in the field, T Plant personnel (both at 221-T and 2706-T) can provide a valuable service by developing, demonstrating, and testing decontamination tools and techniques that can be transported to the field.
A single facility or approach for dealing with the diversity and volume of possible waste streams is not practical. The optimal solution will likely involve a combination of alternatives and will be phased in as the site decontamination/treatment needs evolve and regulations change.

RECYCLING RADIOACTIVELY CONTAMINATED MATERIALS: EXPERIENCE AND EXPECTATIONS
Dewey E. Large
The Scientific Ecology Group, Inc. (SEG)
ABSTRACT
Just in recent years, Federal Agencies, especially the Department of Energy (DOE); the Department of Defense (DOD); the Environmental Protection Agency (EPA); and the Nuclear Regulatory Commission (NRC), as well as the commercial nuclear enterprise, have begun to consider radioactively contaminated materials as resources for beneficial reuse rather than wastes. Most outstanding among these materials are metals and concrete which have become radioactively contaminated in various nuclear enterprise activities.
The DOE Oak Ridge Operations Office (ORO) began to move in the early '70's to manage, to a recognizable degree, contaminated scrap metals as resources rather than wastes. In the mid '80's, ORO involved private industry in responding to DOE needs in dealing with scrap metals. From among several industrial firms, the Scientific Ecology Group, Inc. (SEG) was selected to deal with the specified ORO scrap metals inventories.
SEG has Metal Processing Facilities in Tennessee, where effective technologies and techniques are used to process radioactively contaminated metals to remove contamination from both surface and volumetrically contaminated metals and form them into items for beneficial reuse. Currently, feeds for these facilities are provided from commercial nuclear power plants, DOE, and DOD.
Customized products from volumetrically contaminated scrap metals are cast shielding, canisters, boxes, and reinforcing rebar mats and fibers for use within the DOE complex. Decontaminated items which meet the criteria of the State of Tennessee, NRC Regulatory Guide 1.86, and the SEG approved procedures are "free released" to the industrial community for "unrestricted use."
Several million tons of radioactively contaminated scrap, currently in inventories, have been identified. Programmatic redirection and decommissioning of nuclear facilities are producing many millions more. Meeting identified and expected needs for metals will require the use of these amounts.
SEG is processing these metals to meet the prescribed requirements using innovative technologies and techniques to reuse a tremendous national resource. In the SEG metal processing facilities, beneficially reusing contaminated metals from DOE, DOD, and commercial sources is achieved. Customized cast shielding is produced in four sizes of shield blocks for use in nuclear physics and high energy research. In this area, needs for more than 200,000 tons have been identified. 65,000 tons of recycled metal shielding are being produced for the stated needs of DOE. Canisters for high level glass logs are to be made from SEG smelted stainless steel. Smelted stainless steel ingots will be available when required for use in fabricating containers for wastes. Metal boxes and other specified containers for low-level wastes are being fabricated. Construction activities and container fabrication of

recycled concrete will be provided rebar, mats, and fibers.
SEG stands ready, in current and planned facilities, to respond appropriately to dealing with recycling-contaminated materials, especially metals and concrete. Other companies are beginning to enter this endeavor. The DOE is moving positively toward making these recyclable materials resources for recycle and beneficial reuse. A trade association has been formed composed of private firms with capabilities and interests in processing metallic scraps from the federal and commercial nuclear enterprises.

INTRODUCTION

This paper focuses upon opportunities and necessities to reuse valuable materials for tremendous cost savings, waste minimization, pollution prevention, conservation of important resources, and providing socio-economic benefits. Identification of needs, resources, responding technologies and techniques, products, and impacts will be discussed.

A very important consideration is the sheer volume of the large amounts of metal that have been, and will be, generated as a result of DOE decontamination and decommissioning activities. The preliminary estimate of metals generated from decommissioning activities over the next 15 years is in excess of 1.5 million tons. This includes metallic equipment, piping, structural steel, and other metal components that are housed in buildings that no longer have functional value to the DOE in this Post-Cold War Era.

DOE considers this metal as both an asset and a liability. If this metal were to be buried, it would consume six million cubic feet of scarce disposal space. At a minimal cost of $50.00 per cubic ft., this results in a disposal cost of $300,000,000.00. The value of the 1.5 million tons, if it can be recycled and beneficially reused, is in excess of 1.5 billion dollars.

Of special interest are results of an ongoing execution of a Program Research and Development Announcement Project (PRDA). The objective of this project is to demonstrate how contaminated metal can be utilized to produce storage, transport, and disposal containers for use within the DOE system for the disposal of radioactive waste. Containers have been produced and are in use. These disposal containers have been specially designed to meet transportation and disposal requirements of both the Department of Transportation (DOT) and the DOE. Several other containers made with recycled metal and concrete are still in process.

The PRDA program involved transporting contaminated carbon and stainless steel materials from the Fernald Environmental Management Project (FEMP) to SEG where it was decontaminated, melted, rolled into sheet, and fabricated into 4 x 4 x 6-ft. containers. These containers were designed not only to meet today's requirements but also to comply with new anticipated requirements expected from the DOT some time in 1995. The containers are also designed for a higher payload in order to meet DOE's need to transport more dense material, such as the soil, metal, and concrete which will result from environmental restoration and decommissioning activities.

These containers made from recycled steel are destined to be returned to the Fernald Site where they will be utilized to transport and dispose of radioactive materials at the Nevada Test Site (NTS). In addition to the FEMP, several other DOE facilities have indicated an interest in receiving prototypes of this container for an independent review and evaluation of their use.

Development and production of these containers from recycled metal is significant because this success has shown how the DOE and private industry can work together to produce valuable products from an asset which would otherwise be a liability. This project has shown recycling metal to be economically feasible, DOE could avoid the cost and need for the disposal of the metal, while creating a whole new business and market within the private sector that will create jobs across the country. This program which will arise from this project can utilize surplus DOE facilities and equipment as part of the program and extend their usefulness and longevity which will strengthen the American economy.

Combining the beneficial reuse of recycled metals with supply of needed waste containers is now a successful technological and sociological achievement in DOE privatization venture.

More than a million tons of radioactively contaminated metals, considered scrap and waste, have been identified at the many sites under the purview of the DOE and many more with the DOD, and in the commercial sector. Many more quantities will be coming from the decontamination and decommissioning activities. Several concerns exist

regarding the disposition of existing inventories and potential generations of contaminated scrap metals. In the past, good potentially reusable metal has been buried as waste. Time has come, and is much overdue, for that practice to cease. Capability to process these scraps to needed products exists, and responding facilities are in operation.

In the late eighties, the DOE's Oak Ridge Office (ORO) pioneered the move to involve private industry in dealing with the contaminated scrap metal under its purview. Consequently, SEG emerged as the leader in processing contaminated metal for beneficial reuse.

Now, DOE has an active scrap metal management program. Materials, equipment, and facilities that exceed their useful life or are no longer necessary to support DOE's mission are either stored on-site, decontaminated and released, or processed and sent to disposal sites. Considerable development has been performed by DOE contractors on the metal-refining (smelting) of contaminated metals. SEG has enhanced and implemented those technologies and developed new technologies and techniques at its own expense. Some decontamination processes are acceptable for unrestricted sale (e.g., aluminum), while others do not meet regulatory limits. DOE supports efforts to find effective means of recovering the value and utility of contaminated materials.

Using effective technologies and techniques for processing radioactively contaminated metals, SEG has built with private funds and has in operation in Oak Ridge, Tennessee a Metal Processing Facility (MPF). This MPF is used to process radioactively contaminated metals, rid them of the majority of contamination, and form them into customized shield blocks and other beneficial use items. Significant volume reduction for scrap metals (in excess of 20 to 1) is achieved with metal melting services.

This facility has the capability to decontaminate metals, including lead, carbon steel, stainless steel, copper, aluminum, and various alloys. Feed for the MPF is currently coming from commercial nuclear power plants, DOE, and DOD.

STATUS

In the early days (1940's, 1950's and into the 1960's) of the Nuclear Enterprise, the principal thrust under Clinton Laboratories, Manhattan Engineering District, and the United States Atomic Energy Commission (AEC) was production of fissionable materials for military uses, with consideration of nuclear science for peaceful purposes being secondary, but recognizably emphasized. During that period, surplus equipment and scrap materials contaminated with any degree of radioactivity were moved to storage, scrap piles, and waste disposal areas with little attention beyond getting the materials and items out of the way of research and production and to make room and convenience for new equipment for expanding and new programs. Minor effort was made to make a few facilities and some equipment and materials available for uses other than they were originally intended.

In the mid 1960's and early 1970's, focus was turned upon peaceful uses of nuclear energy and the associated activities. Serious consideration began to be given to the psychological, physiological, and economical impacts of all aspects of both the public and private involvements in nuclear energy and its applications. Initially, mild interest, then funded activities, arose to examine the enterprise's little used and surplus facilities, inventories of materials, scraps, and wastes. Special attention was given to those which were contaminated with radioactivity acquired in research, development, and production of nuclear materials, parts for weapons, and fuels for nuclear reactors.

The moves toward identifying and decontaminating materials and items which were contaminated with uranium, fission products, and other radioactive materials were first motivated by desire to recover uranium, when that material was scarce in available form. Although tempered with the federal desire to get the most production for the least dollar-cost with little regard for other impacts, other motivations entered. Among those motivations were declassification, maximum utilization of little used and surplus items, decommissioning, control of nuclide migration from scrap yards, aesthetics, waste management, and public concern. This led to a few alert and astute management considerations in the late 1970's and early 1980's responding to obvious and anticipated needs revolving in somewhat ineffective ways around utilization of surplus materials, program changes, aesthetics and public concern, imagery improvement and clean-up, decontamination, waste containment, volume reduction, waste minimization, pollution prevention and known and anticipated

needs in scrap and waste management and facility decommissioning and transition. Beginning in the mid-1980's, the acts began to come together. That move carried to implementation such watchwords as "Conservation of Strategic National Resources," "Maximum Utilization," "Decontamination," "Waste Minimization," and "Privatization." During that evolution of management concern, the DOE and its predecessors and contractors began to recognize outstanding needs for dealing with its massive amounts of contaminated scrap metal and metallic waste materials. In 1983, based upon earlier research, surveys, findings, and recommendations, positive funded action was initiated to respond to the needs in management of scrap metals. This resulted in positive actions to involve the private sector in demonstrating technologies and techniques and to implement approaches for processing those materials to acceptable forms for beneficial use or disposal. Among those actions was a request to private industry to assist in characterizing, sorting, and volume-reducing a portion of DOE scrap metal. Subsequently, interested commercial firms were invited by DOE to participate in a two-phase effort to decontaminate, process, and remove the respective scraps for beneficial reuse or appropriate waste disposal. SEG responded to that invitation and in partnership with DOE demonstrated its technologies and techniques appropriate for dealing with all aspects of the thousands of tons of scrap composed of ferrous, nickel, copper, aluminum, and miscellaneous scraps.

Now, these materials are being moved from DOE, DOD, and commercial sources for processing to beneficial reuse and appropriate disposal of any resulting secondary waste. SEG is acquiring that scrap to process it, using proven environmentally safe and regulatory acceptable technologies and techniques in accordance with DOE desires, to move the maximum amount possible into beneficial use.

Of particular concern and high motivation to SEG is arranging for the ferrous scrap materials (and some copper and aluminum) to be fabricated into customized shielding blocks for use in DOE's high-energy and nuclear physics programs. Those programs, particle acceleration and beam projects, require high tonnages of high density shielding. Since the early planning stages of SEG's response to this scrap project and continuing to date, SEG has been in contact with DOE contractors who have defined and anticipated needs for large quantities of molded-to-design shielding materials for use in funded and proposed major experiments. They have great interest in SEG's supplying their needs from at least five justification standpoints.

Customized Shielding

Much conservation of personnel, energy, and time, structure flexibility, facility efficiency, and engineering and construction accuracy are afforded by made-to-order shielding. At the potential users' requests, SEG has spent much time in planning and design efforts for current and planned shielding requirements and is producing four types of customized shield blocks.

Resource Utilization

Many tons of valuable steel are required for these experiments. The shielding materials, when in place in active experiments, acquire high induced radioactivity. This condition does not significantly reduce shielding efficiency, but will present a very troublesome problem when disposal is required. If virgin steel were used, additional radioactive waste would result and tremendous cost avoidance would not be realized.

Waste Minimization

Since the DOE scrap is only slightly contaminated and as such might be difficult to decontaminate to meet regulations for free-release to American public and noncontaminated steel shielding would become radioactive in the experiments, using DOE scrap material would reduce the waste potential by the amount of recycled materials used in shielding.

Pollution Prevention

The propagation of waste migration and expansion for several miles is reduced.

Economics

The scrap metal, an excellent source of shielding, is already owned by DOE and can be processed by SEG to the users' requirements.

The identified near term shielding needs show more than 65,000 tons of customized shielding blocks. Continuing annual requirements have been indicated and estimated, showing an increasing requirement.

The development of this beneficial reuse of scrap steel has involved: extensive negotiations with the interested parties, modification of the processing that will

have to be performed, and the development of close tolerances for the fabrication of the shielding blocks. SEG has conducted these negotiations with the principal laboratories.
This beneficial reuse methodology is independent of any proposed regulatory change; it directs the metals toward a substantial beneficial reuse with virtually no chance of inadvertent release to the public. This method will also provide a beneficial reuse of future quantities of metals.
Other uses for the metals have been found such as metal boxes, canisters, and drums for DOE and commercial radioactive waste; target material and armor plate for the DOD; and reinforcing rebar and mats for use in the nuclear enterprise. Metal and concrete containers have been developed, tested, and are ready for use.
Your attention is invited to Tables I and II for a perspective of quantities, values, and potentials of a representative portion of our national resource of inventories and requirements. Table I gives selected scrap metal volumes and values; Table II gives SEG products and quantities of specific materials needed for required items.
Advantage of reclamation or reuse of these DOE materials are many; a few of which are:
1. The beneficial reuse of valuable metal thereby reducing the potential environmental impacts and health and safety risk inherent in the mining and refining of virgin ore and the production of power required to obtain and refine the ores.
2. The beneficial reuse of nonreplenishable scarce resources.
3. The beneficial reuse of volumetrically contaminated metals in radioactive environments, thereby reducing the nonradioactive metals that would otherwise become radioactive and increase the total amount of radioactive material requiring disposal.
4. The potential reduction in cost of high energy physics or other nuclear research programs requiring large volumes of ferrous metals that can be volumetrically contaminated. (This customized 35,000 tons of shielding for Los Alamos National Laboratory alone is estimated by DOE to save twenty million dollars.)
5. Generation of the least amount of waste requiring disposal or any other ultimate solution alternative. Thus, potentially reducing the amount of disposal space required and the amount of land removed from productive use.
6. The potential reduction in costs of radioactive material management from both "3" and "5" items previously listed.
7. The potential to turn an apparent liability (i.e., stored contaminated scrap metal) into revenue or equivalent U. S. Budget savings.
8. The removal of an apparent and/or potential contamination source term from the DOE, DOD, and commercial sites.
9. The permanent isolation of a majority of contaminating radionuclides from people and the environment.
10. A proactive response to a need (the disposition of the scrap metal) that has existed for over thirty years.
11. Resolution of the disposition of the scrap metal in accordance with all existing statutory regulations.
12. Providing the most outstanding waste minimization endeavor.
In addition to customized shield blocks, fabrication equipment makes possible production of other steel components such as sheet steel, centrifugal cast containers, rebar, and fiber reinforcing mats for use in meeting requirements of the nuclear enterprise.
Cast shielding is being produced by SEG for use in high energy and nuclear physics studies. Needs and requirements for more than 200,000 tons of products have been identified for those studies. Soon, stainless steel ingots are expected to be produced and stockpiled for use in making canisters for high level waste glass logs and possibly for use in fabricating containers for transuranic wastes. Moves are underway to fabricate boxes for containing low level wastes for use in both public and private sectors. Extrusion capability can be used for producing rebar for use in construction activities. Reinforcing mats will be produced using a new fabrication technique.
All in all, the MPF is a valuable asset for meeting the many needs for the total nuclear enterprise and simultaneously beneficially reusing a tremendous national resource through innovative technologies and techniques.
Recycle of radioactively contaminated metals is underway but needs the incentive

that can be provided by Congressional understanding, endorsement, and emphasis and by properly motivated groups. A few very minor efforts have been effected at some DOE installations resulting in low tonnage being decontaminated on-site and released to the public. SEG has produced approximately 8,000 tons of customized shield blocks and decontaminated more than 1,000,000 pounds of lead and more than 6,000,000 pounds of brass. SEG is obtaining more than 68,000 tons of scrap from the DOE Oak Ridge Operations Office including more than 9,300 tons of nickel ingots. SEG has and is currently processing many tons of scrap metal from the FEMP site. SEG has a contract with Martin Marietta Energy Systems to remove scrap metal from the Oak Ridge site waste streams being sent to SEG for processing. More than 8,000 tons of scrap metal have been received for processing by SEG from DOD. Scrap metal is being received from more than 100 nuclear power plants.

Since 1980, the commercial nuclear industry has decontaminated more than 150 million pounds of metal.

DOE has not recycled metal to the extent of the commercial industry or other government agencies. Some of the barriers limiting or delaying DOE participation are:

- unrealistically low burial costs which do not reflect total life cycle costs or the projected costs of new disposal sites. However, action seems to be underway by DOE to adjust this situation.
- extended Procurement cycles
- no release criteria for volumetrically contaminated bulk material
- reluctance to certify secondary waste for disposal at Nevada Test Site and Hanford Reservation
- lack of mission orientation

SEG has appropriate permits and licenses to deal with all scrap metal requirements and stands ready to process DOE scrap metal or scrap from any other source. Further, SEG offers a full menu of services dealing with all aspects of Environmental Management. Other qualified companies are showing interests and experience and offer services in processing scrap metal. A Trade Association has been formed composed of private firms with capabilities and interests in processing metallic scraps from federal and commercial sources.

There is and will continue to be a great challenge for recycling metals from the nuclear and related enterprises. Let's respond intelligently.

ABSTRACT

The potential for the reuse of uncontaminated structures at federal facilities that are being remediated should be evaluated. Although various factors often limit the viability of such reuse, it may be economically attractive to reuse selected structures. Consideration of a hypothetical reuse scenario for the U.S. Department of Energy's Fernald, Ohio facility shows that the reuse of selected buildings that were not significantly contaminated by production activities at the site may be considerably less expensive than the construction of new ones. The cost of removal of existing buildings is a major factor influencing the relative advantages of these two options. For Fernald, no need for the facility's buildings has been identified; however, the reuse of structures may be a viable option at other facilities.

INTRODUCTION

The U.S. Department of Energy (DOE) and other federal agencies are currently

planning the remediation of numerous contaminated facilities. Some of these facilities are quite large and contain many buildings and other structures having varying degrees of contamination. What is the potential for the reuse of such structures? This paper will address issues related to this question by examining the potential for the reuse of structures at one large DOE facility that is in the early stages of remediation. No plan exists for the long-term reuse (i.e., use not associated with remediation) of any structures at the facility; however, development of a scenario for the hypothetical reuse of structures at the facility allows the identification and evaluation of issues associated with the reuse of structures at large, contaminated federal facilities that no longer are carrying out their original missions.

The facility considered in the hypothetical reuse scenario is the Fernald Environmental Management Project (FEMP), located near Cincinnati, Ohio. The FEMP was used by DOE and its predecessor agencies to produce high-purity uranium metal from 1952 until 1989. The former production area of the FEMP contains over 200 structures, including about 100 buildings. Most of the structures at the FEMP date from the 1950's and many of them and portions of nearby soil and groundwater are radiologically contaminated as a result of the production activities at the facility. It is currently planned that all the structures at the FEMP will be removed during remediation. Remediation is being carried out in accordance with the requirements of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), as amended. Decontamination and dismantling of structures from the production area will be managed using an interim remedial action being carried out for Operable Unit 3, which addresses improvements located in the 136-acre former production area. Environmental media are addressed by a different operable unit. Remediation will continue well into the next century.

This paper considers three major topics related to the hypothetical reuse of structures at the FEMP: 1) What are the major factors that would limit the potential for the reuse of structures at a facility such as Fernald? 2) What opportunities are available for the conservative reuse (i.e., reuse that minimizes the potential for any future human exposure to contamination) of structures at Fernald? and 3) What are the expected costs of a conservative reuse scenario for the facility?

FACTORS LIMITING THE REUSE OF FEMP STRUCTURES

Is long-term reuse of some of the structures in the Fernald production area a reasonable alternative that should be considered? Although a large number of structures potentially suitable for use as offices, warehouses, or manufacturing facilities are available, their reuse is generally limited by a number of factors:

The presence of contamination in most structures, particularly those that were actually involved in production activities.

The presence of transite in the walls and roofs of many structures. Transite is made from cement and asbestos and, although the asbestos is not friable, buildings constructed with this material are not considered suitable for reuse.

The age of the structures. Most of the structures date from the 1950's.

The potential for obstructing the remediation of environmental media if the structures are left in place.

The location of structures in the footprint of any likely on-property disposal cell and the potential for conflicts with the construction of any such facility. Also, structures may be utilized to support remedial activities and may not be available for other uses.

The potential for future liability if undetected contamination is present in reused structures.

No identified need for the structures by the federal government. Assuming continued DOE control of the facility, future use is likely to be limited to DOE or other federal activities.

These factors are expected to be relevant to the potential reuse of many structures at other major DOE facilities also.

At the FEMP, many of the factors limiting the potential for the reuse of structures apply primarily to those structures that were used for actual production activities. Various other structures that have been used for administrative activities have fewer constraints on their reuse because of their generally uncontaminated state, the nature of their construction, and their location outside the likely footprint of any on-property disposal cell. The following section considers opportunities for the conservative reuse of structures at the FEMP and develops a reuse scenario for the

property. The costs associated with the scenario are then evaluated in the subsequent section.

DEVELOPMENT OF A REUSE SCENARIO FOR THE FEMP

A reuse scenario for the FEMP was developed for the time period following the completion of all remedial action activities, except for the restoration of the Great Miami Aquifer, the major groundwater resource underlying the facility. Following remediation, decontamination and dismantlement activities addressed by the interim remedial action would be complete, contaminated soils and construction debris would be removed, and it is assumed that the majority of these contaminated media and wastes would be placed in an on-property disposal cell.

Structures defining the reuse scenario for the FEMP were selected to provide a refurbished property that would be suitable for future industrial or commercial development, as well as for federal government use. Candidate structures for reuse were selected from the approximately 100 buildings available; buildings are the most valuable structural resources at the FEMP. To be considered for reuse, buildings must:

Have only limited or no radiological contamination.

Have no transite used as a construction material.

Be permanent structures in sound condition.

Not be connected to non-reusable structures.

Have a floor area greater than about 900 square meters (about 10,000 square feet) (unless connected to another structure that would result in a total combined area exceeding that amount). Small isolated structures are assumed to have limited value.

Be currently envisioned to present no conflict with site remediation (i.e., not limit access to contaminated environmental media and not obstruct disposal cell construction or operation.)

Buildings meeting these requirements will require relatively limited effort to make them available for reuse. Since only buildings with limited or no contamination are considered for reuse, only minimal soil contamination is expected to be present around or under them, limiting the potential for any conflicts with the remediation of environmental media. The following paragraphs discuss the development of a reuse scenario on the basis of the constraints established by expected post-remediation conditions at the FEMP and the application of the criteria listed above for selecting buildings.

Following remediation, the property is assumed to include an engineered disposal facility, a network of approximately thirty groundwater extraction wells in groups of five to eight wells each, a groundwater treatment facility, and a set of refurbished buildings consistent with a reasonable reuse scenario. The existing parking lot is assumed to be present but greatly reduced in size to be more consistent with the work force required for the reuse scenario.

The engineered disposal facility required to accommodate site-wide needs is anticipated to be approximately 670 m (2,200 ft) by 490 m (1,600 ft) by 12 m (40 ft) high. As presently envisioned, the disposal cell is expected to hold an estimated 1.8 million cubic meters (2.3 million cubic yards) of contaminated soil and construction debris. Due to the large footprint of the disposal cell, which includes land utilized as a lay-down area, a significant portion of the structures in the FEMP production area would have to be removed to accommodate an on-property disposal alternative. The disposal cell is anticipated to be located in the northeast corner of the FEMP. A stormwater control channel around the disposal cell is anticipated to be required to control stormwater runoff.

The groups of groundwater extraction wells are assumed to be located predominantly on the western and southern portions of the FEMP, where there are no current or planned improvements. The groundwater may potentially be treated before being discharged to the nearby Great Miami River. The groundwater treatment facility is scheduled for start-up in early 1995 and is located in building 51.

A reuse scenario was developed using the criteria and constraints discussed above. The approximately 100 existing buildings were first screened to determine those that have only limited or no contamination and that are not constructed of transite. Next, the remaining buildings were evaluated to determine whether they are permanent structures in sound condition, are not connected to non-reusable structures and do not conflict with any anticipated remedial activities, such as the construction and operation of the engineered disposal cell. As noted above, small isolated buildings were assumed to have limited value and were eliminated from consideration.

The structures selected for the reuse scenario are the service building (building 11), administration building (14A), laboratory building (15), security building (28A), human resources building (28B), safety and health building (53A), in-vivo monitoring building (53B), finished products warehouse (77), plant 6 warehouse (79), and the receiving and incoming materials building (82). A simplified perspective view of the FEMP is provided in Fig. 1, with the buildings selected for the reuse scenario highlighted. Assuming that these buildings are refurbished for use as offices and warehouses, the FEMP would potentially have about 32,500 square meters (350,000 square feet) of available floor space. The buildings retained would be the former administration buildings located on the southern portion of the production area and some warehouses located on the eastern edge of the production area but south of the disposal cell footprint. These buildings are readily accessible to the parking lot and main access road. Among the buildings selected, only buildings 11, 15, 77, and 79 would require some decontamination before reuse. A simplified perspective view of the FEMP following remediation is shown in Fig. 2, assuming an on-property disposal cell and a groundwater treatment facility, plus implementation of the hypothetical reuse scenario involving the buildings identified in this paragraph.

EVALUATION OF COSTS FOR THE REUSE SCENARIO

If no actual uses can be identified for the space provided by the buildings included in the reuse scenario, it would be most reasonable to remove them rather than provide maintenance and security for unneeded buildings. No such uses have been identified and current plans call for all buildings at the FEMP to be removed. However, if a potential for reuse actually existed for them, then the major factor determining whether their reuse is reasonable is the relative cost of reuse versus the cost of providing acceptable alternative space. The evaluation of the reuse scenario presented here consists of a consideration of these relative costs. Issues other than those involving costs are considered above in the development of the reuse scenario.

The estimated costs for the reuse of existing buildings and the estimated costs for their replacement with new ones are summarized in Table I. The estimates in the table are provided to allow a rough comparison of the two cases considered and to allow identification of the major factors contributing to differences in their costs. The cost estimates provided were developed to allow these evaluations to be conducted and are not intended to be any more definitive. The cost comparison in Table I does not account for the fact that refurbished buildings would likely be worth less than newly constructed buildings and would have a shorter expected period of use. A more detailed evaluation of the potential for the reuse of structures would account for these factors. No cost is assigned to the land needed for any new construction because it is assumed that any new buildings would be located on uncontaminated areas of the FEMP outside the former production area.

The unit costs for construction used in Table I are approximate values for new construction in the Cincinnati area (1). The cost of refurbishing the existing buildings is based on industry standards (2), assuming that the labor and material components of the total refurbishment cost are 60% and 40%, respectively. The refurbishment cost is estimated to range between 15% to 50% of the costs of new construction for the building types being considered. Given that many factors (e.g., custom fabrication of components to match existing construction) can significantly increase the costs for refurbishment, it was conservatively assumed that refurbishment costs are 50% of the costs of new construction.

Reuse of an existing building may involve removal of any asbestos that is friable or in poor condition. A small amount of asbestos-containing material is present as piping and ductwork insulation in building 82; however the costs of its removal were determined to be negligible in comparison with the other costs for building reuse.

The cost for surface decontamination was estimated assuming that all interior surfaces in buildings with some contamination present (buildings 11, 15, 77, and 79) were cleaned using a high-pressure power washer and that a fixative coating was then applied to all the surfaces. Recent experience at the FEMP indicates that such surface decontamination can reduce removable contamination levels by a factor of fifteen (3). Application of a fixative coating (acrylic latex paint) is used to "lock down" any remaining loose surface contamination. The costs for surface decontamination were estimated from (4) and exclude treatment costs for the resulting wash water.

The cost of providing a replacement for the existing buildings includes the cost of removing the existing buildings. If not reused, these buildings must be removed. If it were decided to construct new buildings on the FEMP to provide space that could be provided by existing buildings, then the cost of removal of the existing buildings is a cost that must be added to the cost of new construction. If buildings are reused, then the cost of their removal is avoided.

The costs for removing buildings were developed using a "bottoms-up" cost methodology. Contaminated buildings are assumed to be decontaminated before being dismantled. Direct costs associated with decontamination and dismantlement include containment of potential airborne contaminants, surface decontamination by water washing as needed, disassembly and dismantling, wrapping, and transporting waste materials to interim storage areas. A non-productive time allowance for the use of personal protective equipment was included in all applicable activities. Factors for the various indirect cost components (e.g., overhead and profit, contingency) were applied to complete the cost estimate for the individual buildings. The costs were estimated for each building and combined to give the total in Table I. Values presented here should be considered to be conceptual with an estimated overall level of accuracy of +50 percent/-30 percent.

The costs for decontamination and dismantlement of the buildings were developed for this study and do not represent official estimates for the FEMP. Note that the estimated costs given in the table apply only to the specific buildings considered in the scenario; the costs do not apply to any other structures.

Disposition costs associated with the wastes produced by dismantlement of the buildings were estimated on the basis of a preliminary cost estimate developed for an on-property disposal cell (5). The incremental costs of on-property disposal are about $84 per cubic meter ($64 per cubic yard) and the disposal volume for the wastes generated from the ten buildings would be about 33,000 cubic meters (43,000 cubic yards), yielding a cost for on-property disposal of about $3 million.

The cost of providing replacement space in new on-property buildings that would be equivalent to that provided by buildings identified in the reuse scenario (Case 1 in Table I) is estimated to be about $47 million or about $1,400 per square meter (about $130 per square foot) of floor space. Reuse of the buildings (Case 2) would cost about $11 million or about $340 per square meter (about $30 per square foot). The relative cost advantage of reuse of the buildings over replacement is not sensitive to uncertainties in costs for refurbishment or decontamination. Even if the refurbishment costs are as high as the costs of new construction, reuse may still be advantageous from a cost perspective because of the high costs of dismantling all the structures compared to the costs of decontaminating only several. Decontamination costs are estimated to be only a small fraction of the total costs associated with building reuse and very large increases in decontamination costs would be necessary to significantly affect total costs for reuse. For example, doubling decontamination costs would increase total costs for reuse by less than 10%. Therefore, if additional decontamination such as scabbling of concrete or metal is required in some areas, the effect on total cost for building reuse would be small.

Costs associated with the eventual removal of new or refurbished buildings are not included in the cost estimates developed. Including such costs would decrease the relative cost advantage of building reuse. However, such costs likely would not be incurred for some decades and, particularly in terms of a present-worth analysis, the total costs for the reuse of the buildings would remain well below those for their replacement.

The most critical factor related to evaluating the reuse scenario is the cost of removing existing structures. If uncontaminated structures are dismantled using the same methods as those used for contaminated structures (except for worker protection), then expected costs will be high. The CERCLA Record of Decision for the interim remedial action (6) does not specifically discuss methods that might be used, but always discusses "dismantlement" as opposed to "demolition." Practices at other DOE facilities also appear to favor dismantling as opposed to demolition, even for uncontaminated buildings, if the buildings are located in generally contaminated areas (7). Defining the approach that will be used to remove buildings with little or no contamination is critically important to understanding any cost advantages associated with reuse. If the costs of removing the existing buildings constitute a significant fraction of the cost for the replacement case, then avoiding

dismantlement costs by reuse of buildings could potentially result in substantial cost savings, assuming a need for such space is identified.

CONCLUSIONS

In general, the potential for the reuse of buildings and other structures at the FEMP is limited by the lack of an identified mission for them, by the current condition of most structures, and by the possibility for interference with the remediation of environmental media. These conclusions apply in particular to the buildings that were used for production activities.

Opportunities for conservative reuse may exist for some selected buildings at the FEMP that together contain several tens of thousands of square meters (several hundreds of thousands of square feet) of floor space, that are in sound condition, and that have limited or no contamination. These buildings are administrative and warehouse buildings located outside the major areas of contamination and in areas that would not interfere with the construction of an on-property disposal cell. If a need existed for such space, it might be economically preferable to reuse these buildings as opposed to removing them and constructing new ones. However, the attractiveness of reuse is sensitive to dismantling costs. High dismantling costs favor reuse.

The methods to be used for the removal of FEMP structures having little or no contamination need to be better defined. Such information is important both for evaluating any potential reuse of the structures and for evaluating the total costs for the interim remedial action that will remove them.

Arguments favoring the reuse of some buildings on the basis of cost alone are insufficient to justify retaining such structures in the absence of any specific, identified need for the structures. For federal facilities that are planning remedial activities, the viability of reuse of any buildings will depend on the levels of contamination in the buildings, the level of any contamination around and under the buildings, the state of the buildings, and the future land use anticipated for the facility. However, if constraints involving these factors are not present, long-term reuse of the buildings may be economically attractive. Reuse of structures with limited or no contamination should be considered as a serious option at federal facilities if a need for such structures can be identified.

ACKNOWLEDGMENT

Work at Argonne National Laboratory was supported by the U.S. Department of Energy, Assistant Secretary for Environmental Restoration and Waste Management, under contract W-31-109-Eng-38.

ABSTRACT

To achieve an optimized solution of the overall material management problem, the options of radioactive wastes management, the options for recycling and reuse and, last but not least, the options for disposal of the material as non-radioactive waste should be considered.

A survey is provided on the current status of these options available in Germany. Special emphasis is given to the possibilities of reuse and recycling. Criteria for clearance of material are available for metals. As a principle, the recycling of scrap into products for the nuclear industry like waste containers or shielding plates is the preferred way. If this is not feasible or economically justified, material can be released either without restrictions or with conditions on its further treatment.

Furthermore, the present planning work regarding the management of material arising during decommissioning is presented; aspects of final disposal of radioactive waste are finally addressed in more detail.

INTRODUCTION

In the Federal Republic of Germany, nuclear electricity generation has a share of more than 30 % of the overall production of electrical energy. Most of the nuclear power plants, presently in operation, are expected to end their service life not before some decades from now. Based on an operational time period of 35 years, decommissioning and dismantling will start in the next century. According to current plannings, shut-down of commercial scale power plants will commence in the year 2002. Service life will be followed by preparation for safe storage and a safe storage period of 30 years. The dismantling and demolition period of a modern light-water reactor is estimated to last up to 8 years.

In Germany, a total of 15 nuclear power plants were finally shut down and are in the decommissioning phase or have already been dismantled. It is therefore substantial experience available with decommissioning of nuclear power plants.

Shut-down, dismantling and demolition of research and prototype reactors, installations of the nuclear fuel cycle and research facilities have to be planned as well. There is ongoing planning, e.g. the decommissioning of a fuel fabrication plant, or the ongoing planning for the dismantling of the WAK pilot reprocessing plant in Karlsruhe.

During backfitting and decommissioning of nuclear installations, and to a more limited extent also during normal operation, a considerable amount of radioactive residues, dismantled parts and equipment arises. The management of this material is an important task. In the Atomic Energy Act, the basic modes of material management are set out. The arising material - either residues or dismantled parts - can be recycled or reused without harmful effects or be disposed of as radioactive waste; interim storage before final disposal is possible.

The purpose of this papier is to provide an overview of German policies, regulations, experiences and status of planning for the future tasks of decommissioning of nuclear installations and the corresponding material management.

OPTIONS FOR MATERIAL MANAGEMENT

Overview

In the Atomic Energy Act it is distinguished between radioactive residues and dismantled radioactive parts, which can - according to an article law passed on April 29, 1994 -either be reused or recycled without harmful effects or disposed of as radioactive waste. Before the article law was passed, reuse and recycling were given priority as compared to disposal. Now these two basic options are equally ranked.

An overview of the different possibilities for disposal and recycling or reuse available in Germany is provided in Fig. 1.

Radioactive waste is finally disposed of in deep geological formations. Shallow land burial of radioactive waste is not practiced in Germany. However, if radioactive waste fulfills the condition of "very low specific activity" it can be categorized as non-radioactive material and be disposed of like conventional waste, which is

either incinerated or disposed of in a municipal landfill.
A more complicated pattern is formed by the possibilities of reuse and recycling. In the case of reuse, items from the nuclear field are used elsewhere in their original form and function. Recycling means that the material is taken as input for the production of "new" material. A typical and practically very important example is the recycling of dismantled metallic scrap for the production of waste containers or shielding plates.
Material to be disposed of as conventional waste or recycled or reused will in general be subject to an act of clearance from the system of regulatory supervision. This clearance can be unconditional in the sense that there are no restrictions in terms of reuse, recycling or disposal after clearance. Conditional clearance would for example be steel scrap released for recycling, the condition being that scrap is indeed processed and melted for the production of new steel. Disposal as waste or reuse of items would have to be excluded in such a case. Obviously, criteria for conditional clearance need not be as restrictive as for unconditional clearance.
On the other hand, material has not necessarily to be cleared for recycling or reuse if it can be further treated or used under regulatory supervision. Examples would be the transfer of one piece of equipment from one nuclear installation to another or the melting of radioactive scrap from a nuclear facility in a licensed melting facility.
Radioactive Waste Disposal
According to the concept developed in Germany, radioactive waste is disposed of in deep geological formations. Interim storage before final disposal is possible.
Presently, the Morsleben facility is available for disposal of short-lived low and intermediate level radioactive waste with rather low alpha emitter concentrations (1). This repository constructed in a salt formation has resumed its operation in mid-January 1994. Since then radioactive waste is disposed of in this facility. Operation is presently planned to continue until the end of June in 2000 when the operation license expires. 40,000 m3 radioactive waste shall be disposed of in the Morsleben repository in this period.
The Konrad repository, a former iron ore mine in Salzgitter, is characterized by very dry conditions and substantial layers of clay as a geological barrier (2). The results of a research and development programme on behalf of the Federal Government confirmed that Konrad is in principle qualified as a disposal site for radioactive wastes with negligible heat generation. The licensing procedure was initiated in 1982, and waste disposal can commence at the end of the century provided the license is granted until then. Operation can continue for more than 40 years, with 650,000 m3 waste package volume being disposed of in that period.
Since 1979, an extensive site exploration programme is conducted at the Gorleben site. Presently, two shafts are being sunk for underground exploration to provide necessary information on the geological structure and on the available repository volume in the salt dome being necessary for the assessment of the site's suitability. Start of operation of the Gorleben repository is expected after the turn of the century.
Recycling, Reuse and Disposal as Non-radioactive Waste
Early practices related to recycling, reuse and conventional disposal were based on regulatory guidance issued in 1979 (3). However, criteria have been reconsidered since IAEA has issued basic recommendations on acceptable public exposure in Safety Series 89 (4). On this basis, a number of recommendations has been issued by the German Commission on Radiological Protection (Strahlenschutzkommission - SSK) which are the basis of present licensing.
The first recommendation "Radiological Protection Principles for the non-detrimental Recycling and Reuse of slightly radioactive Iron and Steel from Nuclear Power Plants" was published in 1987 (5).
It is related to the clearance of metal scrap and components leaving a nuclear power plant, which are valid for activity spectra from light water reactors (LWR). Such spectra are dominated by Co-60 and Cs-137. Furthermore, the recommendations are explicitly not to be used if a-contamination is suspected. The recommendations for the release of ferrous and non-ferrous metal give clearance levels for the total activity and are summarized below.
The first priority is to reuse or recycle within the nuclear industry, if this is not feasible then several release options are available.
1. Unconditional release is possible if the mass specific activity is below 0.1 Bq/g

for each piece and the surface activity is below the limits prescribed by the German Radiation Protection Ordinance (RPO).
2. Release of scrap on the condition of melting is allowed if the mass specific activity is below 1.0 Bq/g for each piece and the surface activity is below the limits prescribed by the RPO.
3. Controlled recycling can be considered when the mass specific activity is higher than 1 Bq/g and/or the surface activity higher than the limits prescribed by the RPO. Within controlled recycling scrap is not released but rather melted under license. After melting the product can be unconditionally released if it meets the requirements put forth in point 1.
On a case by case basis the licensing authorities can allow products with a mass specific activity between 0.1 and 1 Bq/g to be used in applications where an increased radiation exposure is not expected. This option is not of great practical importance.
The surface contamination clearance levels of the RPO require the prove, for the entire surface, that the total surface activity (fixed plus non-fixed) is less than
0.05 Bq/cm2 for Alpha-emitters (e.g. Pu-239, Am-241),
0.5 Bq/cm2 for Beta/Gamma-emitters (e.g. Co-60, Cs-137) and
5.0 Bq/cm2 for weak Beta/Gamma-emitters (e.g. Fe-55, Ni-59).
These limits are averaged over any 100 cm2 of the surface.
This recommendation was later extended to non-ferrous metals using essentially the same principles and clearance levels (6).
Based on a model developed by BfS for the incineration of waste and disposal on a municipal landfill, criteria have been derived for conventional disposal (7, 8). A corresponding recommendation by the SSK will be issued in the near future.
A study has been conducted on the recycling and disposal of concrete and building debris (9), but has not resulted in regulatory guidance up to now.
It can be summarized that regulatory guidance for the clearances required for material management has been developed to a fairly complete system so that a basis has been provided for future licensing for decommissioning.

DECOMMISSIONING OF NUCLEAR FACILITIES

Decommissioning Projects

In the Federal Republic of Germany, 21 nuclear power plants are in operation which roughly contribute one third to the overall electrical power generation. On the other hand, 14 units including demonstration and prototype plants, have been taken out of service (Table I).
In 1995, the complete dismantlement of the KKN plant is expected. Decommissioning of the KRB-A plant is undertaken and licensed in the steps turbine building, contaminated equipment in the reactor building and finally dismantling the activated parts. Presently work on step two is underway. Valuable experiences and data for future planning were collected (10), especially regarding radiological and economic aspects of decontamination and dismantling.
Different approaches are taken in terms of decommissioning strategy, e.g., for KWL safe storage for a 30 year period has been implemented.
Decommissioning of the units at the Greifswald site is a major task for the next decade. First applications for decommissioning licenses have been made.

Material Management for Decommissioning

Based both on the criteria for radioactive waste disposal and for recycling, reuse and conventional disposal as well as on the experiences already gained in decommissioning and dismantling projects, the licensees have performed adequate plannings for future decommissioning and dismantling projects. To provide an example, in Table II the amounts of radioactive waste and the materials that can be recycled are presented according to the planning for the dismantling of a 1000 MWe LWR.

Radioactive Waste Arising from Future Decommissioning Projects

Information on radioactive waste arisings is collected by BfS and used in disposal planning. An estimate of radioactive waste originating from decommissioning projects can be outlined in the following way:

A total of about 50,000 m3 of waste package volume is expected from research, demonstration and prototype reactors and from nuclear power plants already finally shut-down as well as from the WAK reprocessing facility at Karlsruhe. According to preliminary plannings, this waste volume is to be expected until the end of 2010.

The 21 nuclear power plants in operation will contribute a total volume of about

57 700 m3. Based on a safe storage period of 30 years before dismantling an average rate of 1900 m3/a is projected for the period from 2033 to 2063.
These planning figures are subject to regular updates by BfS based on information provided by the licensees.

SUMMARY AND CONCLUSIONS

Present material arisings during operation of nuclear power plants and even more those from present and future decommissioning necessitate a well balanced concept for material management. This concept must cover both the criteria for disposal of radioactive waste and for clearance derived from safety assessments. On this basis, optimization of material management can be achieved taking into account economic aspects.
In Germany, the regulatory basis for material management has been developed. As far as recycling, reuse and conventional disposal are concerned criteria have been derived and formulated in SSK recommendations, which are consistent with the fundamental guidance document Safety Series 89 issued by IAEA/NEA. Conditional clearance criteria for disposal, recycling and reuse are available. The derivation of criteria for unconditional release is a major task that is being discussed on the national and international level. Harmonized solutions for transboundary movement of material are urgently needed.
A very attractive option is recycling without any clearance from the nuclear industry. In this case, the new products (e.g. waste containers) are fabricated in a licensed company and subsequently reused in the nuclear field. This is established in Germany on an industrial scale. It must however be recognized, that the need for this type of products could turn out to be rather limited.
The German concept for disposal of radioactive waste is exclusively based on deep geological disposal. One repository licensed for disposal is available at Morsleben at least until the end of June in 2000. Licensing for the Konrad repository which will be limited to radioactive waste with negligible heat generation is in a very advanced state. Planning for the salt dome repository at Gorleben continues.
The utilities are planning the future material management on the described basis formed by the options of radioactive waste disposal and recycling, reuse and conventional disposal.
The BfS is committed to further extend and optimize the regulatory guidance in this important field. It participates actively in the international process to achieve harmonized solutions for transboundary movement of cleared material.

