for their LLW disposal. Barnwell is still open to Southeast Compact generators, but under South Carolina law the LLW facility is slated to close forever on December 31,

1995. Nuclear stations which do not have access to a disposal site are forced to store waste on site. Industry experts caution that this interim on-site storage is not long-term storage(3). The result of this situation is that each plant storing LLW on-site will likely have to handle the waste twice adding to the incentive to minimize the volume each plant produces. Current estimates for the cost of disposing spent ion exchange resin are $750 per cubic foot at Millstone Station. Other nuclear station's circumstances can result in a higher or lower cost ascribed to spent resin waste.

Radwaste Discharge Limits

Nuclear plants are well below the legal limits for activity discharged as specified by two parts of the Code of Federal Regulations (CFR). The radioactive materials release limits of Title 10 of the CFR, Part 20 (10CFR20) governs the concentrations which may be released, on an instantaneous basis, from the plant release paths at the site boundary. Appendix I of 10CFR50 contains additional release restrictions which govern cumulative releases throughout the year. This regulation requires the calculation of real exposure pathways to the general public outside the restricted area, based on actual radioactive releases to the environment. This regulation is more stringent than 10CFR20, limiting exposure to no more than 5 mrem a year, much lower than from background sources. Most nuclear plants desire to continue to reduce their radioactive discharges by employing new technology. An approach based on replacing existing resins with more selective resins could address the goals of reducing the quantity of activity discharged and reducing the amount of spent resin generated to do this.

Examples of metal isotopes in PWR radwaste are Co-58 and 60, Cs-137 and 134, Cr-51 and Mn-54. BWRs that are injecting zinc note that Zn-65 is a major component in their radwaste along with cobalt and cesium. Zn-65 is important because of its high relative contribution to whole body dose.

The Liquid Radwaste Process

During the operation of a nuclear power plant, various radioactive materials and chemical wastes are formed. These materials will be in the form of gases, liquids, or solids. These materials must be safely collected, processed and disposed of to minimize radiation exposure to plant personnel and to the general public. The liquid radwaste process essentially consists of collecting and treating the liquid from various operations including floor and equipment drains. The collection tanks feed treatment systems that typically include components of filtration and ion exchange. The ion exchange process is usually performed by a mixture of sulfonic acid functionalized polystyrene/DVB strong acid cation exchange resin in the hydrogen form and quaternary amine functionalized polystyrene/DVB strong base anion resin in the hydroxide form, hereafter referred to as the 'standard mixed bed'.

The selection of resins for radwaste processing can be improved in two key areas. First, the standard mixed bed is removing many ions that are not required to be removed such as sodium and calcium. The removal of these non regulated ions consumes the ion exchange resin's capacity. By comparison, a resin that is selective for the activated metal ions, present in much lower concentrations, would result in greater throughputs and thus generate less spent resin waste. Second, the sulfonic acid functional groups on the cation exchange resin are not always strong enough to remove the activated ions to the desired concentrations. Decontamination factors for activated cobalt range from 1 to 50 at Millstone Station using standard mixed bed resin. Millstone desires to improve on this level of decontamination by eliminating activated metals in their discharges to less than detectable levels whenever possible.

OBJECTIVES

The challenges faced by nuclear power station radwaste managers are clear:

1. Lower the radioactivity content of the plant's waste
2. Minimize the creation of solid waste requiring disposal, and
3. Accomplish both of the above without requiring expensive new capital equipment.

DIPHONIX RESIN

Diphonix resin represents a new technology specifically developed to accomplish these objectives. R&D Magazine recently recognized Diphonix resin as one of the 100 most technologically advanced products of 1994. The following highlight the chemical and performance attributes of Diphonix resin. (4,5)

Highly Effective Radionuclide Uptake

The primary exchange group in Diphonix resin is diphosphonic acid, known to form

very stable complexes with metal ions including zinc and cobalt. Table I shows that this functionality drives the concentration of metallic species to the lowest achievable concentration, on average 100 times lower than conventional cation exchange resins. This testing was performed with the resins treated with calcium to simulate resin that had been in use for some time. Distribution values for cobalt and zinc on Diphonix resin are 20,000 and 100,000 respectively. The distribution values can be considered to give an approximate idea of the selectivity of Diphonix resin and cation resin for the different ions relative to calcium from neutral solutions. The distribution value is defined in equation 1. Ao and Af are the metal concentration before and after contact with the resins. W is the weight (g) of the resin and V is the volume (mL) of the aqueous phase.

Eq. (1)

TABLE I

Selective Metal Capacity

The diphosphonic acid groups react selectively with metallic ions, and not with common, non-regulated species such as calcium, magnesium and sodium. Because radionuclides are present at extremely low concentrations, compared with typical sizable concentrations of common species, the ability of Diphonix resin to use capacity selectively makes a major impact on economics. Results of Millstone's side stream testing of Diphonix resin on unit 1's radwaste show significantly greater throughput per unit of resin than with conventional strong acid cation exchange resins. Details of this testing are provided latter in this paper.

Quick Reaction Kinetics

A second functional group, sulfonic acid, is also incorporated into Diphonix resin. This functional group provides for quick reaction kinetics, making the diphosphonic acid group readily available to target species. Excellent kinetics allows Diphonix resin to operate at high flow rates. This makes possible the use of existing plant resin vessels operating at current flow rates.

Gel Type Polystyrene/Divinylbenzene Polymer Matrix

This is the same base polymer combination currently used in most operating radwaste systems. Diphonix resin is compatible with existing resin vessels and underdrain systems. It is supplied as 20 to 50 mesh beads
for radwaste applications.

MILLSTONE RADWASTE CHEMISTRY

A review of the chemistry of the radwaste liquids to be treated is the appropriate first step in any radwaste system upgrade program. Figure 1 shows the total effluent activity in curries for each Millstone unit for 1993. The Fig. also shows the percentage that each isotope contributed to this total. The sum of Co-58 and Co-60 contributed greater than 50% of the effluent curies for each unit. Unit 1 is a 660 MWe GE BWR which went commercial in 1971. Its total 1993 liquid effluent activity was the lowest of the three Millstone units at 0.128 curies. Zn-65 was 23% of unit 1's activity and 1% of the site's activity but contributed 75% to the site's whole body dose of 0.1456 mRem. Due to environmental accumulation factors, Zn-65 contributes a proportionally larger dose than either cobalt or cesium nuclides. Unit 2 is a 875 MWe Combustion Engineering PWR which went commercial in 1975. Its total 1993 liquid effluent activity was 0.952 curies. Unit 3 is a 1149 MWe Westinghouse PWR which went commercial in 1986. Its total 1993 liquid effluent activity was 2.24 curies.

Fig. 1.

The activity data helps identify which metals to target for removal but does not establish what competing ions might be present and their relative concentrations. Table II provides data on the variation of ionic and radioactive constituents in Millstone unit 2 radwaste liquid. Variations in the content of liquid radwaste is caused by the wide variety of systems that flow into the radwaste system and the various operations that the unit goes through during the fuel cycle. The ratio of common ionic constituents to radioactive constituents is approximately one billion to one. It is this infinitesimal fraction of the total ionic content that requires removal prior to discharge.

TABLE II

The Multiple Challenges Of Radwaste Chemistry

Removal of all activated corrosion and fission products typically requires the availability of both an ion removing component and a particulate removing component. The focus of this paper is on the removal of ionic (dissolved) activity. It is

appropriate, however, to mention that Millstone has studied the use of coagulants as a means of removing colloidal constituents through a combination of cartridge filtration and organic carbon bed filtration. Unit 1 currently uses coagulant injection and carbon bed filtration as a means of enhancing activity removal. The ratio of activity present as a filterable solid to ionic species is variable. Current plant activities such as shut down and start up chemistry changes will likely impact this ratio. The key is to have a system in place that can handle either form.