ALPHA CHARACTERIZATION OF CONCRETE-SURFACES AT D&D SITES
T. Q. Vu
M. W. Rawool-Sullivan
J. Koster
D. Stout
A. Beasinger
Los Alamos National Laboratory
ABSTRACT
Waste minimization and worker protection at decontamination and decommissioning (D&D) sites requires continual and extensive characterization for radioactive contamination. Contamination detectors that are sensitive, rugged, fast, and capable of covering large areas are needed. The concrete surface monitor (CSM) developed at Los Alamos National Laboratory supports both characterization and waste minimization efforts at D&D sites containing large concrete surfaces and structures of different forms and shapes. This report describes the CSM design and the results of several field experiments.
INTRODUCTION
Typical radioactive contaminants consist of uranium or plutonium. These isotopes emit alpha particles. An alpha particle can travel approximately 4 cm through air; with such a short range, traditional direct detection methods are often ineffective. Instead of detecting the alpha particle directly, the concrete surface monitor (CSM) detects the ion pairs created as alpha particles interact with air molecules. As a 5-MeV alpha particle interacts with air molecules, it will generate an average of 150,000 ion pairs, resulting from the 35-eV energy loss for every ion pair production (1). An electrostatic field in the CSM transports these ion pairs to a detection plate. The ion pairs generate a small current, proportional to the alpha source strength, that is detected by an electrometer. As compared to traditional detectors, the CSM can operate effectively at a much higher level of sensitivity while allowing real-time and in situ operation.
Using the 300-cm2 CSM, large concrete surfaces can be characterized effectively. An active detection surface ranging from 300 cm2 to 2500 cm2 allows CSMs to monitor a larger surface area with a single measurement. By characterizing concrete surfaces before, during, and after decontamination and decommissioning (D&D) work, the amount of radioactive waste could be minimized. The use of the CSM to support waste minimization will effectively cut the cost of D&D.
CSM DESIGN
The CSM is based on the electrostatic Long-Range Alpha Detector (LRAD) (2). The current generated by the CSM is detected by the sensitive electrometer developed by Guy Arnone at Los Alamos National Laboratory (LANL) specifically for LRAD detectors. The reading can either be sent to a portable computer or read out directly on a portable oscilloscope for a visual interpretation. There are two types of surface monitors; the 2500-cm2 monitor includes background subtraction technology while the 300-cm2 and the 1431-cm2 CSMs do not. The LRAD Surface Monitors have already been described in more detail in several reports for soil surface applications (3,4). The CSM was built specifically for field demonstrations and characterization of

concrete block edges at a D&D site at LANL. Due to the large concrete block surface area, we designed a CSM with an aluminum box monitor 27 cm x 11 cm x 10 cm with an opening on the bottom, yielding a 300-cm2 detection surface. An adjustable clamp was used to fasten this monitor to the block creating a firm contact between instrument and detection surface with varying degrees of freedom.

A background-subtracting surface monitor is shown schematically in Fig. 1. In this detector the alpha particles emitted from the concrete surface create ions only in the lower chamber, and hence a signal only from the first signal plane. All of the ions created by surface contamination will be transported to the lower signal plane; none pass into the upper chamber. Radioactive radon gas that enters the lower chamber from the concrete surface is not electrically charged, so it can freely pass into the upper chamber. This gas will decay equally in both chambers, resulting in an identical contribution of signals on both the first and second signal planes. To speed up the mixing of radioactive gas into both chambers, a small fan is inserted between the chambers (5).

A CSM with an active volume of dimensions 50 cm x 50 cm x 10 cm, and a 2500-cm2 detection surface, allows measurements over larger surfaces with a single reading. Again, the response time for both CSMs is between 30 and 120 s per reading depending on the strength of the contamination.

In the final analysis, the current was measured from the top chamber (instrumental background at that level) and subtracted from the current measured from the bottom chamber (signal from floor plus instrumental background at that location). The calibration factor for the background subtraction CSM was measured at 6 dpm/fA. Two instrumental background readings were taken on the aluminum plate. The results of the instrumental background readings are in Table I, showing both the upper and lower chamber activity.

This data for both the upper and lower chamber shows essentially the same reading.

FIELD DEMONSTRATIONS

Concrete Block Measurements

On July 15, 1994, the first-generation CSM was used to measure the residual alpha contamination on concrete blocks that came out of trenches at Technical Area-21 (TA-21) at LANL. The dismantling of trenches is a part of the D&D effort currently in progress (6).

The 300-cm2 CSMs were used due to their appropriate size and attachment clamps. Prior to the demonstration, the detectors were calibrated using a set of National Institute of Standards and Technology traceable 239Pu sources ranging from 100-5620 dpm. The sensitivity of the 300-cm2 CSM is 7.1 dpm/fA. The sensitivity of other CSMs ranges from 5.5 to 7.1 dpm/fA.

The concrete blocks to be monitored were cut out of trenches. The surface to be monitored was relatively flat, although some areas were rather rough and irregular. These blocks were placed with varying angles, hence at some locations a clamp attachment was used to secure the detector and create an air seal between the surface and the detector volume. For background measurements, an aluminum plate was used. The aluminum plate underneath the detector prevents penetration of any alpha radiation from the concrete or ground into the detector. This gives an instrumental background measurement consisting of leakage current, electronic noise, leakage of outside air into the monitor, and the ambient level of gamma radiation but does not measure any alpha emissions from the surface.

Ten readings were taken from various locations on three different concrete blocks. For each point the instrumental background was subtracted from the measured reading to give the surface activity. For comparison, readings from concrete surfaces around the town of Los Alamos were taken from nine different locations. These locations included an apartment complex, sidewalks in front of businesses, an historical landmark, the Aquatic Center, a church, a library, and the local Post Office totaling 27 readings. In Table II the results from both experiments are compared. For comparison, readings within the city of Los Alamos range from 62 to 93 dpm/100 cm2 above background due to the natural activity in concrete. The measurements were taken from apartment complexes, sidewalks of businesses, an historic landmark, the Aquatic Center, a church, a library, and the local Post Office.

A potential error of 20 dpm/100 cm2 was determined to be a direct result from the portable oscilloscope and the concrete. Concrete has an intrinsic activity level (even when concrete is "uncontaminated") and these readings may be showing variations in the "natural" activity of the concrete.

Water Tower

On May 31, 1994, the 1431-cm2 CSM was used to characterize an 18-m2 area under a water tower at TA-21. A total of 24 points were taken at 50-cm intervals. Instrumental background was again taken on an aluminum plate. Relative to this background, the highest observed points were 160 dpm/100 cm2. This area is relatively clean based on the Department of Energy public release limit of 300 dpm/100 cm2 for transuranics. Figure 2 shows the water tower at TA-21 prior to demolition and removal to a dump site.

Most of the readings were between 40 and 80 dpm/100 cm2 above the instrumental background. Figure 3 shows the contour plot covering the accessible area. The result yielded a maximum count of 160 dpm/100 cm2. This area is relatively clean. Independent measurements performed by the site's health physicist with a commercialized detector confirmed our evaluation.

Previous measurements using similar LRAD soil surface monitors found a naturally occurring alpha emission background around 200 dpm/100 cm2; therefore, most of these readings above instrumental background can be ascribed to naturally occurring activity.

Figure 2. The water tower at TA-21. The area under this tower was characterized.

Figure 3. A contour plot of the measured activity level under the water tower.

Utility Pads and Concrete Floors

On August 30, 1994, both the background-subtracting and the 1431-cm2 hand-held CSM were used to measure the residual alpha contamination on the floors of Building 146 and surrounding concrete pads at TA-21. Depending on the size of the area to be monitored, appropriate CSMs were used. The background-subtraction CSM was used on the floor in Building 146 because it has the larger detection area. The utility pad and water tower outside Building 146 were sampled with the hand-held CSM. Instrumental background was checked using the aluminum plate at a regular interval. The collected ions were read out using the LANL electrometer and a portable oscilloscope.

Figure 4 shows the 24 readings taken from the concrete floor. Some regions were inaccessible as shown by the single-hatched marks.

We took 42 readings on a 61-cm grid on the utility pad. The measured activity varied from 0-40 dpm/100 cm2 above instrumental background for most readings. The concrete floor was measured using the background-subtracting CSM. With an active-detection surface area of 2500 cm2, each measurement covered a larger area than the other detector.

Generally the activity ranges from 0-50 dpm/100 cm2. Three of the 24 readings show higher levels of alpha activity. One reading shows 193 5 dpm/100 cm2; visually, this location shows a fairly large grease spot. Two other locations close to this spot gave readings of 51 3 dpm/100 cm2 and 83 19 dpm/100 m2. Wherever possible, the site health physicist verified the high readings to provide an independent confirmation.

In addition to the Building 146 field experiment, the background-subtraction CSM was also used to monitor the concrete floor in Building 324 at TA-21. Instrumental background was recorded at 62.2 fA and 26 readings were taken over an 89-m2 area. The results show activity ranging from 0-30 dpm/100 cm2. Again, this is equivalent to "normal" concrete.

Figure 4. A contour plot of alpha activity on the concrete floor at TA-21 (Building 146) D&D site.

CONCLUSION

The task of waste minimization of concrete surfaces and structures requires detectors that are sensitive, rugged, operate in real time and in situ, and capable of measuring large surfaces. CSMs have been designed to meet those requirements in addition to being cost effective. Using these CSMs, concrete surfaces and structures can be characterized effectively and efficiently.

ALPHA CHARACTERIZATION INSIDE PIPES USING ION-TRANSPORT TECHNOLOGY

Los Alamos National Laboratory

ABSTRACT

Many DOE facilities have several miles of waste pipe systems that are internally contaminated with various and often undetermined radio nuclides. Unfortunately, currently acceptable alpha detection technologies are inefficient, time consuming, and do not address the problems presented by small diameter or curved pipes. In general, the problem of detecting alpha contamination on the inside surface of pipes is complicated by the fact that alphas do not penetrate the pipe walls. Unlike their conventional counterparts, alpha detectors based on ion transport technology sense alpha particles by collecting the ions created in ambient air as the particle loses its kinetic energy. The ions inside the pipe are transported by a fan-generated air current to an electrode inside the detector, which is attached to one end of the pipe. The collected charge at the electrode is proportional to the number of ions created inside the pipe, which in turn is proportional to the number of alphas emitted.

Typically, monitoring for alpha contamination inside pipes or ductwork involves disrupting the operation to access as much surface area as possible for standard alpha monitoring. The detector based on ion transport technology effectively minimizes such disruption and in many circumstances will allow for in situ monitoring of a system that might otherwise not be practically accessible to standard methods.

INTRODUCTION

According to a recent call for decontamination and decommissioning (D&D) proposals by DOE, "A method is needed for performing non-destructive, in situ measurements to detect radioactive contamination inside enclosed volumes. These volumes may include, but are not limited to, pipes, ducts and process equipment." Currently acceptable technologies cannot address the problems presented by alpha contamination located in small-diameter pipes, complex process equipment, and inaccessible volumes. Yet every DOE facility has waste pipe systems or equipment or both that is internally contaminated with possibly undetermined radio nuclides. In addition, gaseous-diffusion plants, like the one at Oak Ridge, Tenn., will require significant internal radiological characterization of their process equipment. Clearly, some kind of internal volume monitor (IVM) is required.

Los Alamos National Laboratory (LANL) is currently developing various IVM detectors, based on ion transport technology (1), which use airflow for ion collection. For such detectors, an air current (generated in the enclosed volume by an external fan) transports the ions to the electrode inside the IVM. The current that is measured is directly proportional to the number of ions (either positive or negative) in the enclosed volume which, in turn, is directly proportional to the total contamination level on the interior surfaces.

Understanding the relationship between the following six parameters is crucial to the future success of monitoring both large and small volumes with IVMs: ion lifetime, grid voltage, airflow, pipe geometry, and detector response. These

parameters are empirically investigated in this paper for one specific IVM currently under development at LANL: the pipe IVM. This detector is designed to non-intrusively detect contamination in pipes and ducts ranging in size from less than 1 cm to greater than 1 m. Most gases can be used for ion transport so pipes and ducts filled with various gases, as well as with ambient air, can be monitored effectively. In addition, because ions can pass through almost any convolution in the pipe, complex plumbing can be readily monitored. This document summarizes the results from laboratory tests performed at LANL in 1994. Over this time, the relationship between the six parameters mentioned above was studied using a prototype pipe IVM.

EXPERIMENT SETUP

The basic mechanical components that constitute a pipe IVM include the grid and associated standoffs, a fan, a spacer to isolate turbulent back flow, and a filter. This hardware is assembled into a detector system and attached onto the end of a length of possibly contaminated pipe as shown in Fig. 1. A spacer filled with flow-straightening straws is required to prevent turbulent back drafts from the fan from affecting the collection of the ions at the grid and effectively lowering the response. A 3M FiltreteTM filter (G-100) at the end of the pipe opposite the detector is also necessary to prevent ions from the room from getting inside the pipe volume. (For stronger sources, such a filter was not necessary because of the large difference between detector response and ambient background.) The single-grid pipe monitor used for collecting the data presented here is shown in Fig. 2.

Two basic pipe IVM designs were tested: the single-grid IVM and the double-grid IVM. As shown in Fig. 2, the grids used for ion collection are basically perforated circular copper disks. For the single-grid design, the signal is taken directly off of the lone grid, to which a nominal 300 V is applied. In contrast, for the double-grid design, the ions are collected on one grid that is kept at ground while the other grid receives the 300 V necessary for sweeping ions onto the collection grid. In both cases, primary ion transport is accomplished by fan-generated airflow through the entire length of the pipe. Comparisons under like conditions (e.g., same airflow and pipe length) between the single-grid and double-grid designs yield a single-grid response that is approximately twice the double-grid response. (The pipe used for this test was 2 ft, or ~ 61 cm, long.) For this reason, the single-grid design was chosen as a benchmark for studying the relationships between response and voltage, airspeed, pipe geometry, and source strength. In addition, the single-grid pipe monitor was used to estimate ion lifetime and study the effect of pipe geometry and airflow on the lifetime of ions within the pipe.

RESPONSE VS VOLTAGE

This test was performed using a 20-ft-(~600 cm) long straight pipe with the goal of determining the optimal voltage for ion collection. The schematic diagram of the experimental set-up is shown in Fig. 1. For this test we used a 217,642 dpm 238Pu source and varied the voltage from 25 V to 1100 V. The airspeed at about 6 in. (~15.2 cm) from the grid was kept at a constant 180 fpm (.35 m3/min) and the source was placed 18 ft (~548 cm) from the detector as the voltage was varied. Plotting response in fA (1x10-15 A) vs voltage, yields a curve that plateaus at approximately 600 V. The experiment confirmed predictions that if voltage is too high, an unusable large signal results from grid-voltage-induced ionization. Traditionally, ion transport detectors have used 300-V batteries because they are commercially available; however, the test results indicate that the optimal voltage that does not ionize surrounding air, yet collects the ions efficiently, is approximately 600 V. This optimal voltage is a function of grid material and geometry.

RESPONSE VS SOURCE POSITION

This data was taken to see how the response from a given source varied as a function of the distance between the grid and the location of the source within the pipe. Figure 3 is one such data set, which clearly illustrates the powerful utility of ion transport technology. As shown in Fig. 3, a clear distinction can be made between a 1000 dpm source and a 2500 dpm source from a distance of 18 ft (~548 cm). Another feature that is apparent in this plot is that, as expected, the sensitivity is lower at 18 ft (~548 cm) than at 2 ft (~61 cm) corroborating the notion that most of the ion losses are caused by interactions with the walls of the pipe.

ION LIFETIME

Similar data involving detector response and source distance was taken using a 217,000 dpm source to calculate the lifetime of the ions. For our purposes, ion

lifetime is defined as the time (distance/air speed) at which the response falls to half the value of the number of ions obtained when the source is placed directly next to the grid inside the pipe. For an airflow of 180 fpm (~.35 m3/min), ion lifetime was calculated to be 8.4 s. Figure 4 shows one such plot of the ion lifetime and a fit obtained using the function

Eq. 1

where N0 is the initial number of ions, t is the life time of the ions and t is the time. Ion lifetime varies as a function of air flow and pipe geometry. Initial experiments indicate that ion lifetime is also a strong function of the radial position of the source within the pipe. A source placed at the center line of the pipe will generate alpha particles that will last much longer than those generated from a source placed at the bottom or top of the pipe; a result which makes sense considering that the velocity profile inside the pipe is maximum at the centerline and minimum at the outer diameter walls.

RESPONSE VS AIRSPEED

For the next set of tests, the grid voltage and source strength were held constant and the airspeed was varied. Figure 5 shows one data set from these tests in which 300 V was applied to the grid using a 217,000 dpm 238Pu source. As shown in Fig. 5, the highest airspeed used was 400 fpm while the highest response was obtained at a setting of 180 fpm (~0.35 m3/min). This data seems to indicate that after a certain high velocity, the ions are simply getting swept through the grid without being detected. The previous data sets discussed have indicated that the probability of capturing an ion on the grid is proportional to airflow and applied voltage. The optimal value of each of these parameters has been determined using the single-grid pipe IVM. We suspect that response is also directly proportional to the grid surface area and that increasing the surface area will yield a higher optimal value for the airflow (and perhaps grid voltage). It is our thought that using a parallel plate "venetian blind" grid design will counter the effect of response degradation at higher airspeeds and also enable detection distances greater than 18 ft (~548 cm). Whether the surface area directly facing the flow ("wet" surface) or the total surface area in contact with the flow is of primary interest will be determined in future tests using the second prototype pipe IVM with a venetian blind grid. Experiments conducted using a monitor fitted with a parallel-plate, venetian blind grid design do indicate increased detection efficiency so application of the concept to pipe monitoring may prove very beneficial.

In another set of similar test runs we observed that there were ranges of velocity over which detector response was constant. This range was fairly wide at 2 ft (~61 cm) and narrower at 18 ft (~548 cm). This suggests that in the limit as source distance decreases to zero, primary ion transport is no longer from airflow, but rather from the electrostatic field around the grid.

RESPONSE VS PIPE GEOMETRY

The next set of data involved placing a 217,000 dpm 238Pu source at four different positions along a pipe with a 90 bend in it. The pipe used was 4-ft long with a 90 bend in the middle and four holes drilled into it. The first and second holes, which were before the bend, were 1 ft (~30.5 cm) and 2 ft (~ 61 cm) away respectively. The third and fourth holes, which were after the 90 bend, were 2 ft 8 in. (~81.2 cm) and 4 ft (~122 cm) away from the detection grids respectively. A grid voltage of 300 V was used along with a 180-fpm (~.35 m3/min) airspeed. A plot of response vs distance is shown in Fig. 6. The decrease in the response between 2 ft (~61 cm) and 2 ft 8 in. (81.2 cm) mainly comes from the increased distance between the detector and the source rather than the bend in between. This particular observation is crucial for facilitating monitoring in bent pipes or process equipment and suggests that such monitoring may be limited by the traditional parameters discussed earlier (e.g., airflow and grid voltage) rather than pipe geometry if laminar flow can be maintained in all sections. In other words, wall recombination effects do not appear to be any more significant in curved pipes than in straight pipes if laminar flow is achieved.

FUTURE DIRECTIONS: SOURCE LOCALIZATION

We are entertaining two ways of localizing sources within pipes. The goal is to be able to pinpoint the location of a point source within a pipe. This may ultimately lead to the ability to detect large concentrations of accumulated material in a pipe containing an otherwise uniform distribution of contamination.

The first method attempted involved shuttering a source to determine the time for

the signal to reach the grid. Knowing the airflow and measured time, we can then calculate the distance from the source to the grid. The accuracy of this measurement will depend on the time resolution of our data acquisition system and the accuracy of the airflow measurement. A simple proof of principle test using a fan and the pipe IVM was performed to investigate the ability to localize the position of a source inside a pipe. A 238Pu source was placed at the end of the pipe and the time between source placement and signal observation was recorded. This time was then used to back-out the approximate position of the source in the pipe. The calculated distance of 16 ft compared very well with the actual distance of 20 ft considering the coarseness of the experiment. These results seem to suggest that with a more refined setup, source positions could be determined to within 2 ft using this preliminary method. Prior to conducting this experiment, a similar attempt was made at determining the source position by pulsing the fan at a very low airspeed (~170 fpm). The negative spike caused by pulsing the fan made it very difficult to see the negative signal caused by the source. If source localization is to be made field-ready, such problems will have to be addressed. Two possible solutions include digital signal processing of the grid signal to separate out fan effects from the actual source response or a double monitor configuration utilizing a detector at each end of the pipe. Such solutions will be investigated and the general feasibility of source localization with temporal data will be researched further. The second method involves taking data from one end of the pipe and then moving the detector to the other end of the same pipe and taking data again. By looking at the responses at the two ends one should be able to tell at what section of the pipe the source is located. This particular method will localize contamination but it might pose practical drawbacks in real life. For example in some D&D scenarios the pipe might be accessible from only one end. Therefore we believe that further exploration into both methods of localization is quite necessary at this point. Also differences in the response from different ends of the pipes will vanish when we start using higher airflow with venetian blind designs for grids. Thus depending on the application we might want to retain a single-grid design for pipe monitors along with the pipe monitors with venetian blind grids.

CONCLUSIONS

In conclusion, with further development we believe that we can provide nondestructive, in situ and real time measurements for contamination within the pipes. A fully developed pipe monitor technology should be capable of characterizing pipes ranging in diameter from 1 cm to very large pipes. In addition to the straight pipe, we should be able to give reliable information on curved pipes. Moreover, localization of the contamination appears possible to some degree. It is important to note that the ion collection technique using airflow within pipes is the simplest case for detecting contamination within more general internal volumes. Other possible volumes include glove boxes (2) and truck trailers filled with cargo. (In fact, we are studying assay of glove boxes.) In addition the pipe monitors shown in Fig. 1 have been used to assay weapon cartridges (3).

A PORTABLE ALPHA DETECTOR FOR FAST, LOW-LEVEL, REAL-TIME MONITORING

J. P. Johnson
J. E. Koster
P. A. Steadman
Los Alamos National Laboratory

ABSTRACT

We have developed a portable Medium Object Monitor (MOM) that is based on Long-Range Alpha Detection (LRAD) technology at Los Alamos National Laboratory. This monitor is

a very fast, mobile, sensitive alpha detector. We have begun a series of laboratory and field tests with the monitor. We will present data detailing the monitoring of contaminated objects in a laboratory setting, along with some comparative results from traditional monitoring techniques. We will also present data derived from the monitoring of "clean" material, stressing the expediency of an LRAD-based detector.

INTRODUCTION

Introduction to LRAD-Based Technology

At Los Alamos National Laboratory (LANL), the Environmental Applications (EA) section has been developing an alpha particle detection system (Long-Range Alpha Detection, LRAD) based upon ionization detection. It is well known that the mean energy expended in a gas per ion pair formed is approximately 35 eV/ion pair (1). As such, a typical 5-MeV alpha particle will produce about 140,000 ion pairs per disintegration. We have found that if these ions are transported onto a charged grid the current produced is proportional to activity (2).

An LRAD-based detection system has many advantages over traditional alpha monitoring methods. The short range of the alpha particle implies that all of its energy produces local ionization. If the ionization is contained within an enclosed area, then it becomes easy to transport the ions onto a detection grid.

Amplification of one alpha particle to 140,000 ions provides numerous benefits. Ions are much longer lived than alpha particles. One experiment determined an ion cloud half-life to be about 8 s when the ions are being propagated down a 3.5-in. diameter pipe at 180 ft/min (3). Only a fraction of the ions will recombine in air or onto a surface. The remaining ions allow effective monitoring on convoluted objects or interior surfaces such as beakers, nuclear instrumentation modules, or pipes. The large number of ions ensures that the signal responds rapidly to activity. Once an object has been placed into the detection chamber, and it has been sealed, only a few seconds are required to clear the chamber of ambient ionization and observe the signal rise (if there is a signal to observe) over background. Alternatively, if the object being monitored is not contaminated with alpha activity, only a few seconds are required for the signal to return to its background level. The automated nature of LRAD-based systems ensures consistent results, eliminating the variability of hand monitoring.

Ion Collection Methods

Ion collection to the charged grid can be facilitated two ways. With an electric field, the ions can be electrostatically accelerated onto a grid. Ions can also be swept onto the grid via airflow.

Electrostatic Monitors

An electrostatic detector is typically a five-sided rectangular or square box with a shallow profile. The open face can be placed over the surface of interest with the sides of the detector forming a seal to the surface. The charged detection grid, usually held at 300 VDC, is about 4 in. away from the grounded surface creating an electric field from the ground to the grid. The charged grid is mounted to the detector with Teflon or lexan standoffs to reduce leakage current. Electrostatic monitors are best used for monitoring two-dimensional media, such as the earth, floors, walls, or ceilings. LRAD-based detectors are very good at providing accurate activity levels when monitoring flat sources of activity. This has been proven in many field monitoring demonstrations at Fernald, Sandia, and Los Alamos monitoring surfaces such as concrete, grass fields, laboratory flooring, dirt lots, and New Mexico desert. Electrostatic monitors are the most efficient monitors of an LRAD design. A typical electrostatic monitor will detect 75% to 95% of the ions that are liberated into the electric field (4). It is thought that the static nature of the electrostatic monitor makes it ill suited for monitoring objects that have complex convolutions.

Airflow Monitors

Airflow monitors use airflow to sweep the ions onto a charged grid. An airflow monitor has, on the intake end, a fan manifold and two filtration systems: one for particulates and one for ions. The fans force air through the system, creating the airflow that is essential for ion transport in this type of detector. The particulate filter screens out dust, dirt, and other airborne debris that could contaminate the chamber interior or act as a surface upon which ions could plate out. The electrostatic filter is a charged grid between two grounded screens that filters out ambient ionization from the air. The air flowing into the detection chamber should be relatively free from ions and particulates. The detection grid, on

the outtake end of the detector, is usually held at 45 or 90 V and segregated from the detector with Teflon or lexan guarded stand-offs. The grid is sandwiched between two grounded screens. Ions are swept out of the contaminated media by the air stream and onto the detection grid. Airflow detectors are useful for objects and other convoluted items because the airflow can sweep the ions out of the structure. Although sensitive, airflow monitors are not effective assay devices; the non-uniform distribution of activity on three-dimensional objects makes it very difficult to precisely calibrate the detectors. For example, if a cube of metal were being monitored and the contamination were on the upwind face of the cube, many of the ions would be swept into the block and recombine. If the contamination were on the top of the block, all of the ions would be liberated into the airstream immediately. If each scenario had identical activities, the second scenario would yield a higher current flow on the detection grid. Airflow detectors are not as efficient as the electrostatic designs, able to optimally detect 40% to 50% of the liberated ions.

Combination Electrostatic/Airflow

Another type of detector is a combination airflow/electrostatic detector. These monitors are identical to airflow monitors, except the electric field of the detection grid extends into the detector system to assist in the ion transport, whereas airflow monitors rely only upon the airflow to transport the ions. This type of detector could offer improved efficiency over the standard airflow designs, because of the additional advantage of the electric field. These detectors are ideal survey devices, able to quickly monitor objects of many shapes and sizes. They are also very sensitive, able to quickly (15-20 s) detect source activities of less than 100 disintegrations per minute (dpm). However, these detectors have a disadvantage because it is more difficult to precisely assay objects for precise activity levels.

Intent

This paper presents data from laboratory experiments using a variety of convoluted objects with an imbedded source. We compare the response efficiency of an electrostatic, airflow, and combination detector. Where applicable, we compare these with a traditional hand-held probe. We also present data obtained while monitoring noncontaminated objects, focusing on expediency and accuracy.

While laboratory tests are important, the real test of any radiation detector is how well it works in the field under uncontrolled conditions. We have had the opportunity to monitor several objects, including a contaminated sweater. We discuss the monitoring of this sweater.

PROCEDURE

Detectors Used

The laboratory experiments used three detectors. We used an electrostatic monitor, an airflow monitor, and a combination detector, all described above. The electrostatic monitor is a floor monitor mounted on a hand cart; the detector has a footprint of 50 cm x 50 cm, or 2500 cm2. The grid was charged with 300 VDC, and the detection grid was about 4 in. from the floor. The electrometer was a Kiethley 617; our data acquisition system provided current levels with full statistical accompaniment. The airflow detector was a commercially available Eberline LRAD-1. The LRAD-1 is a rectangular detector with a sample chamber volume of about 76 L. The LRAD-1 only provides an activity level in dpm, with no statistical information. The quoted activity levels have a confidence level of 95% (5). The combination detector is the Portable Object Monitor (POM), a prototype portable detector designed and constructed for the Department of Energy. It has a cylindrical detection chamber that has a volume of about 2.2 L. The electrometer is a LANL-developed current-to-voltage proportional electrometer. The POM used the same data acquisition system as the electrostatic detector.

Experimental Hardware

We placed an 1100 dpm 239Pu source into three convoluted objects: an electronics module, a square metal tube, and an aluminum pig with and without a cap on it, viewed in Fig. 1. The aluminum pig is a block of aluminum with a small (1.3-cm diameter) hole bored through its length with a larger (2.5 cm) hole drilled into the top to provide access for the source. The pig is 9.8 cm long, 6.4 cm high, and 3.8 cm deep, with about 164.2 cm2 of area or an effective contamination level of 382 dpm/100 cm2. The cap is a small copper plug that fits over the source access hole. The square aluminum pipe is 18.1 cm long and 2.5 cm square. It has an internal area of 181 cm2 and an external area of about 181 cm2 for a total of about 360 cm2. The

effective activity is about 300 dpm/100 cm2. We placed the source into the middle of the tube. The electronics module is a box 10.8 cm long, 6.4 cm high, and 4.1 cm deep for a surface area of about 279.3 cm2 and an activity of 197 dpm/100 cm2 with a screw-on lid and perforated aluminum grids on each end. The source was placed into the approximate center of the electronic module. Assuming that the "contamination" were fixed transuranic material, the release limit would be 300 dpm/100 cm2. The "activity" on the pig exceeds that limit. The activity on the electronics module and the aluminum tube is below that limit. The pig, with the cap on, has the most constrained geometry, being the most difficult to monitor. In each case, when the object was placed into an airflow-style detector it was placed so that the airflow was perpendicular to the open end of the object to facilitate the most efficient ion sweeping.

Calibration

Each detector was calibrated using a 239Pu National Institute of Standards and Technology traceable source set. The LRAD-based detectors have a source response that is linear with activity, as such, the following calibration coefficients are optimum:

Electrostatic Activity = .180 dpm/fA x (current)
Airflow Activity = N/A
Combination Activity = .109 dpm/fA x (current)

Therefore we are able to predict current for a given activity or the activity for a given current. Based upon the listed calibration constants, we know that an 1100-dpm source should produce the following results for the following detectors:

Electrostatic Current = 198 fA
Airflow Current = 1100 dpm
Combination Current = 120 fA

Results

The first object that we tested was the pig without the cap on it; results are shown in Fig. 2.

This configuration allowed ions to drift out of the top of the pig because the copper plug did not cover the source access hole. This configuration also proved to be the most balanced, with each detector able to monitor about 25%-30% of the optimum signal. This was the only configuration for which a handheld probe detected any activity.

The configuration in Fig. 3 offered the tightest geometry, and the most "contamination," with an activity level of about 380 dpm/100 cm2. The hole through which the ions traveled was 1.3 cm in diameter. It is important to note that the range of an alpha particle at this altitude (6600 ft) is greater than 3.5 cm. Because of Bragg peaking, most of the alpha energy was embedded in the wall. Even with these handicaps the two airflow detectors measured between 10% and 15% of the optimum signal, an increase large enough to have warranted further investigation if this reading had taken place in the field.

The airflow monitor and the combination monitor work about equally well for the metal tube case shown in Fig. 4. The airflow helps facilitate ion removal out of the tube so that the ions could be transported to the ion detection grid. In each case, the signal was evident within seconds. The source was placed in the middle of the tube and with the 9-cm drift space between the source and the detector the ions recombined in air or with the wall of the tube before reaching the detector. The electrostatic detector did not monitor any ions. This configuration had a surface activity of 300 dpm/100 cm2 at the release level, and both airflow monitors detected the activity.

The electronics module is large enough for the alpha particles to completely ionize, however, many of the ions recombine on the interior of the electronics module as they exit through the screen. The results are shown in Fig. 5. This object had an activity of 197 dpm/100 cm2 or about 66% of the release limit. Both airflow monitors detected the activity. The combination monitor measured a signal rise of about 40 fA over background. This detector normally has a background level of about 12 fA. A rise of 40 fA would be an acutely noticeable signal increase that would be noticed within 8 to 10 s. To compare, monitoring the exterior of this item with a hand probe would take at least 4 to 5 s per side, or 25-30 s total, and there would still be no information concerning the interior of the module. The LRAD-based detectors were able to detect a point source on the interior of this item whose activity was below the release level.

MONITORING UNCONTAMINATED ITEMS

We are in the process of monitoring potentially contaminated items at the Chemical Metallurgy Research (CMR) facility at LANL. The first objects that we monitored were a pile of scrap metal and other debris that had been cleared for release. Although we found no contaminated items in the pile, we did obtain valuable data concerning the speed of item monitoring using LRAD-based detectors. Using the POM, we monitored 70 different items in 7 batches of 10. Our primary goal was verification of noncontamination, and our secondary consideration was fast, timely monitoring of the items. Some of the different items/materials we monitored were copper piping, metal scraps, wire pieces, carbon rods, cardboard boxes, phenolic, brass scraps, Plexiglas, graphite tubing, hunks of concrete, and various aluminum pieces. None of the items we monitored had any detectable activity. We found that we could monitor the metal pieces at a rate of one item every 10 or 15 s. The more nonconductive items, such as the cardboard or Plexiglas, sometimes took longer to monitor because the static charge took a while to discharge and come to equilibrium inside the detector. One person both monitoring and documenting was comfortably monitoring each batch of 10 in about 30 minutes. We determined that two people could consistently monitor and document 10 items in under 10 minutes (6).

SWEATER MONITORING

At the CMR building we monitored a sweater that had become contaminated with an alpha point source of about 200-250 dpm, as seen by a hand-held probe.

LRAD detectors have had difficulty detecting alpha activity when the activity is located on non-conductive surfaces. Recently LRAD researchers have begun experimenting with "ion flooding" techniques. This involves saturating the object of interest with ions to neutralize the static charge that is created on the nonconductive object. Once neutralized, the object will not attract any of the ionization created by the alpha activity. We used three Static Masters, a static removal product, each containing 500 mCi of 210Po. Polonium 210 is an alpha emitter that decays to stable 208Pb. Taking decay into account, the three Static Masters had a combined activity of about 4.2 x 106 Bq. We used these as our ion saturation devices.

Our first monitoring attempt on the sweater proved unsuccessful. A radiation technician remonitored the sweater with the hand probe and found the contaminated spot to be on the front of the sweater near the bottom fringe area. It was determined that we had covered up that area on the earlier monitoring attempts. We decided to remonitor the sweater in the detector, exposing the contaminated area. We took three measurements of the sweater in the detector: two measurements using the ion saturation technique and one measurement without using the ion saturation technique. The measurement that did not employ the ion saturation yielded a no contamination response. The two measurements that did use ion saturation yielded measurements of 190 dpm and 252 dpm. These readings corresponded to the measurements of the hand probe (7).

CONCLUSIONS

The airflow monitors have a unique advantage over any other type of detector available today. If there is an airflow, these detectors have the ability to detect contamination in a three-dimensional configuration. The open top of the pig without the cap provided an easy exit point for ions and alphas to drift out of the object. Once the ions or alphas were liberated they could be detected with both the electrostatic monitor and a traditional hand probe. Each of the monitors detected about 25% -30% of the optimum signal, and this was the only configuration in which the hand probe was able to detect any activity. The other three graphs show that the electrostatic monitor did not detect much, if any, of the ionization. This was because the last three configurations required the ions to be swept out of the medium to be detected. A pure electrostatic monitor cannot do this, the air flow monitors can.

LRAD-based detector systems are proving that they possess capabilities that, if utilized properly, make them a valuable waste management tool. These monitors are automated, sensitive, and fast. The laboratory tests begin to prove that detectors of this design can detect alpha activity that could not otherwise be detected using conventional methods. Often, when confronted with objects that may be contaminated or if there are numerous items, it becomes easier and cheaper to just dispose of the material as if contaminated. LRAD-type detectors provide an expedient and sensitive method for monitoring these types of items, ultimately saving landfill space,

improving labor costs, saving natural resources, and improving site accountability.

ABSTRACT
A real-time monitor for radioactive liquid waste is being developed at Los Alamos National Laboratory (LANL). This detector system is designed to monitor for large changes in alpha activity in a liquid waste stream. The detector is unique in that it monitors the ionization created by alpha interactions with air, using long-range alpha detector (LRAD) technology (1). This is a non-intrusive method that can be used in various complicated geometries. This technique only allows for the monitoring of the surface of the liquid, however, preliminary tests indicate that the technique should allow for real-time, sensitive monitoring of a well-mixed liquid waste stream. This technique will require further research and development, but the final system should be an inexpensive detector system for segregating and monitoring radioactive liquids at national laboratories, processing facilities, and nuclear power plants.
INTRODUCTION
A prototype radioactive liquid waste monitor is being developed for the group CST-13 at Los Alamos National Laboratory. This monitor will be used in the radioactive liquid waste treatment facility (RLWTF) so that the operators know when there is a large change in the activity of the influent waste stream. These spikes in activity will be 10 to 100 times above the average influent activity. The average influent typically has an activity of tens of nano-Curies. Measurements were made in 1994, and the detector was able to monitor liquid below the 100pCi/L level. Current regulations mandate that both influent and effluent be monitored to determine the overall effectiveness of the treatment process. Traditional methods require up to a day and a half for analysis. This monitor will be able to monitor the gross alpha activity from the surface of a liquid stream in real time, giving the operators a chance to better segregate the liquid as well. This technique will save both time and money and may eventually be applied to effluent monitoring before discharge into the environment.
DESIGN
Traditional alpha detectors monitor the alpha particles directly, requiring that they be close to the object being monitored. It is difficult to design a detector to do this because of the changing levels of the liquid stream, humidity, and other engineering concerns. The radioactive liquid waste monitor being developed by LANL is not subject to these constraints because it monitors the airborne ionization created by the surface alpha particles. Tests at LANL have shown that this

ionization can be transported via an electrostatic field or by airflow up to distances in excess of several meters, depending on the application. Each 5-MeV alpha particle can create approximately 150,000 ion pairs, therefore this technology has proven to be highly sensitive for monitoring alpha contamination.

This prototype design is based on the electrostatic long-range alpha detector (LRAD). As shown in Fig. 1, the influent is placed in a stainless steel sink. The top portion is removable and consists of two stainless steel signal planes and two electrometers. A current, at the fA level, is measured on each signal plane. These signals are then converted to mV and output to a computer for storage and analysis. The bottom plane measures the ionization of the volume beneath it, which includes the background ionization and the ionization from the sample. The top plate measures only the background ionization in the volume above it. By taking the difference of these two signals, one gets a background-compensated signal that is representative of the alpha activity from the sample surface (2). By calibrating the detector, it is possible to directly convert this signal into a measure of activity. Figure 2 shows the standard calibration using a standard set of National Institute of Standards and Technology (NIST) traceable Pu-239 sources. The source strengths range from 100 to 1100 dpm-alpha. For this prototype, the conversion for dry samples is 1 mV = 58.98 dpm. This detector is clearly able to discriminate dry samples with less than 100 dpm-alpha activity. Initial tests using liquid samples show the prototype to be sensitive to samples of 100 pCi/L. The efficiency of such an electrostatic design is roughly 40%.

Fig. 1. Schematic drawing of the LRAD radioactive liquid waste monitor prototype. The top volume only measures background ionization, therefore the difference of the two signal planes gives only the contribution to the signal from the surface alpha contamination.

Fig. 2. A linear curve fit of the LRAD radioactive liquid waste monitor prototype using a NIST traceable set of Pu-239 sources. For these sources, the conversion was 1 mV = 59 dpm.

It should be noted that tests will also be made using the airflow LRAD design. In this design, a fan will be used to draw the ions to a detector grid. This design would be useful in monitoring liquid inside large sewer pipes. This type of detector is more subject to noise and has an inherently lower efficiency than the electrostatic design, however it might provide a better indication of the surface activity since it would be able to draw air from a larger volume. All the air drawn off would then be recycled back into the volume.

PRELIMINARY RESULTS

Tests have been performed at the radioactive liquid waste treatment facility at LANL using actual radioactive influent samples. These preliminary tests have shown that this prototype is able to monitor low-levels of alpha contamination in liquids. These tests have consisted of putting both radioactive samples and distilled water in the detector for lengths of time more than three days. As shown in Fig. 3, these tests show that this design is able to adequately compensate for changes in background radiation levels. In Fig. 3, the signals from both the top and bottom signal planes are shown. Both signals track each other well, and the difference of these signals is a smooth line corresponding to the activity of the sample only. Figure 4 shows the results of running with a radioactive liquid sample over a 3-day period at the RLWTF. The mean signal for this period was 23.5 1.4 mV. This prototype has shown no problems with humidity, despite the fact that a considerable amount of condensation builds up inside the detector. Additional testing has been performed that shows that this detector is also fairly immune to mechanical noise.

Fig. 3. The top detector plane reads only the background ionization. The result of taking the difference of these two signals is a smooth signal corresponding to the activity of the sample being monitored.

Fig. 4. This plot shows the response of the LRAD radioactive liquid waste monitor over a 3-day period using background compensation. The mean signal was 23.5 1.4 mV.

All of these tests will be repeated and a comparison to laboratory analysis using traditional alpha monitoring will be made. This will allow us to determine a conversion to alpha activity per unit volume. These tests, as well as testing with an airflow LRAD, will be made in February 1995, after which a new prototype will be built for inline testing at the treatment facility. A working real-time monitor for spikes in activity should be installed at the treatment facility and operational in the first half of 1995.

CONCLUSION

This detector has been shown in preliminary tests with radioactive liquid samples to be a sensitive alpha monitor. It is able to compensate for changes in background radiation and it operates in real time. Because the design of this system does not require costly parts and labor, it is inexpensive compared to other real-time alpha monitoring systems.

The preliminary tests carried out at LANL indicate that this detector can be used to monitor for large changes in alpha activity in liquid streams. Further funding will allow further development of this system so that it can be used as a sensitive assay device as well. This type of detector can be used for monitoring before, during, and after processing liquid waste. It can prove valuable to treatment facilities by monitoring processed liquids before release into the environment, thus ensuring regulatory compliance. It could also prove beneficial to the commercial power industry. We are currently seeking an industrial partner to assist in carrying out this development.

INNOVATIONS IN SOIL WASHING AT THE DEPARTMENT OF ENERGY HANFORD SITE

Michael J. Mann, P.E.
Alternative Remedial Technologies, Inc.,
Tampa, Florida
Jhivaun Freeman Pollard
Westinghouse Hanford Company
Richland, WA

ABSTRACT

This paper presents the background, procedures, and results of a soil washing treatability test at the 300-FF Operable Unit (OU) of the Department of Energy (DOE) Hanford Site, Richland, Washington. The treatability test was designed to demonstrate on a pilot scale that physical/chemical treatment techniques could provide very significant volume reductions in the remediation of target soils contaminated with uranium and cobalt-60.

BACKGROUND

Physical separation processes are used extensively in the mining and mineral processing industries to assist in the recovery of valuable constituents. These physical processes have been demonstrated by the United States Environmental Protection Agency (EPA) Superfund Innovative Technology Evaluation Program for hazardous waste remediation and the Defense Nuclear Agency for the cleanup of radiologically contaminated sands.

Many physical separation systems are commercially available. A schematic of the physical/chemical soil washing system used at Hanford is shown in Fig. 1. The system consists of a feed hopper, a vibrating screen, high pressure spray bars, a hydrocyclone for the separation of sands and fines, a dewatering screen, a sludge settling tank, and a process water tank.

Fig. 1. Soil washing process flow diagram.

For the pilot study, the DOE and the Westinghouse Hanford Company (WHC) decided to conduct specific investigations into processes that could be utilized to perform required separations. For the study, Alternative Remedial Technologies, Inc. (ART) was competitively selected. The study area was the North Process Pond in the 300-FF OU of the Hanford Site. The 300-FF OU is a CERCLA NPL site and the North Pond is within the 300-FF OU.

The North Pond was constructed in 1948 to receive process wastewaters from fuel fabrication operations, cooling water blowdown, steam condensate, and a wide variety of waste liquids from laboratory drains throughout the 300-FF OU. The ponds were deactivated in 1975 and currently do not contain any liquids. The soils in the 300-FF OU of the Hanford Site are predominantly coarse granitic sands and gravels, with less than 5% silts and clays, and are therefore well suited for physical separation processes. From earlier work in the area, it appeared that the highest

concentrations of contaminants in the 300-FF OU are in the form of coatings or particulates residing on or within the soil particle size fraction less than 100 microns. Lower contaminant concentrations were found on larger soil particles mostly in the form of coatings. Additionally, the North Pond Area contained a "green" sludge material that appeared to be a copper-uranium carbonate. Both the coating/particulate and the "green" material were a feed material for the treatability test.

TREATABILITY TEST OBJECTIVES

The objectives of the treatability study were to:

1. Achieve a 90% or greater weight reduction of contaminated feed soils, while;
2. Meeting the treatment standards for the>90% clean fraction as shown in Table I; and
3. Developing practical engineering information that can be used for the remediation the North Pond Area.

TEST ORGANIZATION AND PROCEDURES

The treatability study was managed by WHC with ART acting as the prime contractor for the work. WHC provided the management team and technical support while ART provided the required equipment, personnel, and operating expertise to conduct the test, develop the required data, and report on the findings. WHC provided the required interface with DOE and the State of Washington Department of Ecology and Environmental Protection Agency.

Because the test was intended to provide scale-up information, it was necessary to have a continuous process facility in the North Pond as opposed to a bench-scale unit that could be operated on a batch basis in the laboratory. ART, working with its parent company Heidemij of The Netherlands, mobilized the 10 ton per hour (tph) soil washing pilot plant from Holland to the Hanford site. The plant was staged near the North Pond work area, inspected by WHC from a safety and health physics standpoint, and then erected in the work area.

During the period March 7, 1994 - April 1, 1994, the target soils were pre-screened, staged, and fed into the treatment plant. Four fractions, a gross oversize, a normal oversize, sand, and fines, were produced. The individual fractions were weighed and analyzed to confirm the attainment of the treatment standards. The information from this study and the methodology employed is presented in this paper.

CONCLUSION

The pilot study, believed to be the first separation-based soil treatment study, was very successful. During the study, 380 tons of contaminated soil were treated, resulting in an average volume reduction of greater than 93% while significantly improving upon the treatment standards with an average activity of 28 pCi/gm based upon Uranium-238. Based upon the work performed in this assignment, several key lessons were learned that may be helpful to other remedial contractors or complex site cognizant managers.

1. The soil matrix/contaminant relationship. The Hanford soils are extremely coarse, consisting generally of 55% oversize (greater than 2mm), 40% sand, and 5% fines (less than 0.075 mm). The contaminants encountered, principally uranium, cobalt-60, lead, and copper, are predominantly concentrated in the fines fraction. ART found that physical separation, classification, attritioning, and concentration allow a simple, proven method for attaining very high volume reductions. The ability to quantify the location, concentrations, and volume of contaminated soil is difficult, and ART believes this must be finally determined during the remedial process. In some cases visual indicators are helpful; at this site, a "green" material, consisting of a copper-uranium carbonate sludge could be identified in the field. ART also found, particularly in the case of uranium, that x-ray fluorescence (XRF) can be a very dependable field analytical tool.
2. Procedures and Planning. Working at any DOE facility can be very complicated, and thus time consuming and expensive. With proper planning and some creativity, many barriers can be overcome. Probably more than any other type of project, DOE projects demand that you be proactive as a contractor. It is essential that upon selection, focused efforts are undertaken to work very closely with the assigned DOE point of contact. Operational plans should be developed to anticipate problems, particularly in the area of sampling, analyses, product measurements, and decontamination. Pay particular attention to the Federal Acquisition Regulations (FAR) as it pertains to work stoppages, delays, and the methods whereby compensation is determined for equipment that cannot be "free released" from the work area. A very important player

in this process will be the site health physics technicians (HPTs). Generally, and certainly in the ART work at Hanford, the HPTs are always present whenever there is entry into a radiologically controlled area. During that period, the HPTs have a unilateral responsibility to control and, if necessary, stop work based upon potential exposure to, or release of, radiological contaminants.
3. Plant Description. A pilot study, by definition, consists of facilities and capabilities required to test and confirm that a particular arrangement of equipment can achieve a specified, full-scale outcome. The ART pilot plant, as described earlier, had a process throughput capacity of approximately 15 tons per hour. The plant required an on-site generator to provide power since commercial power could not be extended into the radiologically controlled area (RCA). Water for the process needed to be stored and trucked in. All of the real-time analytical equipment needed to be conveniently located, but not in the RCA. Wherever possible, try to keep supporting facilities outside the RCA where they will not require HPT control, nor will they need to be decontaminated at the completion of the project. The plant itself needs to have the flexibility to treat the anticipated feeds, while also providing the ability to add unit operations that become necessary during the performance of the project. Often, ART has found that adequate excavation, loading, and screening equipment does not exist at DOE facilities. If possible, we recommend that contractors try to provide all of the required equipment under the contract and do not rely on "site available" equipment. One particular equipment detail can become very complicated ... decontamination. It is very difficult to estimate, prior to the performance of a project, whether your particular plant will be able to be released from the site. If it can be, how do you manage the process? If it can't be released, how is the owner compensated? Of course, the ability to decontaminate will be based upon the concentrations/activity of the feeds, the type of soil, and the intricacies of the equipment itself. Many precautions can be taken on the plant even before it enters the RCA. Taping, welding, intermediate barriers, and so on, may limit component exposure even in the area. Further, it is very important to have a written, and approved decontamination survey and release plan with the HPTs. For equipment that cannot be decontaminated, the FAR will prevail on value determinations. The FAR recognizes only a documented book value for equipment, so be prepared with good records!
4. Plant Operations. The testing/operations period can easily be disrupted by weather, high winds, union problems (most DOE sites are unionized), equipment availability, and so on. Strong working relationships and a good understanding of the interests of involved parties cannot be beat! On most DOE sites, overtime labor often is not authorized. But, because of the demands of the study and the priority under which they must be performed, longer hours are often required. These additional demands require arrangements to be made for additional labor support. At the Hanford site, the management team supported the additional demands and was extremely and constructively supportive in providing the required resources. These projects, based upon the ART Hanford experience, require very close management, and a strong contractor project manager is essential.
5. Use of the Pilot Study Findings for Full-Scale Implementation. The ART treatability study was an important component of the final feasibility study for the 300-FF OU at the Hanford Site. The study was included in the final report submitted to the USEPA and the State of Washington Department of the Environment for consideration in the development of the Record of Decision (ROD). Three alternatives were submitted: excavation and removal of the contaminated soils to an "Environmental Restoration Disposal Facility" (ERDF) which is an on-site landfill currently being constructed, capping of the entire site, and soil washing. The final decision will be based upon the CERCLA selection criteria and will be highly dependent upon the accepted risk level. The ROD is expected to be issued in the first quarter 1995 and will set an extremely interesting precedent for similar DOE facilities.

ABSTRACT
Laboratory batch tests were performed to study the sorption of 60Co, 90Sr, 137Cs, 233U, 239Pu, and 241Am in basalt and sedimentary interbed from the Snake River Plain at the Idaho National Engineering Laboratory. The tests were performed with a model solution simulating regional groundwater. Sorption of the radionuclides to the solid phase was inferred from changes in aqueous phase concentrations. The data were analyzed in two ways . In the first, distribution coefficients were determined from steady-state concentrations. In the second, distribution coefficients and rate constants were determined by least squares fits of the data to two time-dependent sorption models. In one of the models sorption is approximated as a single first-order process. In the other, it is approximated as two first-order processes, one fast and one slow.
For all but 233U, sorption to basalt was greater than to sedimentary interbed. Distribution coefficients obtained were: for basalt, 60Co(30-54 mL g-1), 90Sr(9-13 mL g-1), 137Cs(38-43 mL g-1), and 233U(4-5 mL g-1); for sedimentary interbed, 60Co(1148-3912 mL g-1), 90Sr(42-63 mL g- 1), 137Cs(2228-3255 mL g-1), and 233U(3-6 mL g-1). In the initial experiments, loss of 239Pu and 241Am to container walls masked sorption by the soils. Subsequent testing with revised experimental procedures yielded 241Am distribution coefficients of 45-210 mL g-1 for basalt and 450-1100 mL g-1 for sedimentary interbed. Follow-up tests with 239Pu are currently underway. Generally, sorption was faster with sedimentary interbed than with basalt. With the exception of 60Co in basalt and 233U in interbed, both of the time dependent models produced good fits to the data.
INTRODUCTION
The development of a remediation strategy for Pit 9 at the Radioactive Waste Management Complex (RWMC) at the Idaho National Engineering Laboratory (INEL) requires reliable models of contaminant fate and transport in the hydrogeologic system of the eastern Snake River Plain subsurface. The subsurface in this region is dominated by a layered sequence of fractured volcanic rocks (primarily basalt) and sedimentary interbeds. However, the system is highly heterogeneous and complex, and there is significant uncertainty in both the hydrological and the geochemical parameters that are needed for subsurface flow and contaminant transport modeling. A combined field and laboratory program (known as the Integrated Field-Scale Aquifer Pumping and Infiltration Tests) was initiated in 1993 to improve the availability of hydrological and geochemical data for the site. To expand upon the existing base of relevant data (1-4), laboratory column tests and batch tests are being performed. Results of column tests have been reported previously (5). Presented here are preliminary results of batch tests to determine distribution coefficients and sorption rate constants.
THEORY
In the batch tests, simulated groundwater spiked with radioactivity was added to containers with either basalt or interbed material. The tests were designed to yield a detectable decrease in the aqueous phase concentration, which was measured as a function of contact time. The aqueous phase concentrations typically decreased initially and then either reached steady state or appeared to be approaching steady state level. These data were analyzed in two ways. In the first, the distribution coefficients were determined from the apparent steady-state concentrations. In the second, distribution coefficients and rate constants were determined from least squares fits of the data to two time dependent sorption models. These methods are

described below.
The equilibrium distribution coefficient, Kd, is defined as
Eq. (1)
where Cs,e is equilibrium solid phase concentration (Bq g-1) and Ca,e is equilibrium aqueous phase concentration (Bq mL-1). Under the assumption that all of the aqueous phase activity goes to the solid phase (i.e. there are no losses to the walls or the head space), solid phase concentration, Cs(t), can be inferred from aqueous concentration by
Eq. (2)
where Ca(0) is initial aqueous phase concentration, Ca(t) is aqueous phase concentration at time t, V is volume of the aqueous phase (mL), and m is solid phase mass (g). Thus, Eq. (1) can be expressed solely in terms of aqueous phase concentrations,
Eq. (3)
In one of the time dependent models sorption is approximated as a first-order process, and the rate of change of solid phase concentration is given by
Eq. (4)
where is a first-order rate constant (s-1). As above, if losses to the container can be neglected, Eq. (4) can be rewritten in terms of aqueous phase concentration and solved to yield
Eq. (5)
Presented in Fig. 1 are predictions based on Eq. (5). Aqueous phase concentration is plotted as a function of time for Kd = 0, 1, 10, and 1000 mL g-1, Ca(0) = 10 Bq mL-1, m/V = 0.033 g mL-1, and k = 0.0378 hr-1.
The second time dependent model was based on Wilczak's (6) modification of Dzombak and Morel's (7) "two-box" model in which sorption is approximated as having two independent first-order components, one rapid with rate constant l1 and one slow with rate constant l2. Wilczak's modification is basically a method for applying the model to experimental data in which equilibrium may not be reached. It includes two additional parameters, pc, the percent deviation of the measured aqueous phase concentration from equilibrium and t, the time at which pc is determined. The equation for aqueous phase concentration based on this model is
Eq. (6)
METHODS
Experiments were performed with basalt and interbed material from the INEL site. The basalt was from a boulder removed at one of the burial pits in the RWMC. The sample was crushed and sieved, and the fraction larger than 250 mm was used in the experiments. The basalt was composed primarily of the minerals pyroxene and plagioclase, and it had a rather low cation exchange capacity (6.05 meq 100 g-1) (8). Sedimentary interbed was obtained from an uncontaminated region adjacent to the RWMC. The material was composited from well cores collected at five different depths ranging from 50 to 120 mm and sieved to the size fraction smaller than 250 mm. The interbed was composed primarily of silt and sand particles with varying amounts of clay materials. It had a higher cation exchange capacity (17.39 meq 100 g-1) (8) than the basalt. The physical and chemical characteristics of the two subsurface materials are given in Table I.
TABLE I
Groundwater in the area is typically alkaline (pH8) with elevated bicarbonate concentrations (50-500 mg L-1) (9). A synthetic groundwater (SGW) was formulated which approximated the actual major ion concentrations as determined from analysis of field samples (9). The compositions of typical field samples and the synthetic groundwater are given in Table II.
TABLE II
The groundwater was spiked with the radionuclides by evaporating an aliquot from a standard and redissolving the activity in the synthetic groundwater. This solution was filtered through a 0.1 mm polysulfone filter and allowed to equilibrate overnight. The aqueous phase concentrations ranged between 1.5 and 18 Bq mL-1.
The testing procedure was adapted from ASTM method D4319 (10). Using values of distribution coefficients in the literature for similar soil, the mass of soil required to reduce the aqueous phase concentration by a factor of 10 was calculated. This ranged from 0.05 to 1.0 mg. This amount of soil (either basalt or interbed) was added to tared 15 mL polystyrene screw cap centrifuge tubes and weighed. Synthetic groundwater (5-15 mL) was added to each tube and tumbled at 10 rpm for two

consecutive 12 hour equilibration periods. At the end of each 12 hour equilibration the synthetic groundwater was discarded and replaced. The final weight of the tube was taken prior to spike addition to determine the exact amount of synthetic groundwater present.
One mL of the spiked groundwater was added to 28 centrifuge tubes containing equilibrated basalt or interbed. Aqueous phase concentration was measured in duplicate samples at the following times: 5, 10, 20 and 45 minutes, 1, 2, 4, 6, 12, 24, 50, 100, 200, and 400 hours. An additional 14 tube blanks (no solid present) were analyzed at the same times. Three solid blanks were analyzed at 1, 50, and 400 hours to check for radioactivity that might be associated with the soils. At the designated sampling time the supernatant was removed from the tube and filtered through a 0.2 mm cellulose acetate filter. One mL aliquots of the filtrate were analyzed with a liquid scintillation counter (Wallac Model 1415)
Distribution coefficients were calculated from Eq. (3) using measured concentrations at large times as approximations of equilibrium concentrations. Distribution coefficients and rate constants were determined from Equations (5) and (6) through least squares fits. In the fits to Eq. (6), pc was set at 1%.
RESULTS AND DISCUSSION
Batch test data are presented in Figs. 2 and 3 for basalt and interbed, respectively. In each figure, aqueous phase concentration is plotted as a function of contact time for 60Co, 90Sr, 137Cs, and 233U. For these radionuclides, the concentrations in the blanks remained approximately the same as the initial concentration throughout the testing period. The time dependent curve fits are also shown in Figs. 2 and 3. With the exception of 60Co and 233U in interbed, both models provided good fits to the data. Generally, sorption was more rapid in interbed than basalt. Strontium-90 sorbed relatively slowly in both basalt and interbed. A possible explanation for this is that natural strontium may have been in equilibrium prior to spike addition due to large amounts in the basalt (11). Uranium-233 exhibited an initial rapid decrease of aqueous phase activity that was followed by a rapid increase to steady state. Possible explanations for this behavior include a speciation change from a uranyl nitrate in the spike solution to a uranyl carbonate in the synthetic groundwater or a change in surface conditions of the solid material.
FIG. 2
FIG. 3
Initial tests with 239Pu and 241Am were unsuccessful due to large decreases in aqueous phase concentrations in the blanks, presumably due to loss to the walls of the tubes. Corrections for these losses could not be made because the aqueous phase concentrations in the blanks were actually lower than those in the tubes with solid present. Tests performed in glass tubes and in silanized glass tubes resulted in similar losses. Subsequent tests performed with 241Am in polycarbonate tubes yielded better results . The decrease in aqueous phase concentrations in the blanks were less than 10 percent in these tests. These subsequent tests were performed at a single contact time of 120 hours, which should have been sufficiently long for equilibrium to be reached based on the initial batch tests.
Results of the data analyses are given in Table III. Although the distribution coefficients as determined by the three different techniques showed some differences in magnitude, the trends were consistent. The distribution coefficients were ordered, from largest to smallest, as follows: 241Am>60Co/137Cs>90Sr>233U in basalt and 60Co/137Cs>241Am>90Sr>233U in interbed. Except for uranium, distribution coefficients were larger in interbed than in basalt. For 90Sr and 241Am, the difference was approximately a factor of eight; for 60Co and 137Cs, the differences were almost two orders of magnitude. For uranium, the basalt and interbed values were within about 30 percent of one another.
TABLE III
CONCLUSIONS
1. Except for 233U, distribution coefficients were larger in interbed than in basalt. For 60Co, distribution coefficients were approximately equal in the two models.
2. Distribution coefficients were ordered, from largest to smallest, as follows: 241Am > 60Co/137Cs > 90Sr > 233U in basalt and 60Co/137Cs > 241Am > 90Sr > 233U in interbed.
3. With the exception of 60Co, sorption was more rapid in interbed than in basalt.

In interbed steady state was reached in less than 100 hours. In basalt, steady state was reached in less than 400 hours.
4. With the exception of 60Co and 233U in interbed, both of the time dependent models provided good fits to the data.

PHYSICAL TREATMENT OF CESIUM CONTAMINATED SOILS

Dirk Gombert
Thomas K. Honeycutt
Lockheed Idaho Technologies Company, Inc.

ABSTRACT
Treatability studies were conducted at the Idaho National Engineering Laboratory (INEL) to evaluate the most promising means of volume reduction for cesium contaminated soils. Earlier testing for remediation of an infiltration pond at the INEL led to the conclusion that extractive soil washing could not meet the cleanup criteria designated in the Record of Decision for the pond sediments. Preliminary data also indicated that even gravels and cobbles were contaminated to levels greater than the risk-based limits. Due to concerns over generation of secondary wastes by chemical decontamination methods, the treatability studies reported here were limited to primarily physical treatment methods including screening, flotation, low-energy attrition (tumbling), and attrition scrubbing. Brine extraction of fines was also evaluated to determine if silts and clays could be decontaminated.
Four soil samples were chosen representing sites with significant areal extent and various levels of contamination. These studies provided the data to evaluate segregation of cesium contaminated particles by density, particle size, spallation of surface coatings, and simple ion exchange. Partitioning to organic detritus such as grasses and sage was evaluated by flotation: both skimming off large material that floats on water, and froth flotation using hydrophobic agents and injected air to remove finer material while minimizing carryover of inorganic silt and clay particles. Inorganic material greater than 4 mesh was separated by screening and tumbled to cause some surface abrasion to determine if removal of lightly adherent

surface deposits could yield gravels and cobbles suitable for return to the excavation. Sands were scrubbed by high-energy attrition to remove surface coatings of transition metal oxides which have significant capacity for binding ionic contaminants. Finally, material smaller than 100 mesh were contacted with a potassium nitrate brine to evaluate the potential for cesium removal by simple ionic displacement.

INTRODUCTION

A large volume of radionuclide-contaminated soil exists at the Idaho National Engineering Laboratory (INEL). After four decades of reactor research, fuel reprocessing and waste management activities, surficial soil contaminants include many fission products, heavy metals, and some organics. The treatability studies reported here were focused on cesium-137 because risk assessment calculations indicate this isotope is the primary contributor to future cancer risks for residential use of the lands included within the INEL (1).

Studies done in 1992-93 to evaluate chemical extraction for decontamination of sediments in an infiltration basin concluded that the criteria specified in the Record of Decision for that site could not be met (2). Estimates based on the data from those studies indicated that even if the extent of decontamination was acceptable, the chemical handling hazards and the amount of secondary wastes generated would make chemical treatment a questionable choice. Additionally, the data indicated significant contamination in the gravel and cobble-sized material which would require further treatment prior to free release for residential use. Therefore, treatability studies were designed to evaluate physical processes applicable to all soil size fractions for reducing the volume of radionuclide-contaminated soil at the INEL.

INITIAL CHARACTERIZATION

Surface soil samples were collected from locations where increased levels of radioactivity were known to be present from past releases. The four selected contaminated samples provided a considerable range in observed radionuclide distribution to give sufficient representation of conditions expected to be encountered during operation of a full-scale system. In addition, a non-radioactive (below background) sample was used as a control sample. Surface soils ranging in depth from 0 to 0.3 m were sampled from each of the sites described below.

1. Sample CPP-03 was collected from a contaminated equipment lay-down area of approximately 75,000 ft2. The average 137Cs activity of the CPP-03 sample was 213 pCi/g.
2. Sample CPP-22 was collected from a site of approximately 130,000 ft2 contaminated by an air release of solid particles. The average 137Cs activity of the CPP-22 soil sample was 66.8 pCi/g.
3. The West SL-1 sample was collected from a site with an area greater than 150,000 ft2 contaminated by wind blown particles. The average 137Cs activity of the West SL-1 sample was 224 pCi/g.
4. The SL-1 Soil Box sample was collected from a more contaminated area of the same site as the West SL-1 sample. The SL-1 Soil Box sample had an average 137Cs activity of 1,855 pCi/g.
5. The CPP-1604 control sample was collected from an uncontaminated site on the northwest side of the Idaho Chemical Processing Plant (ICPP), in the lawn area near an office building. Field screening was performed at collection time and indicated that the sample showed no radioactive contamination above background.

Duplicate samples were wet sieved into +4, -4+10, -10+40, -40+100, -100+200, -200+400, and -400 mesh (fines) size fractions and the cesium distribution was measured by gamma spectroscopy. One sample was wet sieved in its as-received condition, and the other was pre-treated using a vigorous washing procedure supplied by the Environmental Protection Agency (EPA). This procedure involves shaking a slurry of soil which induces a mild abrasion to enhance the separation of fine particulate from the more coarse grains. Data for all samples showed the expected 10-100 fold increase in activity over the range of decreasing particle size, though not all samples showed a monotonic increase, with maximum activity levels in mid-range sand fractions. No significant difference was observed with the agitated slurry pretreatment versus simple wet sieving. This data confirmed the need for treatment of most or all of the soil fractions to achieve a significant reduction in volumes to be managed.

EVALUATION CRITERIA

Acceptable residual levels of radioactivity have not yet been codified or negotiated in a consent order. However, estimates of additional cancer risk for residential use of lands within the INEL indicate approximately 2.4 pCi of 137Cs per gram of soil would result in one additional cancer in a population of 10,000 (1). For scoping purposes, the decontamination effectiveness of all treatments was evaluated versus a residual level of 10 pCi/g, and weight percent (wt%) of treated soil meeting this criteria was reported. No other criteria such as cost or implementability were evaluated.

TREATMENT

The treatability studies were conducted at the bench scale using initial samples of one kilogram split from five gallon sample buckets. The random splitting provided a rough homogenization of the entire five gallon sample. This step is shown in box 1 at the top of Fig. 1. Major steps in the treatment train are described below:

Primary Separation

The sample material was subjected to a rough flotation (box 2) to remove low density organic matter such as grasses and sage that might interfere with sieving and physical treatment of individual particle size fractions. The primarily inorganic soil matrix was then sieved at 4 mesh (box 4) to separate a +4 mesh fraction for treatment by tumbling, from a -4 mesh fraction to be floated using chemical additives and air injection to remove remaining fine organic material (box 10). The grasses and debris were rinsed on a 100-mesh screen (box 9) to wash off fine organic and inorganic material entrained in the rough flotation. The rinsate was then added to the -4 mesh fraction prior to air flotation.

The combined -4 mesh fine material was treated in a Denver Equipment D-12 froth flotation unit using 302 pine oil to aid in attracting air bubbles to the organic matter. Low density fines removed in the final flotation were added to the organic fraction (box 11) for radiological determination. These partitioning steps were conducted for triplicate aliquots from each of the five samples described above. The products from the primary separation steps were: 1) an organic fraction which could be analyzed to determine how much cesium could be removed by simple density separation, 2) an essentially inorganic +4 mesh fraction which could be processed by low-energy attrition (tumbling), and 3) an essentially inorganic -4 mesh fraction which could be homogenized and attrition scrubbed.

Low Energy Attrition

The low-energy attrition (tumbling) treatment of the +4 mesh material (box 6) was to evaluate the benefit derived from partial surface spalling of the gravel and cobbles. This material is too large for an attrition mill containing water to impart significant energy to it, but tumbling could conceptually be accomplished with extended contact time in a rotating screen (trommel) or on a vibrating screen. With adequate contact time, the autogenous grinding caused by particle collisions could potentially remove enough contamination from low-surface-area material to meet release criteria. The +4 mesh fraction was tumbled air dry at 24 rpm for 4 hours. These conditions were not optimized in any way. The experiment was only meant to fracture a few weight percent of the material to determine if significant decontamination could be accomplished without generating an unacceptable quantity of contaminated fines. As a result of the scrubbing of the surfaces, a mixture of +4 mesh and finer material was produced. The tumbled product was split on a 4-mesh screen (box 7) to determine the decontamination effectiveness for the +4 mesh fraction, and the amount of fines (-4 mesh) produced by the treatment.

Homogenization

The triplicate -4 mesh inorganic samples from box 10 were then composited and homogenized using a multiaxial Turbula mixer (box 12). New triplicates were then prepared for radionuclide analysis. As necessary, samples were rehomogenized until the 137Cs values of the triplicates confirmed a precision of +20%. The homogenized samples were then split using a 100-mesh screen to generate a -4+100 mesh fraction for attrition scrubbing, and a -100 mesh fraction for brine extraction.

Attrition Scrubbing

The -4+100 mesh material was then attrition scrubbed at 800-850 rpm for 20 minutes to aggressively scrub the surfaces of the sand fraction (box 15). During attrition scrubbing, particles are forced to collide in an intensely mixed zone between two opposed impellers which fractures and removes some of the particles' contaminated surface exposing the underlying core. In practice, particles as large as 10 mm (3/8") and as small as 200 mesh (76m or .003") can probably be effectively attrition

scrubbed in water, but to maximize the effectiveness of this treatment for evaluation purposes, a narrower size range was used. As a result of the scrubbing of the surfaces, a mixture of +100 mesh and some finer material is produced. The scrubbed product was split on a 100-mesh screen (box 16) to determine the decontamination effectiveness for the +100 mesh fraction, and the amount of fines (-100 mesh) produced by the treatment.

Brine Extraction

The final test in this study was to treat the silt and clay fractions which cannot be decontaminated by any practical physical processes. Cesium is not believed to form any naturally occurring insoluble salts, but is known to readily sorb at ion-exchange sites. For this test, the soil fractions passing a 100 mesh sieve were exposed to 0.1 M potassium nitrate brines to determine the extent of decontamination achievable by displacing cesium with its chemical analog, potassium. The -100 mesh fractions were weighed out in 250 gram samples and contacted with 1 L of solution for two hours in a rolled 2 L sample bottle.

RESULTS

Cesium Distribution

The initial separations typically split the samples into 20-40 wt% greater than 4 mesh, 60-75 wt% smaller than 4 mesh, and less than 1.5% organic material. Weight and activity distribution data for all samples are shown in Table I. The mass balance for this separation was very good, with no losses over 5%. The +4 mesh materials ranged from essentially zero activity for the control site, up to almost 40 pCi/g for West SL-1. Based on the 10 pCi/g goal, the material from the CPP sites could potentially be released without further treatment, but the West SL-1 samples would still require decontamination by at least 70%. The SL-1 Soil Box coarse material was measured in the nanocurie range, 100 times over the risk-based value.

The -4 mesh fractions were 10-100 times more contaminated than the +4 mesh material, which could be largely explained by surface area. Even the fraction from the control (CPP-1604) sample exceeded the 10 pCi/g level with the larger material removed. Though some of the organic material was considerably more contaminated than the total soil matrix or either inorganic fraction, removal of the small fraction had no significant impact on the total sample activity. Of particular interest is the organic material from the control site which shows significant activity (273 pCi/g) after concentration by a factor of 1000 (removal of 99.9% of the sample as inorganic). The anomalous organic material from the CPP-22 sample, makes up only 0.02% of the matrix, and is only about 3% as contaminated as the inorganic -4 mesh fraction. This datum may simply result from the extremely small amount of organic media from this sample available for measurement.

The activity balances for the four contaminated samples were 30% rather than the established goal of 20%. This result is reasonable based on the amount of mixing required to bring some of the samples to within the 20% precision envelope. The data shown for the initial activity of the as-received soil are probably most suspect because the data were from a separate split taken in parallel with the material actually processed. The only mixing conducted on the as-received material was due to the splitting process.

The anomalous data for the CPP-1604 control sample yield activity balances well in excess of 100%. This may be due to the removal of the cobble and gravel size material and the subsequent concentration of trace activity into a very small amount of fine material which is completely exposed to the surface of the gamma radiation detector. The error in the measurement of trace activity in the heterogeneous mixture again makes the initial measurement highly suspect.

Low-Energy Attrition

Low-Energy Attrition (tumbling) reduced 1-2 wt% of the initially +4 mesh samples to finer material, and, as shown by the data summarized in Table II, lowered the contamination of the gravels and cobbles by 7-25% (shown as the percent decontamination factor or %DF). Extrapolation of the data suggests tumbling might reduce contamination in the +4 mesh fraction by 20-30% (equivalent to 10-15 years of radioactive decay for cesium) while generating up to 5 wt% fines. Thus tumbling may decontaminate cobbles and gravels containing activity marginally greater than release limits, but this treatment does not appear to contribute significantly to the overall process. The mass balance for this treatment was essentially 100% and the activity balance was within about 25% for all data with the exception of the CPP-1604 "control sample." Though the initial +4 mesh fraction from CPP-1604 counted

at only 0.1 pCi/g, the tumbling created 1.2 wt% fines which measured almost 40 pCi/g. By eliminating the intrinsic problems caused by self shielding and the unusual geometry of the large gravel and cobbles through tumbling, which concentrates surface contaminants in a small fine grained sample, the activity of the fines was much more exposed to the detector surface, and the measured data was much greater than that predicted from the original heterogeneous matrix.

Attrition Scrubbing

As shown in Table III, attrition scrubbing typically generated about 2-3 wt% additional -100 mesh material while removing up to 20% of the activity on the remaining -4+100 mesh particles. The SL-1 Soil Box sample was scrubbed long enough to generate 7 wt% waste fines (24 minutes), which reduced activity by over half, but due to the high initial activity of the -4+100 mesh material, the product was still over 10,000 pCi/g. The mass balance for all samples was within 2%, and the activity balance was within about 20%. The worst activity balance was for the control sample at 123%. This may be due to the variability in the measurement of the extremely low activities (<10 pCi/g) for the +100 mesh fractions both before and after treatment. Extrapolation of the data suggests attrition scrubbing might be refined to reduce contamination in the -4+100 mesh fractions by up to a factor of 2 to 3 (equivalent to 30-48 years of radioactive decay for cesium), while reducing 10-15 wt% of the material to additional fines. Thus, soils similar to the samples from CPP-03 and CPP-22, with very low initial activities, might be partitioned to recover 20-40 wt% in the 10-20 pCi/g range by sieving, and with enough contact time, an additional 30-40% by attrition scrubbing.

Brine Extraction

Up to 17% of the activity in the fine fractions was removed by this treatment, but due to the high levels of activity found in the fine fractions initially, none were reduced to below 100 pCi/g (Table IV). The mass balances for this treatment were within 2%.

CONCLUSIONS

Simple sieving provided the most effective partitioning of low activity material from relatively high-activity material. Scalping the soils at 4 mesh separates 20-40 wt% of the soils as a gravel/cobble mixture containing only 2-10% as much activity on a mass basis as the original soils. For soils within a factor of 10 of the cleanup criteria, the total soil under control could potentially be reduced by as much as 40 wt% by sieving. Separation of organic material may remove the most highly contaminated particles, but because of the small quantity of this material in the samples tested, the overall impact on the matrix is inconsequential. Tumbling does not appear to provide significant decontamination. Data from attrition scrubbing of the mid-size fractions indicates some benefit, and may be extrapolated to an estimated decontamination by a factor of 2 to 3 while converting 10-15 wt% of these fractions to waste fines. Ion-exchange by brine extraction displaces up to 21% of the cesium contamination, but starting with the fine fraction which is the most heavily contaminated, the decontamination is not significant when compared to risk-based residual contamination levels. Thus, for low activity soils with contamination within a factor of 10 of the risk-based value of 10 pCi/g (137Cs), a total of potentially 50-70 wt% of the soil could be salvaged by a combination of sieving (scalping the lowest activity fraction) and attrition scrubbing (of the mid-activity fraction), with the remainder requiring additional management. For more highly contaminated soils, treatment may be limited to recovery of some fraction of low surface area material by scalping at a size greater than 4 mesh.

RECOMMENDATIONS

Although the risk-based treatment criterion (10 pCi/g for 137Cs) was generally not achieved, sieving and attrition scrubbing are potentially useful treatment methods for low activity soils. If they are to be employed, sieving and attrition scrubbing will require additional consideration to evaluate cost-effectiveness of volume reduction versus mitigating factors such as projected costs for alternative forms of residuals management and worker risks due to activities such as excavation, additional handling, etc. Flotation of organic material, low-energy tumbling, and brine extraction can probably be eliminated from further consideration based on process complexity, ineffectiveness, and waste generation.

ABSTRACT
The partitioning of uranium in an aquifer down gradient of two large mixed waste sites was examined with respect to the solution and soil chemistry (e.g., pH, redox potential and contaminant concentration) and aqueous-phase chemical speciation. This involved generation of field-derived, batch sorption, and reactive mineral surface sorption data. Field-derived distribution coefficients for uranium at these waste sites were found to vary between 0.40 and 15,000. Based on thermodynamic speciation modeling and a comparison of field and laboratory data, gibbsite is a potential reactive mineral surface present in modified soils at the sites. Uranium partitioning data are presented from field samples and laboratory studies of background soil and the mineral surface gibbsite. Mechanistic and empirical sorption models fit to the field-derived uranium partitioning data show an improvement of over two orders of magnitude, as measured by the normalized sum of errors squared, when compared with the single Kd model used in previous risk work. Models fit to batch sorption data provided a better fit of sorbed uranium than do models fit to the field-derived data.

INTRODUCTION

For 33 years, low-activity liquid wastes from the chemical separation areas at the U. S. Department of Energy's Savannah River Site (SRS) were disposed of in unlined seepage basins. These basins were designed to allow the natural processes of evaporation and infiltration to dispose of the polluted effluent streams. These operations have resulted in groundwater in the vicinity of these basins with lowered pH values and elevated levels of metals, radionuclides and nitrate. Additionally, it is believed that acidic waste streams associated with basin operations have significantly altered the mineral surfaces on the soils downgradient of these basins through accelerated acid weathering. On November 7, 1988, discharge to the basins was terminated in accordance with requirements of the Resource Conservation and Recovery Act. Before a multi-layered cap was placed over the basins, the liquid was removed and each was filled with a gravel bed and topped with layers of calcium carbonate and blast furnace slag (1).

Attempts to select an appropriate remediation technology for groundwater at this site have been hampered by an inability to adequately predict the transport of pollutants through, and the amount of contaminants in, the subsurface environment. The models previously utilized for risk assessment employed a single literature reported or "best guess" distribution coefficient (Kd) and predict that certain contaminants should be sorbed by the soil and not substantially transported (2,3).

Groundwater monitoring of the waste site, however, shows significant groundwater transport of some contaminants not predicted to be mobile (4,5).
Kd values (i.e. ratio of contaminant concentration sorbed to concentration in the aqueous phase) are generally valid only for the mineralogical and geochemical conditions under which they were determined. The inherent heterogeneity and geochemical variations of real aquifer systems, reduce the applicability of a single Kd value to natural systems (6,7,8). Additionally, equilibrium conditions may not be established if the groundwater velocity is fast relative to the sorption rate. These variables impact the partitioning of contaminants in natural systems; consequently, field systems are usually best represented as a function of these factors rather than a single constant Kd.
The objectives of this research were to: (1) develop a more representative model of uranium sorption at this SRS waste site which accounts for pH, ionic strength, and competitive ion sorption effects; (2) compare the uranium sorption data from field-derived porewater/soil sample sets to batch sorption studies with background soils and an aluminum hydroxide reactive mineral phase; and (3) evaluate the effects of using single Kd and non-linear isotherm approaches to predict remediation effectiveness for a simple system.

METHODS

Uranium partitioning was examined in sample sets collected at the waste site using an in-situ method and in the laboratory by performing batch sorption studies on an uncontaminated background soil and a gibbsite [Al(OH)3] mineral surface.

Field-Derived Partitioning Data

Fifty-three sets of soil and porewater samples were collected under inert conditions from the saturated zone downgradient of the waste sites using an electric friction-cone penetrometer system (9). Both the soil and porewater samples in each set were collected from the same depth, at the same location. Sampling locations and depths were selected such that they spanned a range of groundwater pH (pH 3-7), and had previously shown groundwater contaminant concentrations above the analytical detection limits. The temperature, pH, redox potential, and conductivity of the porewater samples were measured immediately upon sampling.
Porewater samples were filtered through 0.45 m filters and screened for 3H using liquid scintillation counting. Cl-, F-, NO3-, PO43-, and SO42- concentrations were determined using ion chromatography. Total organic and inorganic carbon concentrations were measured using an automated carbon analyzer. The filtered porewater samples were analyzed quantitatively using inductively coupled plasma (argon) mass spectrometry (ICP-MS) for 43 isotopes representing 28 elements. Additionally, a semi-quantitative ICP-MS scan was conducted for the isotopes of Hg and the actinides (mass less than 246 AMU).
Total digestion soil extracts were prepared in triplicate by digesting approximately 200 mg of air-dried soil in 1 ml of ultra-pure aqua regia and 10 ml of ultra-pure HF heated at 100C for 3 hours in Parr acid digestion bombs. The extracts were then filtered through 0.45 m Teflon filters, and diluted to 50 ml with deionized water. A seven step sequential extraction procedure modified from Miller (10) was performed on each soil sample to selectively remove uranium sorbed to particular soil surface coatings. This procedure was performed in triplicate using 0.75 g of air-dried soil in a 50-ml HDPE Oak Ridge centrifuge tube for each individual sample. Contaminants associated with the soil residue present after the final extraction step were HF acid digested as described above for the total digestions.
Like the porewater samples, isotopic concentrations of trace contaminants in the total digestion and sequential extracts were determined using ICP-MS. 235U and 238U concentrations in each extract were converted to soil concentrations. Concentrations of individual replicates were averaged using a weighted average method (11). In this work, it is assumed that any uranium remaining in the residual phase (after the seventh sequential extraction step) was associated with the soil matrix and not able to participate in equilibrium reactions with the uranium in the aqueous phase. The sorbed uranium concentration was assumed to be equal to the difference between the concentrations in the total digestion and residual digestion analyses. This definition of sorbed uranium probably represents the maximum amount of uranium that can participate in sorption reactions (i.e., exchangeable uranium). An alternative method to account for nonexchangeable uranium is to assume that the total concentration measured in unimpacted soil is equal to the nonexchangeable fraction. This approach was not applied because soil at the site was affected by an acidic

plume and some natural uranium has presumably been leached. Uranium distribution coefficients for each sample were calculated by dividing the sorbed uranium concentration (in g kg-1) by the uranium concentration of the associated porewater sample (in g l-1).

In addition to contaminant concentration, other physical and chemical characteristics of each soil sample were also examined. The particle size distribution of each sample was determined in duplicate using the procedure presented by Gee (12). The cation exchange capacity (CEC) of each soil sample, also performed in duplicate, was measured using the barium-magnesium exchange technique described by Rhoades (13). Soil pH was determined using a procedure derived from ASTM procedure D4972-89 (14) and EPA method 9045 (15) in deionized water and 0.01 M CaCl2. Net soil charge and the point of zero salt effect (pzse) were measured by an acid/base titration of the soil in 0.0, 0.002, 0.01, 0.1 and 1.0 M CaCl2 backing electrolyte solutions (16).

Background Soil Batch Sorption Studies

Laboratory studies on the sorption of uranium to an uncontaminated soil collected from the same lithological unit upgradient of the waste site have been performed. In this study, 1.00 g of soil was allowed to react with 42 ml of 10-5 M UO2(NO3)2 solution in a 50 ml HDPE Oak Ridge tube. Carbon dioxide was controlled in these experiments using a glove bag and CO2 scrubbed air and reagents. Before adding the solution to each tube, the pH was adjusted to an initial value of between 3 and 10 using HNO3 or NaOH. Two samples and one matrix blank at each initial pH were equilibrated overnight in a shaking water bath controlled at 25 C. Previous kinetics studies have shown that this amount of time was sufficient to achieve equilibrium. Samples were then centrifuged at 10,000 rpm (16,000 g) for 10 minutes, after which the supernate was decanted and filtered through a 0.45 m cellulose nitrate membrane. After measuring the final pH, samples were acidified to 1% v/v with 70% ultra-pure HNO3. The aqueous uranium concentration of each sample was measured via laser-induced fluoroscopy of the UO22+ ion. Sorbed uranium was calculated as the difference in concentration of the matrix blank solution and the final sample solution.

Gibbsite Batch Sorption Studies

Because thermodynamic models predict that the mineral gibbsite [Al(OH)3] will precipitate from the groundwater at the waste site and, therefore, could be a reactive surface, a laboratory study to determine stability constants for uranyl ion sorption to gibbsite was performed. In this study, fresh gibbsite was prepared by precipitation from an Al(NO3)3 solution after pH adjustment with 50% w/w sodium hydroxide (17). The gibbsite was purified by dialysis to remove excess sodium nitrate salts and then lyophilized for storage as a dry powder. The gibbsite was characterized using x-ray diffraction and thermogravimetric analysis. The surface area of the mineral was determined to be 178 m2 g-1 by a N2 BET surface area measurement. Sorption experiments were similar to the above described in the background soil sorption experiments. A gibbsite to solution ratio of 1 g l-1 was used. Solutions had NaClO4 backing electrolyte concentrations of 0.0, 0.05 or 0.1 M and were pH adjusted using either HClO4 or NaOH. A 4 hour equilibrium time was used with total uranium concentrations of 10-4, 10-5 and 10-6 M.

RESULTS

The field-collected porewater samples spanned a wide range of geochemical conditions. Sample pH varied from 3.1 to 7.1, while Eh values were between +41 and +442 mV. All samples typically had high nitrate and 3H concentrations. Nitrate levels varied from 3.9 to 1600 mg l-1. 3H levels ranged from 180 to 1.12x106 Bq l-1. The major cations in the samples included Al3+, Fe3+, K+, Mg2+, and Na+. Although not specifically analyzed for, other groundwater monitoring data from the waste site show that H4SiO4 is also present at elevated levels (4,5). The major ion chemistry is consistent with the dissolution of clay minerals (e.g. kaolinite) and existing surface mineral coatings (e.g., iron (oxy)hydroxides) resulting from the addition of large amounts of nitric acid to the system. Estimates of sample ionic strength based on major cation concentrations ranged from 1x10-4 to 4x10-2 M, with a mean value of 8x10-3 M. Conductivities varied widely and were inversely correlated with pH. At low pH values, where the effects of the contaminant plume were most obvious, sample conductivities ranged between 0.05 and 0.35 S m-1. Aqueous samples with minimal impact had typical conductivities of less than 0.03 S m-1. Aqueous inorganic carbon content was found to be < 1 mg l-1 in all samples.

As a result of basin operations, elevated levels of uranium have been observed in groundwater downgradient from the seepage basins. 238U concentrations were above the detection limit in 43 of 54 porewater samples collected for this study. Concentrations of these samples varied from 0.082 g l-1 to 3.2x103 g l-1. 235U concentrations were measurable in 26 of 54 aqueous samples with values varying between 0.040 g l-1 and 14 g l-1.

Equilibrium uranium speciation was calculated over the observed range of geochemical conditions using MINTEQA2 (18). The result was very similar to the theoretical speciation of a 10-6 M U/10-2 atm CO2 system reported by Langmuir (19). Based on these calculations, the dominant uranium species in this study are UO2+, UO22+, UO2OH+, and UO2CO30. At pH values less than 5.0, UO22+ is predicted to be the dominant aqueous species, between pH 5.0 and pH 5.7, UO2OH+ is dominant, while at pH values greater than 5.7, UO2CO30 is predicted to be the major aqueous uranium species present. The charge of the aqueous phase uranium species will have a large influence on binding to soil surfaces with the neutral and negatively charged species being generally more mobile. For example, groundwater with higher pH and inorganic carbon values is predicted to have a larger percentage of mobile uranium as the neutral UO2CO30 species is formed. For nearly all samples for which Kd values are reported in this work, groundwater chemistry is in the pH-Eh range for which UO22+ is the dominate form of uranium in the aqueous phase.

73% of the collected soils were determined to be sand or loamy sand; 25% sandy loam or sandy-clay loam, with the remainder being sandy clay. The mean CEC of the soils was 9.66.3 meq kg-1. The total carbon content was determined for 27 of the soil samples and all were found to contain less than 0.05% w/w carbon. The net surface charge of all soils measured was found to be very low, less than 0.5 eq g-1, with a typical pzse of 3.8.

238U concentrations were above the detection limit in all soil samples and ranged from 490 to 19,000 g kg-1. The average soil concentration of 238U downgradient of the waste sites was 3500 2800 g kg-1 (1.20.9 pCi g-1). This compares with previously reported value of 1.050.75 pCi g-1 for unimpacted shallow sediments at the SRS (28). 235U was detected in 79 of 86 samples with a range of 4.23 to 115 g kg-1, with an average concentrations of 2712 g kg-1.

Based on the difference between uranium concentration in the total soil and that of the residual phase remaining after the sequential extraction, an estimate of the uranium concentration potentially available for exchange with the groundwater was made. The concentration of sorbed 238U in the 78 soil samples examined varied from 0 to 17,000 g kg-1, with an average value of 2700g kg-1. Expressed as a percentage of the total 238U concentration, the soil phase exchangeable fraction ranged from 0 to 98% of the total soil concentration with a mean value of 70%. In the 50 soil samples in which 235U concentrations were above detection limits in both the total digestion and residual phases, exchangeable 235U represented between 0 and 98% (average of 46%) of the total concentration. This corresponds to a concentration range of 0 to 99 g kg-1 with an average value of 14 g kg-1

The 38 238U and 16 235U samples for which the porewater, total soil, and residual soil concentrations were greater than the detection limit, had field-derived uranium distribution coefficients between 0.4 and 15,000 l kg-1. Figure 1 shows that a marked increase in the fraction of uranium sorbed occurs above pH 4.0. Differences in the fraction of uranium sorbed at this waste site can be explained primarily by changes in aqueous pH, and, presumably, the associated change in soil surface charge. The partitioning behavior can not be explained in terms of the physical properties of the soils (i.e., particle size distribution, or CEC).

Fig. 1. Fraction of Uranium Sorbed as a Function of pH from Field-Derived Data and Laboratory Experiments of U(VI) Sorption onto Gibbsite and a Background Soil.

Laboratory data on uranyl sorption to kaolinite (20) and gibbsite are very similar to the field-derived data. Iron (oxy)hydroxides are mineral surface coatings that have also been shown to control the sorption of metal ions in many natural aquatic systems (21, 22). Iron surface coatings, however, were excluded from consideration in our model because the sorption edge of uranium in the field-derived partitioning curve occurs at hydrogen ion concentrations two orders of magnitude greater than previously reported laboratory data for uranium sorption to goethite (23). Recent data on the sorption of uranyl to ferrihydrite shows a sorption edge at a pH of about 4.5 (24). This is also consistent with the field-derived sorption data and will require further evaluation. Because sorption is not well correlated with the

soil clay content or cation exchange capacity, a reactive mineral coating (e.g., gibbsite or ferrihydrite), rather than kaolinite, is thought to be the reactive phase present in the modified soils at the waste site.

MODELING

Seven types of models were fit to field-observed uranium partitioning data. Partitioning data from laboratory batch sorption experiments were fit to four models. (See Table I.) The goodness of fit of each model was evaluated by the normalized sum of error squared (NSES) for each set of model fitting parameters. For this purpose, NSES was defined as:

(Eq. 1)

where n is the number of observations and concentrations are in M.

The sorption model most commonly applied in risk assessment is the single Kd model (Eq. 2a). In this isotherm, the concentration of contaminant sorbed (S) onto the soil surface is a linear function of the contaminant concentration in solution (C). Another isotherm commonly used to describe contaminant sorption is the Langmuir isotherm (Eq. 2b). The Langmuir isotherm is a linear model at low aqueous concentrations, but accounts for the finite number of sites that exist on a surface by limiting the sorbed concentration at higher aqueous concentrations. The Freundlich isotherm (Eq. 2c) may be used to model contaminant sorption at low aqueous concentrations. It has been shown that it may be considered as the log-normal distribution of the Langmuir terms (25) and is well suited for uses in heterogeneous media.

Models fit to the field-derived data showed an improvement of over two orders of magnitude, as measured by the NSES, when compared with the single Kd (Kd = 40) model used in previous risk assessments (Table II). In fitting the Langmuir isotherm to field data, two methods were used to determine the number of available binding sites (parameter 'b' in Eq. 2b). In the first method, the maximum concentration of sites for each sample was determined based on the CEC of the sample. The second method assumed an equal concentration of sites for all samples, but allowed it to be an adjustable fitting parameter.