The detailed listing of the constituents in liquid radwaste in Fig. 1 and Table II define the challenge of removing the activity. Whether an element is activated has no impact on the mechanism required to remove it. Diphonix resin should be a key component of any radwaste system desiring to remove ionic activity consisting of divalent, trivalent, tetravalent and hexavalent metals. The powerful complexing strength of Diphonix resin may also help remove complexed metals which might otherwise be unreactive with the standard mixed bed. An example of this is antimony. Some of the activity listed in Fig. 1, however, exists as anionic complexes which are not reactive with Diphonix resin. These anionic complexes require that an anion exchange resin continue to be used in the radwaste process. Millstone has also studied the use of cesium specific synthetic zeolite materials. Diphonix resin and standard cation resin both remove cesium. Millstone has concluded, however, based on laboratory and field testing, that the synthetic zeolite material results in greater throughput per unit material than either Diphonix resin or standard cation resin. The synthetic zeolite material has now become part of the radwaste systems in units 1 and 2 for cesium removal.

DIPHONIX RESIN TESTING

The data in Table I confirms that Diphonix resin possesses the necessary attributes to merit further study as a replacement of Millstone's cation exchange resin. The selectivity and reactivity of Diphonix resin for cobalt and zinc and other metals over sodium and calcium is superior to cation exchange resin. A test program was established by the Millstone chemistry department to evaluate the performance of Diphonix resin on radwaste liquid samples in laboratory scale columns operating at the same flux rate as the existing standard mixed bed system. These tests will focus on Diphonix resin's ability to completely remove activated metals and to process greater volumes of radwaste than conventional cation resins.

Test Column Scale Up

The initial work was performed using unit 2's radwaste. The Diphonix resin used was 20-50 mesh bead size. Bench scale parameters are as follows:

Radwaste Demineralizer Vessel: 42 in (ID) X 63 in height
Cross sectional area: 9.62 ft2
Influent Flux at 35 gpm: 35 gpm/9.62 ft2 = 3.64 gpm/ ft2 = 14.83 (mL/min)/cm2
Bench Test Vessel: 2.5 cm (ID) X 30 cm bed height
Bench Vessel Cross Sectional Area 4.91 cm2
Bench Vessel Flow Rate (14.83 mL/min/cm2)(4.91 cm2) = 72.8 mL/min

The test column bed height of 30 cm will likely result in faster breakthrough than would occur in the operating vessels. Bed depths of 90 cm are typical in operating vessels. The advantages of shorter test columns are less time and labor to achieve complete breakthrough curves.

Eichrom Cobalt Characterization

Initial tests of unit 2's radwaste showed that decontamination factors 10 to 20 for cobalt were less than expected based on earlier batch uptake work shown in Table I. A hypothesis was formed that a small non-cationic portion of the cobalt activity was unreactive with the powerful diphosphonic acid functional groups on Diphonix resin. Samples of this radwaste were sent to Eichrom for further study. Similar decontamination factors were achieved for the cobalt during the initial testing at Eichrom. Total decontamination of Mn-54 and Cs-137 through the Diphonix resin was achieved during the Millstone and Eichrom work. The Eichrom work (6) next characterizeed the species not complexed by the Diphonix resin and devised a procedure for its removal. This work concluded that all detectable cobalt could be removed by passing the radwaste through Diphonix resin followed by a strong base anion exchange resin in the hydroxide form. The

decontamination factor for this treatment was greater than 1000 based on the detection limits of the intrinsic germanium counter used. Other treatments using submicron filtration, macroporous resin, precipitation and digestion were incapable of improving the removal of this 5-7% fraction of cobalt activity that passed the Diphonix resin. The conclusion is that this radwaste sample contained both cationic and anionic forms of cobalt. To remove both cobalt species, Diphonix resin can be used as a replacement of the cation resin component of a standard mixed bed or, where multiple vessels are available, Diphonix resin can be used in series with anion exchange resin. Additional details on the use of Diphonix resin is found latter in this paper under the headings, 'System Design Upgrade' and 'Operational Action Plan'.

Unit 3 Test

Millstone also conducted laboratory column testing on a small volume of radioactive waste water from unit 3. Initial treatment was performed by coarse filtration and carbon. The water passed through the Diphonix resin contained activity from Mn-54, Co-58, Co-60, Cs-134, Cs-137 and Sb-125. In each case but antimony, Diphonix resin was able to remove all detectable activity. The sample from unit 3 apparently did not have any anionic cobalt present. A small fraction of the antimony was removed from the waste with the Diphonix resin.

Unit 1 Test

Laboratory testing of waste from unit 1 indicated that Diphonix resin was capable of removing Zn-65 from the waste stream. Because Zn-65 is the major contributor to off site dose, this Diphonix resin capability is a significant benefit. Approximately 20-25% of the zinc activity and 5-10% of the cobalt activity was removable on anion exchange resin. Together with Diphonix resin, total decontamination of the waste was accomplished.

A slip stream from the unit 1 radioactive waste system taken prior to the system's ion exchange vessels, was connected to a Diphonix resin column. This test was set up to quantify throughput to transition metal activity breakthrough. The same size test column was used as described earlier in the test column scale up section of this paper. The flux rate was 100 mL/min (equal to 5 gpm/ft2), slightly higher than with the laboratory test runs. Just as with the operating radwaste system, flow to the test column is intermittent based on processing batches of radwaste liquid. The test started on December 17, 1994. At the end of January, the Diphonix resin column had processed 45,000 gallons per cubic foot of resin without transition metal activity breakthrough. The test is continuing to be run. For comparison, standard cation resin typically processes between 5,000 and 10,000 gallons of unit 1 waste prior to transition metal activity breakthrough. The influent water conductivity during the test ranged from 140 to 1780 S. Figure 2 provides a graphical representation of the data collected from this test so far. Conductivity is reported as microsiemens 'S' and decontamination factors are listed as 'DF'. High conductivity water causes the effluent activity from the operating standard mixed beds to increase. This increase is due to influent activity not being held on the resin and the release of collected activity being bumped from the resin's exchange sites. Although the conductivity range indicates that other ions were competing for exchange sites, Diphonix resin removed 100% of cationic transition metals from the slip stream. This was verified by placing an anion resin column down stream of the Diphonix resin. No transition metal activity was measured.

Fig. 2.

SYSTEM DESIGN UPGRADE

Northeast Utilities is in the process of switching from two 40 cubic feet standard mixed beds to a system consisting of three 15 cubic feet volume, 24 inch diameter stainless steel vessels. Liquid radwaste is collected from various floor and equipment drains and fed through a spiral-wound cartridge filter prior to entering the series of three vessels. The primary vessel contains a cesium specific zeolite identified as D-230 by its supplier. The secondary vessel contains 10 cubic feet of Diphonix resin sandwiched between 2 cubic feet of 20 to 50 mesh granular activated carbon on the top and bottom. The final vessel in the series contains 10 cubic feet of Dowex SBR-C hydroxide form, type I, strong base anion exchange resin. Previously, when effluent concentrations of nuclides exceeded acceptable limits, the entire 40 cubic feet of mixed resin bed required disposal. The fact that the high effluent nuclide concentration was caused by exhaustion of either the cation exchange resin component or the anion exchange resin component was not consequential as it was

impractical to isolate the exhausted component of the mixed resin bed. The new system is more flexible and will generate less LLW.

OPERATIONAL ACTION PLAN

The new system provides Millstone with an improved ability to control radwaste costs and reduce curies discharged and personal dose. Routine laboratory analyses consist of a gamma isotopic analysis and conductivity measurements of the liquid prior to discharge. Table III outlines a series of additional tests which provide direction on which component of the system should be replaced once routine analysis shows isotopic concentrations exceeding desirable levels. These tests were developed based on the potential presence of a different species of activated elements. Gamma counting data does not provide information on the species of a particular isotope. The additional tests prevent the premature disposal of components of the radwaste system prior to the end of their useful life. The testing is performed on aliquots from the radwaste system discharge.

TABLE III

The samples from each test listed in Table III should be gamma counted. Decontamination factors (DFs) can then be calculated for each set of media tested. For instance, if the decontamination factor is maximized by test 5, it is likely that the anion exchange resin should be replaced. Chromium and iodine are usually present as anions. Their presence in the radwaste discharge indicate breakthrough from the anion exchange resin in the system. Cobalt can be present as an anion and may be the cause of reduced system DFs despite the fact that the Diphonix resin is removing all soluble cationic cobalt. If the DF in test 5 is higher than test 4 it is likely that the cobalt in the radwaste effluent is anionic.This result would signal the replacement of the anion resin if effluent activity justified this action.

SUMMARY

The Millstone testing of Diphonix resin for the treatment of liquid radioactive waste revealed several positive results:

The polystyrene-divinylbenzene base material and mesh size are the same as commonly used cation exchange resin, which is compatible with existing plant systems.

The effective capacity of Diphonix resin was much greater than standard cation resin because of demonstrated selectivity thus reducing the LLW generated.

Diphonix resin is capable of holding transition metals on the resin exchange sites during transients of high conductivity water.

Millstone focused their efforts to improve their radwaste systems by first identifying the major contributors to effluent activity and personal exposure dose. Non-activated elements present in the radwaste liquid were also identified. The data targeted cobalt and zinc activity for removal from waters containing high relative concentrations of common elements including sodium and calcium. These conditions favor the use of Diphonix resin for improving effluent water quality (lower activity) and reducing resin waste by treating more waste per cubic foot of resin then with standard cation resins. The testing led to the installation of Diphonix resin as part of a three bed radwaste system. This provides Millstone with a flexible design capable of handling a variety of radwaste streams. The authors conclude that a similar approach would be effective at other nuclear plants.

ACKNOWLEDGMENTS

The authors would like to thank the staffs and management at Millstone Station, Eichrom Industries and Argonne National Laboratory for their assistance. In particular, special thanks to Herb Diamond and Phil Horwitz at Argonne, Jeff Peters, Mike Gobeli and Mark Rodriguez-Goldstein at Millstone and Julian Jenkins of Chem Nuclear for performing much of the laboratory and side stream testing reported here.

ABSTRACT

In 1987, the JGC Corporation was contracted to engineer, design, construct, and operate an independent, dedicated radwaste treatment and decon facility at the Surry Power Station. Since beginning operations in 1991, more than 67.5 million liters (18 million gallons) of radioactive liquids have been processed with no detectable activity, excluding tritium, in liquid effluent. The key element in achieving this performance is the Bitumen Solidification System.

The Surry Radwaste Facility Bitumen Solidification System is capable of processing many types of radioactive liquids, sludge and resin slurries. The NRC approved Topical Report, "High Strength Asphalt Solidification Process for Low Level Radioactive Waste", and the Vendor Process Control Program (PCP) allows stabilization of Class B or C boric acid waste within a bitumen matrix. Because boric acid from the primary coolant let-down is not recycled at Surry, the Bitumen System processed approximately one thousand 200 liter drums of boric acid waste stream solids as Class-A waste during the first two and one-half years of operation.

To reduce the volume of waste generated, Virginia Power had a new PCP developed to process the waste as Class A. The Class A PCP has resulted in significant savings and benefits to Virginia Power.

INTRODUCTION

Virginia Power's Surry Power Station is a two unit Westinghouse PWR. Both units began commercial operations in the early 1970s. Within three years, the installed Liquid Waste Evaporator had failed and portable vendor supplied ion exchangers were placed in service to process liquid waste. These systems processed liquid waste in compliance with regulatory requirements, but resulted in high annual releases of radioactive materials to the environment. In 1985, Virginia Power implemented aggressive feasibility studies for the improvement of radwaste treatment processes. Visits and technical discussions were conducted with radwaste facility operators from the US, Europe and Japan. In these studies, Virginia Power focused on:

- Providing greater on-site storage capabilities;
- Reducing the volume of radwaste generated for disposal;
- Reducing releases of radioactivity and pollutants to the environment;
- Reducing radiation dose to operating and maintenance personnel;
- Providing reliable operation with proven state-of-the-art technologies; and
- Incorporating lessons learned from Virginia Power and other processors.

As a result of these studies and evaluations, Virginia Power completed a conceptual design for an integrated Radwaste Processing and Storage Facility. In 1987, the JGC Corporation was contracted to engineer, design, construct and operate the radwaste

facility. The facility systems were selected based on technical and economic evaluations of competing alternative technologies. The stand-alone, dedicated Surry Radwaste Facility (SRF) began operations in 1991. Since beginning operations, approximately 67.5 million liters (18 million gallons) of radioactive liquids have been processed and released with no detectable activity, excluding tritium. A key element to achieving this performance is the Bitumen Solidification System.

Why Bitumen Solidification?

Virginia Power selected the Bitumen Solidification System to process waste because:

The technology and operational experience proved very versatile and effective overseas and in the United States for processing boric acid, sodium borate, sodium sulfate, resins and various sludge,

The technology provided good volume reduction ratios and used inexpensive non-specification packaging materials,

The binder, High Strength Asphalt, is relatively inexpensive, leach resistant and has a high compressive strength. It is also readily adhesive, highly waterproof and durable,

The system design provided proven safety benefits for personnel and the environment by using moderate temperatures (under 230C) to produce a homogeneously mixed monolithic form and incorporating remote technology to support ALARA goals.

THE BITUMEN SOLIDIFICATION SYSTEM

The Bitumen Solidification System is composed of several subsystems, each performing a specific purpose to support processing the waste into a solidified product in accordance with Licensing Requirements for Land Disposal of Radioactive Waste, Title 10 of the Code of Federal Regulations, Part 61.

The subsystems include: (See Fig. 1)

Waste Feed Subsystem
Waste Pretreatment Subsystem
Bitumen Storage and Feed
Heating Fluid Subsystems
Thin Film Evaporator Subsystem
Distillate and Ventilation
Drum Handling Subsystem
Solvent Recovery Subsystem

Basic Principle

The System uses a chemical and mechanical process to uniformly disperse and solidify waste solids into a bitumen matrix. The Thin Film Evaporator (TFE) is the heart of the system. The TFE uniformly mixes waste and bitumen in the upper processing area at a predetermined ratio. Four mixing blades in the TFE rotate and cause the bitumen/waste mixture to be spread over the internal heated surface. The mixture is heated to 230C along its entire length with a synthetic heating fluid. The high temperatures evaporate free water from the liquid waste and bound water from the sodium borate compound. Heating also reduces the bitumen viscosity to ensure better mixing with the waste solids. Bow waves created by the rotating blades cause turbulent flow conditions which further improves evaporation (See Fig. 2). The mixture flows downward through the TFE by gravity to a bottom cone and discharge area. The cone provides a reservoir to hold the bitumen mixture while switching drums. The final product temperatures average 175C as it exits the TFE into a drum on a remotely operated conveyor. Solidification of the end product occurs upon natural cooling of the bitumen binder. The evaporated water flows upward through the blades to a moisture separator which strips liquid droplets from the vapor, returning them to the processing area. The vapor flows to a condenser.

WASTE PROCESSING EXPERIENCE

Virginia Power received NRC interim approval to solidify boric acid waste to a stable waste form in 1991. The final NRC approval followed in January 1993. Because boric acid from the primary let-down is not recycled at Surry, approximately one thousand 200 liter drums of Class A waste were generated to Class B standards during the first two and one half years of operation. While the bitumen system worked extremely well, it was believed that the process could be improved to reduce the volume of waste generated.