The fourth model examined in this work is an equilibrium model. Assuming the simplified case where a uranyl ion is bound exclusively to a negatively charged soil binding site (XO-), the reaction may be described by the equation:

(Eq. 3)

where XOUO+2 represents a soil sorbed uranyl ion. This equilibrium reaction has a stability constant (K) defined in terms of solid concentrations ([ ]) and aqueous activities ({}) as:

(Eq. 4)

This equilibrium model was implemented using the nonlinear fitting program FITEQL 3.1 (26). It was assumed that the total concentration of available binding sites (i.e. sum of [XOH],[XO-], {XOH2+] and [XOUO2+]) was equal to the CEC of each sample. All soil samples were assumed to have a bulk density of 1200 kg m-3, a porosity of 0.3, and a surface area of 1000 m2 kg-1. Based on the combined soil titration data of 17 soil samples, the average protonation (log K+) and deprotonation (log K-) equilibrium constants of the soil samples were determined to be 2.00 and -5.44, respectively. Using these constants, functions relating the fraction of sites deprotonated (XO-) and protonated (XOH2+) to -log[H+] were developed. Using these relationships, and the estimated total binding site concentration of each sample, K values for the reaction in Eq. 3 were determined for both field and laboratory uranium partitioning data.

The constant capacitance and diffuse layer electrostatic models were also fit in this work. Both of these models account for the electrostatic effects between the charged surface and ions in solution. The difference in the models is the way in which the surface potential (y, units of V) is determined. In the constant capacitance model (Eqs. 2e and 2f), the surface potential is directly related to the charge density of the surface (s, units of C m-2). This condition is applicable under conditions of constant ionic strength and low surface potential (18). The diffuse layer model (Eqs. 2e and 2g) accounts for electrostatic effects of all charged ions in solution by relating surface potential to ionic strength.

In implementing electrostatic models, the total charge on each surface was allowed to vary with aqueous pH. As in the simple equilibrium model, the concentration of protonated and deprotonated sites for each sample was assumed equal to the maximum concentration of sites, based on the CEC, multiplied by the -log[H+] dependent site

protonation and deprotonation functions developed in the simple equilibrium model. The total charge density was then calculated by the equation
(Eq. 5)
where D is a conversion factor relating charge density in C m-2 to site concentration in molarity. Unlike the simple equilibrium model where uranium was assumed to only bind to the negatively charged sites, sorption was allowed on all sites in the electrostatic models.
In applying the constant capacitance model, Hayes (27) reports that fitting with a capacitance (C1) outside of the range of 0.1 to 2.0 F m-2 is an indication the constant capacitance model is inappropriate. In modeling the batch uranium sorption data, a capacitance of 2.0 provided the best fit of the data. The constant capacitance model failed to provide an adequate fit of field-observed uranium partitioning data. The NSES continued to decrease as capacitance increased well beyond a capacitance of 2.0 F m-2. This may be due to the varying ionic strength conditions present under natural conditions.
Fits of the diffuse layer model to uranium partitioning data did not provide as good of a prediction of sorbed uranium concentration as the constant capacitance model. This may be because the diffuse layer model only has three adjustable parameters (K, K+, K-) , whereas the constant capacitance model had four adjustable parameters (K, K+, K-, C1).
In addition to applying mechanistic models to the data, an empirical rise function was fit to the fraction sorbed versus aqueous pH of the field and soil batch study data using Eq. 2h. While this model results in the smallest NSES, it is purely empirical and, hence, can not be expected to fit the uranium sorption characteristics at other waste sites or under other experimental conditions.
Fitting parameters from sorption models were implemented in MINTEQA2 (18). Using typical field aqueous conditions, the fraction of uranium sorbed was predicted for varying pH and Eh conditions. Both the effects of uranyl ion adsorption and precipitation were accounted for in this modeling and reported as the fraction sorbed. Not surprisingly, the most empirical models (i.e. Kd, Langmuir, and Freundlich) were unable to account for the changes in the fraction of uranium sorbed with changing pH. The model that best represented field and laboratory partitioning data in these MINTEQA2 runs was the diffuse layer model. The thermodynamic modeling results using this model predicted that the fraction of uranium sorbed varied not only with pH, but also with Eh. Under slightly reducing conditions (Eh=-100), the sorption edge was at pH 2.9 and increases under more oxidizing conditions (+400 mV) to a pH of about 4.2. The constant capacitance model produced sorption edges at lower pH values, from 2.2 to 3.0, with no discernible trend with Eh.
To illustrate the potential impacts of the choice of sorption model and fitting parameters on the remediation of an actual waste site, a simple system was modeled using a single Kd model with values of 40 (a value used in previous risk assessment efforts) and 2.2 (the best-fit value from field data for the site) and the empirical rise function fit to field data. The simple system was assumed to have an initial pH of 3.0. The pH response of the system was calculated by assuming that pH 5.6 rainwater mixed with existing porewater and that one-half of the hydrogen ions were retained by the system due to soil buffering. All the aqueous-phase uranium was assumed to be removed from the system as a new porevolume of water was added to the system. From this, the fraction of remaining uranium in the system as a function of porevolume was calculated for the three models and is shown graphically in Fig. 2. Modeling of a simple system suggests that a technology such as pump-and-treat would be more effective in removing uranium than previously predicted using literature Kd values. The use of the field data best fit Kd value of 2.2, however, will likely underestimate the time required for remediation because the aqueous fraction is expected to decrease as the pH of the system returns to more neutral conditions. Therefore, a model which accounts for the pH-dependence of uranium sorption is expected to provide a much better estimate of remedial effectiveness.
Fig. 2. Estimation of the Fraction of Uranium Remaining as a Function of Porevolume.
CONCLUSIONS AND IMPLICATIONS
The partitioning of a contaminant between the aqueous and solid phases in a natural system can not be described by a single linear isotherm in situations where the surface or aqueous-phase chemistry exhibit large variations. A simple method of obtaining the actual distribution of contaminants in a polluted aquifer is to analyze sets of porewater and soil samples obtained at the same location in the

aquifer, at the same time. The actual distribution coefficients of an SRS waste site determined using this method vary several orders of magnitude.
In this study, uranium sorption can be explained largely in terms of aqueous sample pH. The sorption isotherm for uranium obtained laboratory data shows a significant increase in sorption above pH 4.0. The sorption isotherm for the field data has a sorption edge at a lower pH value than either the 10-6 M uranium on gibbsite or the 10-5 M uranium on background soils. This may be because the sorbed uranium phase, as defined by the sequential extraction, includes some nonexchangeable uranium. Further analysis of the sequential extracts is necessary to refine the uranium concentration in the sorbed phase.
This work demonstrates that the uranium in the low pH plume of the Water Table Aquifer at this waste site is more mobile then had been predicted in previous modeling efforts. The data also suggests that removal of aqueous-phase uranium will become less effective over time as the pH of the waste site aquifers returns to more neutral conditions. This is due to the gradual change in groundwater chemistry (i.e. increasing pH) due to the discontinuation of use and closure of the seepage basins. Since the inflection point of the uranium sorption isotherm in this study occurs at about pH 4.0, and a large fraction of the uranium at the site is currently associated with the low-pH portion of the plume, aqueous-phase uranium is expected to be more easily removed while the pH of the system is lower.

EVALUATION OF IN SITU PHYTOREMEDIATION OF URANIUM-CONTAMINATED SOILS IN OHIO AND MONTANA

ABSTRACT
The U.S. Department of Energy (U.S. DOE) is investigating the use of plants to remove heavy metals and radionuclides from contaminated soils (phytoremediation). As a first-step in the development of phytoremediation for uranium-contaminated soils, test plots were established in the summer of 1994 at the Fernald, Ohio, DOE site incinerator area and at a uranium waste rock dump in southwestern Montana. The test plots were designed to develop experimental protocols as well as carry out a preliminary screening of uranium accumulation by several crop plants (mustards, legumes, rapeseed), and indigenous plants. At Fernald, soils and plant biomass were sampled during and at the end of the growing season. Only modest uptake of uranium was observed, from 1 to 10 ppm in the leaf and stalk biomass (mg/kg dry weight biomass), compared to about 50 ppm in the soil. Similar uranium levels were observed in aboveground biomass from the mine site, although uranium concentrations averaged 340 ppm in waste rock "soils". Nevertheless, the methodologies applied are judged sufficient for verification of contaminant hyperaccumulating plant species in a field setting. So-called "hyperaccumulator plants" are known for some heavy metals, such as Zn and Ni, that concentrate these metals to over several thousand ppm. Plants species and strains that accumulate U to at least 100 ppm will be required

for phytoremediation. A screening program for uranium accumulating plants is underway at the USDA-ARS Laboratory at Cornell University.

INTRODUCTION

At many Department of Energy (DOE) sites, surface soils are contaminated with heavy metals and radionuclides (1). In many instances, levels of contamination exceed regulatory standards by relatively small amounts. Remediating these soils with conventional technologies is costly and produces significant secondary environmental impacts. Phytoremediation, in which plants are used to remove toxic elements from soils into harvestable biomass, could be a cost-effective alternative. Growing and harvesting plants is relatively inexpensive, and can be accomplished with minimal soil disturbance, compared to conventional soil remediation technologies. The harvested biomass could be thermally treated to reduce the volume requiring ultimate disposal by an order of magnitude.

For phytoremediation to clean up a site in a reasonable period of time, i.e, 10 to 20 years, the concentration factor (dry biomass to dry soil contaminant ratio) must be about 40, and the annual plant productivity be at least 10 metric tons/hectare (t/ha). These factors will vary depending on depth of contamination and degree of contaminant reduction desired (2). Successful phytoremediation will require: 1) identification of the appropriate plant species able to accumulate uranium in sufficient amounts; and 2) agricultural management to optimize biomass production as well as enhance bioavailability and uptake of the contaminant(s) of concern from soil.

From a review of the literature (3), dry plant biomass typically contains less than one ppm (mg/kg) of uranium, when growing on uncontaminated soils. Some plant families, the mustards and legumes, exhibit higher uranium concentrations, 10 to 20 ppm in LSB when grown in soils containing elevated levels (i.e., >5 ppm) of uranium. Occasional, but thus far not verified, reports of even higher uranium contents in isolated field samples are found in the literature.

The ultimate program goal is to develop phytoremediation technologies applicable to site remediation problems of the DOE complex. One problem is extensive surface contamination of soils with uranium, at relatively low levels, but still above regulatory limits. Low cost technologies for the remediation of such sites are required. The immediate objective was development and demonstration of protocols for field evaluation of potential plant species useful in phytoremediation of uranium-contaminated soils. For the initial test, examples of mustards, legumes, crop plants, and indigenous plants, were used. Two field studies were carried out, one at the Fernald, Ohio, DOE site, and the other at a uranium waste rock dump site in southwestern Montana.

EXPERIMENTAL DESIGN AND METHODS

At the Fernald, Ohio, DOE site, the experimental plot was located at the Incinerator area, immediately east of the main production facility. The test plot consisted of three replicate blocks with ten 1x2 m cells per block. Five plant species were tested on two randomly selected cells per block: from local seed sources, alfalfa (Medicago sativa cv. WAMPR) and red clover (Trifolium repens cv. "medium red"); wild mustard (Brassica kaber) and rapeseed (Brassica napus) from a California seed supplier; and tall fescue (Festuca arundinacea), an introduced grass growing naturally on this site.

Prior to seeding the test plot, the existing vegetation was removed by spraying with glyphosate and rototilling; the individual cells were delineated with plastic piping. A composite soil sample was collected from each of the test cells and analyzed for total uranium. The individual cells were then seeded without the addition of soil amendments. Midway through the growing season one cell of each of the species was harvested. In September the remaining cells were harvested (both roots and shoots). Phytomass and soil samples from each cell were analyzed again for total uranium content.

A second field experiment was established on a waste rock dump at the W. Wilson mine, an abandoned uranium mine, about 15 kilometers southwest of Helena, Montana. At this site, two blocks of 12 cells of 1 x 0.5 m each were established, each block was used to test six different plants, each represented by two provenances. Plant species acquired from Big Sky Seed (Shelby, Montana) included: tansy mustard (Descurainia pinnata), fringed sage (Artemisia frigida), hard fescue (Festuca longifolia cv. Durar), redtop (Agrostis alba), creeping red fescue (Festuca rubra cv. Boreal) and birdsfoot trefoil (Lotus corniculatus cv. Empire). The following

species were purchased from Granite Seed (Lehi, Utah): fringed sage, hard fescue (cv Aurora), redtop, creeping red fescue (no variety specified) and birdsfoot trefoil (variety not specified). Tansy mustard was also purchased from Valley Seed Service, Fresno, California. The test blocks were prepared by rototilling the top 25 cm of soil followed by removal and stockpiling of the top 5 cm of soil. Each cell was treated with 1.3 g of (NH4)2HPO4 (reagent grade) and the excavated soil replaced. A soil sample was collected from the center of each cell.

Environmental (e.g., soil, plant, irrigation water) and quality control (e.g., duplicate samples, equipment rinsate) samples from Fernald were shipped by overnight mail to Accu-Labs Research, Inc. (Golden, Colorado) for determination of those parameters requested in the test plan (4). Agricultural parameters for soils included pH, Eh, organic matter, soil texture, etc.; agricultural analyses on plant tissues included NPK levels, percent ash, etc. Radiochemical analyses focused on determination of total uranium by Kinetic Phosphorescence Analysis (KPA; ASTM D5174-91) and isotopic uranium by USEPA Method 908.0. All root samples were washed in tap water, followed by sonicator bath in deionized (DI) water and rinsed with DI water before drying.

The respective analytical parameters for environmental and QC samples taken from the Montana uranium site are described in the test plan (5). Notable differences from the Fernald analyses are: 1) determination of strong acid (HNO3) and weak acid (ammonium acetate, pH 5.5) - extractable levels of select "heavy metals" in mine soils and "total" metals in leaf and stalk biomass, using; 2) inductively coupled argon plasma emission spectroscopy (ICPAES) at the MSE Laboratory (Butte, Montana).

RESULTS

Table I summarizes the results from the Fernald site. The average U content of the soils at this site was approximately 36 pCi/g (equivalent to 54 mg/kg of soil), similar to the anticipated (though not yet finalized) soil clean-up level (about 35 pCi or 51.8 mg/kg of soil). Thus, this specific plot may not require remediation, although other areas at this site exhibit higher average levels, and will likely need soil remediation. It is in such marginally contaminated soils, where uranium need only be reduced by only a few tens of ppm, to achieve regulatory compliance, that phytoremediation would be most applicable.

Inspection of the "grand mean" uranium levels in soils implies an apparent decrease of 7 mg U/kg dry soil over the course of the growing season; a two-tailed Student's t test rejected the null hypothesis (i.e., no difference in June vs. September U mean levels) at p 0.01. However, for reasons discussed below, MSE does not attribute this change to U uptake by plants. The alternative hypothesis is that such difference is due to heterogeneous distribution of uranium oxide particles (i.e., fallout from the adjacent incinerator stack) within a given volume of soil. Although cell-specific uranium levels generally declined between the June and September sampling episodes, in a few instances U levels appeared to increase over time (e.g., from 49 to 68 mg U/kg soil in Block 3, cell1 and from 48 to 55 mg U/kg soil in Block 3, cell 10). Thus, sampling error is more likely an explanation than is analytical error, given the 15 percent differences in replicate sample results as well as close agreement between certified and reported results for the laboratory control standards.

The results for the Fernald site (Table I) indicate very little accumulation of uranium in any of the plants. The highest uranium content in any LSB sample was for a red clover at 10 ppm (from Block 3, cell 6), but there was a large variability between different plots and cells for the various plant species. Roots contained considerably more uranium, ranging up to 43 ppm in red clover from Block 2, cell 5. However, total U levels in the species evaluated are still too low to allow significant site clean-up, as supported by the mass balance data presented in Table II. Division of each species' average U content (in shoots and roots) by the respective mean U levels in baseline soils indicates annual plant U uptake rates ranging from 0.024 percent year -1 for alfalfa to 0.045 percent year -1 for wild mustard. At such rates of U removal, cleanup of the incinerator area soils would require well over a century to remediate to regulatory acceptable levels.

Table IIIa,b summarizes the results from the Montana site. In this case both acid extractable and bioavailable metal levels were determined. Plant growth was poor at this site, presumably due to the poor soil fertility (e.g., 0.01 percent N, 18 ppm NH4F-extractable P and 64 ppm NH4OAc-extractable K), strongly acid pH (5.4 avg.) and potentially phytotoxic levels of Cu (and U?) in the soils. Thus, for many samples,

the biomass from the two replicate cells was composited to produce sufficient sample biomass for chemical analysis. Note that U levels in LSB are of similar magnitude to those observed at Fernald, despite nearly 10-fold higher total U levels in "soils" at the mine site. For example, the maximum U concentration in LSB was approximately 10 ppm in tansy mustard. The presence of 119 mgAl/gLSB (vs. 3318 mg/g in the other species) in this mustard indicates the potential for soil contamination; however, the other heavy metal levels are not unreasonable in this species. Anecdotal evidence for root U concentrations exceeding those in LSB is indicated by the respective 7.8 and 2.7 ppm levels observed in spotted knapweed (Centaurea maculosa) plants growing in waste rock material immediately west of the test blocks. Background levels of Cd and Zn rarely exceed 3.0 ppm and 150 ppm, respectively, in aboveground biomass from nonmineralized soils in southwestern Montana; thus, the concentrations of these two elements in LSB from the (mineralized) mine soils are greater than typically observed in the area. This observation is particularly true for metals levels seen in the tansy mustard. Nevertheless, none of the heavy metals data indicates the presence of hyperaccumulator species at this site. Finally, as the birdsfoot trefoil germinated well and survived (albeit with stunted growth) under the harsh site conditions, it should be considered as a viable species for revegetating this abandoned mine site's waste rock dumps.

DISCUSSION

The primary objective of this investigation was demonstration of useful field and laboratory protocols required for evaluation of this innovative technology, not site remediation per se; the study was initiated using cultivated and indigenous plant species believed to accumulate (based on literature review) elevated levels of uranium from soils. Although many of the species tested did this much, the above initial field trials did not identify any plants that exhibited sufficient U uptake to meet the minimal requirements for phytoremediation. For example, to reduce soil concentrations by 10 ppm to a depth of 30 cm (about 4,000 metric tons/hectare, t/ha, of soil), would require cultivation for 20 seasons of a plant that accumulates 100 ppm of uranium with a productivity of 20 t/ha/yr. Obviously, even greater than 100 ppm levels in the harvestable biomass (both shoots, and to the extent feasible, roots) would be desirable, and even required in most cases. Although some literature data suggests the possibility of such plants, this has yet to be confirmed. However, by analogy with other metals and known hyperaccumulator plants (USDOE, 1994), some of which exhibit many thousands of ppm of toxic elements in the plants, it is likely that such plants may already exist or could be created by genetic selection.

The major challenge in phytoremediation of these sites is to find uranium hyperaccumulating plants. Productivity is, of course, also a major requirement. Present results of field trials at Fernald and Montana were not encouraging in either respect. However, they have demonstrated some basic requirements to testing phytoremediation in the field. These results also demonstrate that commonly available plants are unlikely to exhibit sufficient U accumulation. Nevertheless, the U levels in mustard plants, being an order of magnitude higher than many plants, suggests significant potential for metals accumulation, likely under genetic and environmental controls.

Work is planned for further field tests of plants known to hyperaccumulate heavy metals such as Zn, Cd and Ni, and for plants that exhibit uranium accumulation in larger laboratory screening experiments, currently being carried out in the laboratory of Dr. Leon Kochian (USDA Plant Nutrition Laboratory, Cornell University, Ithaca, NY). Even if phytoremediation of uranium contaminated sites proves not to be practical, other types of radionuclides (e.g., 90Sr) and toxic elements (e.g., Cd) are more amenable to site clean-up with this emerging technology. Such field tests are being planned for implementation in the summer of 1995.

ABSTRACT
The VORCE (volume reduction and chemical extraction) Pilot-Plant (VPP) was developed to remediate radioactively contaminated soils at the Montclair/Glen Ridge, New Jersey Superfund sites. The development, design, fabrication, and testing was under the direction of the U.S. Environmental Protection Agency (EPA), Office of Radiation and Indoor Air (ORIA) and performed under contract by Sanford Cohen & Associates, Inc. (SC&A). A majority of the preliminary design work and the testing of the plant were conducted at the National Air and Radiation Environmental Laboratory (NAREL). The plant was designed to separate the contaminated soil fraction (-200 mesh) from the bulk soil using various physical separation techniques. The pilot-plant was fabricated primarily from off-the-shelf components proven in applications related to mining and mineral processing. The present design is based on the Phase II plant, which resulted from modifications of a Phase I plant.
The Phase II plant was completed and successfully tested on clean and contaminated Montclair soil in September 1992. The conceptual retrofit was initiated to allow the pilot-plant to more effectively treat Department of Energy (DOE) Superfund and FUSRAP (Formerly Utilized Site Remedial Action Program) sites, to improve the plant feed and materials conveyance systems and the initial liberation process, and to allow a feed input rate of from 2 to 5 tph.
Each modification is based on the analyses from the prior test results and computer modeling performed by SC&A, Carpco, and Virginia Polytechnic Institute and State University. These modifications produce a conceptual retrofit design that could recover up to 65 percent of the feed soil with a radium-226 and radium-228 concentration of less than 5 pCi/g. The conceptual retrofit design is an innovative remediation technology that could reduce large volumes of contaminated soil being disposed as radioactive waste. Although the retrofit is considered to be innovative, it is based on separation technology that has been used extensively in the mineral processing industry. However, the retrofit is based on characterization studies of the samples from the DOE Superfund sites, it could also be successful at other contaminated sites where the majority of the radionuclide contaminants are concentrated in the fine-size particles. Many radioactively contaminated sites are in that category, including some DOE sites.

INTRODUCTION
The Department of Energy's (DOE) Formally Utilized Sites Remedial Action Program (FUSRAP) is proposing to demonstrate the feasibility and cost effectiveness of treating soils contaminated with uranium and thorium and their decay products to reduce the volume requiring costly transportation and disposal. The demonstration is

planned at two DOE Superfund sites. The platform for the volume reduction treatment pilot-plant is the VORCE (volume reduction and chemical extraction) Phase II Pilot-Plant (VPPII). The existing pilot-plant requires modifications to correct operational and performance deficiencies found during testing, and to account for characteristic differences between the DOE Superfund soils and those for which the VPPII was originally designed to remediate. The reconfigured pilot-plant is hereafter called the Radioactive Soil Washing and Particle Separation (RSWAPS) pilot-plant.

The VPP was developed to remediate radioactively contaminated soils at the Montclair/Glen Ridge, New Jersey Superfund sites. The development, design, fabrication, and testing was under the direction of the U.S. Environmental Protection Agency (EPA), Office of Radiation and Indoor Air (ORIA) and was performed under contract by Sanford Cohen & Associates, Inc. A majority of the preliminary design work and the testing of the plant (Phases I and II) were conducted at the National Air and Radiation Environmental Laboratory (NAREL). As extensive characterization had indicated, the plant was designed to separate the contaminated soil fraction (-200 mesh) from the bulk soil using various physical separation techniques. The pilot-plant was fabricated primarily from off-the-shelf components proven in applications related to mining and mineral processing. The present plant, Phase II, is the result of extensive modifications of a Phase I Plant, which was completed in 1990.

The VPPII was completed and successfully tested on clean and contaminated Montclair soil in September 1992. After completing these test runs, it was recognized that design modifications would be necessary to allow the plant to operate more efficiently.

A preliminary assessment of the current plant design has been completed by SC&A and Carpco. Data considered in the assessment were the preliminary characterization studies on a limited number of samples from the DOE Superfund sites (1, 2), the results of radioactive and clean soil testing of VPPII, and available mineral processing information. Based on those analyses and a somewhat limited characterization of the test soils, recommendations for modifications to the existing plant have been made. By incorporating one of these design modifications, the RSWAPS plant will be able to consistently achieve the desired level of remediation at rates of either 2 or 5 tph.

PROPOSED MODIFICATIONS

Based on the initial VPPII data and operating experience during testing, several deficiencies were identified with the existing system. These problems presented operating difficulties and limited the maximum plant efficiency. The major operational problems and recommended solutions are discussed below.

Feed Conveyance System

The introduction of raw soil into the plant presents the single greatest design challenge. The physical characteristics of raw soil can vary widely during an application, and the necessity to handle relative large soil particles at the design, low input feed rates require compromises in the selection of a raw-soil feed conveyance system of a pilot-size plant.

The VPPII feed conveyance system proved to be inadequate for input rates greater than 800 - 1000 lb/hr. The system consisted of a steep-pitch feed hopper covered by a 2 x 3.5-inch openings grizzly screen. The feed hopper discharged onto an inclined screw conveyer which discharged directly into the trommel. It was intermittently filled using a "Bobcat" loader.

This system presented three problems during operation. This first problem was blockage of the feed hopper because material bridged above the screw conveyor. The short-term solution to this problem was assignment of an operator at the feed hopper to manually dislodge blockages. This arrangement, however, is not practical for long-term operation of the plant because of manpower requirements and potential radiation exposure (the feed hopper is the highest risk area for exposure to respirable dust).

The second problem encountered was binding of the screw conveyor by oversize material. Although these larger particles (2 to 4 inches) passed through the grizzly screen, they would subsequently become lodged between the conveyor flights and the hanger bearings that support the screw above the trough. The only solution to this problem was to shutdown the feed system and manually remove the blockages. In addition to limiting the plant capacity, this latter problem was detrimental to the

operating efficiency because of intermittent feeding.
The third problem was controlling the volume of material conveyed by the screw. The tapered screw did not control the rate of material flow. The result was overloading of downstream sections of the screw conveyer. The solution to this problem during testing was to limit the rate at which soil was fed into the hopper. This solution, of course, limited the overall plant feed rate.
Two different feed system configurations have been employed on the pilot-plant. A belt conveyor was used on VPPI. As stated above, a screw conveyor was used on VPPII. Both have proven to be unsatisfactory due to their inability to deliver soil to the scrubber in a consistent manner with no spillage. The only remaining options for feeding the plant were:

- bucket elevator
- slurry pump
- direct feeding via hopper and vibrating pan feeder
- apron conveyor
- drag conveyor

It is possible to eliminate the first three from consideration for the following reasons: with very low feed rates and soil characteristics, Bucket Elevator problems are anticipated with discharging the buckets from the Bucket Elevator; with very low feed rate and the existence of large particles, pumping with a Slurry Pump is not possible; and Direct Feeding would require construction of a highly elevated feed ramp to make the hopper accessible by a loader.
The remaining two options (apron conveyor and drag conveyor) function in a similar manner. The primary difference is that the apron conveyor provides a surface to carry the material, vs. sliding. This feature requires a more complicated design for the apron conveyor. It is constructed of an endless apron of overlapping pans attached to two strands of chain. The chain is equipped with chain rollers (wheels) riding on tracks. In contrast, the drag conveyor merely slides the conveyed material across the surface of a stationary conveying pan. Since this conveying pan can also serve as the main structural element, construction is simplified. The primary disadvantage of the apron conveyor is, therefore, one of increased cost and maintenance.
Another disadvantage concerns the method of feeding. The apron conveyor requires some method for controlling bed depth on the pans. The apron pans will inherently carry all material deposited on them and are limited only by their structural strength and the depth of any skirtboards provided by the design. It is therefore necessary to provide a shearing device at the discharge throat of the feed hopper. This device produces a "strike-off point" above the pan surface that limits the depth of material on the pan. This strike-off point can create flow problems if the unit is not properly designed. In contrast, the bed depth is essentially self-limiting in the drag conveyor because of the drag chain design. The chain essentially shears material to be conveyed from the feed hopper. Factors influencing the bed depth include: 1) height of the chain, 2) conveyor incline, 3) particle size, and 4) material flowability.
Based on the above considerations, a drag conveyor is the choice for feeding the RSWAPS. In the modified design, the existing screw conveyor is replaced by a drag conveyor mounted to the existing chassis. The existing variable speed drive is retrofitted to the new conveyor. The existing feed hopper is replaced. The new feed hopper is smaller in design for better accessibility by a small skid-steer loader. The loader approaches from the rear of the conveyor. In addition, the grizzly passes a larger particle size (4-in vs. 2-in minimum openings). The increase to 4 x 4 in grizzly opening size is made to improve material flow into the hopper.
Additional changes in the feed system include the removal of the feed scale and a redesign of the scrubber feed chute. The purpose of the scale in the VPPII configuration was to provide a means of controlling the plant feed rate. The scale produced a signal, proportional to feed rate, which was used by the PLC to control the speed of the feed screw. Actual operation of the plant revealed that feed rate could be easily controlled visually. Removing the feed scale simplifies operation of the plant and reduces flow problems encountered between the feed system and the trommel. The feed chute redesign is necessary with change of conveyor type.
Trommel Screen/Washer
The trommel screen was originally placed in the circuit to scrub and remove coarse material (+1/4-in) from the feed. According to the data obtained from the initial

test runs, the coarse material was adequately rejected. However, both test data and visual observations have shown that this material would benefit from additional washing/scrubbing to remove the small amount of fine particles still clinging to the +1/4-material. It was noted that the trommel was insufficiently loaded during operation such that the residence time of the material (+1/4 in) was inadequate. This indicates that either the plant feed rate was too low, the trommel screen was oversized, or that design of the trommel did not provide adequate residence time for the larger material. Since the plant feed rate is limited downstream by the throughput of the screw classifiers, increasing the plant feed rate is not recommended. Increasing the trommel screen opening would introduce material to the attrition mills too large to effectively pass through them. Therefore, to provide additional scrubbing action through particle contacting by increasing the material residence time, modifications to the original trommel design are required.

Based on designs from typical mineral processing applications, a tapered discharge added to the end of the trommel screen restricts the flow of material discharging the mill resulting in a hold-up of the coarser material. The increased working load in the mill provides better particle-particle contact and should result in improved scrubbing of the coarse material. To further ensure sufficient particle contacting, the trommel is retrofitted with an electronic variable speed drive, which allows the operator to fine tune the rotational speed of the unit to maximize its performance. Specifically, the unit should be designed and operated so that the material in the drum exhibits a cascading action rather than tumbling. This approach maximizes abrasion while minimizing particle breakage. Finally, the taper is fitted with screw-type lifter bars to remove the coarse particles from the end of the mill.

Water carry-over with the coarse product also presented a problem in the VPPII trommel. This was simply a result of leakage through the open-end design. The addition of the tapered discharge with appropriately located water sprays eliminates this problem.

Transfer Conveyors

The transfer screw conveyors from the attrition scrubbers to the screw classifiers also had problems with occasional overflow. This was most apparent when the scrubber pulp density dropped, resulting in a surge in the attrition mill discharge rate. With the nature of the system, it is assumed that this problem will always persist. Two possible solutions to this problem are considered. The simplest approach is to totally enclose the transfer conveyors and increase the speed to minimize this problem. The second, and selected, approach is to replace the screw conveyors with a viscous slurry pumping system. These types of systems are routinely used for conveying concrete over long distance and should work quite well in this system.

Launders

The launder that transferred material from the secondary screw classifier overflow to the cyclone feed sump experienced problems with sanding of material that was a result of insufficient incline between the feed and discharge end of the launders. The short-term solution on site was to add additional water to the launder to minimize sanding.

It is recommended that the launder be replaced with a vertical sand pump that directly conveys the material to the cyclone feed sump. This approach is typically used in particulate processing operations to handle potentially intermittent flows. These pumps are ideal for this situation since they can run empty for extended periods of time.

Dewatering System

After solving a few start-up problems, it appeared that the water clarification system worked very well. However, dewatering of the fine waste fraction using the filter press presented some operational problems. In addition to the operational problems, the capacity of the filter press is also a serious concern. According to the documentation provided, the rated capacity of this unit is 1100 lb/hr. Based on the feed particle-size distribution, the weight percent of one of the test soils passing 200 mesh is approximately 30 percent. At a feed rate of 2 tph, the filtration system would be required to handle 1200 lb/hr. Under realistic conditions, the solids feed rate to the filtration system would approach 1500 lb/hr. For the other test soil, where the weight of the material finer than 200 mesh is approximately 45 percent of the total soil, the solids feed rate could approach 2200 lb/hr. Thus, based on the current design, the system cannot be operated continuously. A shift-type approach would be required to operate the press while the

wash system is idle, thus allowing the dewatering system to catch-up with the remainder of the plant.

Considering the constraint placed on the plant feed rate by the dewatering system, the current filtration system must be replaced for the 5 tph option. The possible choices are to either install a dewatering centrifuge or a belt-type filter press with a capacity in excess of 4-5 tph. A centrifuge appears to be a better choice since it is more reliable and less operator sensitive. The latter is particularly important considering the nature of the material. At this point in the process, there is nearly a four-fold increase in the radioactivity of the material.

Stacking Conveyors

In the VPPII system, clean product streams were diverted to 55-gal drums placed on roller conveyors. When the drum filled, it was manually moved and replaced with an empty drum. Actual testing has proven this method to be very cumbersome and labor intensive. Spillage of material was also a problem. Therefore, the addition of stacking conveyors at the clean product stream discharge points is recommended. We believe this is absolutely necessary on the 5-tph plant. These conveyors will discharge to stockpiles. Material stockpiled will be moved using a skid-steer loader.

Stacking conveyors for the clean sand and clean fines streams will be fabricated using available screw conveyor components from the present 12-in feed screw. Two complete screw conveyor drives to be purchased and supports to be fabricated.

A new drag conveyor, similar in design to the feed conveyor, will be used to stockpile the clean gravel. This design has been chosen because of large particles in the stream. These particles would most likely cause binding in a screw conveyor. They would also tend to roll back on a belt conveyor. Spray nozzles will be used to provide an additional rinse step for this stream. Rinse water will flow to a containment sump. The rinse water will then be pumped to the cyclone feed sump.

SIMULATED PLANT PERFORMANCE

Based on the information available from the previous test runs, a series of simulations were conducted for the redesigned plant. These simulations provide an indication of plant performance and are based on the data collected during the initial test runs with Montclair soil.

Particle-Size Separation

Since the VPPII was performing only a size separation on the raw feed, simulations can be based on the partition curve for each unit operation. A partition curve represents the size-by-size mass recovery for a particular unit operation. Mathematically, it is expressed as follows:

Eq. (1)

where Xi represents the weight percent of material in size class (i) present in either the feed (f) or the product (p) streams and M represents the solids mass flow rate in the stream of interest. The partition curve is simply the size-by-size recovery plotted as a function of particle size. A perfect separation is represented by a step function which increases from 0 to 1 at the particle size of separation. Based on the available data, partition curves were constructed for the screw classifiers and the classifying cyclone (see Fig. 1). These two unit operations are the two main separating units used in the VPPII plant. These results illustrate that the units provided a reasonably efficient separation as indicated by the steep slope of the partition curve. However, in both cases, the partition curves have a significant y-axis offset. This well-known phenomenon represents short-circuiting of fine feed material to the oversize product. In the case of the classifying cyclone, 20 percent of the material finer than approximately 20 microns reported non-selectively to the cyclone underflow. Likewise, approximately 5 percent of the material finer than 100 microns fed to the secondary screw classifier reported with the oversized product. This represents significant remediated product contamination considering that essentially all radioactive contamination is present in the fines fraction (<75 microns).

Short circuiting can be avoided by eliminating the potential for fines recovery with the coarse product through multiple stages of separation (e.g., three cyclones in a series configuration) or by incorporating a unit operation that reduces or eliminates short-circuiting of material. As shown by the partition curve for the secondary screw classifier, multiple processing stages reduces the impact of fines carryover. In this case, the primary screw classifier had a fines carryover rate approaching that of the cyclone. However, multiple processing stages tend to become

quite cumbersome, particularly with cyclones. In this application at least three cyclone stages would be required to achieve the required separation. This approach could create operational problems regarding feed solids density, flow rate, etc. The best solution is to incorporate a unit operation that eliminates the problems associated with fines recovery. In this application, a hydraulic classifier, such as the Floatex unit, would be the best choice to ensure a high quality washed product. The partition curve for a Floatex classifier is also shown in Fig. 1. The Floatex classifer is capable of providing the same classification as other unit operations; however, the carry-over of fine material is largely eliminated. The Floatex Density Separator is a hydraulic classifier designed to achieve extremely sharp particle-size separations. Unlike a vibrating screen, the Floatex separator classifies material based on the principal of hindered settling. Since the separation occurs in an open tank, mechanical problems associated with screening (i.e., blinding and tearing of the screen cloth) are eliminated. In addition, by settling against a clear stream of counter-current water, inefficiencies resulting from fines carrying-over with the process water (typical of classifying cyclones) are eliminated. As a result, the Floatex separator provides a more efficient and cost effective separation.

The product quality depends on the composition of the feed material and the desired separation size. The Floatex is generally utilized for size separations on particles finer than 1/4 in. Efficient separations are achieved when the desired cut-point (i.e., separation size, d50) ranges from 14 to 200 mesh (1 mm to .075 mm).

To illustrate the advantage of the Floatex separator, simulations were conducted using this device as a final cleaning step on both the 1/4-in x 65 mesh and 65 x 200 mesh products. The results from this simulation are shown in Fig. 2 that illustrates the comparison of a Floatex unit separation to an ideal separation (laboratory wet screening) and to these results from the previous VPPII tests. As shown, the circuit including the Floatex separators provided an extremely efficient separation, approaching the results obtained by screen analysis (ideal). In this case, less than 3 percent of the material finer than 200 mesh would be recovered with the coarse product from the Floatex unit. In comparison, approximately 20 percent of the material finer than 200 mesh reported to the coarse product using the existing VPPII system. The relatively large amount of misplaced fines makes it difficult for the existing VPPII system to maintain the required product grade. These results clearly illustrate the advantage of a final clarified water washing stage such as that provided by the Floatex separator.

Flowsheet Recommendations

Based on the simulation results presented, several modifications to the original flowsheet are recommended. These modifications are illustrated in the process flowsheets shown in Fig. 3 and Fig. 4. In all cases, the mechanical modifications to the feed system, trommel screen, transfer conveyors, and launders are assumed.

Figure 3 illustrates the modifications to the circuit configuration to make the plant completely operational at a feed rate of 2 tph. In this case, two Floatex units have been added. The first Floatex unit has been installed to provide the primary remediation step after attrition scrubbing. The Floatex underflow would be equipped with a screw auger to remove the coarse material so that the washed product is also dewatered prior to discharge. This modification is greatly needed since there is only one remediation step after attrition scrubbing. Depending on the nature of soil being treated, the stream may contain excessive amounts of fine material generated during scrubbing. A second Floatex classifier has been installed on the cyclone underflow stream since, in the current configuration, this material has the largest detrimental effect on the quality of the overall plant product. The arrangement will ensure that the 65 x 200 mesh fraction is a high quality, thoroughly remediated product.

Figure 4 illustrates the modifications that would be required to convert VPPII into a 5-tph facility. The secondary screw classifier would be relocated to operate in parallel with the existing primary screw classifier. Relocation is essential to handle the tonnage present in the trommel underflow. In addition, all four attrition scrubbers would be used to handle the increased capacity. As described above, the product from the scrubbers would be remediated in a Floatex separator.

To handle the increased capacity in the fines circuit, a second classifying cyclone would be installed in a parallel arrangement. The cyclone feed system would be arranged to allow either one or both units to operate. The configuration would

depend upon the nature of the soil (i.e., loading in the fines circuit). The cyclone underflow will report to a second Floatex unit, as in the original 2 tph circuit. In this case, however, the size of the unit would be increased to handle the additional material.

Testing the VPPII revealed that the Montclair soil finer than 200 mesh collected from the filter press contained 35 percent water (65 percent solids). Modifications shown in Fig. 3, retaining the batch filter press to collect the material finer than 200 mesh, should produce a product with the same moisture content. The modification shown in Fig. 4 that replaces the filter press with a bowl centrifuge will collect the material finer than 200 mesh at 55 percent solids. Each of these modifications can include a hollow-tube dryer that will dry the product to 90 percent solids. The results of an economic analysis considering the capital investment for a dryer versus the savings realized from the transporting for disposal the drier product would be primarily affected by the amount of soil to be treated. Beyond some minimum amount of soil to be treated, the dryer would pay for itself and then reduce the overall cost of remediation or the expense of transporting the drier material.

It should be noted that the increase from 2 to 5 tph requires only a minimal increase in equipment, unlike that for dewatering. According to the above analysis, all the existing equipment (with the exception of the filter press) would be used in the final design. This represents a significant cost savings in comparison to the construction of a completely new facility.

CONCLUSIONS

A preliminary assessment of the current plant design was completed by SC&A and Carpco, Inc. Considered in the assessment were the preliminary soil characterization studies samples from the DOE Superfund sites, the results of radioactive and clean soil testing of the Phase II plant, and available mineral processing information. Based on those analyses, recommendations for modifications to the existing plant were made. The following conceptual design modifications to the Phase II plant are: 1) Replace the existing feed screw conveyance system with a drag conveyance system to achieve a desired remediation feed rate of 2 to 5 tons per hour (tph); 2) Modify existing trommel screen/washer is modified by the addition of a tapered discharge added to the outlet end of the trommel screen to increase the residence time of the coarse (+1/4-in) material and to allow adequate removal of fine particles; 3) Replace the existing transfer screw conveyors from the attrition scrubbers to the screw classifiers with a viscous slurry pumping system to handle the occasional problem of material overflowing in the existing transfer screw conveyors; 4) Replace the launder that transfers material from the secondary screw classifier overflow to the cyclone feed sump with a vertical sand pump which directly conveys the material to the cyclone feed sump to prevent problems with sanding of material; 5) Install a dewatering centrifuge, replacing the belt-type filter press that cannot match the throughput capacity of the remaining components of the plant; 6) Add stacking conveyors at the clean product stream discharge points, replacing roller conveyors that proved to be very cumbersome and labor intensive; 7) Add a hydraulic classifier designed to achieve sharp particle-size separations to ensure a high quality clean product by eliminating displacement of up to 20 percent of the fines (-200 mesh, -75 microns) to the remediated product by several of the separation units.

Each of the aforementioned modifications is based on the analyses from the testing of the existing plant, preliminary characterization studies on DOE Superfund site samples, and computer modeling performed by SC&A, Carpco, and Virginia Polytechnic Institute and State University. These modifications produce a conceptual retrofit design that could recover up to 65 percent of the feed soil with a radium-226 and radium-228 concentration of less than 5 pCi/g. The conceptual retrofit design is an innovative remediation technology that could reduce large volumes of contaminated soil being disposed as radioactive waste. Although the retrofit is considered to be an innovative remediation technology, it is based on separation technology that has been used extensively in the mineral processing industry. The retrofit is based on characterization studies of the samples from the DOE Superfund sites, however, the retrofit could also be successful at other contaminated sites where the majority of the radionuclide contaminants are concentrated in the fine-size particles. Many radioactively contaminated sites are in that category, including numerous Superfund, DOE, NRC licensee, and DOD sites. Many are being remediated by a process that consists of excavating large volumes of soil and transporting them to an approved landfill. This is a very costly remediation process and volume reductions of up to

65 percent represent significant cost savings while meeting site remediation criteria and goals.

ABSTRACT

Laboratory studies were conducted to support the design and construction of a full-scale, in-situ sorbent barrier for intercepting a 90Sr plume within a surficial water-bearing sand and gravel layer. Evaluation of a set of materials for use as a passive sorbent wall was first approached through a series of batch sorption tests, using 85Sr tracer, on a set of natural zeolites and metal oxides to determine their effectiveness for sorbing 90Sr. These candidate materials were selected on the basis of commercial availability, cost, and anticipated performance. Selected materials, based on their performance in the screening experiments, were further tested to assess hydraulic performance and sorptive characteristics under dynamic flow conditions. Test data were incorporated into a one-dimensional finite difference model and estimates were made of in-situ performance over extended time frames. The data developed during this study may be applicable to other DOE facilities.

INTRODUCTION

In this paper we present a study combining laboratory experiments and modeling intended to support the design and construction of a sorbent barrier (a passive filter wall) for retarding the migration of 90Sr within a water-bearing surficial sand and gravel layer. Evaluation of a set of materials for possible use as a passive sorbent wall to intercept and remediate the plume was first approached through a series of batch sorption tests, using 85Sr tracer, on a number of materials for screening purposes. A few materials showing the greatest amount of sorption were subsequently selected for column testing. Column tests were performed in order to evaluate the performance of short-listed materials for removing 90Sr from groundwater under dynamic flow conditions. A one-dimensional finite-difference model (1) was used to simulate the observed laboratory data so that predictions could be made regarding 90Sr behavior on a larger scale and over longer time frames. This model accounted for advection, dispersion, diffusion, radioactive decay, and linear adsorption.

Recent studies have promoted the potential use of in situ reactive barriers for remediation of contaminated groundwater. The emplacement of in situ reactive barriers may enhance the removal of groundwater contaminants through alteration of pH or Eh, precipitation, sorption, or nutrient supply for biodegradation.(2) For trace contaminants, the barriers need to preferentially adsorb contaminants as groundwater flows through the material. Candidate materials for passive barriers must be tested under site specific chemical conditions to determine if materials perform as expected in the presence of competing ions. Two major classes of materials for this application are natural zeolites and metal oxides and oxyhydroxides. The sorption properties of both materials have been studied in great

detail. (3,4,5)

METHODS

In these tests we used site specific groundwater and attempted to maintain site specific conditions, such as flow rates. The methods are described below.

Material Screening Experiments

A set of screening tests were run to provide an initial assessment of the effectiveness of a broad range of materials to sorb low concentrations of 90Sr from groundwater. These tests were simple batch sorption experiments in which 0.5 grams of the granular sorbent materials (as received) were exposed to 5 mL of filtered groundwater containing from 11 to 23 nanocuries per mL of 85Sr tracer. The specific activity of the tracer was 15.54 nCi/ng of Sr. After several days the liquid was sampled with plastic disposable syringes, filtered through 0.45 micron syringe filters and analyzed on a high purity germanium gamma-detector. All results were corrected for the mass of the counting sample as well as the mass of solid and the total liquid in each experiment. Experiments were conducted in duplicate for 20 different materials.

Column Studies

Two sizes of plexiglass columns were used depending on the grain size of the material they were to contain. Columns used for two coarse grained materials had average internal dimensions of 3.17 cm in diameter and 3.8 cm in length. For the fine grained materials the diameter was 1.52 cm and the length averaged 6.4 cm. Each column was set-up vertically with the inlet at the bottom.

Groundwater was prepared for these experiments by means of a soil column (with a cross-sectional area of 15.5 cm2) that contained site-specific soil from the geological unit of interest. Filtered site groundwater was pumped through the column at the rate of about 400 mL per day. The effluent from this column had a slight yellow color and a pH around 8.1. Turbidity measurements using method # 750 of the Hach Kit indicated very little turbidity; 2 Formazin Turbidity Units (FTUs). To this water the 85Sr tracer was added so that the count rate of the groundwater, at the beginning of this set of experiments, was about 1.7 nCi/g (~100 cpm/mL). For one of the clinoptilolite columns (CH-A) a different liquid was used; filtered groundwater plus tracer.