Virginia Power contracted the ADTECHS Corporation, owner of the approved topical report and Process Control Program (PCP), to develop a PCP to process the Class A waste to Class A standards and improve volume reduction. ADTECHS approached the NRC with the Class A PCP. The NRC's position was that the January 1991 "Technical

Position on Waste Form" Revision 1, provided adequate guidance on the characteristics expected of a Class A solidified waste form. The Class A PCP and waste processing requirements were reviewed by the State of South Carolina Department of Health and Environmental Control and Chem Nuclear and found to be in compliance with the Barnwell License. The Class A PCP was finalized in January 1994.

Class B PCP Experience

The Class B PCP:

Allowed a maximum solid-to-bitumen ratio of 38:62. The system operated at maximum target feed rates with the solids-to-bitumen ratio driving the system efficiency.

Processed an average of 946 liters of concentrated waste liquids at 10.4 percent solids to generate one bitumen drum. This resulted in an average volume reduction of 4.7.

Required the concentrated waste pH be maintained in the narrow range between 9.0 and 9.5.

Required 10 to 14 hours of cooling/hardening time for each bitumen drum. Resulted in the average contact radiation levels of the drums between 125-150 mrem/hr.

Class A PCP Experience

The Class A PCP:

Increased the maximum waste solid-to-bitumen ratio to 60:40 allowing the mechanical limitations of the equipment to drive the system efficiency.

Increased the average concentrated waste volume processed to generate one bitumen drum to 1325 liters at 11.1 percent solids. This resulted in a volume reduction of 6.6.

Expanded the concentrated waste pH range between 7.0 and 10.0.

Reduced the average cooling/hardening time to between 6 and 8 hours because of the increased solids loading. This resulted in less contraction of the final product.

Increased the average contact radiation level of drums to between 350 and 400 mrem/hr. Because processing evolutions are performed remotely, the higher dose rates did not appreciably increase dose to personnel.

Reduced the volume of waste generated by 25 to 30 percent, thus saving Virginia Power approximately 25 to 30 percent in shipping and burial costs. The waste reduction amounted to a savings of approximately 120 to 130 drums per year.

Effectively increased the drum storage area capability from 1.5 years (470 drums/year) to 2 years. The drum storage area can store up to 693 drums.

To ensure the waste solidified using the Class A PCP is Class A and not Class B, a comparison is made of the liquid waste batch isotopic analysis report to a list containing the highest isotopic activity of previous batches.

A simple calculation using these comparisons can determine potential Class B waste. The waste feed rate of the potential Class B waste can be reduced to ensure the solidified drum is Class A.

Other Experiences with Bitumen Solidification

Strong acids, such as sulfuric acid, tend to hold heat longer thus increasing the bitumen cooling/hardening rate.

A higher waste solids-to-bitumen ratio increases compressive strength and produces less contraction in the final product.

Solvent cleaning and hot water soaking is required every 80 to 100 drums. Extending the cleaning time may result in a higher product temperature, excessive TFE vibrations, high TFE Drive Motor amperage and high upper processing area dose rates.

Solvent cleaning reduces bitumen buildup in the distillate and ventilation pathways to improve evaporation. The solvent is non-hazardous. Each cleaning uses about 40 to 55 gallons of solvent. This solvent is reused several times and can be disposed of like oil.

Hot water soaking is performed after each solvent cleaning to dissolve boric acid and sodium borate crystals which plate out in the processing area. This reduces dose rates and also improves vapor flow out of the TFE.

SUMMARY

A Bitumen System is designed for personnel and environmental safety. It operates at moderate temperatures and incorporates remote technology to support ALARA goals. The Bitumen Solidification Thin Film Evaporator System is an excellent choice for processing concentrated liquid waste because of the economical packaging and binding materials used, the versatility of the types of waste that can be processed and the

competitive volume reductions achieved with both the Class A and Class B PCPs. Also, the processed drums can be easily stored and easily shipped. As operational experience continues and is further refined, additional economic advantages are sure to follow.

NUCLEAR ELECTRIC'S APPROACH TO THE MANAGEMENT OF INTERMEDIATE LEVEL RADIOACTIVE WASTES

Roger E. Streatfield
Engineering Division
Nuclear Electric plc
Barnwood, Gloucestershire
United Kingdom.

ABSTRACT

Nuclear Electric (NE) is the major nuclear power plant operator in the United Kingdom (UK), and operates six Magnox and 5 Advanced Gas Cooled Reactor (AGR) stations all with twin reactors, a PWR, and has two Magnox stations in the early stages of decommissioning. Quite a range of waste types are produced, from lightly contaminated items suitable for shallow land burial to more active materials such as sludges and resins. Since 1959 Low Level Waste (LLW)* has been routinely disposed of to a shallow land burial site at Drigg in Cumbria, operated by British Nuclear Fuels plc, and this is the basis of the NE disposal strategy for this category of wastes. No disposal route is available at present for Intermediate Level Waste (ILW) and such wastes are currently accumulated in purpose built facilities. Eventually these wastes will be disposed of to deep land burial.

With the exception of some ILW which has already been treated and Magnox fuel element debris, the general approach for ILW is encapsulation in a cementitious matrix, either intimately mixed in the case of resins and sludges or grouted in the case of discrete solids. Wet slurry wastes are organic/inorganic ion exchange materials from pond water treatment, filter pre-coat material, sludges arising from fuel clad corrosion in storage ponds and from drains and laundry wastes. They are stored under water in special tanks, will be retrieved hydraulically and passed through a de-watering plant to ensure that the feed to the encapsulation plant has acceptable properties.

Magnox fuel assembly components are items which are removed at the station prior to transport of the fuel off-site for reprocessing, and are mainly magnesium alloys. As such they are amenable to a dissolution process from which the effluent can be discharged to sea following removal of insoluble material containing virtually all the activity. One plant is operating with this process.

NE is currently investigating a process in which ion exchange resins are destroyed by chemical means, resulting in a reduction in the predicted organic inventory of the repository and a significant reduction in the waste volume. The activity remains with the small amount of secondary waste residue which is encapsulated in cement as ILW.

NE is involved in the search for novel ion exchange materials which either show a marked increase in their adsorption capacity for particular chemical species and can therefore yield decreased arisings of ion exchange resin or show a high degree of specificity for a particular species. There is also the strategic element in guarding against the non-availability of currently used materials. Electrochemical

ion exchange is another area of interest in which the normal process is enhanced by the application of a potential. The process appears to be very versatile, however direct experience so far is limited. Ultrafiltration is being investigated as a means of removing colloidal or soluble radioactive species. These are either rendered insoluble by chemical addition or absorbed onto added seed material and removed by cross-flow filtration.

BACKGROUND

When the UK Government privatized the Electricity Supply Industry in 1990, the nuclear component of the Central Electricity Generating Board (CEGB) was retained in the public sector under the name Nuclear Electric (NE), with responsibility for operating Magnox and Advanced Gas Cooled Reactor (AGR) stations and for completion of the Sizewell B Pressurized Water Reactor (PWR). At its formation NE inherited from the CEGB a well developed strategy for the management of those radioactive wastes arising during station operation.

Subsequently the strategy was updated to take into account the new Company's objectives, and is kept under review to ensure that NE is able to take advantage of developments in waste management techniques and to respond to changes in legislation, etc. At all times NE has endeavored to produce a strategy which not only meets its own stringent requirements but which is consistent with the UK Government national policy. Reference (1) gives a recent statement on NE's radioactive waste and decommissioning strategy.

Previous documents relating to the NE waste management strategy deal primarily with waste management issues on a Company-wide or generic basis, though site specific aspects are mentioned as necessary, for instance in discussing potential shortfalls in accumulation capacity. A further and more detailed appraisal is currently under way and this will result in each power station having its own specific documentation detailing the waste management strategy for that site. This is being carried out partly at the request of the UK nuclear industry regulators (HM Nuclear Installations Inspectorate HMNII, Ministry of Agriculture, Fisheries and Food MAFF and Her Majesties Inspectorate of Pollution HMIP), but is timely for other reasons. Firstly great progress has been made in recent years in the development of technologies for the retrieval, processing and packaging of ILW and it is appropriate to consider the ramifications of this for individual sites. Secondly plans for the construction of a UK deep repository for the disposal of wastes are becoming more clear and it is useful to consider any effects this may have on current and future waste management proposals. Thirdly as the Magnox stations approach the end of their useful lives it is appropriate for NE to begin to plan for the retrieval and packaging of the radioactive ILW at its sites, converting strategies for the management of ILW into action plans.

INTERMEDIATE LEVEL RADIOACTIVE WASTE ARISINGS AT NE POWER STATIONS

Both wet and dry operational ILW arises as a result of spent fuel handling, plant maintenance and the treatment of gaseous and liquid effluent. To date these wastes have been accumulated in purpose built facilities, approved by the UK Regulator and in most cases sized to accommodate the predicted station lifetime arisings. The type of accumulation facility depends upon the waste type, with wet slurry waste being kept under water in tanks and other solid waste being stored dry. The initial characterization of ILW is into the following types:

- Wet slurry wastes
- Fuel assembly components
- Miscellaneous contaminated items (MCI)
- Miscellaneous activated components (MAC)
- Desiccant/catalyst/charcoal

Wet slurry wastes comprise organic and inorganic ion exchange materials, filter pre-coat materials often mixed with sand, sludge or ion exchange resins, sand and sludge materials which can contain detergents and other chemical agents from the laundry, wash areas, etc. and oily sludge. In the case of the Sizewell B PWR this category includes the primary and secondary ion exchange resins and boric acid concentrate from the evaporator. These wastes derive from the management of liquid effluent, which involves collection, monitoring, treatment for the removal of activity as appropriate, further monitoring and discharge against approved limits via the station cooling water outfall.

Fuel assembly components are items which are removed from the fuel, and for Magnox reactors this includes gas flow diverters, fuel spacing components and a variety of

end fittings. Most of these fuel components consist of magnesium with small alloying additions such as aluminum and zirconium, although other alloys and graphite are found at some stations. They are removed at the station prior to transport of the fuel for reprocessing. AGR fuel element debris consists of various steel and graphite components, many of which can be reduced in size for more efficient storage. Miscellaneous contaminated items (MCI) comprise a range of combustible and non-combustible materials including items of plant arising from maintenance and consumable items such as cartridge filters. Miscellaneous activated components (MAC) comprise irradiated reactor components including shield plugs, stand pipe assemblies, flux measurement probes, control rods and fuelling machine grabs. Desiccant is used to dry the reactor coolant gas on all AGR and some Magnox reactors, and catalyst only arises on AGRs. Alumina, silica gel and molecular sieve desiccants have been used and in the case of some AGRs desiccant containing platinum/alumina catalyst can arise as a mixture in the accumulation vault. The activity in the desiccant is dominated by tritium.

INTERMEDIATE LEVEL RADIOACTIVE WASTE MANAGEMENT AT NE POWER STATIONS

Active Effluent Treatment Plant (AETP)

All stations have plant items such as filters and ion exchange units which, together with the accumulation facilities and the discharge system, comprise the AETP. On some stations the AETP is located in a separate building connected to the reactor building by a pipe bridge or tunnel. Where appropriate collection of the primary wastes is with segregation on the basis of activity level and/or chemical composition, as this may dictate the treatment technique. The waste treatment produces secondary wastes.

In addition to the main purpose of filtering and monitoring all liquid effluent prior to discharge, the AETP will also provide a route for collecting backwashed sand or filter pre-coat material, used ion exchange resins from effluent treatment and pond water clean-up, sludges from tanks and similar materials, and directing them to storage tanks. When exhausted pond water ion exchange resin or sludge is sent to storage, the AETP would process any supernatant liquid prior to discharge. Active drain liquids are collected from areas such as the reactor cooling ponds and floor and sump drains from the AETP. These liquids would be treated to remove oil using a separator tank or coalescing plate separator, and particulate material removed in a sand pressure filter. The latter utilizes a bi-modal particle size distribution to give good filtration efficiency and long service.

Figure 1 shows a flow diagram for the liquid effluent treatment plant at the Heysham 2 AGR, which also has a number of waste accumulation facilities and a high degree of waste stream segregation.

Fig. 1.

Pond Water Treatment Plant (PWTP) Effluent

All Magnox stations have a pond water filtration loop to remove particulate material, and a bleed from this loop forms a second loop for chemical control. In the latter water is passed through cation and anion ion exchange units, which are preceded on some stations by an additional guard bed to remove caesium using a non-regenerable ion exchange material. AGRs have a similar pond water treatment loop with mixed bed ion exchange resins. These are not regenerated but replaced when exhausted and there is not in general a requirement for dedicated caesium removal plant due to the low incidence of AGR fuel clad failure.

Active Laundry Effluent

This is a high volume but low specific activity waste and treatment is usually filtration in deep bed filters containing anthracite, sometimes coupled with cartridge filters prior to monitoring and discharge. Ion exchange treatment is usually unnecessary for this effluent.

Tritiated Water

This arises from regeneration of the silica gel desiccant in the reactor coolant gas dryers on AGR stations. It is transferred to tanks or drums prior to sampling, monitoring and discharge against approved limits via the station cooling water system. No specific treatment is carried out.

Secondary Wastes

Wastes arise as a result of encapsulation plant operation, and consist of active drains, ion exchange and filter materials from the treatment of effluent before discharge, filters from the filtration of gaseous discharges and possibly residues of encapsulant. Also there will be sludge and residues from the treatment of Magnox

debris by the carbon dioxide dissolution process. These secondary wastes will generally be accommodated in the existing waste accumulation facilities, noting that some of these may be extended during station life.

Accumulation Facilities

Early accumulation facilities were simple shielded mild steel or concrete tanks, which often hold several related waste streams. More recent designs incorporate waste stream segregation, double containment and improved accessibility. Many of the accumulated sludges and resins on Magnox stations are notionally classified as ILW but it is likely that prior to retrieval they will be shown to be LLW and therefore disposable to the UK shallow waste disposal site after solidification. Since about 1990, a significant amount of these low level wastes have been successfully retrieved and immobilized in cement in a mobile plant, and sent for shallow disposal.

Historically the Magnox power stations have used a range of materials for effluent and pond water treatment, and these have not generally been segregated, but stored under water in shielded tanks. The AETP sludges, although nominally ILW may be LLW, and the radionuclides will be a mixture of activation and fission products with some actinides. The fission products, especially caesium 137, will dominate the activity in the resins.

Encapsulation Plant

NE policy is to use either fixed or mobile encapsulation plants depending on the particular circumstances at individual sites. Trawsfynydd Magnox power station, which, due to restrictions on discharges into an inland lake has always generated more active waste arisings during operation than coastal stations, has a fixed encapsulation plant (2) which operates with a polymer encapsulant. The other NE fixed plant is located at the Sizewell B PWR and is intended to encapsulate ILW arisings in cement on a routine basis for interim storage prior to disposal in the proposed deep waste repository. All other Magnox and all AGR stations are located on coastal or estuarine sites and therefore have lower secondary waste arisings due to the higher discharge authorizations. NE's strategy is that these stations will be served by mobile encapsulation plants, one for ILW and a smaller, simpler one for LLW.

It is anticipated that the mobile ILW encapsulation plant will be straightforward in operation, with emphasis on the quality of the product and the Quality Assurance (QA) record for each package produced. A cylindrical `liner', nominally of 2.6 m3 capacity, complete with a mixing paddle and lid will be removed from the store and moved into the active plant area through appropriate barriers. The waste is monitored into the drum and de-watered as necessary. With the mixing paddle rotating at the correct speed the ingredients of Ordinary Portland Cement (OPC), Blast Furnace Slag (BFS) and other additives will be metered into the drum and the mixing continued for the required time. When the mixing is stopped and the motor drive withdrawn, the drum is moved to another location within the active conditioning area for curing or setting. The drum contents are tested for set by the use of a weighted point and any surface (or bleed) water may be removed. The drum then passes to another location where an inactive grout is added to form a cap, and when this is set the lid is put in place and bolted or welded on. The surface of the drum may then be decontaminated if needed, the QA record checked and the drum removed to the on-site storage facility. The drum is identified by means of a laser etched alpha/numeric hexadecimal number which allows a high degree of internal cross checking to cover the possibility of operator error in entering the number into the computer.