The prepared groundwater was pumped through the columns with a Gilson Minipuls low-speed peristaltic pump. Adjusting flow to the porosity of the material, attempts were made to maintain flow-rates that are typical of a rapidly moving groundwater (~40 cm/day). For the small diameter columns this is equivalent to 25 mL/day and for the larger diameter columns, it is about 120 mL/day. Effluent was collected daily in pre-weighed polyethylene bottles. These were weighed to determine the daily flow-rate. Aliquots were taken for radionuclide counting.

85Sr on the Solid Phase of the Columns

After periods of time ranging from 28 to 46 days, flow through the columns was stopped. Each column was then sectioned for analysis of the solid phase for 85Sr activity. This was done by extruding the material from the column in small increments that were wiped into pre-weighed counting bottles. Attempts were made to obtain as small and spatially discrete samples as possible, with distance measurements being made every few samplings. Sampling and measurement were particularly difficult for the two coarse grained materials since the material was not cohesive (the fine grained materials held together quite well) and the larger grains necessitated larger sampling intervals. Each sample was weighed and analyzed for 85Sr on a high purity Ge gamma-detector. For the fine grained materials, essentially all of the material was recovered during the sampling, allowing a relationship to be determined between sample weight and thickness of the sampling interval. For the coarse material, this was much more difficult because some grains were inevitably lost during sample collection. Since the grains at the bottom of each column (the inlet) contained the most activity and this activity changed rapidly with distance, loss of a few grains could be significant. Nevertheless, the profiles of activity as a function of distance, even for the coarse grained columns, are quite reasonable.

Desorption Treatment of Barrier Materials

Two zeolites, mordenite and clinoptilolite, were selected as possible barrier materials based on the column tests. These materials, after having served as permeable barriers, will contain appreciable activities of 90Sr. While the final disposition of the barrier materials has not been decided, it may be necessary to

remove as much activity as possible prior to disposal. It may also be desirable to regenerate the barrier. Experiments were performed to determine what solutions would be optimum for regenerating the materials. Two solutions were selected as potential regenerants; NaCl solution and HCl. Each was tried at 1, 2 and 4 molar concentrations. Six sorption experiments were set up for each of the two materials. After allowing them to sorb 85Sr, the liquid was decanted and counted. Test tubes containing the wet solids were reweighed to determine the quantity of water remaining; then the treatment solutions were added to the tubes. After standing overnight the solutions were sampled, filtered, and counted to determine the activity of 85Sr returned to solution.

RESULTS

Screening Studies

Results of the screening study to determine the materials most effective at removing 90Sr from the groundwater are summarized in Table I. This table shows only the better performing materials that were tested. The most effective were natural zeolites and metal oxides, particularly activated alumina and MnO.

Selection of Materials for Column Tests

Based on results of the screening tests, five flow-through column experiments were performed for four materials:

1. clinoptilolite (CH 20 x 50) - 2 columns; CH-A and CH-B
2. clinoptilolite (CH 5 x 20)
3. mordenite (8 x 14)
4. activated alumina (14 x 48)

The clinoptilolite and mordenite are natural zeolites; the activated alumina is a synthetic product. The numbers in parentheses beside each material refer to grain sizes. For example, an 8 x 14 product refers to particles that pass a No. 8 sieve and are retained on a No. 14 sieve.

The MnO was dropped from consideration since it contains trace amounts of Cu, As, Pb and Cd. All of the chabazites were eliminated based on material costs. Depending on the supplier, prices for this type of zeolite can exceed $ 1400/m3. In comparison, the price for clinoptilolite (CH) is about $208/m3. Results from a column test on "as received" mordenite (14 x 40) indicated that this material contained large quantities of fines that could clog pore spaces within and downstream of the barrier. Because of this result, the coarser grained mordenite (8 x 14), with less fines, was selected for column testing.

Column Studies

Results of the column studies are summarized in Table II. Only alumina actually attained breakthrough. This took place after 37 days; consequently no further consideration was given to this material. Both coarse grained zeolites were about to breakthrough, as indicated by analysis of the solid phase of the column.

Desorption Treatment

Results of the desorption treatment are shown in Table III. The 4 Molar NaCl solution was effective in desorbing 85Sr from the mordenite while a 1 to 2 Molar HCl solution was more effective for the clinoptilolite. This appears to be an advantage in the use of the clinoptilolite. Other solutions may be more efficient at removing Sr; this has yet to be determined.

MODEL SIMULATIONS OF LABORATORY COLUMN DATA

The laboratory column experiments provided a distribution of concentration or activity of 85Sr on the sorbent media at discrete intervals across the columns. Measuring concentration on the solid phase was necessary since breakthrough in the effluent was not observed during the zeolite column runs. Knowing the length of time for each column test and the average column discharge rate (along with other parameters), an analytical model was fitted to the laboratory data by adjusting the distribution coefficient (Kd) within the model until an approximate concentration match was observed on the solid phase, near the source end of the modeled column. When this was achieved, the dispersivity within the model was adjusted until a similar concentration profile was observed over distance. In this way, a unique Kd was derived for each material under dynamic flow conditions, similar to what would be experienced in the surficial sand and gravel.

Figure 1 presents two examples of the laboratory column data versus results generated by the calibrated analytical model. Significant model input parameters, such as Darcy velocity (Vd) and dispersivity, are listed in Table IV. In all cases, the model fit with the lab data is considered good. It is pointed out, that some

experimental error cannot be avoided with this type of laboratory experiment, i.e., counting on discrete sections of material extracted from the columns. As a result, a slight adjustment in experimental positioning data, to compensate for possible counting-distance errors, provides a better fit of the model. Derived Kd's from the model simulations are given in Table IV. It is noted, that the Kd's derived from model simulations of the column test data are significantly different (i.e., lower) compared to those determined in batch, "closed-system" laboratory tests. It is believed that the column tests, coupled with the analytical model simulations, provide the most useful information regarding sorptive behavior of materials under dynamic, "open-system" conditions.

The mordenite surprisingly provided the lowest Kd, which was approximately 25 times less than average values obtained from standard laboratory batch tests (on a fine grained mordenite (14 x 40)). It is apparent that the coarse grain-sized products will have less sorptive capacity under dynamic, open-system conditions. On the other hand, the fine-grained CH material (i.e., 20 x 50) yielded Kd's only slightly lower than those determined in standard batch tests (~760 mL/g). Considering the complex nature of the testing, the similar results obtained for Tests A and B provide a certain level of reliability and verification of the test methodology and the model simulations as well.

MODEL SIMULATIONS OF BARRIER PERFORMANCE

Figure 2 is an example of a model simulation which illustrates 90Sr loading on the CH 20 x 50 material as a function of time and distance. Model input parameters for porosity, density, and Kd, are listed in Table IV. A longitudinal dispersivity of 5% was used for the media in all of the simulations. This value equates to 6 cm in reference to a total barrier thickness of 120 cm. A seepage velocity of 4.6 x 10-4 cm/sec was used for all cases, which approximated in-situ field conditions. (Seepage velocity equals Darcy velocity [Vd] divided by the material porosity.) A barrier thickness of 120 cm was evaluated over a 12 year maximum time frame.

An initial 90Sr activity in the groundwater of 5.0 x 10-12 Ci/mL (5000 pCi/L) was used in all of the simulations. This was based on current groundwater sampling data. In reviewing gross beta increases in monitoring wells from 1990 through most of 1994, an average yearly increase by a factor of 1.3 was postulated. This multiplier accounts for a 90Sr migration rate of approximately 14.5 m/yr. Based on these analyses, it was estimated that it would take approximately 11 years before 100,000 pCi/L (90Sr) would be observed in groundwater at the proposed barrier wall location. Table V shows times to breakthrough of 90Sr at the downstream end of a 120 cm thick barrier. Breakthrough times for 10 pCi/L and 100 pCi/L were evaluated for four materials. The CH 20 x 50 provides the greatest attenuation followed by a "blended" CH 5 x 50 product. Table VI shows 90Sr activity on the barrier material for 7 and 10 year operating periods. For each period, an average activity was calculated for the entire 120 cm as well as a smaller thickness pertaining to the first 30 cm at the upstream end (higher activities will undoubtedly be present within this area as indicated by the model simulations). The activities were converted from Ci/g to Ci/cc for comparison to 90Sr limits as listed in 10CFR61. This conversion is accomplished by multiplying by the density of the material in question. The Class A limits for 90Sr as listed in 10CFR61 are 0.04 Ci/cu.m (4.0 x 10-8 Ci/cc). The data on Table VI indicate that for the CH 20 x 50 material, depending on how the barrier is evaluated, activity levels in the upstream portion of the filter media could exceed Class A limits within 10 years.

SUMMARY AND RECOMMENDATIONS

The summary information presented in Tables V and VI indicates that the clinoptilolite (CH 20 x 50) material will attenuate 90Sr for longer periods of time compared to the other materials that were evaluated. The estimated performance of the clinoptilolite (CH 5 x 50) is also viewed as being adequate to good. In spite of acceptable levels of 90Sr activity that could be allowed in the groundwater downstream of the barrier wall, it appears that the maximum life expectancy for the material (i.e., prior to removal with possible regeneration) will be approximately 10 years based on allowable limits of 90Sr loading on the in-place barrier. This time period is a function of site-specific conditions and assumptions regarding: increases of 90Sr in the groundwater over time, flow velocities and dispersivity. As a result, even if materials with higher sorptive capacities for 90Sr were used (which would be more expensive), they too would need to be replaced after the same amount of time.

The clinoptilolite (CH) material is presently being pursued for use within the proposed barrier wall. Based on model simulations, a minimum barrier thickness of 1.2 meters was recommended. The selection of grain size (i.e., 20 x 50 vs. 5 x 50) will be based on final design considerations and further limited laboratory testing to address concerns pertaining to in-situ hydraulic performance.

ABSTRACT

A study was performed to evaluate the application of ion chromatography and radiation detection to characterize the radionuclides in nuclear reactor coolant water. In this approach, cationic radionuclides in an aqueous sample are loaded onto an ion exchange column and subsequently separated by an appropriate set of chemical eluents. The resulting effluent passes sequentially through an on-line scintillation flow-cell for quantitative measurement. Further identification/analysis was performed on the collected fractions by gamma-ray spectroscopy with a high-purity germanium detector and electron/beta spectroscopy with a liquid scintillation counter. These off-line techniques assist in the identification and quantification of radionuclides that are either below the detection limit of the on-line detection system and/or not present in the calibration standard. The ion chromatography technique was found useful in identifying common non-gamma emitting (55Fe, 63Ni, 89Sr, 90Sr and 90Y) as well as gamma-ray emitting (58Co, 60Co and 140La) fission and activation products found in nuclear reactor coolant water. Preliminary quantitative results for some of the radionuclides are also presented.

INTRODUCTION

Currently, most commercial nuclear facilities find compliance with regulations that require characterization of non-gamma emitting radionuclides in reactor related samples expensive and problematic. The regulatory requirements for radiological characterization of wastes from commercial nuclear facilities is typically comprehensive in that it must account for fission products, activation products, and transuranics with requisite sensitivities on the order of 10-1 - 102 MBq m-3 (10-5 - 10-2 mCi mL-1) (1). High resolution gamma-ray spectroscopy produces efficient and accurate results for radionuclides that emit measurable gamma rays. However, other important radionuclides either do not emit gamma rays or have emission energies or frequencies that are too low for gamma-ray spectroscopy to be practical. These are operationally defined here as "non-gamma" emitters and include pure beta emitters such as 63Ni, 89Sr, 90Sr and 99Tc, electron capture radionuclides such as 55Fe, and transuranics such as 239Pu and 242Cm. Radiochemical separation techniques for the

non-gamma emitters typically involve long, complex procedures which are costly and which tend to be less accurate due to the low and variable product yields. There is interest in the development of rapid analytical techniques for the analysis of samples containing activation/fission products as well as actinides. One system that shows potential for characterization of "non-gamma" activation and fission products is an ion chromatography system sold under the trade name of ANABET (ANalyis of Alpha Beta and Electron capture Technology (Bradtec, United Kingdom)). The ANABET system was originally developed specifically for anionic (e.g. 14C, 99Tc, 129I) and cationic (e.g. 55Fe, 60Co, 63Ni, 89,90Sr, 90Y, and 134,137Cs) activation/fission products (2). This ion chromatography system was further characterized and used to quantify activities of cations and anions in aqueous effluents (3). In addition, an elution scheme was developed to separate Np, Am, Cm, Th, Pu, and U from a relatively high-purity, high-activity solution (4). The actinide elution system was used to analyze the above six actinides that were spiked into an synthetic natural water (distilled water containing humic acid, dissolved ions and radium). The resulting chromatogram under these conditions resulted in poor resolution of the elements and poor quantification (5). Reboul and Fjeld (5) indicate that significant pretreatment of samples is required for samples that are not of high-purity. Reported previously (6) was the implementation of the ion chromatography system and the evaluation of its performance for characterizing synthetic reactor coolant water. With this scoping study complete, this paper presents the results of the ion chromatography system on actual reactor coolant water from a pressurized water reactor.

EXPERIMENTAL METHODS

Apparatus

The ANABET system used in this study has been described previously (2,3). Ionic radionuclides in an aqueous solution are concentrated on an ion exchange pre-concentration column and subsequently removed to a separation column with chemical eluents. Through the appropriate selection and sequencing of the eluents, elemental separation of the radioactive constituents is achieved. The effluent stream then passes through a flow-cell scintillation cell packed with polycrystalline calcium fluoride which detects the radioactive constituents. Peaks in the chromatogram occur as each "packet" of radioactivity passes through the detector and elemental identification is based on elution time. For background reduction, the scintillation cell is located between two photomultiplier tubes operating in coincidence. The active volume of the scintillation cell is 0.4 mL with a background count rate of approximately 1.5 counts per second. The eluent flow rate is 1 mL min-1 and the effective counting time is 24 seconds. Data collection and reduction is accomplished through an external personal computer. Count rates are determined by integrating the net areas (i.e. background subtracted) and dividing by the count time.

In the work presented here, off-line analysis was performed on some samples so that isotopic identification of peaks in the chromatogram could be made by gamma spectroscopy (using a high purity germanium detector) and electron/beta spectroscopy (using a liquid scintillation counter). For the off-line analysis, a fraction collector (Model Retriever IV, ISCO Inc., Lincoln, NE) was connected to the waste stream to collect fractions at 1 minute intervals. Fractions were analyzed by liquid scintillation counting (Model 1415, Wallac Oy, Finland) and high resolution gamma-ray spectroscopy (Model IGC 17, Princeton Gamma Tech., New Jersey) for qualitative identification of the radionuclides present in the fractions.

Interferences

The principal potential chemical interferences in the reactor coolant were boric acid, lithium hydroxide and hydrazine. These chemicals have a very minor effect on the radionuclide elution time (7). Cesium is known to interfere with the elution time and detection of radionuclides by masking the presence of radionuclides such as iron (7). The preconcentration column was washed, after sample loading, with 0.05 M nitric acid in an attempt to remove monovalent cations (i.e. cesium) Two wash times were used 10 minutes (1 mL/min) for sample 2 and 20 minutes (1 mL/min) for sample 2.

Analysis of Reactor Coolant Water

Two 0.5 liter aliquots of coolant water, one from Reactor Unit 1 and the other from Unit 2, were obtained from Duke Power Company's Oconee Nuclear Station. Due to limited sample volume and relatively high minimum detectable activity of the ion chromatography system, the coolant water from units 1 and 2 were combined to form a

composite for the three analyses. Analytical methods for pretreatment of the samples are summarized in Table I.
The first sample (RCS040894) was a 750-mL aliquot that was reduced to 70 mL by evaporation and then filtered through a 0.45 mm filter to remove suspended solids which could block the IC columns. After loading the sample onto the preconcentration column, the column was washed with 0.05M nitric acid for 10 minutes using a flow rate of 1 mL/min in an attempt to eliminate monovalent cations (e.g. cesium).
The second sample (RCS041294), a 50-mL aliquot, was loaded onto the preconcentration column without sample pretreatment and the column was subsequently washed with 0.05 M nitric acid for 10 minutes (1 mL/min). Because of the smaller sample and the need to identify some of the unknown elution peaks that were observed in the sample 1 chromatogram, both on-line and off-line analyses were performed.
The third sample (RCS041994), an 84.5 mL aliquot, was filtered through a 0.45 mm filter prior to being loaded onto the preconcentration column. Again the column was washed with 0.05 M nitric acid, but this time for 20 minutes. As with sample 2, the waste stream was collected with a fraction collector for further analysis.

RESULTS AND DISCUSSION

Analysis of Reactor Coolant Water

Figure 1 displays the chromatogram of sample 1 which had six well resolved peaks at approximately 5, 9, 10, 12, 33, and 43 minutes and a small broad peak at 53 minutes; these peaks are labeled peaks 1 through 7 respectively. Identities of the peaks 1, 3, 5 and 6 were not immediately known because the elution time was not consistent with any cations in our standard solution. Peaks 2, 4 and 7 are due to 63Ni, 55Fe, and 89Sr respectively, based on previous laboratory studies (7). Peak 3 could be due to either cesium or cobalt. To identify the elements of these unknown elution times, subsequent samples were fraction collected for off-line analysis.
Samples 2 and 3 were loaded and fractions were collected to resolve the identity of the peaks as well as the effects of sample pretreatment. As noted in Experimental Methods, sample 2 was washed with 0.05 M nitric acid for 10 minutes and sample 3 was washed for 20 minutes in an attempt to remove cesium. It was determined from sample 2 that a 10 minute wash was inadequate and therefore increased to 20 minutes for sample 3.
The identify of peak 1 (approximate elution time of 5 minutes) is unknown since it failed to appear in either the chromatograms from samples 2 or 3. It is assumed that its concentration was sufficiently low to be undetected during the on-line and off-line.
Off-line analysis using liquid scintillation yielded the spectrum for peak 2 presented as Fig. 2. The spectrum is consistent with a beta emitter with an endpoint energy in the 0.06 to 0.08 MeV range. This analysis confirms the assumption that the fraction contains 63Ni, which emits a beta particle with an endpoint energy of 0.067 MeV.
Sample 3, which received the 20 minute wash, revealed peak 3 to be cobalt. The analysis of the fraction was performed using the gamma-ray spectrometry to reveal both 58Co and 60Co. The fraction from sample 2, which received a 10 minute wash, showed considerable cesium (134,137 Cs) activity which may have masked any cobalt. Cesium was also detected in peak 4 of sample 2.
The liquid scintillation spectrum for peak 4 (Fig. 3) appeared to have two components. There was a large peak at 0.01 MeV that was likely due to low energy monoenergetic x-rays from 55Fe. In addition, there was a beta spectrum with an endpoint energy in the 0.4 to 0.5 MeV energy range and a smaller peak in the 0.5 to 0.6 MeV range. This signature suggested 137Cs which emits a beta particle with an endpoint energy of 0.514 MeV and conversion electrons of 0.620 and 0.656 MeV.
Similar analyses of the liquid scintillation spectrum for peak 5 suggested a beta emitter with an endpoint energy in the 1.3 to 1.5 MeV range. This is consistent with 140La, which emits a beta particle with an endpoint energy of 1.4 MeV (79%). The gamma-ray spectrum of this fraction confirmed the presence of 140La. The spectrum also revealed 134,137Cs to be in this fraction. Surprisingly the gamma-ray spectrum of the peak 6 also indicated the presence of 140La. Since the fractions were analyzed a few days after they were collected, elution of 140Ba (th = 12.8 d) at either peaks 5 or 6 would explain the presence 140La in both the peaks. For 140La to be present, it must be in secular equilibrium with 140Ba since the half-life of 140La (th = 40 h) is too short to be present 60 days after withdrawal from the reactor. Furthermore, since 140Ba and 140La are both cations and since

ion-chromatographic separations are based on chemical differences between elements, one could speculate that one of the peaks may be due to 140Ba. However, gamma rays from 140Ba were not seen in either of the fractions. One possible explanation is that the low energy gamma rays of 140Ba may have been masked by the cesium gamma rays. The decay rate of the fractions (peaks 5 and 6 in Fig. 1) were quantified by gamma counting them at five to six days intervals. The half life determined by this method was approximately 50 hours, indicating the presence of only 140La.
Liquid scintillation analysis of peak 7 (Fig. 4) of samples 2 and 3 indicated the presence of 89Sr (Emax = 1.480 MeV). This confirms the elution time characteristics of strontium.

Quantification of Non-Gamma Emitting Radionuclides

Non-gamma emitting radionuclide concentrations were calculated by integrating the area under the peaks from the on-line chromatograms and using the efficiencies determined in earlier studies (7). These analyses were compared with those of an independent contractor, Rust Federal Inc.-Clemson Technical Center. The 63Ni concentration (0.11 MBq m-3) determined by ion chromatography was within 50% of the independent analysis. The 89Sr concentration (0.78 MBq m-3) was within 1% of the independent analysis. These results are encouraging, but further test and more elements are warranted.

CONCLUSIONS

Based on these results ion chromatography and on-line scintillation counting as implemented has considerable potential for the radiological characterization of non-gamma emitting radionuclides in primary reactor coolant water. The advantages of this technique over traditional methods are minimal sample pre-treatment, analysis speed, process automation, on-line analyses and collection of fractions for isotopic identification. The analysis speed (60 minutes for cations) is the principal advantage, reducing analysis time by as much as factor of 100 over traditional methods. The limitations of this method include interference of cesium isotopes and low detection sensitivity due to a short counting time (24 s). Further investigation is required to develop a method for removal of cesium from reactor coolant water and to decrease the minimum detectable activity.

ACKNOWLEDGMENTS

We would like to acknowledge Ms. Suzzane Couch of Duke Power Company's Oconee Nuclear Station for her assistance in obtaining the reactor coolant water samples and providing technical information about the samples.

ABSTRACT
Radiological surveys are a time consuming component of the total decommissioning process. Manual gridding is the common and accepted method used by survey teams to give spatial significance to the measured levels of radiation found on site-specific surveys. However, the gridding process requires substantial man-hours and is not conducive to real-time data analysis and assessment. In addition, several forms, pertaining to the results attained during the survey, are required to be completed manually as a part of the final report necessary to complete the decommissioning process.
An automated, computer-based system of performing radiological surveys has been developed and tested at an indoor site. The system was used to determine spatial data automatically for a characterization survey at a formerly utilized radiochemistry lab. Thus, the labor-intensive gridding technique was eliminated from the survey/decommissioning process in total.
Two methods of obtaining positioning data were piloted. The first method involved the use of an ultrasonic range finder interfaced through a PCMCIA data acquisition board to a notebook computer. The second method utilized a relative positioning technique called "mouse-traverse" to resolve sampling locations and subsequent measurements. In both cases, the Ludlum 2350 datalogger/ratemeter/scaler, coupled with the appropriate detector, was used to measure the activity at the sampled locations. As a control, the radiochemistry lab was characterized using traditional instrumentation and manual gridding.
The three methodologies (i.e., ultrasonic ranging, mouse traverse, and gridding) were then compared on merit. The methods were compared on such attributes as time allocation, costs, accuracy, precision, resolution, etc. It was found that, when compared to the manual gridding method, both of the automated methods reduced the time necessary to perform the radiological survey several-fold. However, the initial costs, instrument lack of ruggedness, and range limitations are the major drawbacks to the automated approach.
In conclusion, a technique for providing automated positioning to the radiological survey process was elucidated. The integrated system, whether using either the mouse-traverse or the ultrasonic ranging positioning method, reduced the time to perform the radiological survey. In addition, the data handling, control, and management capabilities of the notebook computer made it possible to manipulate and report survey results in a more timely fashion. However, system modifications need to be made to increase user friendliness, ruggedness, and ranging capabilities.
INTRODUCTION
The objective of the indoor radiological survey is to identify the levels of radiation in a potentially contaminated room. The levels are then compared with the existing regulatory criteria and an assessment is made on whether or not the site will require further remediation before being classified as uncontrolled (1,2,3,4,5). However, surveys are currently performed manually with somewhat primitive recording and spatial measurement techniques (6).
The purpose of this paper is to discuss the progress of an automated radiological survey technique developed for performing indoor site surveys. An experimental design was devised that included a characterization survey study of a potentially contaminated building. The rooms within the building varied in size from approximately 6 m2 in area up to 100 m2 in area. The building was previously used as an instrumentation laboratory. The expected contaminants were alpha emitters from the U-238 decay chain (i.e., U-238, U-234, Th-230, etc.).
Specifically, the main objective of performing the surveys was to test two automated positioning techniques (i.e., ultrasonic positioning and mouse-traverse positioning) for field viability. The experimental design included statistical measures of comparing the automated methods to the traditional, manual methods of performing the indoor survey. The purpose of the rest of this paper is to elucidate the methods and procedures utilized during the evaluation, to present the results on the accuracy

and repeatability of the two automated techniques, and to provide a real-time data output generated by the total automated system.

METHODS

Figure 1 shows the total automated system as designed and piloted. Figure 2 gives a detailed illustration of the necessary system interfaces. The main components of the survey apparatus included a NEC 486 notebook computer with a configured National Instruments DAQ-700TM PCMCIA data acquisition card, a Ludlum Model 2350 Ratemeter/DataloggerTM, a Ludlum Model 43-89 Alpha Scintillation DetectorTM, and two spatial positioning assemblies (i.e., ultrasonic positioning and mouse-traverse positioning).

The ultrasonic assembly included a mechanism for accurate positioning as well as a Piezo-type transducer/circuit board. The mouse-traverse technique employed a computer trackball that rolled along the surface of the floor (7). Thus, this technique is a relative positioning methodology that must be zeroed at point (0,0). The surveys were limited to floor locations in the various rooms.

The necessary computer protocol modifications were made based on the site data and the techniques previously employed on the site survey. While the normal process of performing indoor site surveys was to take five samples from each 1 m2 survey unit, the system protocol was written to include nine sample points per survey unit. This not only would increase data confidence, but would also provide a more energy efficient means of collecting the data. In addition, the nine points could help to serve as justification for not needing to sample in the difficult to get to corner and wall areas (i.e., only six points are taken in the one meter square area defined by one or more walls/surfaces).

The Environmental Survey software, written in Microsoft Visual BasicTM, was developed to include a spreadsheet that identified spatial coordinates, cpm/100m2, dpm/100m2, survey unit average, and a 95% confidence comparison value. In addition, the software included algorithms for detector efficiency, minimum detectable activity (MDA), the survey unit mean, the survey unit standard deviation, and the 95% confidence value. Code was written that would not allow a value of less than the calculated MDA to be logged. Computer forms (screens) were also created that provided for survey background counts and detector/ratemeter configuration. Since the WindowsTM software environment was used, dynamic links between the various software packages made it easy to move data to and from various software programs (e.g., Visual Basic to Microsoft AccessTM, Access to Stanford GraphicsTM, etc..)

The algorithm entered for determining the MDA was as follows:

Eq. (1)

where

MDA	=	activity level in disintegrations/minute/100 cm2
B	=	background rate in counts per minute
t	=	counting time in minutes
E	=	detector efficiency in counts per disintegration
A	=	active probe area in cm2

Since the counting time is usually set for one minute and the active probe area of the Model 43-89 detector is 100 cm2, the MDA is primarily a function of the site background rate.

The equation used to determine the 95% confidence comparison value was as follows:

Eq. (2)

where

95% CCV	=	95% confidence comparison value (positive side)
1.86	=	the t-value for sample size equal to 9
s	=	the standard deviation for the survey unit
n	=	the number of samples per survey unit

For this survey, the value for n is equal to nine and the calculation for the mean and standard deviation is dependent upon the sample measurements for each survey unit. The standard statistical equations used to determine the sample mean and the sample standard deviation are included in the computer code to determine the appropriate 95% confidence comparison value.

Prior to leaving for the site, a calibration curve was generated by using a check source of thorium-230. In order to determine the ideal high voltage value to use for the survey, an optimum threshold value must be first decided upon. A good "rule-of-thumb" on determining the threshold is to use a value that, with several subsequent measurements, a background rate of not greater than 3 dpm is found. The

threshold value that met this criteria for the thorium source was 30 mV. At this threshold, the calibration curve resulted in a plateau midpoint of 850 volts. This value would be used as the survey high voltage and would be entered during the Ludlum 2350 configuration routine.

Upon arrival at the facility, it was resolved that alpha characterization surveys were to be performed on floor areas of 6 m2, 12 m2, 25 m2, and 42 m2. Due to the security and time constraints at the facility, the manual method was performed on-site by the health physics technicians and observations were made for comparison. In addition, the mouse-traverse technique and the ultrasonics positioning method were both utilized to survey the 6 m2 room. However, compatible "clean" rooms off-site were used to obtain the data for the other three areas.

The operational check-out and calibration procedures were completed prior to beginning the first survey. A 20,000 dpm calibrated check source of thorium-230 was used to determine the efficiency of the detector. The procedure included taking the mean of five subsequent one minute counts from the detector and dividing it by the calibrated value. Then, by multiplying this resultant by 100, the survey detector efficiency was attained. This value was found to be 19.6%.

A survey background rate was determined both manually and automatically. Nine points were taken from adjacent, unaffected areas. The mean of these nine samples was then used to set a baseline for determining net sample counts. In addition, the background mean is an important parameter used in the calculation of the detector MDA. The time required to take the background readings first manually and then automatically was essentially the same.

After a detector efficiency was determined from a calibrated thorium-230 check source, two survey technicians proceeded with a calibrated field survey meter (with attached alpha detector) to perform a quick alpha scan of the rooms to determine potentially affected areas. The technicians then began to grid the rooms into survey units of approximately one square meter. The technicians used a calibrated field measuring tape and duct tape to grid the room. Five sample points were taken (i.e., the four corners and the midpoint) to define each survey unit. In addition, one sample location was repeated for every two survey units completed. This is in compliance with the 10% quality assurance criteria recommended for the detector. Since one of the primary contaminants was thorium-230, which has a rather stringent release criteria (i.e., 100 dpm/100 cm2 average), the count time was one minute for each sample. One technician operated the instrument while the other manually documented the readings. The detector was moved around the sampling area in a "snake-like" fashion for the duration of the one minute sampling. The manual surveys were observed for time requirements and technique. After a survey was complete, the technicians calculated the required values.

After the background rate and detector efficiency was determined, each of the automated characterization surveys began with an initial tape measurement of room dimensions. The procedures for operational check-out, site calibration, and standard operating procedures are detailed in another document and are beyond the scope of this paper. A special effort was made to determine values for repeatability (both spatial and magnitude) and spatial measurement error/accuracy. In order to do so, some of the sampling locations had to be specified as either control or repeat sampling locations. The control data points are defined as those points used as a means of showing spatial repeatability and accuracy. The control points are marked with a pencil or a piece of tape, and the surveyor returns to this location, during the course of the survey traverse, to determine the level of positioning repeatability. In addition, these control points are compared to actual tape measurements for accuracy.

A repeat sample point is one in which the surveyors just repeat the count with the detector/ratemeter. The repeat points are necessary as a quality control measure, required to meet the 10% repeat point criteria recommended by ORISE. The repeat points are usually taken at the midpoint location on the survey lines of adjacent survey units.

Specifically, the experimental design followed for the automated techniques involved data gathering methodologies aimed at gaining an incite on the actual process viability. As was hinted to in the previous paragraph, spatial accuracy, temporal efficiency, and measurement repeatability are critical indicators of process field viability. In order to provide some indication of the viability of the automated positioning techniques for field use, the values for spatial accuracy and

repeatability for the three meter by four meter room were taken. The survey traverse for the 12 m2 area (i.e., 3 meter by 4 meter room) is shown pictorially in Fig. 3. Figure 3 defines the twelve survey units, with specific identification made to the sampling locations that were used as control points (CP) and repeat points (RP).
A viability and time efficiency comparison, between the traditional manual method and the two automated techniques, was performed. This was accomplished by defining a man-hour comparison coefficient, the dependent variable, and plotting it versus the room floor area, the independent variable. Thus, an equation can be determined from the data taken from the smaller rooms to help describe the time component for surveys of larger areas. The man-hour comparison coefficient, k, was defined as follows:
Eq. (3)
where
k = man-hour comparison coefficient
ta = total man-hours for automated survey
tm = total man-hours for manual survey
In addition, to show the real-time data analysis capabilities of the system, a real-time profile of spatial and magnitude components for a 2 meter by 3 meter room was generated on-site. The data was taken from the one minute alpha counts at each floor location and plotted three-dimensionally by linking the database with Stanford Graphics. Finally, a total area assessment was made by determining the population mean and standard deviation for the 6 m2 area.
DATA AND RESULTS
The main purpose of this research was to show that automated positioning could provide an effective and efficient means of replacing the time consuming efforts involved in the manual gridding of indoor survey sites. Calculations for spatial accuracy and spatial repeatability provide two objective measures for the evaluation.
The mean accuracy for the ultrasonic positioning technique was 99.6% in the x-direction and 98.5% in the y-direction. The standard deviation was calculated to be 1.7% in the x-direction and 1.5% in the y-direction. Thus, at the 95% confidence level, the accuracy for the ultrasonic positioning technique can be stated as 99.6% +/- 0.8% in the x-direction and 98.5% +/- 0.6% in the y-direction. The 95 % confidence levels for these and the following spatial parameters were calculated by using the following equation:
Eq. (4)
where
P95 = the 95% confidence parameter desired
X-bar = the mean of the data
s = standard deviation
n = the number of samples
The mean calculated for the relative percent difference (RPD) between the control points was 0.3% in the x-direction and 0.1% in the y-direction. The standard deviation was found to be 0.5% in the x-direction and 0.5% in the y-direction. Thus, at the 95% confidence level, the RPD for the ultrasonic positioning technique can be given as 0.3% +/- 0.2% in the x-direction and 0.1% +/- 0.2% in the y-direction.
For the mouse-traverse technique, the mean accuracy calculated for the x-direction at the 95% confidence level was 100.1% +/- 1.4% while the 95% confidence level mean in the y-direction was found to be 100.7% +/- 2.0%. The 95% confidence level RPD for the mouse-traverse technique in the x-direction was calculated to be 1.7% +/- 0.7%. The corresponding 95% level for the RPD in the y-direction was determined to be 2.7% +/- 1.2%.
The positioning parameters for both the ultrasonic positioning technique and the mouse-traverse technique are summarized in Table I.
Survey Time Comparison
In order to provide some indication of the time efficiency of the automated techniques, a test was needed that would allow for the comparison of the temporal components of both of the automated survey techniques against the traditional, manual survey. In order to do so, it was necessary to define a man-hour comparison coefficient. In essence, this is just the man-hours required to perform an automated survey of a particular divided by the time required to complete the survey with the manual technique.
Survey areas of 6 m2, 12 m2, 25 m2, and 42 m2 were chosen to perform controlled

surveys utilizing each of the three of the techniques (i.e., manual, ultrasonic, and mouse-traverse). The time component for each of the surveys was recorded and the comparison coefficient was plotted as a function of survey area. An extrapolation was made and an equation was estimated that would help to describe the time efficiency of the automated techniques for very large rooms. Since the relative time component required for gridding and manual calculations would be greater with increasing survey area, it was expected that the plot would follow a negative exponential path.

By extrapolating the plot, it appears that both curves are approaching approximately 0.40. This would indicate that there is a finite limit to the time savings that could be attained by the automated techniques. In essence, the data indicates that the automated processes can result in nearly twice the sampling points in forty percent of the time.

The following equation closely emulates the relationship between the coefficient and the room size:

$$y = 0.9 x -0.16 \quad \text{Eq. (5)}$$

where

y = the man-hours comparison coefficient
x = the survey area (square meters)

From the equation it can be discerned that the optimum man-hours coefficient is approximately 0.40 for the largest of survey areas. Thus, by further evaluation of the man-hours comparison coefficient, it can be determined that the system can facilitate the survey of large rooms at about two and one-half times the rate of that of the manual survey. In addition, the automated survey procedure includes nearly twice as many data points for statistical analyses and site assessments.

The site mean and standard deviation, calculated at the 95% confidence level, was 69 dpm/100 cm2 and 7 dpm/100 cm2, respectively, for the 6 m2 area surveyed using ultrasonic positioning. For the 6 m2 area surveyed using the mouse-traverse technique, the site mean was determined to be 64 dpm/100 cm2 and the standard deviation was calculated to be equal to 10 dpm/100 cm2. These values are less than the 100 dpm/100cm2 release criteria established for thorium-230. All of the unit means were within the criteria.

A three-dimensional profile, generated from the spatial and magnitude data sampled during the survey, is given in Fig. 4. Figure 4 shows the three-dimensional plot of the data from the mouse-traverse survey of the 6 m2 area. It is possible to generate this type of drawing anytime during the survey process, thus, allowing for real-time, analytical assessments.

CONCLUSIONS

In summary, the two automated positioning techniques, ultrasonic positioning and mouse-traverse positioning, provided viable alternatives to the manual survey methods currently employed at indoor radiological sites. The total automated system made it possible to make accurate assessments, of both space and magnitude, in real-time. In essence, the system, as designed, eliminated the need for manual gridding and manual calculations. Thus, since the time requirements for gridding and performing site calculations are a major component of the survey process, the system made it possible to complete each survey more efficiently.

Some of the system problems identified during the surveys include:

1. Durability limitations to the trackball/mouse design
2 .The range capabilities of the ultrasonic device was limited to 10 meters.
3. It was difficult to get the system apparatus into "tight" places.
4. The learning curve for the effective use of the system software.
5. Due to having only one serial port, a data selector was necessary.
6. The positioning techniques required substantial QC/QA measures.
7. Rooms with obstacles or "rough" floors present positioning problems.

A list of the major conclusions drawn from the field surveys were as follows:

1. Both automated techniques provide an effective and efficient means for facilitating the indoor radiological survey process.
2. Even for smaller areas, the automated techniques are viable.
3. For larger area rooms, both automated techniques provide the capability of sampling nearly twice as many points as that of the manual technique in 40% of the time.
4. The temporal characteristics of both of the automated techniques are essentially the same.

5. An equation can be developed that describes the temporal characteristics of the automated methods for larger area rooms.
6. The spatial accuracy characteristics of both automated techniques are comparable.
7. The spatial repeatability of the ultrasonic technique exceeds that of the mouse-traverse technique.
8. Data profiles can be generated in real-time for field analytical assessments.
9. The characterization survey for thorium-230 resulted in criteria compliance for the area.
10. The RPD analysis uncovered three out of fifteen points beyond the 20% criteria.
11. Future research should be directed at extending the range and flexibility of automated positioning survey system.
12. On-site changes to the computer program were sometimes necessary but could be performed in a matter of minutes.

ABSTRACT

Two innovative downhole Volatile Organic Compound (VOC) sampling devices were recently deployed at the U.S. Department of Energy (DOE) Hanford Site in southeast Washington State. The Multisorbent Arrayed Sampler developed by Oak Ridge National Laboratory and the Portable Acoustic Wave Sensor (PAWS) system developed by Sandia National Laboratories were deployed at a VOC-contaminated site in the Hanford 200 West Area. Soil vapor extraction is currently being performed at the site, and these two sampling devices were used to further characterize nearby wells.
The two technologies met well field characterization needs for (1) precise quantitative analysis of VOCs in wells without adequate sample data, and (2) sensors to provide real-time in situ analysis of higher VOC concentrations in wells previously characterized. The Multisorbent Arrayed Sampler collected VOCs on sorbent traps that when analyzed provided precise quantitative analysis of VOCs from the low parts per trillion (ppt) range to thousands of parts per million (ppm). PAWS, available in both a downhole and surface-based system, gave real-time analysis of VOCs up to 100,000 ppm.
These two technologies were selected for field demonstration by the U.S. Department of Energy Office of Technology Development. The demonstration was performed as part of the VOC Arid-ID program. The Arid-ID is designed to support the acquisition, development, demonstration, and deployment of technologies for evaluation and cleanup of VOCs and associated contaminants in soils and groundwater at arid DOE

sites.
The Hanford Site Environmental Restoration Contractor Team is responsible for VOC-Arid ID technology demonstrations at Hanford. When possible, VOC-Arid ID innovative technology demonstrations are conducted as systems and in coordination with an operational environmental restoration project. This allows comparison of two or more technologies under actual field conditions and in conjunction with operating baseline technologies. Such was the case with the two subject technologies.

BACKGROUND

Previous wellfield characterization primarily involved lowering a sampling tube downhole and withdrawing a soil gas sample to the surface. At the surface, the sample would be screened with a hand-held photo-ionization detector, and a portion would be collected in a syringe or bag for analysis with a gas chromatograph (GC). One problem with this method is that wells screened in low-porosity soils may not be capable of replenishing VOCs at the screened interval through diffusion at a rate comparable to the pumping volume. As a result, the subsurface equilibrium may be disturbed, resulting in samples withdrawn to the surface unrepresentative of true soil conditions due to extraction of larger volumes. Additionally, significant losses of VOCs occur through permeable tubing, and absorption and subsequent release of VOCs occur with non-porous tubing. Longer tubing required for deeper wells multiplies this problem.
Field deployments of the Multisorbent Arrayed Sampler and the PAWS System occurred at a VOC contaminated site in the Hanford 200 West Area. Site characterization activities have identified a broad VOC plume in the groundwater and vadose zone. The principal contaminants are carbon tetrachloride and chloroform. These downhole sampling devices were used to help define the nature and extent of VOC contamination.

MULTISORBENT ARRAYED SAMPLER

The Multisorbent Arrayed Sampler is a downhole sampler designed to collect soil gas samples on multisorbent traps while the sampler is deployed at selected downhole intervals (1,2). The sampler body (Fig. 1) consists of a cylindrical stainless steel assembly housing an array of 13 micro-miniature solenoid valves in a mounting structure to accept 6 multisorbent traps, which are connected to the system via Cajon Ultra-Torr fittings. As mounted in the body, solenoid valves are connected to each trap for isolation or sampling as desired. The outlet of each trap is connected (via a solenoid valve) to a common sample conduction manifold. A pump at the surface draws accurately metered sample air through any selected trap via the manifold. An additional solenoid valve in the sampler head provides for rapid direct evacuation of the residual air near the sampler (if appropriate) before sampling through a trap. This valve may also be used to draw soil gas samples directly to the surface. Each end of the sampler body is fitted with an inflatable pneumatic packer to isolate the sampler in a selected well interval. A third detachable dangling packer can be attached to the bottom of the sampler to isolate an extended zone of interest. Pressure and vacuum gauges, a 0-200 ml/min mass flowmeter, power supplies, and all necessary switches and valves are contained in a 43x53x20 cm portable case. The control assembly requires 120 V electric power or a 600 watt portable generator, a source of low-pressure compressed air or inert gas, and a source of moderate vacuum. The vacuum is provided by a small, portable diaphragm pump.
Fig. 1. Multisorbent Arrayed Sampler Diagram.
To operate the system, the sampler is loaded with six fresh multisorbent traps and lowered into a monitoring well to a predetermined depth. The packers are then inflated. To acquire a sample, the operator throws a switch controlling the solenoid valves for one of the six traps and moves the vacuum source control valve to the sampling position. Then the operator records the flow rate through the trap and time of flow. When an adequate volume has collected on the trap, the solenoid valves are closed. Up to six separate samples on separate traps can be collected before the sampler must be returned to the surface where fresh traps are loaded. Downhole times can range from 20 minutes to 4 (or more) hours, depending on data needs.
The multisorbent traps are specially made by sequentially loading beds of Carbotrap C, Carbotrap, and Carbosieve SIII (Supelco, Inc.) in a stainless steel tube (3). These carbonaceous sorbents can retain a variety of VOCs. Prior to shipment to a site for sampling, each trap is spiked with a bolus of vapor containing known quantities of three surrogate standard species. Quantities of these surrogates remaining on the traps after analysis provide an indication of the stability of the

VOCs retained on the traps following collection, sample transport, and storage prior to analysis. The sample traps are returned to the laboratory for thermal desorption followed by GC or gas chromatography/mass spectrometry analysis (4).
Although the sampler may be used in a number of scenarios or concentration ranges to obtain high-quality chronologically and spatially resolved samples, it is intended for use in at least two specific applications. In the first, where relatively large concentrations of contaminants exist (ppm levels), the sampler can be employed to collect samples so small (10-20 mL) that there is essentially no disturbance of the subsurface equilibrium. This is especially important in strata of low porosity. In the second scenario, where porosities are higher, the sampler can be used to concentrate very large samples of soil gas. Typically, such a capability would be important when strict regulatory levels have been imposed. For example, if 1 ng of carbon tetrachloride (CCl4) can be sorbed on a trap and accurately quantified, the collection of soil gas at the rate of 200 ml/min for eight hours on a single trap would permit the observation of CCl4 concentrations of 2 ppt.

HANFORD DEPLOYMENT OF MULTISORBENT ARRAYED SAMPLER

The Multisorbent Arrayed Sampler was deployed at Hanford in May and August of 1994. A total of 20 separate events were sampled, and 129 multisorbent traps were used over a 6-day period. Sample results indicated concentrations of CCl4 ranged from non-detects to a lower value of 42 to a maximum of 94,000 ppbv. Chloroform concentrations ranged from 6 to 1,740 ppbv. Table I is a summary of selected trap analyses. Other previously unidentified compounds retained on the multisorbent trap included a-methyl styrene, 2-phenyl-2-propanol, butanedoic acid-diethyl ester, and 4-methyl-2,6-di-tert-butyl phenol.
Detection of these compounds would not have been possible with other sampling systems, since sorbent trap sampling provides a way of concentrating species present at low pptv levels. Figure 2 is a chromatogram of GC/Flame Ionization Detection analysis of trap #313 from well 299-W15-219.
The multisorbent traps were fortified with three surrogates before deployment to Hanford. The average recoveries of surrogates Hexafluorobenzene, d8-Toluene, and d5-Bromobenzene were 98%, 92%, and 97%, respectively.