Figure 2 shows the mobile ILW encapsulation plant with the transportable unit, liner handling equipment, the processing area and the processed waste storage facility. Figure 3 is a diagram of the NE large liner for the encapsulation of sludges and resins in the mobile plant. It is manufactured from thin stainless steel, the components being formed by rolling, spinning and pressing and welded together by full penetration welds. The materials, welding procedures, construction methods and inspection standards all meet the requirements for packaging radioactive wastes.

Operation of the mobile LLW encapsulation plant is similar in principle, but using 200 liter drums or large liners, and will not have to meet the stringent QA requirements of the ILW product. Experience has shown that the plant is reliable, easily decontaminated for transport, the product drums have very low external radiation levels and the dose to the operators is well within acceptable limits.

Fig. 2.
Fig. 3.
Inventory of Radioactive Wastes
Since the mid-1980s a national inventory of radioactive wastes has been prepared which is funded jointly by UK Nirex Limited and the Department of the Environment. The last completed inventory was in 1991 (3,4 and 5) and the data collection phase has been completed for the current inventory. For each identified waste stream, information is collected on existing and future stocks based upon current and estimated future arisings, physical and chemical properties, radiochemical content and conventional toxicity such as heavy metals and asbestos. All waste producers input to the inventory and the information is checked and validated as far as possible in order to form the basis of the quality assurance system under which wastes will be packaged for disposal. NE is responsible for nearly 600 separate waste streams, including future PWR sources and those which will arise during decommissioning.
NUCLEAR ELECTRIC EXPERIENCE IN MANAGING ARISINGS
Encapsulation in Cement
In common with many other waste producers the NE approach is to immobilize wastes in cement, typically a mixture of Ordinary Portland Cement (OPC) and Blast Furnace Slag (BFS). For slurry and wet wastes this is achieved either by metering the waste, in a pumpable form such as a slurry, into a waste container containing premixed BFS/OPC or alternatively adding the BFS/OPC to the waste, depending on the flow characteristics and the density of the waste material. In either case the contents of the waste container are continuously mixed by a rotating paddle which is left in the container and becomes part of the wasteform. For solid dry wastes, these are either grouted individually in a container or for material such as Magnox debris it can be compacted into a single billet and grouted. Grouting solid wastes sometimes requires a containment cage or restraint to stop items floating in the cement.
The main area of development work has been with wet slurry wastes, including ion exchange resins, sludges, slurries and filter pre-coat material. These wastes have a fairly wide range of chemical and physical properties, and have been addressed as individual wastes at present based on knowledge of their origin and operational practice on stations. However, as some of the wastes will arise as mixtures a methodology is being developed that will permit formulations to be specified for mixed wastes based on those for the individual wastes.
It is usually inappropriate to work at the development stage with actual radioactive wastes, and considerable effort is devoted to identifying suitable simulants. In some cases the wastes can be successfully simulated by non-radioactive unused material, however, this can represent a problem if the materials are no longer available. This is the case with some of the ion exchange materials used on Magnox stations. In the case of sludges from the AETP the composition is complex and a range of materials are assembled to simulate the waste successfully. However the materials may also suffer some form of chemical and/or physical degradation in use and this also has to be taken into consideration.
A formal procedure has been drawn up for formulation development work involving small and large scale testing of the formulation and evaluation of the product properties relevant for storage, transport and disposal. During the course of the development program a number of potential difficulties have been identified with certain wastes, such as the presence of boron which can delay the setting of cement and the presence of certain resins and filter aid materials which have a propensity to swell and cause the cement wasteform to break apart. All development work has followed a similar line, starting with small scale scoping trials to determine the overall performance of selected BFS/OPC mixtures. This may involve monitoring the time for a sample to set against pre-determined criteria of hardness, general appearance, the presence of free water on the surface (bleed water), and how long any water takes to be re-absorbed. The behavior of samples after prolonged immersion in water was also examined and samples prepared for long term monitoring. At this stage some optimization of the waste loading was carried out and any particular difficulties identified. This has on occasion led to the consideration of alternative formulations using specialized cements, materials other than BFS and additives to counter particular physical or chemical difficulties.
The next stage in the development work was larger scale production of samples for product evaluation testing, in which samples were subjected to a wide range of

standardized tests which have been developed for cement formulation development work. For example, the mixing behavior can be characterized by properties such as the torque required by the mixing motor and the viscosity of the mix. Samples were monitored for mechanical properties including compressive strength as measured by the transmission of ultrasound, elastic modulus, dimensional stability, and resistance to fragmentation under water immersion testing. Porosimetry has been carried out after typically 7 days and 90 days augmented with pore water analysis after 28 days and 90 days. Other samples were subjected to gamma-irradiation after 120 days curing, at a rate of about 2 x 103 Gy h-1 and to a total dose of 9 MGy. This represents an accelerated irradiation test in terms of dose rate but is to the estimated whole life dose to be received by the wasteform in the repository. All materials used in the development work are closely prescribed, and the radioactive wastes are represented by simulants which have been agreed to have the necessary physical and chemical similarities to the actual waste.

The underlying requirement in all the cement formulation development work has been to produce a formulation which is robust and can successfully encapsulate all the envisaged extreme compositions of a particular waste. The formulation should also provide the encapsulation plant with a satisfactory operational window within which the components for the encapsulation process can be accurately monitored over the required range. The achievement of these objectives will result in all the wastes being immobilized to form a strong monolith within the container, which is resistant to degrading effects of the environment and will therefore retain its integrity for the required period. This includes interim storage at the station, followed by transport to and possibly further storage at the repository, emplacement in the repository and backfilling. The integrity of the wasteform is also supported by the corrosion resistance of the container, and the overall Quality Assurance record of the package will demonstrate that it meets all regulatory requirements for transport to the repository.

Encapsulation in polymer

Polymer offers particular advantages including higher waste loading, increased processing rate and greater tolerance to variations in waste material and composition. Its major disadvantages are that it is much more costly than cement, and would increase the organic material content of the repository. For these reasons its use for wastes at sites other than Trawsfynydd is being kept under review.

Magnox Dissolution

There are significant amounts of Magnox fuel debris in accumulation facilities at Magnox stations, and some is in a partially corroded condition which could make retrieval more difficult. NE has developed a dissolution process in which the Magnox alloy is dissolved in carbonic acid, which is then filtered, checked for activity, treated by ion exchange where necessary and discharged to sea. The insoluble secondary waste, which represents several per cent of the original mass, contains most of the activity and is accumulated pending encapsulation in cement. A plant using this technology has been in operation for some time at Dungeness B Magnox power station, and Fig. 4 shows a cutaway view identifying the main plant areas. Reference (6) compares the dissolution process with encapsulation in cement and other options and (7) describes the process and equipment for the Dungeness B plant.

Fig. 4.

Safety Case for Continued Accumulation

As a condition of granting a site license the UK Regulators now require that all NE stations have a formal safety case and comprehensive safety case documentation for all safety related activities undertaken on site. This includes the radioactive waste processing and accumulation facilities at each station and covers both current operational safety and long term issues. For all facilities this requires the development of safety arguments for continued waste accumulation at power stations based upon Hazard and Operability (HAZOP) studies. In the case of Magnox stations the safety cases must be available on the Long Term Safety Review (LTSR) timescales laid down by the UK Secretary of State for Energy. In order to meet these timescales NE has developed a generic approach augmented by site specific documentation.