PORTABLE ACOUSTIC WAVE SENSOR SYSTEM

Central to the PAWS system are two polymer-coated surface acoustic wave (SAW) sensors, one acting as a reference and the other as the active sensor. Figure 3 shows the PAWS system schematically. SAW devices are extremely sensitive to changes in the mass or other physical properties of a thin film cast onto the device surface (5,6). Mass changes of tens of picograms can be detected. Using thin films to absorb the chemical species of interest, this sensitivity can be used to detect and monitor a wide range of VOCs (7,8). Current PAWS systems are capable of minimum detections of 0.1 to 10 ppm for typical VOCs.
Fig. 3. Schematic of the portable acoustic wave sensor (PAWS) system.
Diffusional properties of films made with elastomeric polymers such as polyisobutylene result in rapid (few seconds) and reversible responses, enabling real-time and continuous monitoring. Oscillator electronics drive sensors and provide two independent outputs: a mixed frequency that tracks changes in wave velocity and a power detector voltage that tracks changes in wave attenuation. The ratio of these two signals provides limited discrimination of isolated chemical species, while the more sensitive frequency response can be used to quantify isolated species (6,9). This discrimination is made possible by the unique combination of the mass response and the response due to changes in the polymer viscoelastic properties based on the plasticizing action of the absorbed chemical (6). Viscoelastic properties also depend on temperature (6), resulting in a temperature dependence of the device response. Temperature induced drift is minimized in the PAWS system based on active temperature control of the sensor test fixture (10).
The system is configured as a down-hole probe with associated packers for isolating a selected section of a well (11). A cable provides both power and data communication to a notebook computer at the surface, and a stainless steel or teflon sampling line is used to compare the in situ measurements with surface analyses. In addition to the SAW sensors and associated electronics, the probe contains data acquisition and system control electronics consisting of a frequency counter, eight 16-bit A-to-D channels for measuring voltages, eight digital outputs for system

control, a microprocessor, and an RS-232/RS-422 serial interface.
Environmental sampling hardware consists of a pump to pull in a sample and a three-way valve to periodically pass air from the surface across the sensor to establish sensor baseline. (This air is pulled from the line used to inflate the packers and is scrubbed with activated carbon to remove any VOCs.) This in situ determination of baseline enables long-term continuous monitoring. A Nafion membrane on the sample line maintains a constant humidity between sample and baseline gases and prevents errors in baseline determination resulting from the slight humidity sensitivity of the SAW sensor (10).

HANFORD DEPLOYMENT OF PORTABLE ACOUSTIC WAVE SENSOR SYSTEM

As shown in Fig. 4, field demonstrations of the PAWS downhole probe for detection of CCl4 at the Hanford Site have demonstrated accurate in situ analysis from 10 ppmv to over 25,000 ppmv, indicating the wide dynamic range of this sensor. Because the sampling rate is low (<100 ml/min), the system can be used to determine the concentration in the unperturbed well bore. In addition, using either a downhole pump or a large Teflon line connected to a pump at the surface, the system can be used to monitor in real-time the changes in concentrations upon purging of a well. Tests of this type demonstrated that large purge volumes can be required for relatively porous soils typical at the Hanford CCl4 site. For example, during high atmospheric pressure, no CCl4 was observed even after purging 150 well volumes from a well, although more than 1,000 ppmv had been observed during a previous test during low atmospheric pressure. The ability to place the PAWS probe in a well and leave it for long periods with the packers inflated should allow the unperturbed concentration to be determined and tracked as a function of time.

Fig. 4. CCl4 concentration vs. time.

During one field demonstration, the in situ measurements were compared with an above-ground PAWS system and a photoacoustic infrared analyzer (Brel & Kjaer Instruments, Inc., Marlborough, Massachusetts). As shown in Fig. 4, agreement between the above-ground PAWS and the commercial instrument was within 2% from 100 ppmv to over 20,000 ppmv, demonstrating the accuracy of the PAWS system. However, differences were observed between the above-ground and downhole systems. At high concentrations, the downhole readings were higher (by about 20%), while at low concentrations in subsequent wells, the above-ground values were higher. These differences were determined to result from perturbations in the sample being brought to the surface through the Teflon sampling line. The loss of chemical is shown by the data in the main figure in Fig. 4. In contrast, the data in the inset figure were taken prior to turning on the sample pump to the well. In this case, both the above-ground PAWS system and the Brel & Kjaer instrument were detecting about 100 ppmv of CCl4 added to the ambient air being pulled through the sampling line, which had been previously exposed to high CCl4 concentrations.

In the next field test, a stainless steel sampling line was used to minimize these sample perturbations. The only calibrated comparison was with an above-ground PAWS system. The results of this test showed some loss was still apparent at high concentrations; however, no erroneous high readings in the above-ground instrument were observed after purging the sample line. The loss of chemical at high concentrations was determined to result mainly from the piston pump used to pull the sample to the surface. Stainless steel tubing has the disadvantage of being more difficult to deploy into wells than Teflon, which is more flexible. These results demonstrate the difficulty in obtaining a representative sample and the advantage of an in situ monitoring system.

CONCLUSIONS

The Multisorbent Arrayed Sampler allows collecting a high-quality in situ soil-gas sample on a sorbent trap. Compared to existing methods, it can collect and concentrate (1) samples of a wider variety of VOCs and (2) samples having a wider range of concentrations. In some applications, the sampler can acquire samples for analysis in the ppt range (below the detection limits of existing monitoring technology).

The PAWS is a rugged VOC monitoring system capable of providing real-time, continuous, and in situ monitoring of isolated species. The system has been shown to be accurate and have a wide dynamic range, making it well suited for sites having high contaminant concentrations. The probe is easy to deploy, and the data acquisition and analysis is performed with user friendly software that provides real-time display of contaminant concentrations. The ability to establish sensor

baseline in situ permits continuous long-term monitoring of contaminant concentrations during a remediation effort. Results comparing in situ PAWS measurements with analyses of samples pumped to the surface demonstrate the advantage of a downhole system.

STATUS

Both the Multisorbent Arrayed Sampler and the PAWS system were successfully deployed at Hanford and other DOE sites. Current work on Multisorbent Arrayed Sampler technology includes deploying the sampler concept in a cone penetrometer point and deployment of a simplified arrayed sampler in mixed waste underground storage tanks for headspace sample collection. A commercial partner is needed to take the Multisorbent Arrayed Sampler from the development/deployment stage to actual commercial production.

Current work on PAWS is focused on extending the capabilities to analyze mixtures of VOCs using arrays of SAW sensors, to lower detection levels using adsorbent-based preconcentrators, and to analyze water using specially designed sampling modules. Some of this development is being done in conjunction with two industrial partners interested in developing and manufacturing more advanced sensing systems based on the technology demonstrated in the PAWS systems. Additional industrial partners are involved in demonstrating the utility of the PAWS technology for selected applications.

Note: The PAWS work was performed at Sandia National Laboratories supported by the U.S. Department of energy (DOE) under contract number DE-AC04-94AL85000. This work was funded in part by the DOE Office of Technology Development.

The Multisorbent Arrayed Sampler work performed at Oak Ridge National Laboratory was supported by the U.S. Department of energy (DOE) under contract number DE-AC05-84OR21400. This work was funded in part by the DOE Office of Technology Development.

ABSTRACT

Geophysical borehole logging techniques are used for the in situ determination of subsurface physical, chemical, geological, and hydrological parameters. In a project funded by the Department of Energy Office of Technology Development we addressed the adaptation of one nuclear borehole measurement technique, neutron-induced gamma-ray spectroscopy ("multispectral") logging, to map environmental contaminants along boreholes. It has been known for some time that multispectral logging is capable of identifying many elements, but earlier equipment was not very sensitive. To demonstrate that the technique can be made much more sensitive, we have estimated detection thresholds for a number of contaminants for a state-of-the-art borehole instrument.

Experiments in a specially built test facility constructed at the DOE Grand Junction Projects Office with an experimental prototype multispectral borehole instrument developed for this project allowed us to estimate detection thresholds for mercury, cadmium, chlorine, gadolinium, and samarium. Because our experimental prototype instrument was more expedient than elegant, we extrapolated from the experimental threshold values to what we believe a "production" system could achieve using existing hardware and data processing technology. These results indicate that the multispectral borehole logging technique is sufficiently sensitive to be useful in screening for these contaminants; its value is greatly enhanced by the fact that the technique analyzes some three orders of magnitude more material than physical sampling at each depth where a measurement is made. In monitoring applications, this in situ technique can reanalyze the same borehole at any desired time interval for as many years as required.

INTRODUCTION

Some nuclear borehole logging techniques are capable of identifying and mapping specific nuclides in the rock or soil through which a borehole passes. Such techniques can be used to characterize contaminated sites and monitor those sites as long as necessary following either cleanup or stabilization. Nuclear borehole logging techniques have advantages and disadvantages that tend to be complementary to those of physical sampling and these in situ measurements can help address the drawbacks of physical sampling. Drawbacks addressed by nuclear logging include high costs, lengthy delays in obtaining results of analyses from laboratories, under-sampling, sample-handling problems, and ambiguity in long-term monitoring.

One potentially useful borehole logging technique for contaminant mapping is neutron-induced spectral gamma-ray or multispectral logging. Multispectral logging records gamma-ray energy spectra during and/or after irradiation of the borehole environment by neutrons, similar to laboratory techniques such as neutron activation analysis. Neutrons interact with nuclei in a variety of ways to produce gamma rays that enable those specific nuclides to be identified. Detectable contaminants

include chlorine, a component of many organic contaminants, as well as heavy metals and other nuclides. The physics behind this technique is generally well understood and it is known that the technique can identify many radioactive and nonradioactive nuclides. The key question is what is the detection threshold for those nuclides in a borehole environment? We are using a combination of experiments with the experimental prototype, along with computer simulations and analytical calculations, to estimate detection thresholds for a number of contaminants; initial results are presented here.

THE VARIABLE CONTAMINANT TEST MODEL

For this project, we constructed a variable-contaminant test model, a full-scale physical model that allows insertion of various contaminants under controlled conditions. This model, constructed at the DOE Grand Junction Projects Office, provides a known contaminated test environment. Experiments performed in the variable-contaminant model helped determine detection thresholds for the multispectral borehole instrument or tool for several contaminants of concern and provided a final benchmark of the computer simulation program that is being used to investigate other contaminants. To investigate several contaminants, remain within budget, and meet environmental regulations, we chose a design using 15-cm-thick disks of contaminant-doped concrete sandwiched between thicker layers of uncontaminated concrete (Fig. 1). Two contaminated disks were manufactured containing different concentrations of chlorine along with four disks each containing a small quantity of one of the following: mercury, cadmium, samarium and gadolinium. The latter two elements were included to help us understand the instrument response, not because they are considered major contaminants.

The variable-contaminant model includes a gravel-and-water-filled tank surrounding the concrete cylinders to extend the neutron and gamma-ray transport medium radially and provide shielding for personnel during operation of the neutron source. The borehole has a nominal diameter of 15 cm and is air filled. The outside diameter of the contaminated and uncontaminated cylinders, 75 cm, was chosen to provide most of the response that an infinite medium would exhibit while minimizing the amount of contaminant required to build the 15-cm-thick zones. Although the composition of the gravel/water tank is not the same as the concrete, it should be sufficiently similar for these experiments considering its distance from the borehole. The 15-cm-thick zones are not effectively infinitely thick, so the infinite zone response must be constructed from the thin zone response by superposition (1).

EXPERIMENTS IN THE VARIABLE-CONTAMINANT MODEL

Measurements in the variable-contaminant model provided estimates of detection thresholds, the concentration at which one can say with some specified level of certainty that a given contaminant is present, for several contaminant elements.

Equipment Description

A contractor participating in the experiments supplied the self-contained neutron generator package for the logging instrument; the generator package is manufactured by a commercial vendor. The spectroscopy system used in these experiments is a commercially available system with ultra-high-countrate capability. (2,3) The germanium detector is an N-type crystal with an efficiency of 22.5% cooled by liquid nitrogen in a dewar with an outside diameter of about 7.5 cm. The detector and dewar were housed in a brass sleeve that was mated with the neutron generator section of the commercial tool. The preamplifier, contained in the probe, is a transistor-reset type. The detector and its associated instrumentation and software were tested extensively before the experiments began. The detector performed remarkably well, successfully handling count rates of 2,000,000 counts per second while maintaining good spectral performance.

Experimental Procedure

We acquired a 16,000-channel spectrum at each of 13 depth positions in the variable-contaminant model for each of the 6 removable contaminant disks. Repeat measurements were made in some cases to verify reproducibility of results. In addition, spectra were acquired in other Grand Junction calibration models to determine the effects of hole size and formation nuclear properties on the instrument response. Each spectrum was acquired using a timing window selected to ensure that the spectrum was the result only of prompt thermal-neutron activation. Each spectrum was acquired for 1000 s of live time, corresponding to about 1200 s or 20 min of real time in these experiments.

In addition to the capture spectra, inelastic and activation spectra were acquired

for some positions in the variable-contaminant test model. Like the capture spectra, inelastic spectra were accumulated for 1000 s of live time each while activation spectra were accumulated for various times following generator shutdown because of the mix of short- and long-lived decay products. A preliminary examination of the activation and inelastic spectra suggests that they will be of little use in identifying most contaminants, although these other spectra provide important information related to lithology and water content of the material around the borehole and may provide other useful information as well. This report focuses on the capture spectra only.

Results of the Contaminant Tests

Figure 2 shows a portion of the spectrum taken at the position of maximum response with the detector positioned near the mercury contaminant disk. The 368-keV peak from mercury is indicated on the spectrum, and numerous other peaks are present including other mercury peaks. The energy width of each of the 16,000 channels is nominally 685 eV, so the recorded spectrum extends beyond 11 MeV. For the lower energies where most contaminant peaks occur, the energy resolution is about 3.5 keV full-width at half-maximum, corresponding to about five channels of data. Energy resolution is an important system parameter because improved resolution decreases the background count rate associated with each photopeak and improves detection threshold, all else being equal. Also apparent is the continuum background resulting from Compton scattering of gamma rays in the variable-contaminant model and the tool materials, including the detector. The continuum represents a fundamental limitation to the detection limits that can be achieved for a given contaminant for a given counting time.A few activation reactions contribute to the capture spectra because of their relatively short half-lives. Major contributors to all capture spectra are hydrogen, silicon, calcium, and iron (largely from the concrete models) and copper, chromium, and germanium (largely from the logging tool). The atypical peak at 478 keV is a result of Doppler-broadening of the gamma-ray energy line from an (n,a) reaction on 10B.

Detection Threshold Estimates

The working definitions for the detection limits used in this analysis are based on earlier work by Currie (4) and others. Currie showed that the detection limit for radioactivity measurements of this type should be based on the variability in the background. For this preliminary assessment, we have assumed that there was no interference with the signal of interest from anything other than the uncertainty in the background.

Estimated detection thresholds for the contaminants studied in the Grand Junction experiments are given in Table I, along with the energy of the spectral peak used for each contaminant. The contaminant concentrations in the column labeled minimum detectable concentration correspond to the critical level of Currie (4). These are concentrations at which the net peak area is 2.33 times the standard deviation of the background, a level at which one can say with 95% confidence that a particular contaminant is present. The contaminant concentrations in the column labeled quantitative determination level are concentrations at which the net peak area is 14 times the standard deviation of the background. According to Currie, that is the level at which the contaminant concentration can be estimated to a relative accuracy of 10%. Minimum detectable concentration represents a reasonable minimum screening level while the quantitative determination level represents concentrations at which the multispectral logging system could provide fairly accurate concentration estimates.

The estimated detection thresholds given in Table I are based on a thick (say, 1 m) contaminated zone and a spectral accumulation time of 1000 s of live time. Longer counting times would improve the thresholds while shorter counting times would degrade the thresholds. Similarly, the logging system is less sensitive to contaminated zones substantially thinner than the 1-m-thick zone mentioned above; special processing is required to avoid under-estimates of concentrations in the case of thin zones.

Detection thresholds are given in Table I both for the experimental prototype and for a proposed state-of-the-art instrument. Due to budget and time constraints, expediency played a major role in the construction of the experimental prototype. While the detection thresholds listed under "Experimental Prototype" in Table I represent a substantial improvement over previous generation multispectral logging systems, better detection thresholds can be achieved with available technology. Such

enhancements as a larger and more efficient detector, a more intense neutron source, lower-noise electronics, and advanced data processing are currently available, along with increased counting times.

We estimate that the detection thresholds could be improved by as much as an order of magnitude or more for some contaminants. Improving the detection thresholds by a factor of 8 would give the values listed in Table I under "State-of-the-Art Instrument." These estimates are based on a simple analysis that does not address the complicated interactions of the proposed improvements or the energy-or nuclide-dependency of some of those effects. However, the estimates tend to be substantiated by the results of computer simulations, which suggest a detection threshold for mercury of 1 ppm and for cadmium of 0.02 ppm for a perfect detector, where the energy of every gamma ray that enters the detector is determined accurately.

COMPUTER SIMULATIONS AND ANALYTICAL CALCULATIONS

Physical models tend to be costly, especially considering the strict safety and environmental regulations that exist today. Furthermore, if the behavior of the instrument is to be determined for typical field applications, there are many factors that must be studied over a range of borehole and formation conditions, such as borehole diameter, casing, rock chemistry and density, instrument geometry, and specific contaminants. Some of these factors interact, and many physical models would be needed to sort out the various combinations of conditions. In addition, we do not have the kind of detailed and precise control over the properties of physical models that would be required to explore all of the factors that could be affecting the data. Thus, while this approach provides important basic understanding of instrument behavior it is not suitable for studying the details.

Computer codes that simulate nuclear processes are widely used in nuclear engineering applications such as radiation shielding design and criticality studies. Computer simulations have also been used by a number of organizations around the world to help design and understand many nuclear systems, including nuclear borehole logging instruments. The theory behind radiation transport simulations is well understood, as is the process of applying the theory numerically. In this project, we used Monte Carlo computer simulations to help design the prototype instrument and to estimate detection thresholds. Because computer simulations can be very time consuming, we also used analytical or theoretical calculations to extend the detection threshold estimates to other elements.

The Computer Simulation Code

We used the radiation transport code MCNP (Monte Carlo N-Particle) for the computer simulations. MCNP is written and maintained at Los Alamos National Laboratory (5,6). Although MCNP is widely used for simulations of this type, it is designed primarily for other applications such as reactor shielding design and criticality calculations. When we started the simulations we found that MCNP was only marginally suitable for simulating neutron-induced gamma-ray spectroscopy problems where high-purity germanium (HPGe) detectors were used. This is primarily due to the poor treatment of photon production in the ENDF cross-section evaluations, and therefore the MCNP data libraries were not adequate for many nuclides of interest. This also holds true for many other evaluated data libraries, and therefore other radiation transport codes as well. At best, the use of MCNP for simulating gamma-ray spectra for HPGe detectors required a number of compromises and workarounds.

MCNP was primarily limited by the availability and quality of neutron data libraries. Some data libraries were unavailable due to lack of experimental data, something we could not address. Other data libraries were unavailable because existing data have not been processed into the MCNP format, a problem we were able to remedy for some important nuclides with assistance from the Nuclear Theory and Applications group at Los Alamos. That group also improved the accuracy of some of the photon production spectra in the existing evaluations and processed new data libraries for those nuclides. That was needed because, with the exception of some lighter elements, most evaluations represent photon production with wide energy bins (50 keV in the case of iron, 250 keV in most other cases) resulting in spectra that bear little resemblance to experimental data.

Other improvements were made to MCNP which helped to alleviate some of the problems discussed above and to reduce the amount of computer time needed to perform these types of simulations. These improvements included second-order perturbation, a technique for testing the sensitivity of the simulated system to small changes in

the environment, and the ability to generate separate spectra for each element or isotope of interest as well as the total spectrum.

The unavailability of germanium photon-production data made the actual detector response difficult to simulate. The efficiency of the HPGe detector cannot be reproduced; there is no generation of the escape peaks found in HPGe spectra and the gamma rays from Ge(n,) reactions seen experimentally below about 1.5 MeV are also not produced. The MCNP detector response is therefore the response that would be obtained by a perfect detector, accurately detecting all gamma rays entering its space and generating no escape peaks.

Instrument Design Simulations

We used computer simulations to help design the prototype borehole instrument used in the Grand Junction experiments. The simulations indicated that changes in the material composition of the instrument would enhance its detection capabilities. We adopted a brass housing for the detector package because eliminating the steel housing greatly reduced the iron signal present in the experimental data. Simulations also indicated that the detector could be placed as close to the neutron source as possible to increase count rates without causing other problems. Also, 6Li-loaded polyethylene was used for shielding instead of the more common borated-polyethylene or steel, greatly reducing the number of gamma rays from the shielding materials.

Detection Threshold Simulations and Analytical Estimates

We used computer simulations and analytical calculations to estimate detection thresholds for a number of contaminants in addition to those investigated in the Grand Junction experiments. We were unable to study those additional contaminants experimentally because of high cost and environmental issues associated with eventual disposal of the contaminated models. We also used computer simulations to help estimate the improvement in detection thresholds and sensitivity to various contaminants that could be achieved beyond the experimental prototype, as described earlier.

Analytical or theoretical estimates of detection threshold were performed to extrapolate from the detection thresholds determined in the experiments for the five test elements. Key to the analytical estimates is a factor based on the experimental results that includes such quantities as detector efficiency and borehole geometry. This factor and nuclear cross-section data for photon production in the experimental contaminants and additional elements were used to obtain rough estimates of detection threshold for the additional elements. These calculations were approximate with a number of simplifying assumptions. For example, the neutron spectrum was approximated as being monoenergetic and we considered only (n,g) capture reactions, ignoring other, possibly higher yield, reactions. The extrapolated detection threshold results are currently being validated and will be presented in a future report.

CONCLUSIONS

The results presented in this paper indicate that the multispectral borehole logging technique is sufficiently sensitive to be useful in screening for at least the contaminants used in the Grand Junction experiments. The value of the technique is greatly enhanced by the fact that the technique analyzes some three orders of magnitude more material than physical sampling at each depth where a measurement is made. In monitoring applications, this in situ technique can reanalyze the same borehole at any desired time interval for as many years as required.

ABSTRACT

We propose an approach, which we call the Transport Processes Investigation or TPI, to identify and verify site-scale transport processes and their controls. The TPI aids in the formulation of an accurate conceptual model of flow and transport, an essential first step in the development of a cost effective site characterization strategy. The TPI is demonstrated in the highly complex vadose zone in glacial tills underlying the Fernald Environmental Remediation Project (FEMP) in Fernald, Ohio. As a result of the TPI, we identify and verify the pertinent flow processes and their controls, such as extensive macropore and fracture flow through layered clays, which must be included in an accurate conceptual model of site-scale contaminant transport. We are able to conclude that the classical modeling and sampling methods commonly employed in most site characterization programs will be insufficient to characterize contaminant concentrations or distributions at contaminated or hazardous waste facilities sited in such media.

INTRODUCTION

Fundamental to any effective compliance or remediation strategy at a contaminated site is the formulation of an accurate predictive model of contaminant transport and groundwater flow. All successful predictive models must in turn be based upon a valid conceptual model. In practice, conceptual models are often based on general simplifying assumptions of standard saturated and unsaturated flow rather than site specific transport processes and their physical, chemical, geologic, and biologic controls. Predictive models based on these simplistic, generic conceptual models have consistently failed to correctly predict contaminant distribution, even when apparently conservative constraints and parameters have been incorporated (1). As a result, compliance and remediation strategies can fail with associated large remediation costs.

To avoid such failure, we propose that any site characterization or remediation strategy begin with an investigation of the transport processes and their controls active at a site. The TPI integrates information from a sequence of site specific activities in order to maximize the validity of conceptual models, yielding enhanced efficiency and cost effectiveness in compliance and remediation strategies. The TPI incorporates three main steps:

An exploratory phase identifies probable hydrostratigraphic units and their degree of connectivity by integrating a search of the literature and existing site data with small scale field tests and exploratory surveys of local outcrops. Site specific transport processes and associated controls that must be investigated in order to yield a minimal scientific understanding of contaminant movement are hypothesized, and an uncontaminated analog site to test these hypotheses is located.

Testing of hypothesized transport processes and controls is carried out by conducting appropriately designed and sited transport processes characterization tests (TPCTs). As necessary, the TPCTs employ techniques such as pump tests, infiltration and tracer studies, dye pulses and excavation, and detailed soil/rock

sampling in order to thoroughly investigative the field-scale transport processes active at the site.

Analysis of TPCT hypotheses testing confirms or refutes the efficacy of the hypothesized transport processes and determines whether the active transport processes at the site are adequately understood or if additional investigation is required.

Information gained from the TPI must be integrated with information from elsewhere at the site to develop a valid site wide conceptual model of contaminant transport used to guide site characterization activities. This is accomplished by mapping of local geology with an emphasis on the relation of physical characteristics to confirmed transport processes and controls in order to provide a data set adequate for geostatistical and hydrologic transport simulations. These simulations, conditioned on the results of the TPI and other studies, will properly reflect the active site transport processes and their controls. Without this initial study of the physical processes controlling contaminant transport, characterization and remediation efforts may proceed in an expensive and undirected mode governed only by previously discovered contamination and compliance mandates.

The near surface vadose zone of the Fernald site was chosen for the TPI demonstration because of its location within a glacial till typical of deposits covering much of the North American continent (2). Glacial till vadose zones contain complex media and transport processes that provide a challenging conceptual model test. In addition, soluble species of uranium have been identified during surface based testing (3) and have been found at depth (4). Current conceptual models do not provide any reasonable mechanisms for the presence of uranium at depth, implying that unanticipated transport processes are active. In this paper, we present our demonstration of the TPI conducted at Fernald, Ohio as part of the DOE Technology Development Landfill Waste Area program.

EXPLORATORY PHASE

The exploratory phase integrated information gained from a literature search, several small preliminary tests (5), and a survey of local outcrops. The literature search identified transport processes and controls common in glacial tills. In this type of environment, macropore or fracture flow may define fast transport pathways (6, 7, 8, 9, 10, and 11). Media heterogeneity may also create zones of preferential flow (12, 13, and 14). Transport through the matrix of massive clays is likely controlled by diffusive mechanisms (2).

Paddys Run Creek, an intermittent stream crossing the Fernald site, afforded 2.5 km of stream cut bank for a survey of local outcrops. Stratigraphic units at these outcrops were investigated and mapped. Active seeps were noted in structural features (thrust faults) and at topographically low contacts at clay units with sand and gravel channels. Small scale dye infiltration tests were conducted in several outcrops that identified transport processes such as fracture and macropore flow. This exploratory phase suggested a connection among transport processes identified by the small scale dye transport tests, media heterogeniety, and larger scale geologic structural features.

Hydrostratigraphy and Hypothesized Flow Processes and Controls

Uranium is the most important contaminant at the site. Uranium transport may occur as soluble forms or as insoluble forms adsorbed to colloids. In either of these cases, aqueous subsurface transport processes are critical, and lithologic units were consequently defined on the basis of their hydrologic, rather than geologic, characteristics. Figure 1 presents six hydrostratigraphic units that were identified, each distinguished by unique hypothesized flow and transport processes and controls.

Unit 5 is the uppermost unit and contains the topsoil and silty loess comprising the bulk of the rooted zone. It was hypothesized that flow through this unit would be primarily vertical and controlled by plant material, root holes, and wormholes. Unit 4 consists of blocky structured silty clays and sandy silts apparently derived from paleosols. Flow in this unit was thought to be primarily vertical along fracture networks and through the matrix. Unit 3 is composed of bedded and fractured oxidized clays and silty clays. Both horizontal and vertical flow were expected to be possible in this unit, horizontally along bedding planes and laminae, and vertically downward through fractures. Unit 2 is composed of layered and bedded unoxidized clays. It was anticipated that horizontal and vertical fractures and bedding planes provide potential avenues for fast transport and preferential flow. Unit 1, the

lowermost unit investigated, is composed of massive unoxidized clay with frequent and irregular gravels, pebbles, and cobbles. This "gray clay" has often been modeled as a barrier to vertical flow in the Fernald area.
Unit 6 is composed of sands and gravels. In general, the matrix is loosely compacted and was thought to provide the most transmissive avenue for contaminant transport of any unit. The relation of Unit 6 to the other units was varied and its sand stringers or channels were noted penetrating all other hydrostratigraphic units with the exception of the topsoils (Unit 5). Sand and gravel channels, as identified in outcrop, were hypothesized to provide possible avenues for transport through the massive gray clay (Unit 1).

Analog Site Selection

To efficiently investigate the anticipated flow processes at the contaminated site, an uncontaminated test site must be located that will provide an analog with respect to the active transport processes and controls that occur at the contaminated site. The analog site should fulfill the following criteria. It should be uncontaminated so that investigations may be conducted without causing contaminant migration or increased procedural burden. It should be nearby so that proximity provides an adequate analog (climate, weather, geology, etc.). Nearby outcrops for geologic mapping and interpretation are necessary, and ownership is desirable. Implementation of these selection criteria for our demonstration yielded the target selection of FEMP owned land along the west side of Paddys Run creek. This approximately 90 hectare uncontaminated field, used for dairy cow pasture, is within 500 meters of the main processing facilities and within 250 meters of several known locations of uranium contamination. All of these locations are on the East side of Paddys Run. Dissection of the local glacial till to depths of 6 meters by Paddys Run and the high relative topographic elevation of the field suggested hydrologic separation of the near surface from contaminated sites. Dissection also afforded approximately 2.5 km of stream cut outcrops ranging in elevation from 1 to 8 meters for geologic mapping.

TESTING OF HYPOTHESIZED FLOW PROCESSES AND CONTROLS

Design of the Subsurface Transport Processes Characterization Test (TPCT)

Based on the information gained from the exploratory phase, we anticipated the dominant active transport processes would be macropore flow through insect, worm, and root holes; flow along bedding planes and through fractures; and preferential flow due to media heterogeneity. The most important heterogeneity was anticipated to be highly transmissive sand and gravel stringers and channels penetrating more restrictive layers.
To confirm or refute our hypotheses we designed TPCTs that would investigate the presumed transport processes and controls. Because saturated conditions were encountered during an early spring site survey and these conditions can exist for a three or four month period, and in order to provide the worst case conditions for colloidal or dissolved contaminant transport, the test was designed to simulate saturated conditions. A 2.2 meter diameter circular ponded surface infiltrometer was used to produce a steady-state saturated flow field for a fifty to one hundred day period. The pressure field was monitored in time and space throughout the test to allow definition of the overall flow field and to detect any preferential flow. To aid in identifying transport pathways, Cl- tracer pulses were released into the flow system through the infiltrometers after saturated, steady-state conditions had been obtained. Near the end of the test and while still under steady-state saturated conditions, a pulse of FD&C Red #3 dye was introduced through the infiltrometer at one TPCT. The site was then excavated to identify dyed transport pathways and zones of preferential flow. The excavation also allowed inspection of hydrostratigraphic units and their local connections unaffected by weathering or erosional dynamics such as those present along Paddys Run. Site excavation allows us to confirm or refute interpretations derived from sensor and sampling analysis of the Cl- tracer pulses and to visually relate transport pathways to the site geologic conditions and flow processes.

TPCT Site Selection

After appropriate TPCTs have been designed, specific sites suitable for implementation must be located. Within the analog area west of Paddys Run, several candidate sites for the TPCTs were chosen during a preliminary survey in the early spring. An archeological survey was conducted at these locations and in late May a number of exploratory holes were augured. Based on samples from the exploratory

holes and the hydrostratigraphic units and transport controls identified in the exploratory phase, two sites were chosen for TPCTs. The two sites contained distinct geologic sequences that together represented the major hydrostratigraphic units and transport process controls found in outcrop during the exploratory phase, allowing investigation of all hypothesized transport processes and their controls.

The Sand Site (Fig. 1) was composed of topsoils and loess (Unit 5) overlying blocky structured clays (Unit 4). Beneath these units the only geologic unit encountered in any significant amount was a large, unconsolidated body of sand and gravels (Unit 6). This underlying sand and gravel unit could be penetrated only to a depth of approximately 2.5 meters before the borehole walls collapsed. Bedded clays (Units 2 and 3) were encountered at the Sand Site only in isolated samples above the sand and gravel unit.

The Clay Site (Fig. 1) contains a hydrostratigraphic sequence including all of the units at the Sand Site plus horizontal beds of oxidized and unoxidzed clays (Units 3 and 2) extending across the site and overlying the massive unoxidized gray clays (Unit 1). The sands and gravels of Unit 6 were evidenced only in stringers and one sand channel, not in a large sand body as at the Sand Site.

Fig. 1. Hydrostratigraphic units at the "Clay" and "Sand" Sites. A cross section of the instrument array at the Sand Site is also shown. The instrument array at the Clay Site is identical except the upper and lower level instrument packs are approximately 1 m deeper, with the lower packs just above Unit 1.

Instrumentation

Infiltration rates, the pressure field, Cl- tracer concentration fields, and rainfall were monitored by instrument and sampling arrays throughout the tests. The 10 meter wide, bi-level radial design of the array (Fig. 1 and Fig. 2) acquires both three dimensional pressure and solute concentration fields, allowing a sensor derived interpretation of the flow field emanating from the infiltrometer and identification of transport pathways.

The size and design of the instrument arrays and sampling points were intended to allow spatially defined measurements and still ensure interception of field-scale transport pathways. Each instrument array contained forty-four sampling points with each sampling point containing a tensiometer, soil water samplers, and a Time Domain Reflectometry (TDR) probe in a sand filled instrument pack. The dimensions of the sampling point instrument packs (50 cm length by 10 cm diameter) were intended to afford interception of the anticipated macropore and fracture network without requiring integration of results over such large volumes as to render spatial definition of flow paths impossible. The use of sand in the instrument packs provided a high conductivity medium to facilitate interception of macropores. The elevation of the upper and lower sampling levels was determined by the stratigraphy encountered during sampling at each site. At the Clay Site, the upper levels were contained in the layered clays (Units 2 or 3) approximately 2 meters below ground surface, with the lower levels located at the upper surface of the massive unoxidized clay (Unit 1) at approximately 3 meters depth. At the Sand Site, the upper level instrument packs were located in the blocky structured silty clays (Unit 4) at approximately 1.1 meters depth, while the lower level packs were contained in the underlying sands and gravels (Unit 6) at approximately 2.1 meters depth.

Fig. 2. Cl- tracer concentrations distribution at the lower (3 m) level of the Clay Site 119 hours after start of infiltration. White dots are operational sampling points. The 2.2 m diameter infiltrometer is centered in the figure.

The pressure field was monitored by transducer equipped tensiometers at each of the forty-four sampling points at each site. Measurements were collected with a datalogger controlled, automatic acquisition system at fifteen minute intervals throughout the test. Transducers monitored by this system also supplied rain gage and infiltration rate measurements, also at fifteen minute intervals.

Tracer concentration fields were monitored by both passive and active means. Soil water samples for laboratory Cl- tracer analysis were collected on one per day to three per day sampling schedules. TDR probes provided passive monitoring of solute concentrations at fifteen minute to one hour intervals over a multiplexed automated data acquisition system. Soil moisture was not of prime importance under the saturated conditions generated by the ponded infiltration, and TDR soil moisture calculations were made only to determine if saturated conditions did indeed exist in the sampling point instrument packs.

Infiltration and Chloride Tracer Application

Infiltration was initiated at both the Clay and Sand Sites in mid June by pouring water into the circular infiltrometers and simultaneously opening the water supply valves, creating an essentially instantaneous ponded head of 5 cm. Infiltration was terminated at both sites in late August, 66 days after the start of the TPCTs.
Six days after the start of infiltration, an approximately 0.1M $CaCl_2$ tracer pulse was applied through the Clay Site infiltrometer and changing salinity levels were monitored by passive TDR probes and active soil water sampling at the forty-four locations at this TPCT site. On the following day, the same procedure was followed for the Sand Site. The Cl^- tracer pulse at the Clay Site was terminated after infiltration of 1,534 liters in 48 hours. The total Cl^- pulse at the Sand Site was 1,209 liters in 53 hours. The lower volume infiltrated at the Sand Site was due to a lower infiltration rate through the Sand Site infiltrometer surface, which at the time was less conductive than at the Clay Site.

Dye Pulse and Excavation of the Clay Site

After 61 days of infiltration, FD&C Red #3 dye was added to the Clay Site infiltrometer supply tanks. Four days later, after infiltration of 400 gallons of dye, the dye tracer pulse was terminated. At the same time, clean water infiltration was halted at the Sand Site.
Excavation of the Clay Site down to and including the lowermost massive gray clay (Unit 1) was accomplished using both a large back hoe and hand tools. Use of the back hoe allowed rapid removal of one foot to two foot layers. The subsequent hand tool examination ensured that complete and detailed transport features would be revealed.

ANALYSIS OF TPCT HYPOTHESES TESTING

Results from each type of measurement obtained during the TPCTs confirmed the validity of our hypothesized transport processes and yielded a much improved understanding of their active controls at the Fernald site. We are not able to present all results in detail in this paper.

Infiltration

The long time, steady-state infiltration rate should approximate the saturated hydraulic conductivity of the least conductive media being infiltrated (15). At the Sand Site (Fig. 1), the limiting media would be silts and loess with saturated conductivities ranging from 10^{-5} cm/s to 10^{-7} cm/s (16). At the Clay Site, the limiting media would be the massive clay (Fig. 1) with conductivities ranging from 10^{-7} cm/s to 10^{-11} cm/s (16). Instead, infiltration rates at both sites approached 10^{-3} cm/s, exceeding the limiting conductivities by two to eight orders of magnitude and suggesting that infiltration was controlled by the capacity of the conducting macropore system through and below the infiltrometer surface.
Over the sixty-six day infiltration period, 61,000 liters of water were infiltrated through the system at the Clay Site and 78,000 liters of water at the Sand Site. Neither site became saturated at the surface anywhere outside the infiltrometer, also implying an interconnected subsurface transport-pathway system capable of significant transport.

Pressure Head Field

The pressure head field across the 3-D instrument array showed a general pattern of mounding beneath the infiltrometer, with local head perturbations of -10 to -5 cm distinguishing areas of preferential flow. Most sampling points showed rapid response to rainfall events (e.g., approximately 30 minutes at 3 meters depth), indicating that the majority of near subsurface media was well connected to the surface by a macropore system. The rise in head was typically almost ten times the amount of precipitation. However, some sampling points displayed neither rapid nor large rises in head, suggesting that the macropore and fracture system did not connect the entire investigated volume.

Tracer Concentration Field

Based on soil water samples and TDR measurement, overall tracer movement at both sites was initially vertically downward below the infiltrometer, then horizontally. Horizontal distribution of tracer concentrations began sooner at the Clay Site than at the Sand Site and dissipated almost ten days sooner. The distribution of tracer concentrations within the generally vertical and radial flow field was highly heterogeneous at the Clay Site and flow appeared to follow definite pathways (Fig. 2). Arrival times of peak concentrations took less than one hour at some sampling points in the Clay Site and affirmed our hypothesis of rapid transport pathways. Arrival times of peak concentrations exceeded those calculated solely on the basis

of bulk media properties by four to eight orders of magnitude. Contributions of multiple transport pathways at some sampling points were observed as multiple peaks in breakthrough curves (Fig. 3).
Fig. 3. Repeated peaks in Cl- tracer breakthrough curves due to contributions from multiple flowpaths. The sampling point is located 2.5 m East of the infiltrometer at a depth of 3 m (see Fig. 2).
Dye Pulse and Excavation
The dye pulse and subsequent excavation of the Clay Site presented striking visualization of flow processes and transport pathways, and confirmed data from the instrument array (Fig. 4). Dye capture was prevalent in the uppermost layer of topsoils and loess (hydrostratigraphic Unit 5), while vertical root, worm, and insect macropores and fractures transported the dye tracer through the underlying blocky structured clays (Unit 4). The matrix of this unit was stained only in the immediate vicinity of macropore flow and transmissive fractures. Macropores were noticeably missing from sand and gravel media, likely because the unconsolidated matrix does not support pore walls just as it limited instrument borehole depth (see TPCT site selection above). As hypothesized, horizontal dye movement along horizontal fractures and bedding planes was noted both in the oxidized bedded clays (Unit 3) and in the unoxidized bedded clays (Unit 2).
Fig. 4. Plan view of major macropores, fractures, and zones of preferential flow found during excavation at the Clay Site. Noted features are integrated over the depth of the excavation.
In addition to these expected features we found tubular pathways approximately 2 cm by 3 cm in cross sectional area meandering from just beneath the topsoil down to depths well below the upper surface of perched water tables as defined by standing water in boreholes during installation in late May. These large macropores were later identified as crayfish burrows that are endemic to the area. Crayfish burrows and burrow complexes filled with dye connected the topsoils to fracture networks in the bedded clays. These pathways are each capable of transmitting more than the maximum flux observed passing through the infiltrometers. The large incidence of dye stained crayfish complexes in the southern portion of the site (Fig. 4), none intercepted by sampling points, may explain the lack of tracer concentrations sensed in that area by the instrument array. At the Clay Site, these and all other bioturbated fast transport pathways terminated in the unoxidized layered clays (Unit 2).
Sand and gravel stringers and channels were observed at all depths and penetrated even the massive gray clays (Unit 1). Dye transport through numerous silty sand zones was discovered in the layered clays. Unfortunately, at the depths where Unit 1 was encountered (3 to 5 meters), the dye pulse was diluted to an extent that no confident association could be made between the infiltrated dye pulse and flow through sand stringers within the massive gray clay.
CONCLUSIONS
Transport Processes, Controls and Connectivity
The Transport Process Investigation was effective in identifying pertinent flow processes and controls. We can conclude that a conceptual model for the near surface vadose zone at the Fernald site must incorporate the following processes and controls. The dominant flow and transport pathways through the topsoil to the bedded clays are vertical bioturbated macropores and fractures. These pathways are capable of rapid and abundant transport during most of the year, when essentially saturated conditions exist or when rainfall events are of sufficient magnitude to enter the macropore system. The bedded clays support a pervasive network of transmissive horizontal and vertical fractures and are connected to the surface by vertical fractures and macropores. Some crayfish burrows are continuous from the surface to the bedded clays and intersect the fracture network in the clays. Crayfish burrows may provide the dominant transport pathways in some areas, allowing contaminants to bypass extensive volumes of the near surface media.
Channels and stringers of sands and gravels provide localized zones of preferential flow and are well interconnected by fractures and macropores. In this extensively reworked and deformed glacial depositional environment, highly transmissive sand and gravel channels and shear zone fractures penetrate portions of the otherwise impervious massive gray clays, calling into doubt its effectiveness as a barrier to flow and transport. The seeps and preferential flow features noted in the exploratory geologic survey may be representative of field-scale transport pathways.

Trends in infiltration rates and changes in the pressure field indicate that the system is well drained, with a significant potential for contaminant transport.

Further Studies

The connectivity of transport pathways from the surface to depth has been implied at the field scale by the well drained nature of the flow system and should be fully investigated by larger scale tracer or pump tests. Larger scale tests will require that the hydrologic separation of contaminated and uncontaminated sites be conclusively demonstrated. Tests also must be conducted to conclusively determine if the deposits of massive gray clay are effectively breached by discontinuities and penetrations by highly transmissive sand and gravel channels.

Implications for Site Characterization Strategies

Through implementation of the Transport Processes Investigation we were able to distinguish the governing transport processes and controls active in this highly complex near surface glacial till and identify those that must be included in a defensible conceptual model for contaminant transport at the site. Site characterization plans formulated by classical statistics and sampling strategies, and predicated on generic conceptual models of subsurface flow and transport, will likely not recognize the potentially rapid transport processes and controls identified by the TPI. Consequently, such generic conceptual models will characterize contaminant concentrations and distributions only by chance or through prohibitively extensive and expensive classical sampling plans.

ACKNOWLEDGMENTS

We would like to acknowledge the contributions of the following individuals and organizations. Kim Nuhfer of FERMCO provided administrative, logistical, and planning support. Cliff Lee of FERMCO aided in geological sampling and instrumentation support. The efforts of the leaders of the Site Sampling Team, Mike Stott and Tim Smith, and that of the members, Nick Jansen, Bill Neyer, Jenny Milchert, and Andy Cleeter were invaluable. Without the assistance of these individuals we would not have been able to demonstrate the aspects of the Transport Processes Investigation. Support for this demonstration was provided by the DOE Technology Development Landfill Waste Area program.

DETAIL RECONNAISSANCE SURVEYS FACILITATE AN EXPEDITED SITE CHARACTERIZATION
K. M. Skinner
Bechtel Environmental Inc
ABSTRACT
An expedited investigation requires extensive planning in order to accomplish the objectives of the program in a single field season. At the Palos Forest Site a significant portion of the sample planning was facilitated through the use of four reconnaissance surveys and a civil survey. The civil survey established a 100 foot grid across the entire forty acre site. This grid forms the basis for establishing on-site locations for the other surveys and subsequent sampling events.
The reconnaissance surveys included a historic air photo analysis that provided insight to the layout of the original facility and the locations of key features. The historic photos were digitally scanned and converted to image files. The files were manipulated on a VAX workstation where they were scale corrected to the civil survey grid. This scale corrected image allowed locations of key features to be located on the work station with a high degree of accuracy.
A detail surface features map was constructed for the main portion of the facility. This map was constructed on a scale of 1 inch = twenty feet tied into the site civil survey grid. The map showed the location of objects as small as a few inches in area.
A radiological walkover survey was performed using global positioning equipment linked to the radiological metering equipment that was carried over the site by field personnel. This survey produced approximately 150,000 measurements over the site that were linked to discrete coordinate locations.
A geophysical survey was conducted that collected electromagnetic and magnetic data on ten foot centers across the majority of the site and on five foot centers in three areas of interest. The geophysical surveys located shallow buried objects including, water supply lines, utility corridors, underground storage tanks, drain lines and other key features critical to the full characterization of the site.
Integrating the data from the reconnaissance surveys facilitates an efficient targeted sampling strategy. Sample locations can be easily located in the field using the site civil survey. Analytical results are integrated into the reconnaissance survey maps to focus on areas of significant contamination. Using these types of surveys as a presampling strategy saves time and money in the field. The amount of savings realized is dependent upon the complexity of the site and selection of the proper presampling surveys. Time and cost savings can be as high as 30 percent of total investigation costs if significant areas can be removed from further consideration. In almost all situations, reconnaissance surveys provide an excellent basis from which to attach a quick and thorough investigation.
SITE DESCRIPTION AND HISTORY
Following the first successful sustained nuclear reaction attained by Enrico Fermi and his staff at the University of Chicago in the early 1940s a more secluded and secure site was established in the 'Palos Forest preserve southwest of Chicago. Site A was leased from the Cook County Forest Preserve district to support the continuing research associated with the development of the first production nuclear reactors. Two reactors (CP-2 and CP-3) were constructed and operated at this facility between 1943 and 1954 for research purposes. Program research included reactor physics, plutonium production, fission product separation, tritium recovery and laboratory animal experimentation.
Beginning in the late 1940's, facilities at Site A were closed and research operations were relocated. All buildings and equipment were decommissioned and demolished, ongoing operations were relocated by 1956 to Argonne National Laboratory (ANL), approximately three miles west of Site A. As programs were relocated empty buildings were surveyed for radiological contamination, decontaminated as necessary, and razed. The emptied CP-3 reactor concrete bioshield was partially filled with small contaminated items such as hardware and piping, filled with concrete and

buried on-site, in an excavation approximately forty five feet in depth. Remnants of the CP-2 reactor, principally, graphite blocks, and building rubble were entombed in the excavation above the CP-3 bioshield and the entire mass of debris was buried. Subsurface structures such as building basements (partially filled with building rubble and debris), drain lines, utility tunnels, and water supply lines were left undisturbed.