The CEGB strategy was based upon an assumed 30 year lifetime for Magnox plant and 25 years for AGR plant. NE aims to extend the life of these stations, possibly up to 40 years. A direct result of this extended lifetime is that for some ILW waste streams, where accumulation capacity would have been adequate, there is now the possibility

that action will need to be taken to provide more capacity or to undertake retrieval and processing.

Waste Sampling and Characterization

An essential input to the radioactive waste encapsulation development program and all aspects of waste management is the acquisition of sampling and analysis data to provide information on the physical, chemical and radiological characteristics of the waste. This will enable appropriate simulants to be developed for inactive test work, in addition to providing the database for the development of a methodology for the encapsulation of mixtures of wastes. An extensive program of sampling and analysis is both time consuming and expensive. Where several wastes have been accumulated in the same tank or vault over a period of time without mixing, there is also the question of correct interpretation of the data with respect to location within the tank particularly the depth. NE is therefore looking at operational records to identify any information which can be used to augment sampling and analysis data.

AGEING OF WASTES

The NE strategy for waste management takes account of ageing of both accumulation facilities and of the wastes themselves, noting that some wastes could age in a manner and to an extent that there may be difficulties to be overcome in the identification of a simulant or in the encapsulation formulation. Six main mechanisms are identified by which wastes may change their physical and chemical properties with time. Thermal degradation due to heating or thermal cycling of a waste can produce both physical and chemical changes. However, waste accumulation facilities remain below 50C and no evidence of alteration in waste phases has ever been noted by NE. Chemical degradation and corrosion can result from interactions between the waste components and degradation products from adventitious or naturally occurring chemicals such as water and oxygen. Metals will degrade by oxidative corrosion reactions whereas non-metallic inorganic compounds such as clays could degrade over a long period to form gels due to alkaline hydrolysis. Organic materials can degrade by a number of mechanisms. Radiolytic degradation of wastes such as inorganic ion exchange materials, desiccants and clays will produce minor structural changes and perhaps a small amount of oxygen. Organic ion exchange resins will show some loss of functionality and an increase in the level of cross linking, neither of which represents a particular problem. Common to both situations will be the radiolysis of water which will initially produce H2 and O2 as stable products although most of the latter may be scavenged by impurities. Microbiological degradation is not in general supported by inorganic materials and the enzymes that effect the degradation are more effective with simple organic molecules or those with a regular structure rather than those with irregular non-repeating structures. Physical mechanisms which result in damage to waste materials (which in this context constitutes ageing) would be known from plant operational records, and usually fall into the category of mechanical handling and compression due to the weight of accumulated waste in a facility. Both tend to cause the production of smaller particles. Physico-chemical mechanisms are processes such as Ostwald ripening which is mainly a characteristic of colloidal materials, coagulation and flocculation, crystallization, change in electrokinetic properties and loss of volatile species.

DEVELOPMENT AREAS

Desiccant Washing

The water content of AGR coolant gas is controlled using a silica gel desiccant with hot gas regeneration. Desiccant capacity falls during service and the drier beds are periodically replaced, giving rise to silica gel that may contain sufficient tritium to require classification as ILW. A process has been developed whereby most of the tritium is removed by water washing, allowing the desiccant to be classified and disposed of as LLW. The tritium is discharged through normal station discharge routes within authorization.

Ultrafiltration (UF)

Many radionuclides exist in aqueous streams in an insoluble form and under such circumstances UF can potentially play a significant part in their treatment. Unfortunately many of the species to be removed from NE's wastes are soluble or in microcolloidal form under normal operating conditions, and one possible solution is to alter the pH, for at higher pH's many metal ions are easily precipitated as their hydroxides. However there are disadvantages to this if the pH has to be raised significantly, both on the grounds of cost and ease of operation, and important

isotopes such as Cs137 would still not be removed. An alternative approach is to add small quantities of an additive or "seed" material onto which the radioactive species are absorbed, but which is itself insoluble.

A number of seed materials have been identified and are mostly inorganic substances with ion exchange properties typically used in a finely divided form at concentrations in the range 10-100 ppm. No single seed has been identified which can provide a satisfactory performance over a wide range of contaminants and the main thrust of the work has been to develop cocktails of seeds for this purpose. Laboratory work (8) has identified suitable chemical conditions in terms of seed mixture and composition, pH and the number of processing steps, by which PWR effluent might be treated in a UF plant. The results of a demonstration at pilot plant scale using selected seeding material has also been reported (9). The results have been substantiated using real effluent from the Doel PWR in Belgium and it is probable that the same methodology would yield satisfactory materials for Magnox effluent.

Wet Oxidation (WETOX) of Ion Exchange Resins

A number of methods have been suggested for reducing the organic content and volume of organic ion exchange resins, of which chemical oxidation is generally the most preferred because it minimizes secondary waste arisings. Development of a wet process is being pursued in the UK and the complete process involves a radioactive waste concentration step by evaporation and solidification of the residue. The process can therefore reduce waste volumes for disposal, improve encapsulated product quality and enhance the long term safety of geologic disposal by reducing the organic inventory of the repository.

NE is a partner in a process development program which includes small scale experiments with actual radioactive wastes (ILWs) as well as economic and safety assessments of the plant. However the main feature is the construction and operation of a mobile pilot plant that is undertaking radioactive demonstration runs in order to allow confident extrapolation of the process and costs to a full commercial scale. The program specifically addresses NE ILW ion exchange materials.

The adopted process employs an aqueous hydrogen peroxide feed to resins suspended in water at 100C and at atmospheric pressure. A dissolved metal ion catalyst, e.g. Fe2+ and/or Cu2+ is used. The main reaction products are CO2, H2O and mineral salts e.g. sulphate. The hydrogen peroxide process readily destroys about 95% of organic material in a batch process. The remainder can be destroyed but with increasing difficulty and expense. This is expected to be alleviated in the mobile plant by use of a semi-continuous approach. Other chemical, e.g. silver II oxidation, and physical, e.g. UV irradiation, processes may be applicable but tend to be expensive and/or at an early stage of development. On economic grounds a single step oxidation is preferred.

The active mobile pilot plant has been constructed within a single ISO container suitable for normal road transportation. The main plant items are the reaction vessel, batching vessel, condenser, condensate tank, scrubber, HEPA filter, pumps, agitator, air cooler and gas analyzers. Feeds of resin and peroxide will be semi-continuous but evaporative concentration of residue will be performed on a batch basis within the reactor vessel. The design throughput for resin is 0.2 m3 day-1 with an availability expected around 150 days year-1. Reference (10) describes the small scale and pilot scale work together with the conclusions reached for each main type of resin.

Electrochemical Ion Exchange (EIX)

This is an ion exchange process in which the movement of ions between solution and ion exchange material is controlled electrochemically, and is being developed for application to liquid waste streams arising at Magnox, AGR and PWR plants. The ion exchange material is regenerated simply by reversing the polarity of the electrodes and the volume of regenerant liquor is typically 1-2 bed volumes, suitable for direct encapsulation in cement. This contrasts with the behavior of conventional ion exchange materials which are often not regenerable (and hence give rise to appreciable volumes of spent waste which have to be disposed of) or require chemicals such as acid or alkali for regeneration. Each regeneration cycle produces at least a few tens of bed volumes of secondary waste and this requires further treatment before it can be encapsulated for disposal.

Novel Absorbers

Ion exchange materials currently used are quite adequate, however, there is a need

to monitor developments and identify alternative materials which can be specified should those presently employed cease to be manufactured, and to identify new materials with superior properties to those currently used. The important factors are an improved capacity such that rates of arising can be reduced, and improved removal of key radionuclides such as Co60 or Cs137 with ion specific absorbers to produce a stream with lower activity levels.
NE monitors these developments in order to be able to respond should any significant progress be made in an area of relevance to the Company, and also participates in a UK nuclear industry group which undertakes tests of new absorber or ion exchange materials. Such tests involve contacting the materials with several simulated radioactive wastes and measuring how much radioactivity remains in the solution at various times up to 24 hours. In the past five years a significant number of materials have been investigated, including a number of surface modified inorganic materials, complexing ion exchange resins and more general absorbers.

WORKSHOP SUMMARY
Workshop Co-Chairs: J. S. Devgun, ANL;
G. Subbaraman, Rockwell International
"HOW CLEAN IS CLEAN?"
CLEANUP CRITERIA AND PRACTICES
J. S. Devgun
Argonne National Laboratory
9700 South Cass Avenue
Argonne, IL 60439

This workshop was the third in the "How Clean is Clean?" series. Last year's workshop focused on cleanup standards, guidelines, and pathways analysis models, and the year before, on the statistical approaches to final release of cleaned-up sites. The number of sites requiring cleanup in the federal and private sectors runs into thousands, and the cleanup costs are projected to be in hundreds of billions of dollars. With cleanup actions at a number of the sites earnestly in progress, the objective this year was to focus discussion not only on the criteria but also on the practices, i.e., the application of the criteria in a cleanup project.
A panel of experts was convened to discuss and debate the issues related to the theme of the workshop. The panel included representatives from the U.S. Department

of Energy (DOE), U.S. Environmental Protection Agency (EPA), U.S. Nuclear Regulatory Commission (NRC), New York State's Department of Environmental Conservation (NYDEC), Canada's Atomic Energy Control Board (AECB), the International Atomic Energy Agency (IAEA), and the two workshop Co-Chairs.

This year a true workshop-like setting was also provided breaking out into three focus groups and then reconvening for a general discussion. Each focus group was led by one or two discussion leaders. The topics for group discussion were:

1) Risk-Based Criteria vs. Generic Concentration Limits
(Subtopics: Application in the Field - Pros and Cons, Site-Specific Criteria, Pathways Modeling, ALARA),
2) Criteria vs. Cost
(Subtopic: Impact on Project Cost of Cleanup Criteria Being Based on Risk, Technology, Background Level, Detection Limits, Regulations),
3) Who Should Decide?
(Subtopics: Federal Regulators, States, Local Communities, Technical Basis vs. Public Acceptance).

This new format provided an opportunity for the participants to fully contribute their own knowledge, experiences, and ideas, in addition to those of the panelists, discussion leaders, and workshop co-chairs. The primary purpose of this workshop was to provide a forum for discussion and debate to the approximately 70 people who registered for the workshop. A package of papers, notes, or viewgraphs was provided to each participant in advance to stimulate discussion.

In the panel discussions, Anthony Kluk of DOE discussed the DOE Order 5400.5 which lists the release guidelines used by DOE for decontamination of equipment, structures, and sites. Implementation of these guidelines is presented in DOE/CH 8901, "A Manual for Implementing Residual Radioactive Material Guidelines. A Supplement to the U.S. Department of Energy Guidelines for Residual Radioactive Material at FUSRAP and SFMP Sites," June 1989. The release guidelines for surface contamination listed in DOE 5400.5 are generally consistent with standards established by the NRC and equivalent to Section 4 of Regulatory Guide 1.86, "Termination of Operating Licenses for Nuclear Reactors." The DOE applies these limits to non-reactor facilities as well as reactor facilities. These limits apply to interior equipment and building components that are potentially recoverable or reusable.

The guidelines for residual radionuclides in soil are divided into two groups. Generic guidelines exist for thorium and radium. These generic guidelines for Ra-226, Ra-228, Th-230, and Th-232 are: 5 pCi/g, averaged over the first 15 cm of soil below the surface; and 15 pCi/g, averaged over 15 cm-thick layers of soil more than 15 cm below the surface. (This guideline assumes secular equilibrium. If secular equilibrium does not exist, the limit is applied to the isotope with the higher concentration.)

Derived guidelines are used for other radionuclides for residual soil contamination. The basic dose limit, 100 mrem/yr, and the ALARA principle are the basis for these derivations and DOE/CH 8901 specifies the procedures to be used for this determination. External gamma radiation is limited to 20 R/h above background for an average level inside a building or habitable structure.

Practical implementation of the guidelines was discussed at two sites. One of these is Santa Susana Field Laboratory located in eastern Ventura County California. The other is the Laboratory for Energy-Related Health Research, which consists of several DOE-owned buildings located on a fifteen-acre site leased from the University of California, Davis.

The EPA representative discussed Risk Assessment Guidance for Superfund as described in report EPA/540/R-92/003. A demonstration calculation (by Steve Dean) with the risk assessment code RISKCALC (version 3.0) was presented for a hypothetical site with U-238 contamination.

Charles Willis of the NRC discussed the quarter-century-old guidance of Regulatory Guide 1.86 which continues to be used as new criteria are being developed. Despite its age, problems continue to be encountered with the interpretation and scope of this guidance.

Specifically, for Shoreham and for Fort Saint Vrain, the NRC staff concluded that, in accordance with the ALARA principle and for consistency with the criteria for other nuclides, the surface contamination criterion for tritium and for iron-55 should be increased and for Shoreham the maximum value was 200,000 dpm/100 square

cm. At Shoreham, the exposure rate above background from accessible surfaces was limited to 5 R/hr and bulk contamination was not allowed to exceed 8 pCi/g. For Shoreham, the DECON option was selected. The termination survey was conducted in accordance with the June 1992 draft of NUREG/CR-5849 and it entailed over 230,000 measurements.
Paul Merges (NYDEC) discussed cleanup guidelines [Technical and Administrative Guidance Memorandum (TAGM) 4003 Cleanup Guidelines for Soils Contaminated with Radioactive Waste] adopted by New York State in September 1993 for radioactively contaminated sites. The policy in the TAGM states that the total effective dose equivalent to the maximally exposed individual of the general public, from radioactive material remaining at a site after cleanup, shall be as low as reasonably achievable and less than 10 mrem above that received from background levels of radiation in any one year.
Four sites were reviewed: 1) EAD in Tonowanda, New York; 2) Off Site Properties in West Valley, New York; 3) Cintichem Site in Tuxedo Park, New York; and 4) Radium Chemical Site in Queens, New York.
Ivan Vovk of IAEA emphasized the need for internationally agreed criteria. Recently the IAEA has begun preparation of a report which intends to document the latest international approach to the development of cleanup criteria. The approach stems from ICRP publication 60 and the distinctions made between "practices" and "interventions." The objective is to develop a coherent framework through which a logical approach to decision making for all situations can be developed. An IAEA Working Group has been established and discussions are going on for developing criteria for "practice" and "intervention" situations.
Jas Devgun explained the relevant key recommendations of ICRP 60 and the distinctions between "practice" and "intervention." A paper on the topic is available in the Proceedings of Waste Management '92, Vol. 1, p. 499-503.
Bernie Zgola of AECB presented the Canadian approach to the material and site release based on case-specific dose optimization. Decommissioning case-studies discussed included Atomic Energy of Canada Limited (AECL) facilities at Tunney's Pasture, WR-1 Reactor, and the Elliot Lake decommissioning of mines and mills.
The discussion group format on the three topics provided an open forum for groups of participants to discuss and debate these topics. Donald Wood (Westinghouse Hanford Co.), Catherine Sigmon (ORNL), John Corley (Consultant), Adam Levin (TLG), and Lars Soholt (LANL) served as discussion leaders. Each group presented their key points when all participants reconvened for a general discussion. Risk-based cleanup criteria were generally favored by the participants rather than the generic limits. The Canadian approach of case-by-case was generally praised as a sensible approach. It was agreed that the public needs to be better informed of the cost to society of cleaning up sites to background levels for little or no additional benefits in terms of reduced risk. It was also highlighted that the local public at the site should be included in the decision making process from the very beginning of a cleanup project.
In the evaluations, a majority of the participants rated the workshop in the "very good" to "excellent" category.