In 1956 Site A was returned to the Cook County Forest Preserve District. Since that time, several investigations of the site have been conducted. ANL performed limited investigations of the site between 1956 and 1978 and has conducted annual surveillance of groundwater, surface water and sediments since 1978. Illinois Department of Nuclear Safety also conducted periodic walkover surveillance of the site and the surrounding acreage. In 1990 during a routine walkover a small piece of processed natural uranium metal was found west of the main facility in a purported former waste disposal area. Following this discovery DOE- Chicago requested Oak Ridge Associated Universities conduct shallow soil sampling, a radiological walkover survey, and a limited geophysical survey (ground penetrating radar) (Berger 1993). With technical management from DOE-Chicago, Bechtel Environmental Inc. (BEI) was contracted to perform follow-up activities in 1993 that included: securing the site by constructing a perimeter fence, supplying electrical power to the site, establishing temporary working facilities, and clearing and grubbing the site in preparation for a detailed site characterization that was conducted in 1994.

Fig.1 Location of the Palos Forest Site

OBJECTIVE AND PLANNING OF THE FIELD PROGRAM

Previous investigations had been preformed at Site A however the focus had been primarily to determine if. radiological contaminants were present and to what extent. The scope of work to be performed under the phase two investigation involved a full site characterization with emphasis on metals and chemical contamination as well as further definition of the extent of radiological contaminants. The field program was designed to reduce the amount of investigation derived waste and was to be expedited to complete all investigative work in one field season. Limited historical information regarding site operations was available prior to initiating field work. Additional historic information was made available early in the field program that served to help verify information gained from the reconnaissance surveys. As part of the planning phase of the field work , four reconnaissance surveys and a site wide civil survey were conducted. This initial effort served to focus the subsequent field sampling program in areas having a high potential of contamination and cleared large portions of the site from further in-depth sample investigation.

RECONNAISSANCE SURVEYS

Following clearing of the site a civil survey was performed to stake grid corner locations at 100 foot intervals over the entire controlled area. The site grid was established from an arbitrary origin near the center of the site with grid lines oriented north-south and east to west. The grid was not tied into state plane coordinates, which did result in some difficulties establishing the basis for the subsequent radiological walkover survey. Having this grid established early and clearly staked greatly facilitated definition of locations for all the following field activities.

AIR PHOTO ANALYSIS

Historic aerial photographs of the site were available from DOE-Chicago. However, due to the condition of the site most of the cultural features where either altered or obscured by fill dirt and soil that had been used to cover foundations and facilities during and following decommissioning of the facility. Coordinate locations were obtained for the few identifiable cultural features. These grid locations were used to scale correct and rectify the photo imagery to the civil survey grid. This scale correction was accomplished by digitally scanning the photographs at a resolution of three hundred dots per inch (dpi). The digital images were manipulated on an VAX arch/info workstation where the survey points were assigned to the appropriate locations on the photograph, and the images where then rectified to the site coordinate grid. The resulting image was then examined to identify areas that were being impacted during the operation of the facility. Areas of barren ground, small buildings, above-ground piping and dumping areas were targeted. The civil survey grid coordinates were read directly from the digital image, with the corresponding area being located on the ground. These areas were

targeted for emphasis in the following recon surveys and in the initial rounds of sampling. This work greatly assisted the early planning of the field program while providing a satisfactory level of confidence in the locations of the targeted areas.

RADIOLOGICAL WALKOVER

The radiological walkover survey conducted at Site A combined several emerging technologies to achieve a cost-effective means of accurately mapping approximately 23 acres of the controlled area. The technique used integrates radiation measuring instrumentation with the Global Positioning System (GPS). The integrated mapping and radiation survey system (MARSS) developed by J.S. Bland Associates, Inc. simultaneously recorded direct radiation, exposure rate, and position data. The survey covered approximately two acres per day, including background determinations, source checks, calibrations, and downloading of position and radiological measurements. In the field data were automatically recorded and stored electronically each second while the technician traversed specified grid blocks. Real-time differentiation of position data was performed via direct radio link between the roving and the GPS base receivers.

Data were electronically transferred daily to Bland's office in Maryland and also were downloaded at the field office in Chicago. Track maps were viewed on site through Golden Software's SURFER program, version 5.0. At Bland's office, MARSS produced color track maps showing ranges of radiation readings in relation to location. These maps were evaluated in the field and used to verify survey coverage and definition of points of interest.

With this radiological data collection system, the field crew was able to survey 23 acres in approximately 14 working days. Use of this integrated system provided adequate spatial coverage of the site and detected and mapped areas of varying radiation levels. These data were compared with the results of a previously performed, more traditional survey to confirm areas of elevated radiation. The 1994 survey defined in far greater detail the boundaries of areas identified by the previous survey and located and mapped the presence of several other small areas of elevated radioactivity.

Over 150,000 data points were collected on-site during the survey. Bland provided a final composite map that included all of the color track maps in a single display. The high density of data allowed patterns to be observed throughout the site.

The results of this reconnaissance survey were used to select sampling locations specifically targeting areas of elevated radiological readings. This survey was also used in conjunction with the detail surface features map identifying areas of elevated radiological readings that corresponded to
coke slag deposits. In these areas sampling was directed at characterizing the coke deposits which could then be used to characterize large portions of the site highlighted by the radiological survey.

Fig. 2 Radiological Walkover Map Site A

SURFACE FEATURES MAP

While the radiological survey was the application of state-of-the-art technologies, the surface features map was the traditional observational field map created using brute force and a lead pencil. The surface features map was constructed based on the established civil survey grid. Baselines 100 foot survey tape measures were laid out along the north and south boundaries of a grid block. A third tape was laid out north to south between the two baselines and the location of surface features were estimated and sketched on grid paper. The location of any and all surface objects were noted on the field sketches including, concrete rubble, debris, metal objects, pipe, fencing, asphalt debris and paving, road material, building foundations footers and slabs, transite shingles, telephone pole bases, trees, slope breaks, surface drainages, depressions, sidewalks, and any other identifiable objects. No determination had been made prior to the start of mapping as to what features were important and what were unimportant. The mapping work required two field personnel eighteen days to cover the central 20 acres of the facility. Field sketches were composited into a 1"= 20' scale map. This map served as the primary planning reference for subsequent sampling activities. Features identified by surface mapping were targeted for sampling and in many cases served to explain anomalies that were defined by the other reconnaissance surveys (i.e. the coke slag correlation to the elevated radiological signatures).

Fig. 3 Portion of the Surface Features Map

GEOPHYSICAL SURVEY

Information from historic documents and drawings and interviews with personnel who had worked at the site during its operation indicated the possibility of the existence of subsurface features. These features included; underground tunnels, building basements, pipeline conduits, and underground storage tanks. A limited Ground Penetrating Radar survey had been performed in selected areas during a previous investigation. This survey had identified anomalous areas that were interpreted as burial areas, and as a number of underground tanks. The results of the GPR survey were highly subjective due to the nature of the subsurface soils (conductive clays) and the preponderance of scattered debris that would produce point sources on a GPR survey. Also the central portion of the facility where the majority of the subsurface features were expected to be located had not been surveyed. From Applied Technologies was contracted to perform a geophysical survey of the entire central portion of the site and two peripheral waste burial areas. The survey included electromagnetics, magnetics and three limited test areas where GPR was performed. GPR data was collected in conjunction with the other two methods in areas where subsurface conditions were known. While the GPR data collected was very similar to the previously acquired GPR data the results were highly interpretive. The other two methods provided more reliable less interpretive information thus, the GPR survey was deleted from the scope of work. In excess of thirty thousand measurements were taken with the EM and mag surveys site wide. Three areas were surveyed at a five foot station offset the remainder of the central portion of the site was surveyed at ten foot offsets. The high density surveys were conducted in areas where underground tanks existed, and in known waste burial areas. The geophysical surveys identified six anomalies that appeared to be underground storage tanks. Of these anomalies three were found to be tanks. The other three were buried building rubble, and a metals disposal pit. The magnetic survey located two buried building basements and the bioshield burial pit that had been filled with building rubble and trash. The EM survey located a series of underground water supply and drain lines, a utility tunnel, buried steam lines, and water supply feed and return lines that connected to a cooling tower foundation. The geophysics was not capable of locating buried terra cotta drain lines and concrete and clay brick storm sewer lines. Due to the nature of the clay rich soils trenches that were dug to place these lines were indistinguishable from the undisturbed materials.

INTEGRATION OF RECONNAISSANCE SURVEY INFORMATION

Each of the recon surveys provided a specific insight to the facility. Target areas were identified from each survey for further investigation. Integrating the information from all four surveys allowed large portions of the site to be designated as "suspected uncontaminated areas". These areas were sampled using a broadly spaced systematic grid to substantiate the uncontaminated designation. Areas that were targeted on one or more of the surveys as possibly contaminated were initially sampled using four spot composite surface soil samples. A short list of contaminants was identified from these initial screening samples and subsequent bias sampling was performed to define the nature and extent of contamination in the targeted areas. Recon data integration also served to explain anomalies defined on one survey with data from another survey such as metal objects mapped on the surface features map that exhibited a strong response on the geophysics survey, or the correlation between elevated rad levels and coke slag deposits. These correlations further allowed portions of the site to be cleared from all but confirmatory sampling.

Using these four recon surveys focused the sampling efforts into a few small manageable areas where contamination was present. By clearing large areas of the site from further investigation a well focused sampling effort was easily capable of gathering sufficient data to define the nature and extent of all significant contamination in a singe field season.

SUMMARY AND CONCLUSIONS

Five reconnaissance surveys were performed at Site A prior to the initiation of field sampling activities. These surveys included an historic aerial photo analysis, detailed surface features mapping, radiological walkover survey, and geophysical EM and magnetic surveys. This early work facilitated a focused approach to the field sampling portion of the program by removing large areas of the site from extensive sampling efforts. Time and cost savings are difficult to quantify however, Site A

was adequately characterized through an expedited approach, work that would commonly have required two field seasons to complete. Savings estimates from the expedited characterization of the site are on the order of 30 % reduction in costs, with presampling reconnaissance survey playing a key role in completing this effort in one field season.

RECOMMENDATIONS

Establish a clearly identifiable semi-permanent grid system over the entire site.

Tie the grid to state plain coordinates.

Orient the grid north-south east-west even if grid lines are skewed to property boundaries.

Use available aerial photography from state, federal, and private sources as a first look at former site conditions.

Rectify imagery to the established grid for identifying possible target areas.

Select reconnaissance survey that target the type of contaminants expected on the facility.

Run small scale tests of the selected surveys to determine if they will provide the expected information.

Use more than one type of reconnaissance survey on complex sites.

Integrate and evaluate the data prior to planning the initial rounds of sampling.

Emphasize clearing portions of the site from further detail sample consideration.

ABSTRACT

Soil samples from a storage pile at a DOE Superfund site were sent to the National Air and Environmental Radiation Laboratory (NAREL) for initial characterization prior to consideration of a full-scale treatability study. The primary objective was to determine if particle-size separation could be used for volume reduction of the contaminated soil. Since the predominate radioactivity in many contaminated soils is found in the small soil particles (<0.074 mm), partitioning of these fractions by particle-size separation techniques represents an alternate, cost-effective remediation method that might reduce the volume of soil that would, otherwise, require costly transportation and disposal. An initial examination of the soil to determine the particle-size and radionuclide distribution is, therefore, a reasonable study to perform before beginning a full treatability study. It may also suggest a treatment solution with minimum expenditure of funds or provide information to select an alternate approach to remediation, or, at a minimum reduce the scope of the treatability study.

Six samples from within the pile, designated Pile (P) samples, were examined initially. Particle-size separation by wet sieving and hydroclassification was performed after the samples were subjected to particle liberation by vigorous washing. Fractions were analyzed for radionuclides, and select fractions were subjected to petrographic analysis after density separation at 2.89 g/cc. Five additional samples from under the pile, designated Under-Pile (UP) samples, were also wet sieved or hydroclassified and analyzed for radionuclides to provide additional characterization of the site.

The following conclusions were drawn from these studies: a) The particle-size distributions of three Under-Pile samples are very similar to each other and to the six samples from within the pile; each contain approximately 48 percent -200-mesh (-0.074 mm) material. One Under-Pile sample contains approximately 60 percent -200-mesh material, while another contains 40 percent. b) The radionuclide concentrations in the Under-Pile samples are 10 to 50 times those of the Pile

samples. The predominate radionuclides are thorium-232 and -228 and radium-228. The maximum radium-228 concentration is 1700 pCi/g in the Under-Pile samples but only 35 pCi/g in the Pile samples. Uranium-238, thorium-230, and radium-226 are also present in significant but lesser concentrations, with radium-226 up to 330 pCi/g and 15 pCi/g in the Under-Pile and Pile samples, respectively. c) The concentration of each radionuclide in the size fractions generally increases as particle size decreases. In all cases, the -200-mesh (-0.074-mm) or the -400-mesh (-0.037-mm) fractions contain much higher concentrations than the whole soil. d) Wet sieving and hydroclassification produced similar results. Although similar in particle-size distribution, the radionuclide concentrations of the Under-Pile size fractions are much higher than those of the Pile samples and are above most acceptable site clean-up criteria. Therefore, volume reduction of the Under-Pile samples by particle-size separation, alone, is not a viable option for remediation. In contrast, either 53 or 65 percent of the soil of the Pile samples can be recovered with radionuclide-contaminant concentration of less than 5 or 15 pCi/g, respectively, by separation at either 200 mesh (0.074 mm) or 325 mesh (0.045 mm). Analysis of the process water indicates that the radionuclides are insoluble in water. e) The primary source of thorium activity in the Pile samples is monazite. Zircon also contributes a small amount to the activity. These radiominerals are concentrated in the fine-sand to upper silt-size range, -100/+400-mesh (-0.149/+0.0387-mm). The specific gravities of monazite and zircon are about two units above the average specific gravity of the host material. Therefore, density separation might be used to provide additional volume reduction of these fractions. The magnetic susceptibility of monazite is in a unique range offering another potential separation method to reduce the volume of contaminated soil.

INTRODUCTION

Soil samples from a DOE Superfund site storage pile were sent to the NAREL for partial characterization prior to consideration of a treatability study. The primary objective of this study was to determine if particle-size separation could be used for volume reduction of the contaminated soil. The predominate radioactivity in many radionuclide-contaminated soils is found in the small soil particles, typically the silt-size and clay-size fractions. Partition of these fractions by particle-size separation techniques routinely used by the mining industry can represent an alternative, cost-effective remediation method to reduce the volume of soil requiring costly transportation and disposal. An initial examination of the soil to determine the particle-size and radionuclide distribution is, therefore, a reasonable study to perform before beginning a full treatability study. It offers the possibility of suggesting a treatment solution with minimum expenditure of funds or providing an indication of another treatment approach, or, at a minimum, reduce the scope of the treatability study.

Six borehole samples from within the pile, designated Pile 1 (P1) through Pile 6, were examined initially. The specific objectives of the initial study were to assess the homogeneity of the storage pile to determine if the radionuclide contamination is similar throughout the pile, to determine if particle-size separation techniques might be effective in reducing the volume of contaminated soil, to determine the physical form of the contamination, and identify other physical and/or chemical properties of these materials and contaminants that might be exploited for volume reduction.

Five additional samples from under the pile, designated Under-Pile 1 (UP1) through Under-Pile 5, were subsequently examined to provide additional characterization of the site. This paper presents the results of both characterizations.

EXPERIMENTAL

Sample Preparation

Five 3-kg, Under-Pile soil samples were received for study, UP1 through UP5. The samples were screened for gross beta/gamma activity using a Geiger/Muller survey instrument. After screening, each sample was thoroughly mixed and split into 400-mL aliquots using a riffler. Each aliquot was weighed, dried at 60C, and reweighed. Three aliquots from each whole soil were analyzed by gamma spectrometry (see below); one aliquot was also analyzed for uranium and thorium by alpha spectrometry (see below). Six 1-kg, Pile samples were also received, P1 through P6. The samples were prepared and analyzed for radionuclides as described above, except the 400-mL aliquots were split by hand producing two aliquots for each Pile sample.

Vigorous Wash

The vigorous washing process liberates small particles from large particles without generating excessive fines. After sample preparation, each aliquot of all samples was vigorously washed in water for 30 min in an orbital shaker at a rotational velocity of 350 rpm with a liquid-to-solid ratio of 4 mL/1g (1). The aliquots were then fractionated according to particle size using either wet sieving or vertical-column hydroclassification as described below.

Wet Sieving

After vigorous washing, an aliquot of each sample was fractionated by size using wet sieving with ASTM standard sieves (2). The aliquots were separated into size fractions at 6.35 mm (in), 2.38 mm (8 mesh), 1.19 mm (16 mesh), 0.590 mm (30 mesh), 0.297 mm (50 mesh), 0.250 mm (60 mesh), 0.149 mm (100 mesh), 0.074 mm (200 mesh), 0.053 mm (270 mesh), and 0.037 mm (400 mesh). The resulting fractions were dried at 60C, weighed, and analyzed for radionuclide content by alpha and gamma spectrometry. One aliquot of each Pile sample was fractionated by wet sieving at 6.35 mm (in), 0.297 mm (50 mesh), 0.149 mm (100 mesh), and 0.074 mm (200 mesh). The fractions were analyzed by gamma spectrometry. An aliquot of each whole soil and each fraction from sieving sample P1 were also analyzed by alpha spectrometry. A 100-g dried portion of the -0.074-mm (-200-mesh) fraction from wet sieving an aliquot of sample P1 was crushed and further separated using a 0.045-mm (325-mesh) sieve to determine the size distribution of soil particles larger and smaller than 0.045 mm.

Vertical-Column Hydroclassification

Vertical-column hydroclassification is a method for separating soil by settling velocity, which is a function of particle size and density. This procedure closely simulates the process used by full-size hydroclassification equipment. Since hydroclassification is not practical with particles larger than 0.297 mm (50 mesh), after vigorous washing, an aliquot of each Under-Pile sample was first fractionated according to particle size by wet sieving at 6.35 mm (mesh), 2.38 mm (8 mesh), 1.19 mm (16 mesh), 0.59 mm (30 mesh), and 0.297 mm (50 mesh). The particles that passed through the 0.297 mm (50 mesh) sieve were separated at 0.25 mm (60 mesh), 0.149 mm (100 mesh), and 0.074 mm (200 mesh) by hydroclassification (3). The resulting fractions were dried at 60C , weighed, and analyzed for radionuclides by gamma and alpha spectrometry. One aliquot of each Pile sample was separated at 0.149 mm (100 mesh) and 0.074 mm (200 mesh). The resulting fractions were dried at 60C, weighed, and analyzed for radionuclides by gamma spectrometry. A 100-g dried portion of the -0.074-mm (-200-mesh) fraction from the hydroclassification of the aliquot of sample P1 was crushed and further separated using a 0.045-mm (325-mesh) sieve to determine the size distribution of the -0.074/+0.045-mm (-200/+325-mesh) and -0.045-mm fractions.

Process Water

Water from the vigorous wash and separation procedures for each sample was collected and a Percol 788N flocculent was added to settle suspended material. The water was then filtered through a 0.025-mm pore paper filter to separate suspended solids. An aliquot of filtered process water from each sample was analyzed by gamma spectrometry.

Gamma Spectrometry

Aliquots of samples, each particle-size fraction, and process waters were analyzed for gamma-emitting radionuclides using high-purity germanium detectors (4). The water samples were counted for 1000 min and the soil samples were counted for 10, 100, or 1000 min, according to the levels of radioactivity.

Alpha Spectrometry

Analyses for uranium and thorium radionuclides were performed by alpha spectrometry (5). Uranium was extracted from the mixture, coprecipitated with lanthanum fluoride carrier, and analyzed by alpha spectrometry. Thorium was separated by ion-exchange chromatography, coprecipitated with lanthanum fluoride carrier, and analyzed by alpha spectrometry. One whole soil aliquot and each particle-size fraction from UP1 and UP2 were analyzed for uranium and thorium. One whole sample aliquot and each particle-size fraction from P1 were analyzed for uranium and thorium.

Petrographic Analysis

Petrographic examination was performed on the six Pile samples. The samples were separated by size as described above. The heavy (more dense) minerals in the -0.297/+0.149-mm (-50/+100-mesh) and the -0.149/+0.0074-mm (-100/+200-mesh) fractions for each of the samples were separated by the sink-float method using tetrabromoethane (specific gravity of 2.89). The composition of the gravel-sized

(+6.35-mm; +-in) material was determined by megascopic examination. The composition of the sand-sized material was determined by microscopic examination using both binocular and polarizing petrographic microscopes. Sedimented slides of the silt- and clay-sized (-0.074-mm; -200-mesh) material were analyzed by X-ray diffraction at the Auburn University Soil Laboratory (Auburn, Alabama). The X-ray diffractograms were analyzed as part of the petrographic examination.

RESULTS AND DISCUSSION

Particle-Size Distribution

All samples were characterized by particle size after vigorous washing using both wet sieving and vertical-column hydroclassification. Aliquots of Under-Pile samples separated by hydroclassification were first sieved to collect the +0.297-mm (+50-mesh) fractions. The -0.297-mm (-50-mesh) material was then separated by hydroclassification, since hydroclassification is not effective for particles larger than 0.250-mm (60-mesh) size. The Pile samples were not sieved prior to hydroclassification since the first fraction collected was 0.149-mm (100-mesh) size. The particle-size distributions of UP2, UP3, and UP4 are very similar whether wet sieving or hydroclassification is used for separation. They are illustrated by UP3 (Fig. 1). Each of these samples contains approximately 48 percent -0.074-mm (-200-mesh) material. Although UP1 is similar in particle-size distribution to UP2, UP3, and UP4, it contains approximately 60 percent -0.074-mm (-200-mesh) material. In contrast, UP5 contains only 40 percent -0.074-mm (-200-mesh) material.

Each of the five Under-Pile samples reveals an unusual difference in behavior when results from wet sieving are compared to those of hydroclassification. The -0.297/+0.250-mm (-50/+60-mesh) fraction of each sample after wet sieving contains from 1.5 to 4.2 percent of the total soil fractions recovered. By comparison, this hydroclassification fraction contains from 0.3 to 0.4 percent material, an average of about 85 percent less material. When comparing wet sieving to hydroclassification, there are always slight differences in the amount of material collected in a given size fraction produced by the two separation methods. It is exceptional, however, to observe such a large difference in the amount of material contained in the same particle-size fraction when one method is compared to another. This change in amount of material produced by hydroclassification as compared to the amount of the corresponding sieved fraction must be the result of larger-size particles, as determined by sieving, reporting to smaller-size hydroclassified fraction. Vertical-column hydroclassification is based on Stoke's Law that states that the settling velocity of particles in a fluid is proportional to the second power of effective particle diameters and the first power of the difference in density between the particle and the fluid. Thus soil particles with a certain effective diameter that behave in hydroclassification as smaller particles, when compared to other particles of the same size, are likely less dense than those particles. An examination of the particle-size content of the -0.250-mm (-60-mesh) fractions of all soil samples is consistent with this behavior during hydroclassification. In each sample, the -0.250-mm (-60-mesh) fractions contain slightly more particles than those produced by wet sieving (Fig. 1).

The particle-size distributions of the Pile samples, P1-P6, are very similar to each other, whether wet sieving or hydroclassification is used for separation, as exemplified by P4 (Fig. 1). Each Pile sample contains approximately 47 percent -0.074-mm (-200-mesh) material. On sieving, sample P5 contains a slightly higher percentage of -0.074-mm (-200-mesh) material, 55 percent, but less particles in the -6.35/+0.297-mm (--in/+50-mesh) fraction, which balances the higher percentage of -0.074-mm (-200-mesh) material. This difference in particle-size distribution exhibited by P5 from the other five samples, is not observed when hydroclassification is used to separate the sample.

Sample P1 was also examined by additional wet sieving with a 0.045-mm (325-mesh) sieve in an attempt to obtain an estimate of the particle-size distribution of the sample below 0.074-mm (200-mesh) size (Table I). An examination of the radionuclide distribution of the fractions initially produced (see next section) indicates that a favorable particle separation for volume reduction might be made at less than a 0.074-mm (200-mesh) size. The -0.074-mm (-200-mesh) fractions, produced during initial sieving and hydroclassification, had already dried to a hard cake and was crushed for gamma spectrometric analysis before making the decision to further examine the fraction. Crushing the fractions may have altered the distribution of particles that would typically be found in the sample below 0.074-mm (200-mesh)

size. However, the data presented in Table I indicate that the -0.074-mm (-200-mesh) fraction originally produced by sieving or hydroclassification contains more than 30 percent -0.045-mm (-325-mesh) material.

The particle-size distributions of the six Pile samples are very similar to UP2, UP3, and UP4. Each of these soil samples also contains approximately 47 percent -0.074-mm (-200-mesh) material. Thus, nine of the 11 samples contain approximately 53 percent +0.074-mm (+200-mesh) material that might be recovered in a remediation process based on particle-size separation. As indicated in the previous paragraph, there is indication that over 65 percent would be recovered if sample P1 is representative of the site.

Radionuclide Distribution

The results of radionuclide analysis for select uranium, thorium, and radium isotopes in Under-Pile and Pile samples and their fractions reveal that the Under-Pile samples contain from 5 to 100 times the concentration of radionuclides in the Pile samples. Table II illustrates the concentrations of uranium-238 and thorium-232 and select decay products in both series in UP1, a typical Under-Pile sample. The data indicate that the predominant contaminants are thorium-232 and its progeny, radium-228 and thorium-228. Their maximum concentrations in this sample are 760 pCi/g thorium-232, 1020 pCi/g radium-228, and 792 pCi/g thorium-228. Data collected from UP1 and UP2 indicate that thorium-232 and its progeny are present in approximately equal concentrations, indicating that these radionuclides are in secular equilibrium. The data also indicate that uranium-238 and its decay products, thorium-230 and radium-226, are also present in elevated concentrations. The maximum concentrations in UP1 are 51 pCi/g uranium-238, 120 pCi/g thorium-230, and 331 pCi/g radium-226. However, the data reveal that uranium-238 and its progeny are not present in equal concentrations, and, therefore, are not in secular equilibrium. This may result from the presence of tailings from mineral processing operations that selectively concentrated radionuclides of this series in the soils. Although radionuclides in the thorium-232 and uranium-238 series were not determined for UP3, UP4, and UP5, one would expect concentrations of the radionuclides in these soil samples to be similar to those of UP1 and UP2. The expectation is that the other radionuclides in the thorium-232 series appear to be in equilibrium and that the concentrations of these radionuclides are approximately equal to those of radium-228. The radionuclides in the uranium-238 series are not in secular equilibrium in UP1 and UP2 and are not expected to be in equilibrium in UP3, UP4, and UP5. By comparison to the concentration of the series in UP1 and UP2, one would expect radium-226 and thorium-230 to be the predominant radionuclides present from this series.

The data from separation by both wet sieving and hydroclassification of Under-Pile samples, exemplified by the data for UP1 (Table II and Fig. 2), illustrate that the concentration of each radionuclide generally increases as particle size decreases. In each case, the -0.037-mm (-400-mesh) fraction from wet sieving and the -0.074-mm (-200-mesh) fraction from hydroclassification contain considerably higher concentrations of all radionuclides reported. For example, the concentration of thorium-228 in UP1 is 792 pCi/g while the -0.037-mm (-400-mesh) fraction from wet sieving contains 2300 pCi/g. Note that the preceding size fraction, -0.053/+0.0037-mm (-270/+400-mesh), contains less thorium-228 than the whole soil itself, 549 pCi/g. This behavior is likely the result of radioactive cations absorbed to smaller silt and clay particles and the presence of radiominerals of smaller size.

One soil fraction from hydroclassification of both UP1 and UP2, the -0.297/+0.250-mm (-50/+60-mesh) fraction, contains an unexpectedly high concentration of each radionuclide reported. As noted above, this size fraction contains less material than the corresponding fraction from wet sieving, likely because less-dense particles of the -0.297/+0.250-mm (-50/+60-mesh) fraction are reporting to smaller-sized fractions during hydroclassification. Apparently, these less dense particles are natural soil particles, and those particles remaining in the -0.297/+0.250-mm (-50/+60-mesh) fraction after hydroclassification are more highly radioactive particles consisting of the radiominerals that constitute part of the contamination.

The process water from the vigorous wash and separation procedures on the Under-Pile samples contained less than the MDC for radium-226, 102 pCi/L, and less than or equal to 107 pCi/L radium-228, indicating that the contaminants are insoluble.

The results of radionuclide analysis for uranium, thorium, and radium for the Pile samples are presented in Table III. The data indicate that the predominate contaminants are from the thorium-232 series (thorium-232, thorium-228, and radium-228), although they are not in equal concentrations in the samples. The thorium-232 and thorium-228 concentrations range from approximately 3 pCi/g to 27 pCi/g, while the radium-228 ranges from approximately 3 to 35 pCi/g. The data also indicate that these radionuclides are in equilibrium for all but two Pile samples, P4 and P5. Radionuclides from the uranium-238 series (uranium-238, thorium-230, and radium-226) are also present in lesser amounts with concentrations ranging from approximately 2 to 10 pCi/g for uranium-238, 1 to 5 pCi/g for thorium-230, and 2 to 10 pCi/g for radium-226. The data indicate that these radionuclides are not in equilibrium since the thorium-230 concentrations are considerable less than those of uranium-238 and radium-226.

The results of analysis for select radium, thorium, and uranium isotopes for Pile whole-soil samples and their particle-size distributions produced by wet sieving and hydroclassification are illustrated in Table IV and Fig. 2 for P1 which is representative of all five Pile samples. The data from separation by wet sieving and hydroclassification illustrate that the concentrations of radium-226 and -228 generally increase as the particle size decreases. All fractions larger than 0.074*7-mesh) size contain less than 5 pCi/g radium-226 and -228. The majority of the radium contamination is in the -0.074-mm (-200-mesh) fractions ranging from 3 to 22 pCi/g radium-226 with an average of 14 pCi/g, and 6 to 63 pCi/g radium-228 with an average of 37 pCi/g. Radioanalyses of sample P1 for uranium-238 and thorium-232 and -230 (Table IV) also indicate that these radionuclides are concentrated in the -0.074-mm (-200-mesh) fraction.

Additional sieving analyses of the -0.074-mm (-200-mesh) fractions initially produced by both wet sieving and hydroclassification (see Table IV) indicate that the -0.045-mm (-325-mesh) fraction contains a major portion of the radium. Figure 3 illustrates that approximately 65 percent of sample P1 can be recovered with a radium-226 concentration of approximately 2 pCi/g and radium-228 of 4 pCi/g. The separation results of sample P1 at both 0.074-mm (200-mesh) and 0.045-mm (325-mesh) size by wet sieving and hydroclassification. Both methods produce a +0.045-mm (+325-mesh) product with less than 5 pCi/g radium-226 or radium-228 that represents approximately two-thirds of the sample. Crushing the -0.074-mm (-200-mesh) fractions before sieving at 0.045-mm (325-mesh) size (see above) may have generated additional fine particles in the samples thus altering the size distribution that would typically be found in the sample below 0.074 mm (200 mesh). Even if the particle-size distribution of the -0.074-mm (-200-mesh) fractions is not as precise as one produced from a whole Pile sample, the data do indicate that separation at 0.045-mm (325-mesh) size is a reasonable remediation candidate. This conclusion is based on the premise that the separation behavior of P1 is representative of the remaining five Pile samples, a reasonable premise since the particle-size and radionuclide distributions of all six samples are very similar.

The process water from the vigorous wash and separation procedures on the Pile samples contained less than the MDC for radium-226, 41 pCi/L, and less than or equal to 21 pCi/L radium-228.

The five Under-Pile samples contain considerably greater concentrations of radionuclides than the six Pile samples. The Pile samples contain approximately 17 pCi/g of both thorium-232 and radium-228. Radium-226, thorium-230, and uranium-238 are also present in lesser concentrations. Both wet sieving and hydroclassification of the Pile samples separated a -0.074-mm (-200-mesh) fraction that represents 47 percent of the whole sample, producing a +0.074-mm (+200-mesh) product that, in turn, represents 53 percent of the soil with an average radium-228 concentration of 1.6 pCi/g and an average radium-228 concentration of 1.0 pCi/g. Although the Under-Pile samples and Pile samples have similar particle-size distributions and are amenable to remediation from this standpoint, the radionuclide concentrations of the Pile samples from this study are considerably higher, and the concentration of radionuclides in the size fractions may well be above clean-up criteria to be established for this site (see Table II). Therefore, volume reduction by particle-size separation alone is not likely a viable option for remediating the material from under the pile represented by UP1 through UP5 in this study. In sharp contrast, soil represented by the Pile samples is a viable candidate for volume reduction by particle-size separation as illustrated in Fig. 3, with a potential

recovery of 53 percent of the soil above 0.074-mm (200-mesh) size or 65 percent above 0.045-mm (325-mesh) size containing a radium-228 concentration of less than 5 pCi/g and 15 pCi/g, respectively. No samples adjacent to the pile or adjacent to the site were provided for examination, and no conclusions about treatability of these areas can be drawn from the results of this study.

Petrographic Analysis

Petrographic examination was performed on the six Pile samples. The purpose of this examination was to identify the waste forms of the radioactivity and their distribution within the various size fractions. The mineral composition of the six samples is presented in Table V. An inspection of the composition of the soils reveals a variety of materials common to the unconsolidated surface formation of the area. The granitic rocks average 10 percent of the soil samples and are the predominant materials in the medium-to-coarse sand and the gravel-size fractions (+0.297-mm or +50-mesh). Granitic rocks contain 10-20 ppm thorium (6) and 0.15-210 ppm uranium (7) and constitute the bulk of low, and virtually equal, concentrations of the radium-226 and radium-228 reported in the medium and coarse sand and gravel-size fractions of the soil samples.

The concentrations of radionuclides increase markedly in the -0.074-mm (-200-mesh) fractions. The increase corresponds to the quantity of heavy minerals, which averages 4 percent of the soil but is restricted to this fraction. The heavy minerals range from 6 to 10 percent of the -0.074-mm material. The radioactive minerals in the heavy mineral suite are monazite, (Ce, La, Y, Th)PO4, and zircon, ZrSiO4. Analysis of the heavy minerals reveals that monazite, the chief ore mineral of rare earth elements and thorium, comprises 10 percent of the mixture. Its clean, smooth, subrounded-to-rounded appearance reflects a placer deposit origin as do many of the other heavy minerals that are commonly called gangue minerals. Zircon constitutes 7 percent of the heavy-mineral mixture.

Monazite, the principal ore mineral of thorium (primarily thorium-232), contains from 3 to 10 percent by weight thorium oxide and from 0.2 to 0.6 percent uranium-238; zircon can contain up to 4 percent thorium or uranium substituted for zirconium (8). The predominance of thorium-232 and radium-228 over uranium-238 and its progeny, thorium-230 and radium-226, in the -0.074-mm material suggests that thorium-232 and radium-228 are primarily from monazite. The thorium-232 and radium-228 are essentially in equilibrium as are uranium-238 and its progeny, indicating that no isotope has been enriched or depleted by artificial or natural means. Thus, the insoluble monazite appears to be responsible for most of the thorium-232 activity in the Pile samples with very minor amounts from insoluble zircon and possibly absorbed cations. Both minerals are from the placer ore material introduced into the host soil. The absence of specific materials typically found associated with industrial sites that chemically extract rare-earth elements or thorium is also apparent in the Pile samples from the Site. In recent investigations of another Superfund site (9, 10), one location had anthropogenic materials that reflected these industrial processes. Finger-print materials include porous, low-density calcite, gypsum, anhydrite, and calcium (thorium) orthophosphate. It is concluded, therefore, that the thorium contamination at the site is primarily the result of insoluble monazite, which comprises less than one percent of the soil by weight (4 percent of the soil is heavy mineral; of which approximately 10 percent is monazite). Zircon makes a very minor contribution.

The sample host material is generally comprised of fresh to moderately weathered, rough surfaced, subangular-to-angular, rock and mineral particles with a specific gravity averaging about 2.7. Less-dense wood particles and hollow plant stems make up less than one percent of this material. The heavy minerals (approximately 4 percent of the material) consist of fresh, smooth surfaced, subangular to subrounded particles with a grain specific gravity ranging from 3.0 to 5.2. Monazite and zircon, with grain specific gravities of 4.5 to 5.5 and 3.9 to 4.8, respectively, are the most dense of the heavy minerals and are smooth, subrounded materials that could separate well from the host material by settling in a water medium. About one-third of the heavy minerals are tabular-elongate in shape with specific gravities ranging from 3.0 to 3.4 that, because of their shape, would tend to behave more like a less-dense particle; these minerals include hornblende, hypersthene, kyanite, sillimanite, and tourmaline. Although a complete analysis was not performed on the composition of the fine silt (-0.045/+0.002 mm) and clay-size materials (less than 0.002 mm), the -0.045-mm material is believed to be predominantly clay minerals

of flat shape and light-weight specific gravity. A density separation of host materials from heavy minerals in the -0.074-mm (-200 mesh) fraction might be a candidate for removal of large amounts of the radionuclide activity from the fraction to enhance the recovery of soil material with acceptable radionuclide concentrations.

Monazite also has a magnetic susceptibility that might permit its separation on a Frantz Isodynamic Separator. The magnetic susceptibilities of the heavy minerals occurring in the Pile range from 0.0 to greater than 1.7 (11). The monazite has an intermediate magnetic susceptibility with virtually no other mineral except tourmaline, present in minuscule quantities, in the best extraction range on the Frantz Isodynamic Separator. The zircon has a magnetic susceptibility common to several other heavy minerals as well as the abundant light mineral quartz. For that reason, magnetic separation would not be a viable candidate for isolation of this contaminant.

Chemical extraction with select reagents might be exploited to solubilize the monazite and zircon in the -0.074-mm fractions (12). Radiocations absorbed on the surface of silt and clay particles might also be released by this process.

CONCLUSIONS

Soil samples from a storage pile at a DOE Superfund site were partially characterized prior to consideration of a full-scale treatability study. The primary objective was to determine if particle-size separation could be used for volume reduction of the contaminated soil. Six samples from within the pile, P1 through P6, were examined initially to assess the homogeneity of the storage pile to determine if the radionuclide contamination is similar throughout the pile, to determine if particle-size separation techniques might be effective in reducing the volume of contaminated soil, and to determine the physical form and properties of the contamination in order to evaluate other physical and/or chemical properties of these materials that might be exploited for volume reduction. Five additional samples from under the pile, UP1 through UP5, were subsequently examined to provide additional characterization of the site. This section presents the conclusions of these studies. No samples adjacent to the pile or adjacent to the site were provided for examination, however, and no conclusions about treatability of these areas can be drawn from the results of this study.

The particle-size distributions of UP2, UP3, and UP4 are very similar to each other and to the six Pile samples, P1 through P6. Each sample contains approximately 48 percent -0.074-mm (-200-mesh) material. The Pile samples may contain up to 35 percent -0.045-mm (-325-mesh) material, as indicated by additional sieving of sample P1 whose particle-size distribution is very similar to the other five Pile samples. Although UP1 is similar in particle-size distribution to UP2, UP3, and UP4, UP1 contains approximately 60 percent -0.074-mm (-200-mesh) material. Sample UP5 contains only 40 percent -0.074-mm (-200-mesh) material with more particles reporting to the fine sand-size fraction.

While the relative particle-size distributions are similar, the radionuclide concentrations in the Under-Pile samples are approximately 10 to 50 times those of the samples from within the storage pile. The predominate radionuclide contaminants in the Under-Pile samples are thorium-232 and its decay products, thorium-228 and radium-228, with concentrations of radium-228 up to 1700 pCi/g. Uranium-238 and its progeny, thorium-230 and radium-226, are also present in significant but lesser concentrations, with radium-226 concentrations up to 330 pCi/g. The major contaminants in the Pile samples are radionuclides in the thorium-232 series, with concentrations of radium-228 up to only 35 pCi/g. Uranium-238 and its progeny, thorium-230 and radium-226, are present in lesser concentrations with radium-226 concentrations less than 15 pCi/g.

The concentration of each radionuclide in the size fractions generally increases as particle size decreases. In all cases, the -0.037-mm (-400-mesh) fractions contain a much higher concentration of each radionuclide than the whole sample from which it was separated; sample UP3 contains 810 pCi/g radium-226 in the -0.037-mm fraction compared to an average of 231 pCi/g in the whole sample. Radionuclides in the -0.074-mm (-200-mesh) fraction of the Pile samples and the -0.045-mm (-325-mesh) fraction of P1 represent much of the contaminant content in these samples. Radionuclide analyses of the whole sample and size fractions from P1, for example, reveal that the whole sample contains 6 pCi/g radium-226 while the fractions larger than 0.074-mm (200-mesh) contain 3 pCi/g or less radium-226. The -0.074-mm

(-200-mesh) fraction contains approximately 12 pCi/g and the -0.045-mm (-325-mesh) fraction contains 14 pCi/g.

Wet sieving and hydroclassification of the Under-Pile samples produced similar results except for one size fraction, -0.297/+0.25-mm (-50/+60-mesh). This fraction produced by hydroclassification contained approximately 85 percent less material than that produced by wet sieving, likely as a result of hydrodynamic behavior of less dense particles from the -0.297/+0.250-mm (-50/+60-mesh) fraction. Wet sieving and hydroclassification of the Pile samples produced almost identical results. The process water from the separation procedures on the Under-Pile samples contained less than the MDC of radium-226, 102 pCi/L, and less than or equal to 107 pCi/L radium-228. The water from the separation procedures on the Pile samples contained less than MDC of radium-226, 41 pCi/L, and less than or equal to 21 pCi/L radium-228. These results indicate that the radionuclides are essentially insoluble in water.

Radionuclides in the thorium-232 series are in secular equilibrium in the whole Under-Pile samples, while those in the uranium-238 series are not. In the Pile samples, the thorium-232 series is in secular equilibrium, except for samples P4 and P5. The uranium-238 series is not in equilibrium in any of the Pile samples since the thorium-230 concentrations are significantly less than those of uranium-238 and radium-226.

Although the particle-size distributions of the Under-Pile samples indicate the samples from under the pile are conducive to separation by particle-size, the radionuclide concentrations of all radionuclides reported are higher than those of the six Pile samples analyzed from the storage pile, and the concentrations throughout the soils are above acceptable clean-up criteria for most sites. Therefore, volume reduction by particle-size separation, alone, of the Under-Pile samples examined in this study is not a viable option for remediation, although other physical properties of the contaminants, such as density, might be used to achieve this goal. In contrast, the particle-size distribution of the Pile samples indicates that 53 to 65 percent of the samples could be recovered by particle-size separation with radionuclide-contaminant concentration of less than 5 or 15 pCi/g, respectively. The data indicate that these results could be accomplished by separation at 0.074 mm (200 mesh) or 0.045 mm (325 mesh), respectively.

The primary source of the thorium radioactivity in the Pile samples is monazite. Zircon is also present and contributes a small amount of thorium to the sample. The monazite and zircon are concentrated in the fine-sand to upper silt-size range, -0.149/+0.037-mm (-100/+400-mesh). The specific gravities of the monazite and zircon are about two units above the average specific gravity of the host material. Density separation might be used to provide additional volume reduction of these fractions. The magnetic susceptibility of monazite is in a unique range, when compared to other magnetically susceptible minerals, this might also offer a separation method to reduce the volume.

Chemical extraction might be employed to solubilize the monazite and zircon in the -0.074-mm (-200-mesh) fractions. Any radiocations absorbed to the surface of these particles might also be released during these procedures.

TANGENTIAL SCANNING SYSTEM FOR WASTE DRUM INSPECTION

Nand K. Gupta, Ph.D.
Omega International Technology, Inc.
460 Wegner Road, Lakemoor, IL 60050-8653

ABSTRACT

We have developed an advanced x-ray Tangential CT Scanner System to image and automatically detect flaws in rocket motors, warheads and missiles under a SBIR contract from the Naval Surface Warfare Center. The prototype scanner system uses a linear array of 160 solid state x-ray detectors and a 320 kV x-ray tube. During the scan, the rocket motor rapidly rotates around it's own axis and the detector array slowly translates, slowly varying the diameter of the tangential path in the rocket motor. In priciple, this scanning method is analogous to unrolling of a roll of paper towel. The x-ray scanning is continued until the entire radius (for 180oC scans) or the diameter (for 360o scans) of the rocket motor is covered by the tangential path Each individual detector scans a single CT slice of the rocket motor. The 160 detector array simultaneously collects raw data for 160 individual CT slices and covers the entire length of a 10" long rocket motor. Thus such a scanner system is a true volume CT imaging system. In addition to the hardware, we have also developed a windows based unique data analysis and display software with this system. Our software package displays the entire volume of collected data from the tangential scanner in three different modes. In first, mode the data is displayed in the form of Tangential views at various radius of the object. The second mode displays the data in the form of sinogram for each detecor of the detector array. The third mode displays the data in the form of many digital x-ray radiographs of the object from various directions.
Tangential scanning scheme has a great potential for low and high level Nuclear Waste Drum and other similar objects. The tangential scanner system naturally collects hundreds of digital radiographic images at various rotational angles in very short period. For comparison, the recently purchased digital radiographic system by the WRAP-1 at Hanford is expected to collect only two digital radiographs of each waste drum. The tangential views from such a scanner system are very sensitive to the defects in the wall of the drums. Our initial experiments with a simulated waste drums clearly show that quantitative measurements of the actual wall thickness and wall material loss due to corrosion can be easily measured with the tangential scanner system.
At present, we are searching for funds to develop and fabricate a prototype tangential scanner system suitable for actual production applications. Our proposed system will be able to collect individual Digital Radiographs in <5 seconds and complete tangential scans in about 2.5 minutes

INTRODUCTION

We have developed an advanced x-ray Tangential CT Scanner System to image and automatically detect flaws in rocket motors, warheads and missiles under a SBIR contract from the Naval Surface Warfare Center. The prototype scanner system uses a linear array of 160 solid state x-ray detectors which is placed parallel to the axis of the rocket motor. A 320 kV x-ray tube is located on one side of the rocket motor and the detector array on the other side. The x-ray tube and the detector array are

mounted on a C-arm with a pivot point at the x-ray focal spot. The rocket motor sits on top of two rollers. One of the rollers rotates the rocket motor while the other containing an encoder tracks the azimuthal location of the rocket motor. An indexing motor rotates the detector array slowly around the pivot point i.e. the x-ray focal spot. The x-ray beams from the focal spot to the detector array form tangential paths in the rocket motor. Figure 1 show the top and side views of this system. During the scan, the rocket motor is rapidly rotated around it's own axis and the detector array is slowly rotated around the x-ray focal spot (pivot point) to slowly vary the diameter of the tangential path in the rocket motor. In principle, this scanning method is analogous to unrolling of a roll of paper towel. The x-ray scanning is continued until the entire radius (for 180o scans) or the diameter (for 360o scans) of the rocket motor is covered by the tangential path. The detectors measure the x- ray intensity through all possible tangents through the object. Each individual detector scans a single CT slice of the rocket motor. The 160 detector array covers the entire length of a 10" long rocket motor. Thus the scanner system is a true volume CT imaging system.

The prototype system uses a 320 kV Pantak high frequency constant potential x-ray system. The system uses a high performance x-ray detector system specifically developed for this system by Omega. Though the prototype scanner system only uses 320 kV x-ray source, the detector system is designed for up to 450 kV x-ray energy. The hardware design of this scanner system has several unique and substantial advantages over the presently available CT imaging systems. Few of the major advantages are that this system design leads to significantly faster scanning time, better image contrast and simultaneous volume scanning. This system is particularly suitable and extremely sensitive to the unbond type defects in rocket motors.

The tangential imaging is known to be very sensitive for the detection of unbonds and other defects which are parallel to the wall of the object. At present, the motor manufacturers use x-ray tangential film radiography to detect unbond defects. The film radiography requires x-ray exposures from many directions to cover the entire rocket motor. Even with many exposures, often small unbond defects can be missed. The tangential scanner collects data from all directions and thus even small defects are naturally detected with the present system.

In addition to the hardware, we have also developed a windows based unique data analysis and display software with the system. Our software package displays the entire volume of collected data from the tangential scanner in three different modes. All three modes of data display are simultaneously available in real-time. The actual data collection concept and three modes of display are shown at the top of Fig. 2.

In one mode the data is displayed in the form of Tangential views at various radius of the object. This data display is equivalent to unfolding a roll of paper towel one layer at time. This mode displays the unrolled view of each layer at a time. Any and all individual layers of the object can be viewed in this mode. The data display in this mode is very sensitive to the unbond defects.

The second mode displays the data for each detector of the detector array. The individual detector data is a sinogram for an individual slice of the rocket motor. The individual Sinogram from each detector is a complete set of raw data which can be used to reconstruct individual CT slices. Thus the Sinograms from all detectors together can be used to reconstruct all CT slices of the entire object i.e. volume CT image of the object. Data from each detector is contained in one layer of the detector data set. Since our scanner has 160 detectors, there are 160 layers of sinogram data available to the operator.

The third mode displays the data in the form of digital X-ray radiographs of the object. The total data set is organized in layers where each layer contains one radiographic image of the object. The successive layer in this mode are x-ray radiographs after a slight rotation of the object. This mode is similar to radiographic images of a rotating object in a real-time radiography (RTR) system. Operator can roam through various layers of the data set and actually view successive radiographic images as the object rotates. In a typical x-ray data set, there may be several hundred to several thousand such digital radiographs available. For comparison, in a typical digital radiography system, only one or two such digital x-ray radiographs are collected for any object.

The tangential CT scanning system has a great potential for inspecting small and large Rocket Motors, Warheads, Missiles. The data collected from a rocket motor

phantom is displayed at the bottom of Fig. 2. This phantom is made of a 4" diameter cylindrical pipe filled with simulated rocket fuel. Another 1.5" diameter tube is located in the middle of this phantom. This 1.5" diameter tube extends from one end to only the middle of the phantom along it's length. This particular phantom contains two unbond type defects between the simulated rocket fuel and the external 4" wall. It contains two unbond types defects between the simulated fuel and internal 1.5" wall. It also contains two notches cut out at the inside of the internal 1.5" wall along it's full length.

In Fig. 2 all three views i.e. tangential, detector sinogram and radiographic views are shown in that order for the navy phantom. The left side image of this figure shows the tangential view. In this view we see several bright sections in the image indicating larger x-ray signal or loss of material due to unbond defects. Due to 360o scanning, each defect shows up two times in the tangential data, once when the defect is towards the x-ray tube and second time when it is towards the detector side. We also see indication of two notches which extend from one end of the image to the middle of the image.

The middle image of this figure shows the detector sinogram view. In this view we see two faint sine waves in the middle which extend only to the inside wall of the internal 1.5" tube. This is a signal from the two notches towards the inside of the internal tube. These two sine waves are also out of phase from each other, indicating that these notches are 180o. from each other. We also see a fairly bright sine wave which extends to the outside wall of the internal tube, indicating a unbond defect on the outside of the internal 1.5" tube. We also see a faint indication of another sine wave which extends to the outside wall, indicating a unbond at the outer wall. Since the defects are located at different locations along the length of the phantom, all defects do not show up in this particular detector. Other unbond defects are indicated in other detector Sinograms.

The right side image of this figure shows the radiographic view of the phantom. In this image we see the presence of the two notches and several unbond features. When we view the successive layer of the radiographic view images, we view the rotation of the notches and unbond features. Again, the notches extend only to the middle of the phantom along it's length. Two of the unbond features travel to the outside tube while the other two travel to the inside tube of the phantom. Thus each of these three image views contains sufficient information to exactly pinpoint the extent and location of a defect. The three views together make it significantly easier to find the location and amplitude of the problem.

In addition to the rocket motors, the system has a great potential for low and high level Nuclear Waste Drum and other similar objects. The tangential scanner system naturally collects hundreds of digital radiographic images at various rotational angles in very short period. For comparison, the recently purchased digital radiographic system by the Westinghouse Hanford group is expected to collect only two digital radiographs of each waste drum. If desired, the data collected from the tangential system can also be used to reconstruct a volume cross sectional CT image of the waste drum.

The tangential views from the tangential scanner system are very sensitive to the defects in the wall of the drums. Our initial experiments with a simulated waste drums clearly show that quantitative measurements of the actual wall thickness and wall material loss due to corrosion can be easily measured with the tangential scanner system. The wall measurements can be made independent of the complexities and the contents of the drum. This makes such a system concept extremely suitable for quantitative measurement of the drum wall integrity.

We had constructed a small phantom to simulate the waste drum filled with unknown waste. Since our prototype tangential scanner is designed for objects up to 14" diameter only, we can not use an actual waste drum for experimentation. Also, our prototype scanner is designed to scan the objects with their axis in horizontal direction only. To construct the simulation phantom, we used a six gallon water bottle. From the top of the bottle, we mounted three objects to simulate random waste. These three objects are an empty glass bottle, an empty aluminum pop can and a 3/8" diameter threaded steel rod. These objects were mounted on a " thick wood disk and hung from the top of the six gallon plastic bottle. To simulate the steel wall of the drum and it's corrosion, we surrounded the plastic bottle with a 0.031" thick steel sheet. At few places we placed additional pieces of 0.031" thick steel sheets. This gave us the simulated wall thickness of 0.031", 0.062" and 0.093" at

different places of the drum phantom. Also, we had drilled six small holes to simulate pinholes in the drum wall due to corrosion. The diameter of these six holes ranged from 0.037" to 0.127" and they were drilled in region where the wall thickness was only 0.031" i.e. single sheet of 0.031" steel. The photographs of this simulation phantom as constructed and during actual scan in our prototype gantry are shown in Fig. 3. In this figure, the bottom left photograph shows the inside components of the phantom before final assembly. The top left photograph shows the steel band with area of 0.031", 0.062" and 0.093" thicknesses and six holes ranging in diameter from 0.037" to 0.127".

In the right side of Fig. 3, we present part of the data from the simulation phantom. This figure shows the three views of the data display as discussed before. The left side view shows the tangential views of the data. The data shown in this view is the 63rd tangential layer of the data. As discussed before, it is a 360 degree circular layer data unfolded. In this tangential view, one can easily see sections with different thickness of steel sheets. We also see the region with six holes in the steel sheet. As discussed before, all of these features show up twice in the data, once when they are towards the x-ray tube and second time when they are towards the detector array. The data also shows the presence of the glass bottle, empty pop can and other features inside the plastic bottle phantom. In this figure, the middle view shows the detector sinogram data. The data shown in this view is for detector number 80. The data clearly shows the sine waves due to various thickness regions of the steel sheets. When a detector is lined up with one of the holes, data also shows the sine waves due to holes as well. In addition to the steel sheets, the data also shows the sine waves due to other objects inside the plastic bottle phantom. The right side view in this figure, shows the radiographic image of the data. The data shown in this view is the 181th radiographic view. The data in this clearly shows the presence of several thickness of the steel sheet and six holes. It also shows the presence of the glass bottle and empty pop can among other things. If we try to view the successive radiographic views, we find images similar to images from a real time radiography system with the object rotation.

This limited experimentation with the simulation phantom clearly shows that the tangential scanning system has capabilities far beyond any presently available technologies for characterization of waste drums. Specifically, the wall of the drum can be analyzed with the tangential system without interference from the content of the drum. This is an unique and powerful method to examine the condition of the drum wall without an advance need to know what is inside the drum. Figure 4 shows a system concept for scanning a waste drum in production application. The drum is located vertically on a rotary motion stage. The rotary stage is mounted on a linear conveyor belt or some other type of linear motion system. The solid state detector array is located on one side of the waste drum and the x-ray tube on the other side. At present, we are searching for funds from DOE to develop and fabricate a prototype tangential scanner system suitable for actual production applications. In our proposed system, there will be 600 detectors and the length of the detector array will be sufficient to cover the entire drum. The energy of the x-ray tube will be 450 kV and is sufficient to penetrate the drum and it's contents. The drum rotates around it's axis at maximum speed of about 30 RPM and maximum linear speed of the conveyor belt will be about 60 cm per second.

Following are the scanning time estimates for various scan modes for an entire waste drum using the proposed prototype designs.

Digital Radiography for initial mode	< 5 seconds
High Resolution Digital Radiography	< 5 seconds
Regular Tangential scan	2.5 minutes
High resolution tangential scan	10 minutes

Following are the tentative design specifications of our proposed system

1) Detector and data acquisition system

Total number of x-ray detectors	600
Detector active area	3.3 mm x 3.3 mm
Total length of detector array	198 cm
Detector system dynamic range	16 Bits (65535 levels)
Maximum data rate	300,000 readings/second

The detector array will be placed in the vertical direction on an arc and will view the entire height of the waste drum.

2) System geometry

Focal spot-to-detector distance	272 cm
X-ray beam fan angle	40.0o
Focal spot-to-drum distance	132 cm

3) X-ray system

Maximum x-ray energy	450 kV
Maximum mA	10 mA

4) Motion system for drum

The x-ray tube and the detector array will mostly remain stationary in the tangential scanner system. Mostly the waste drum will carry out all required motions to collect the tangential scan data. The drum will sit on a rotary motion stage. The rotary motion stage will be located on the top of a linear motion system. Thus the drum will provide linear and rotary motions. For high resolution digital radiography imaging, the x-ray tube system will provide a very small added up-down linear motion. During the high resolution digital radiography scan, after the first pass of data collection, the x-ray tube will move by 1.6 mm in upward direction to collect the data for the second pass.

Maximum linear speed of drum	60 cm / second
Maximum rotation speed of drum	30 rotations per minute

5) Scanning schemes

For digital radiography for initial sorting, the drum will traverse (without rotation) through the x-ray fan beam at a speed of about 60 cm per second to collect such scans. This will collect a digital radiographic image of the entire drum within < 1 second.

For high resolution digital radiography, the drum will traverse (without rotation) through the x-ray fan beam at a speed of 30 cm per second to collect first pass of the digital radiographic data. After the first pass, the x-ray tube will rise vertically by 1.6 mm and the drum will traverse backwards through the new x-ray fan beam to collect the second pass of the radiographic data. The data sets collected during these two passes will be interleaved to reconstruct a high resolution radiographic image.

For regular tangential scan, the drum will simultaneously make linear and rotary Motion to collect tangential scan data. For 180o scans, the drum will travel by a distance which is equal to it's radius (about 30 cm) while also rotating. For 360o scans, the drum will travel by a distance which is equal to it's diameter (about 60 cm) while also rotating. The linear speed of the drum will be about 4 cm per minute, and the rotation speed of the drum will be about 2.4 seconds per rotation (or 25 RPM).

For high resolution tangential scan, the drum will simultaneously make linear and rotary motion to collect high resolution tangential scan data similar to case before. The only difference between the regular and high resolution tangential scans is the speed of translation and rotation. In high resolution scan, the rotation speed is and the linear speed is 1/4 of the regular scan. Thus the system collects 2 times more data points for each rotation and there are 2 times more rotations in the high resolution data set.

6) Spatial resolution expected in the middle of a 55 gallon drum

Digital Radiography for initial mode	1.6 mm x 1.6 mm
High Resolution Digital Radiography	0.8 mm x 0.8 mm
Regular Tangential scan	1.6 mm x 1.6 mm x 1.6 mm
High resolution tangential scan	1.6 mm x 0.8 mm x 0.8 mm

7) Volume CT reconstruction time estimates for the tangential data

Detectors added together for CT slices	5
Reconstructed CT slice width with 5 detectors	8 mm
Number of CT slices reconstructed	120
Reconstruction time for regular scan	5 minutes
Reconstruction time for High resolution scan	20 minutes

At present, we are fabricating an experimental system which will use fewer detectors and slower data collection system for demonstration to potential users even before DOE funding can be found.

REMOTE TECHNOLOGIES FOR VENTING, PURGING AND OPENING DRUMS OF TRANSURANIC WASTE
J.R. Brault
Westinghouse Savannah River Co
INTRODUCTION
During four decades of operation the DOE complex has produced hundreds of thousands of drums of transuranic (Tru) waste. These drums were packed and have been stored with the best available technology at the time of their creation. Many of these drums are not packed in a manner that is suitable for long term storage by today's standards. Many are in earth covered storage. These drums will be retrieved from their current storage, repackaged and put into a long term storage facility such as the Waste Isolation Pilot Plant (WIPP).
In the summer of 1991 the Equipment Engineering Section (EES) of the Savannah River Technology Center (SRTC) was given the task of developing methods to sample and vent head space gasses in unearthed drums and opening and removing the waste from these drums. EES began this program by investigating the existing technology to accomplish these tasks that already existed within the DOE complex. In meetings with engineers from other DOE sites many concepts were evaluated. During FY92, FY93, and FY94 EES designed, fabricated and tested equipment based on these evaluations. The following report is a summary of this work.
DRUM VENTING AND PURGING
One of the problems of dealing with Transuranic waste is how easily the contamination is spread. Even today much of the waste generated is bagged out of contaminated areas in plastic before being placed into waste containers. Radiolysis of these plastics produces hydrogen. In addition, volatile organics were used in many cleaning processes in contaminated areas and these also were placed into waste containers. Modern waste containers have vents with filters that allows these gasses to vent preventing a build up of dangerous concentrations. During the era when transuranic waste was buried in drums, these drums were sealed with gaskets and had no filter vents installed. During retrieval the head space gasses of these drums must be sampled and analyzed to determine if flammable mixtures of hydrogen or volatile organic vapors are present. If dangerous concentrations are found the vapors will have to be purged from the drum before they can be transported. At that time a filter vent will be installed to prevent further build up.
To sample the head space gasses the drum must be penetrated. This penetration creates a potential path for the spread of contamination. To solve this problem a chamber with a seal at the spindle penetration and a seal where it attaches to the drum are used. This ensures the containment of any contamination. In addition this allows a vacuum to be drawn in the chamber before the drum is penetrated. In this way an undiluted sample of the headspace vapors can be drawn from the drum for analyses. Two other potential causes of releasing contamination are removing the penetration tool and removing the chamber to install the filter. So a filter with a penetration tool attached was designed. In this way the penetration can be made, the gasses sampled and the filter vent installed while the vacuum chamber is installed. Because of solid objects that may be near the top of a filled drum the penetration tool should be designed as short as possible. The penetration tool also has to be designed to minimize the chance of creating an ignition source. 3/8" drills with titanium carbide coatings have been tested on 1/4" plate steel and have not created temperatures that exceed the auto ignition temperature of hydrogen.
At the time the sealed drums of transuranic waste are unearthed they will have to be handled as if the headspace gasses are flammable until the chemistry of the gasses can be analyzed and shown to be safe. Although analyses has shown that detonations will not occur, if a deflagration were to occur contamination would be spread. Workers will have to be protected from the potential hazards. For this reason a system that can be easily transported to the retrieval site is highly desirable.
The potential spread of contamination from a breached drum does not pose a threat to employees not at the immediate work site or to off site exposure. But if the threat of breaching a drum exists the workers in the immediate area must be protected. If this is done with personal protective equipment several operational considerations become factors. Waste in the form of protective clothing is generated every day. In addition there is a loss of productivity when working in protective equipment along

with the time of dressing out several times each shift. By placing the drum in a containment or confinement system the operators are protected from possible contamination if a breach occurs.
Testing was conducted with a variety of penetration tools. Initial tests were performed with slow and high speed punches of various configurations. These produced rough holes that were difficult to seal the filters on. 1" drills were tried but required high torque. Even step drills would stall out a one horsepower spindle when the large diameter broke through the sheet metal drum lid. Hole saws required less torque but had difficulty starting on the sloped drum lid. Hole saws with pilot drills were tried with success. Clean holes were produced consistently without overloading the motor. After producing a series of holes, filter installation was attempted. High starting torques were required for the large filters. This would often cause the threads to strip. Reducing the torque would cause the unit to stall before the filter was completely seated.
Next a series of tests were conducted using filters with 7/16 inch diameter threads. U, V and W drills were tried, all successfully drilled clean holes. Seating of the filters was more difficult. Both the U and V drills would require high torque sometimes stalling before the filter was seated. Other times they would strip the threads off the filter. The W drill provided holes that the filters could be reliably seated in. Several holders for the filters were designed and tried. Ease of loading and concentric holding to prevent drill point wobble were the criteria. Holders using the hexagonal shaped filters proved troublesome and complicated. By using a round filter body with groves for a key way drive a simple filter holder was designed. The vacuum chamber was tested and holds vacuums to less than 1/20th of an atmosphere.
DRUM OPENING
After the drums have been retrieved and sampled they will have to be opened and the contents processed and repackaged for long term storage. This could be performed hands-on because of the low dose rates. Some of the advantages of doing this remotely are the reduction in personnel exposure and the avoidance of new waste generation, in the form of protective clothing. The condition of the drums will be highly variable, some will be dented and/or corroded. The contents will also be inconsistent. Some of the drums will have containers of liquids, glass, heavy objects, aerosol cans, containers of fine powders, etc. The opening equipment will need to minimize the disturbance of the waste and minimize the spread of contamination.
To minimize the spread of contamination it was decided to open the drum and remove the contents rather than to try and pour contents from the drum. In this way the contents could be handled individually without the risk of heavy objects crashing down on soft bags or fragile containers that could cause excessive contamination inside the cell. The equipment was designed to cut the drum away from the liner then cut off the liner top. Attempting to remove the lids remotely introduced several technical problems that would have made the equipment complicated. In addition rotating tools around the drum would add complexity. The design configuration selected has a turntable to rotate the drum and tools mounted to vertical tool posts, basically a vertical turning lathe. Tools were tested to determine which were most effective in remote operations. The main criteria were repeatable remote operation, minimum penetration into the drum and minimum production of secondary waste from the cutting operation. Since the drums will vary in condition a variety of cutters will be required. Tests were conducted on the drum with a rigid pipe cutter, a pneumatically driven compliant pipe cutter, a parting tool, a pneumatic circular saw and a router. Tests on the liner were conducted with a rigid knife, a heated rigid knife, a pneumatic saw and a pipe wheel cutter.
The rigid pipe cutter was tested using a constant RPM on the turntable and a constant feed rate on the cutter. The drum rotation was initiated, then the cutter advanced until it contacted the drum. At that time the constant feed rate was set. Feed rates of .002 to .005 in/rev were tested at turntable speeds of 20 to 70 RPM. When the higher feed rates were tried the surface of the drum would roll into the liner during cutting, producing a large burr and causing it to grip the liner. This made removing the drum from the liner difficult. Turntable rates above 50 RPM caused excessive vibration because the drums are out of round. This also directed us to using a large pipe cutter wheel, 2.2 in. diameter, which helped keep the tool holder from running into the drum side wall. Turntable speeds of 50 RPM with feed rates of

.003 in/rev produced clean cuts. Cycle time at these speeds were between 3 and 4 minutes.
The compliant pipe cutter was tested using a rigid slide driven by a 2 inch pneumatic cylinder, RPM and air pressure were held constant during each test. The cutter would track the surface of the drum as it rotated. Two stand off wheels were mounted above and below the cutter to prevent deep penetration into the drum when it broke through. Tests were conducted between 25 and 75 RPM and with pneumatic pressures of 30 to 70 psig. Again clean cuts were obtained most of the time. Running at 40 RPM and 70 psig the cycle times were between 2 and 3 minutes. Problems observed with this system were a jack hammering effect that would sometimes occur. When this happened the drum would end up with a series of dents that would make removing the lid difficult.
The rigid parting tool consisted of a standard 1/8 in. thick lathe cutoff tool. The parting tool was fed off a rigid arm at a constant feed rate. Speeds tested were 20 RPM and .0015 to .003 in/rev feed. The cuts began nicely but as soon as one section cut through it would snag the drum and lock up the system. Cutting thin wall members with a cutoff tool is difficult because even though the tool may be rigidly held, the wall will flex during the cut and spring out when the first break through occurs. This results in too high a feed to the cutting edge just past the break through.
The pneumatic circular saw was a one horsepower saw with a 4 in. 36 tooth metal cutting blade. The saw was to be slowly brought in and then the drum slowly rotated. Feed rates for the saw were .01 to .001 in. per second. The saw blade stalled each time a cut was attempted.
The router tests were conducted in partnership with Merrick Engineers from Los Alamos who are developing a system for Idaho National Engineering Lab. The router consisted of a one horsepower high speed spindle. Tests were conducted between 2,000 and 12,000 RPM and feed rates 4 to 18 in/min. It was discovered early that very light tooth loading, around .0003 in. to .0004 in. worked the best. Carbide cutters were used that held up to the heat. Best results were with a 1/4 in., 2 fluted end mill run at 6,000 RPM with a 4 in/min feed rate. At this speed it would take nineteen minutes to cut the circumference of the drum. This is a long cycle time in addition to the chips produced. The advantage of this system is it has great flexibility and can be used on seriously damaged or dented drums.
The rigid knife tool on the liner consisted of a modified lathe cutoff tool with a sharpened edge. It was fed at a constant rate into the side of the liner being rotated at a constant rate. Tests were conducted between 10 and 20 RPM at feed rates of .030 to .060 in/rev. This tool produced clean cuts with no chop generation at cycle times of 3 to 4 minutes. However as the tool began to break through, torque generated by the cutter on the uncut edge would cause the top portion to twist and violently whip about. In addition the edge would usually grab at some point and cause the liner to spin inside the rotating drum preventing the cut from being completed. The knife was then electrically heated to 350 degrees F. Cuts were performed in 2 minutes using a feed of .005 in/sec at 10 RPM. When the heated knife broke through the there was none of the violent action seen with the unheated knife.
A pneumatic circular saw was tested in a similar manner as with the drum cut. A 4 in. diameter 20 tooth carbide tipped plastic saw blade was used. It was advanced into the liner and then the liner slowly rotated. Turntable speeds of between .12 and .45 Rpm were tried. Cutting times were between 2.2 and 5 minutes. The saw cut the liners but produced many chips as was expected. In addition the liners had a wide variation of wall thickness, at points being 1/4 in. thick. At these extreme thicknesses the saw blade would stall.
A rigid cutter wheel, similar to the pipe cutter was tested. A wheel made for plastic was used. Feed rates of .003 in/rev with a 30 RPM turntable speed were used resulting in 7 minute cycle times. The cuts were of good quality but had a larger cycle time than other techniques.
SUMMARY
By integrating the penetration tool with the drum filter, drums of transuranic waste can be sampled, vented and have filters installed in a single, sealed operation.
A variety of tools will need to be available for remote opening of drums and liners. The rigid pipe wheel cutter produced good results on the metal drum with good cycle times while producing no chips. The problem with this cutter is that it will not perform on badly dented drums. For this reason another cutter like the router must

be available since some damaged drums are to be expected. A vacuum system will be needed to control chips. The heated knife was a reliable performer as a liner cutter and also produced no chips. This cutter though, can also have some problems particularly if there are large solid objects pressing out from the inside of the liner. Here too the router, running at a lower RPM, will prove effective.

ENVIRONMENTAL RADIOACTIVITY MONITORING, USING HELICOPTER-BORNE GAMMA MAPPING EQUIPMENT RESULTS AND RECENT ADVANCES
C. Bourgeois
M. Fourgoux
L. Guillot
C. Bergey
Commissariat l'Energie Atomique - Centre de VALDUC
21120 IS-SUR-TILLE (France)
ABSTRACT
The French Commissariat for Atomic Energy (CEA) has been developing for some 10 years, at VALDUC Centre, a new system of helicopter-borne gamma mapping. This system enables to map, in a few hours, the radioactivity of large areas spreading over several km up to several hundreds km, by identifying the radioelements involved, with a sensitivity ranging from the natural radioactivity level, up to those man-made radioactive levels due to an accident. In the event of nuclear accidents, such a system may be rushed to the scene, all over the country. Fitting out the helicopter, surveying a 5-10 km2 area and plotting the first contamination maps take approx. 4 hours only.
By developing new methods for analyzing helicopter-borne gamma mapping measurements, provision is made for detecting the major natural and/or man-made radioelements at ground-level, with sensitivities in the order of the natural radioactivity background level (Detection limit for Cs-137=2kBq/m).
The use of digitized 3-D maps in support to isoactivity maps improves the readability and increases the bulk of information available. Furthermore, this mapping method is applicable to environmental monitoring purposes, for the surveillance of industrial and agricultural pollutions.
FOREWORD
In any site restoration operation, the initial step is site characterization. From various characterization methods, the helicopter-borne gamma mapping is a high-grade technique, as it allows to plot, in a few hours only, the whole radioactivity map of extensive areas (from a few to up to several hundreds km), with no need for allocating ground resources, and without exposing any operator to high potential risks.
With the recent improvements brought to this technique, especially in regard of sensitivity, it is possible as from now, to apply it to monitoring the restoration work required for bringing back any contaminated area, to a radioactivity status close to natural background.
The CEA has available, for the 10 past years, a fully equipped system called HELINUC (1,2), which is described hereunder with relevant examples, and information on current developments for improving both sensitivities and map layout.
PRINCIPLE AND DESCRIPTION
Introduction to the Phenomena
The various natural or man-made gamma-emitting radioelements, liable to be detected via helicopter-borne gamma spectrometry range within 0 to 3 MeV. Hence, the spectrum detected after absorption or diffusion in the atmosphere features summing of two components :
  a series of full-absorption peaks centering on the radioelement-emitted energy, and with their FWHM as bound to detector resolution,
  a noise distributed over the whole energy range, denoting the energy distribution of Compton scattering in both the atmosphere and detector, of the cosmic radiation, of the noise originated by the equipment...
Experimental Device
The helicopter-borne device comprises a NaI detector with a capacity of 16 liters, connected to a spectrometer for signal analysis with 256 or 512 channels, ranging from 30 to 3200 keV.
Positioning of the helicopter is ensured by either a Trident transponder or a Global

Positioning System (GPS).
The Trident transponder queries the ground-level beacons set up at known geodetic points, computes the distance between the helicopter and such beacons, inferring the helicopter position with an accuracy within a few meters.
The Global Positioning System (GPS) is a satellite positioning system used in many applications, which has already been fully described elsewhere. The GPS will be soon replaced by a differential GPS featuring an accuracy equivalent to the Trident system.
The flight altitude is accurately measured by altimetric radar. The spectrum and position data management is ensured by a computer that stores the data on a Bernoulli magnetic unit.
Data Collection
The detailed site analysis provides for scanning over the area to be surveyed, according to the following set parameters : pattern size, altitude, speed, and time integration.
Fig. 1. Data collection - block diagram.
Every 2 or 3 seconds, the system records a full spectrum within the 30-3200 keV energy range, together with the helicopter X, Y, Z coordinates.
Mapping
The data collected and stored on magnetic support is processed by a dedicated ground-based computer. On the basis of the flight data record, colour-maps are processed and overprinted on topographic maps. Processing starts with the trajectory checks. Once the potential aberrant points are corrected, then starts reading of the spectra related with every measured point, and also identification of the radioelements involved. Selecting a detection window for each detected radioelement allows further computation and mapping of the standard variation of same at a reference altitude.
The isoactivity map for cesium-137 in Koslodoui N.P.P. (Bulgaria) is shown in Fig. 2.
Such maps provide, in a very short space of time, the position of the contaminated areas, which could be, in the event of any nuclear incident, usefully handed over to competent authorities.
RESULTS AND APPLICATIONS
Equivalent-Surface Activity
Any emission of radioelement detected by the data acquisition unit comprises both :
  the emission of the radioelement at the ground surface,
  the emission of such radioelement migrating into the soil.
The attenuation of the detected signal is all the more significant as such radioelement is deep in the soil and radiation energy is low. The equivalent surface activity refers to the activity arising from the remaining surface deposition of such radioelement and the (non absorbed) detectable portion of same as attenuated by burying.
In practice, with respect to cesium-137, only the initial 5 centimeters contribute to the measurement.
System Detection Limits
Under normal operating conditions :
Integration time : 3 sec.
Flight altitude : 50 meters
Flight speed : 70 km/hour
The detection limits are as follows :
Insert a
Application to Incidental or Accidental Situations
4 people are required to operate the equipment. In France, it can be operational within 12 hours, and moved to any point of the country, in an air-transport vehicle. Fitting out the helicopter, surveying a 5-10 km2 area and plotting the first contamination maps take approximately 4 hours only.
Application to Environmental Surveys
The airborne gamma mapping system offers multifarious applications. In France, the functions assigned to this system cover the following :
  systematic radiological surveillance of military sites,
  radiological surveillance and monitoring of nuclear sites, e.g. environmental surveillance of nuclear power plants,
  environment radiological surveillance of industrial sites ; refer to the

surveillance of the Danube river banks, on behalf of IAEA, in 1992 (3,4).

CURRENT DEVELOPMENTS

Mathematical Processing of Spectra(5)

The gamma spectrum analysis consists in extracting the spectrum full-absorption peaks, as only these peaks depict the nature and activity of the radioelements at ground-level. The method for peak positioning and quantification has to consider the three cardinal constraints in airborne spectrometry, namely :

the scintillation detector (NaI) features resolution varying from 8 to 10%, which makes the nuclide identification a rather tricky point, especially when they are numerous, or when their energy values are close (convoluted picks),

the counting time, necessarily low to keep up with a satisfactory spatial resolution, often results in poor counting statistics,

the distance between the source and the detector attenuates significantly the signal-to-noise ratio.

A genuine mathematical spectrum processing has been developed to analyze airborne gamma spectra. This consists in searching for the absorption peaks over the whole energy range, without making any assumption as to the nature of the radioelements involved. The relevant algorithm includes the following steps :

Use of filter algorithms adapted to the spectrum characteristics enabling to break away from the high statistical fluctuations without changing the spectrum shape.

Searching for the absorption peaks by means of one or two spectrum derivations, with prior filtering. Hence, low-intensity peaks may be located in terms of background noise.

Modelling and subtraction of the Compton scattering background enables to compute the full-absorption peaks of various radioelements.

The absorption peaks derived from processing are then subjected to validity checks for FWMH and from the statistical standpoint.

The advantages of such a process are highlighted in a typical background noise spectrum, as shown in Fig. 3 and Fig. 4. Its purpose is twofold :

systematic detection of those radioelements with absorption peak intensities higher than the detection threshold ;

provision of a sensitivity gain varying by a factor of 2 to 5 in terms of signal-to-noise ratio.

Fig. 3. Background noise spectrum and modelized Compton scattering background.

Fig. 4. Full-sbsorption peaks derived from the above background noise spectrum.

Implementation of this process enables to detect the major natural or man-made radioelements, with sensitivities approximating the natural background activity levels.

Three-dimensional Mapping

The conventional methods used in contamination maps consist in superimposing the isoactivity map and the topographic map of a given site, through scanning of a printed map to the scale of 1: 25 000. This technique is fast and low-cost; however, the plotting quality of the topographic maps is rather poor. Therefore, we have investigated a high-tech method based on the Digital Earth Model (referred to as DEM). Such models performed by ISTAR company are derived from pairs of stereoscopic pictures taken by the SPOT observation satellites.

The DEMs allow computing relief perspective views, and achieving 3-D views by 'matching' with the orthoimago.

This raised relief map will be further used in supporting the airborne gamma spectrometry data, this resulting in very realistic and accurate maps, providing a comprehensive bulk of information (relief, city-planning, etc) as a useful back-up to decision making in many respects.

CONCLUSION

The up-to-date helicopter-borne mapping equipment is a valuable tool for plotting, just in a few hours, accurate radiological-status maps regarding any contaminated area spread over several square kilometers. The detection limits (2 kBq/m for Cs-137), the flexibility in use, the quantity and quality of the measurements, make this method a highly valuable choice for monitoring any remediation work, and for characterizing the reversal to a normal radiological status of the site concerned. Nevertheless, airborne gamma mapping is not limited to this above specific domain, as it is also a requisite method used in geophysical detection as well as in environmental surveillance of nuclear sites.

Recent and forthcoming advances, such as spectrum mathematical processing, use of

digitized geographic maps and of higher-resolution detectors (HPGe) are intended to enlarge and improve the capacity, and the fields of application of such a system.

GROUNDWATER PLUME AND SOURCE CHARACTERIZATION ON THE NORTH PLATEAU USING THE GEOPROBE SAMPLING SYSTEM

Beth A. Carpenter
Mark R. Hemann
Craig L. Repp
West Valley Nuclear Services Company, Inc.

ABSTRACT

A Strontium-90 (Sr-90) groundwater plume at the West Valley Demonstration Project in West Valley, New York, was laterally and vertically characterized in alluvial sediments using a van-mounted Geoprobe sampling system. The Geoprobe system hydraulically advances a 0.025 m diameter probe for discrete-depth sampling. Groundwater and subsurface soil samples were obtained from the Geoprobe system down to depths of 12 m. The heterogenous nature of on-site alluvial sediments have created a complex groundwater flow situation, where Sr-90 migration is controlled by local differences in hydraulic conductivity. Relative flow rates during groundwater sampling, and the gross beta activity in groundwater were used to determine that the Sr-90 groundwater plume, north of the Process Building, funnels down to a narrow flow path. Narrowing of the plume was not obvious from monitoring well sample data alone.

Groundwater and subsurface soil samples were collected in the Process Building with a modified Geoprobe sampling system, due to accessibility limitations. The sampler was driven by an air-powered jackhammer suspended from scaffolding. Groundwater and soil sampling data beneath the building were used for contaminant source identification.

The Geoprobe sampling system was found to have many advantages over conventional groundwater and subsurface soil sampling methodologies (i.e., monitoring wells and soil borings). These advantages include:

- Multiple discrete-depth groundwater samples at each probing location
- Proposed location and number of probing sites able to be modified, based on screening results on groundwater samples
- Significant waste minimization
- Accessible to difficult sampling areas
- Sample collection significantly faster

When combined with monitoring well sampling results, Geoprobe data can provide a better characterization of groundwater flow and contaminant migration in shallow, unconsolidated materials. This data can ultimately be used to develop cost effective remedial solutions, or to locate additional monitoring wells more effectively.

INTRODUCTION

Site History

The Western New York Nuclear Service Center (WNYNSC), located near West Valley, New York, about 50 km south of Buffalo, was the site of the only commercial nuclear fuel reprocessing facility ever operated in the United States.

The New York State Energy Research and Development Authority (NYSERDA) owns the site and facilities. Nuclear Fuel Services, Inc. (NFS), the commercial operator, operated the plant and the WNYNSC under a Nuclear Regulatory Commission (NRC) operating

license from 1966 to 1972 on land leased by NFS from New York State, processing about 640 metric tons of spent reactor fuel. The reprocessing operation generated approximately 2.3 million liters of high-level radioactive waste that was transferred into underground tanks for storage. Reprocessing operations ceased in 1972.

In 1980 Congress passed the West Valley Demonstration Project (WVDP) Act to demonstrate that high-level waste can be solidified in a form suitable for transportation and disposal; suitable containers can be developed and the waste transported to a federal repository for permanent disposal; low-level and transuranic waste from the project in accordance with applicable licensing requirements can be safely disposed and the tanks, facilities, and any material and hardware used in connection with the project can be decontaminated and decommissioned in accordance with NRC requirements. In September 1981, the NRC amended the operating license to transfer possession of the facilities to the Department of Energy (DOE) for conduct of the WVDP (NYSERDA continues to be licensed as the owner). On February 25, 1982, DOE assumed operational control of approximately 89 hectares of the 1336-hectare WNYNSC in order to conduct the WVDP. The DOE through its contractor, West Valley Nuclear Services Company, Inc. (WVNS), a wholly-owned subsidiary of Westinghouse Electric Corporation, is currently performing operations as stipulated in the WVDP Act, the Memorandum of Understanding between DOE and NRC, and the Cooperative Agreement between DOE and NYSERDA.

Scope of Groundwater Sampling Program

In the summer of 1994, WVNS implemented a subsurface probing (Geoprobe) program on the North Plateau of the WVDP. The Geoprobe system collected groundwater and subsurface soil samples by hydraulically advancing a 0.025 m diameter probe to a depth of up to 12 m. Seventy-five locations were sampled outdoors and seven locations were sampled inside the Process Building. Maps of the site showing the probe sampling locations are illustrated in Figs. 1 and 2.

Analytical data from these samples were used to further characterize the vertical distribution and areal extent of the Sr-90 groundwater plume. Preferential contaminant migration pathways were also identified during data analysis. The data helped to identify and characterize potential source areas of groundwater contamination. Geoprobe sample analyses were used to expand upon the existing data obtained from monitoring wells and soil borings.

GEOLOGY AND HYDROGEOLOGY

Sand and Gravel Unit

The saturated interval of the Sand and Gravel unit is the primary zone of groundwater on the North Plateau. The Sr-90 plume shown in Fig. 3 is located within the Sand and Gravel unit. The thickness of the Sand and Gravel unit ranges from 1 to 10.7 m.

This unit can be subdivided into two intervals - an upper sequence of muddy gravels and muddy sandy gravels and a lower sequence of thin-bedded clays, silts, sands, and very fine-grained gravels. The thin-bedded sequence is located in a channel-like depression on the surface of the underlying glacial till. Portions of the thin-bedded sequence that contain sands and fine grained gravels are believed to be more permeable than the upper sequence.

Depth to groundwater varies seasonally, but is typically deepest beneath the Process Building (4.6 - 5.5 m) and becomes shallower, until it surfaces in swampy areas and in the drainage ditch north of Lag Storage Areas 3 and 4 and the Construction and Demolition Debris Landfill, (CDDL). Groundwater flow in the Sand and Gravel unit is predominantly toward the northeast. Hydraulic conductivities in the unit have an approximate range of 1 x 10-6 to 1 x 10-5 m/sec.

Lavery Till

The Lavery Till is a low permeability glacial till that lies immediately beneath the Sand and Gravel unit on the North Plateau. Lavery Till on the North Plateau is unweathered and has an approximate hydraulic conductivity range of 1 x 10-10 to 1 x 10-9 m/sec.

SAMPLING PROCEDURES

Groundwater Sampling Procedures

A van equipped with a Model 8-ML Geoprobe system was used to advance the subsurface probe to selected depths at points located outside the Process Building. A modified Geoprobe sampling system was used to collect groundwater and subsurface samples from within the Process Building, due to accessibility limitations. An air powered,

27.3-kilogram jackhammer was used to drive the subsurface probe at points located inside the Process Building and other locations that could not be accessed by the Geoprobe van. The following procedures were used to advance the probe and collect groundwater samples:

Advance the probe (fitted with 0.01 m polyethylene tubing attached to a screen point sampler) down to a depth at least 1.5 m below the water table.

Pull up the probe rods 0.6 m to expose the screen point to the groundwater.

Attach 0.01 m tubing to a peristaltic pump and purge one probe volume or to dryness, whichever occurs first. Collect all purge water in 19-liter pails and then transport to a central staging area and pour into 208-liter drums. After purging, pump the water directly into the proper sample bottles.

Remove the probe rod and tubing from the test hole. Advance clean probe rod, screen, and sample tubing 1.5 m below the first sampling interval. Repeat the procedure until the entire groundwater zone is sampled.

This procedure allowed groundwater samples to be collected from discrete elevations within the Sand and Gravel unit.

Sample preservatives were added to the bottles by the sampling team prior to sample collection. The containerized and appropriately labelled samples were radiologically surveyed with a beta/gamma frisker and placed in a controlled area prior to shipping.

All groundwater samples were analyzed for gross alpha, gross beta, tritium, and Sr-90. Selected samples were also analyzed for alpha and beta radioisotopes. Unequilibrated gross beta analysis (within 24 hours of sampling) was used as a sample screening methodology. Unequilibrated gross beta results helped in making field decisions about additional or modified sampling locations. Equilibrated gross beta activities were available 10 days after sampling.

Subsurface Soil Sampling Procedures

Subsurface soils were collected with the Geoprobe in the following manner:

Mount a 0.30 m, standard diameter soil sampler to the lead Geoprobe rod and lower to the top of the sampling interval.

Detach the probe point from the soil sampler and drive the sampler 0.30 m to obtain a soil sample.

Retract the probe rods from the hole and remove the sampler.

Extrude soil sample from the sampler and place on clean herculite. Survey soil sample for radioactivity.

Place soil into labelled sample bottles for radiological analysis.

All excess soil was placed in bags and properly disposed.

Approval for hole closure was given after all required samples were collected, logged, and placed in the designated storage area. Bentonite (1/4") pellets were poured down the test hole to the ground surface. For those holes drilled in the Process Building, bentonite was poured to the base of the concrete floor then backfilled with epoxy grout to the floor surface.

DECONTAMINATION PROCEDURES

Prior to commencement of the subsurface probing activities, between sampling locations, and prior to removal from the facility the probing equipment (i.e., probe rods) was thoroughly cleaned to remove oil, grease, mud, and radiologically contaminated material. All equipment decontamination took place in a designated area.

The procedures used for equipment decontamination were as follows:

Wash and brush equipment with nonphosphate detergent to remove contamination

Rinse with clean tap water

Lay the equipment aside on plastic sheeting to dry

Radiation Technician wipes the equipment and screens wipes for radiological contamination

SR-90 GROUNDWATER PLUME AND PREFERENTIAL ROUTES OF MIGRATION

Sr-90 Groundwater Plume

Groundwater analytical data from Geoprobe sampling helped to define the Sr-90 plume on the North Plateau. Due to the heterogeneity of the Sand and Gravel unit, the areal and vertical activity of Sr-90 in the plume does not follow a typical contaminant distribution pattern. The following factors have had a significant influence on Sr-90 levels in the plume:

Preferential Sr-90 migration within the thin-bedded lower interval of the Sand and Gravel unit. Preferential migration is believed to be limited to the areas of the

thin-bedded interval that contain sand and very fine-gravel layers. Sr-90 activity in this portion of the thin-bedded interval was generally higher than the overlying Sand and Gravel sediments.

A narrowing of the Sr-90 plume east of LSA-4. The plume migration appears to be "funnelled" into this area and does not follow the northeast direction of groundwater flow. Monitoring well data alone did not clearly identify this narrowing of the Sr-90 plume.

Geoprobe sampling results were instrumental in identifying these features, when evaluated in conjunction with previously collected geologic and groundwater quality data.

Source Identification

Another goal of the Geoprobe sampling program was to identify and characterize sources of radiological contamination in groundwater. The Process Building and Fuel Receiving and Storage (FRS) area have long been suspected as the primary sources for groundwater contamination. However, prior to the Geoprobe sampling program, it was not possible to differentiate source contribution from these two areas. Groundwater and subsurface soil samples collected within and around the Process Building and FRS enabled WVDP to evaluate the relative contribution from these two potential sources. There were two major obstacles to collecting samples in the FRS and Process Building:

All sampling equipment had to pass through standard doorways. The van-mounted Geoprobe could not be used.

The generation of contaminated soil and water had to be kept to a minimum, to reduce the potential for introducing radioactive contamination into clean work areas.

In the Process Building, a 27.3-kilogram jackhammer was used to advance the Geoprobe sampling tools. The jackhammer was suspended from scaffolding and manned by an operator and a helper. Two 13.6-kilogram "Load Balancers" were used to lift the jackhammer to the top of the sampling rods. The "Load Balancers" were disconnected during probe advancement. Prior to Geoprobe sampling, a 0.076 m core drill was used to penetrate the 0.15 to 0.46 m thick concrete floor of the Process Building. Samples collected beneath the Process Building indicated that the primary source for the Sr-90 groundwater plume was located beneath the Process Building.

COMPARISON OF GEOPROBE AND MONITORING WELL GROUNDWATER SAMPLES

Table I presents a comparison of gross beta activities in groundwater at Geoprobe locations and nearby monitoring wells. Gross beta activity at the WVDP site primarily represents the sum of activities from Sr-90 and its daughter Yttrium-90 (Y-90). In spite of the numerous factors that could produce differences in analytical results, the Geoprobe data appear to be a reasonable approximation of groundwater gross beta activities in on-site monitoring wells. Parameters that could affect monitoring well and Geoprobe sampling results include, but are not limited to: differences in sampling methodology, differences in the thickness of the sampled interval, spacial variations in gross beta concentrations, time variation, geologic heterogeneity, and general sampling variability.

DEPTH DISCRETE NATURE OF GEOPROBE GROUNDWATER SAMPLES

Geoprobe groundwater samples collected at multiple depths appeared to be representative of the sampling interval. For example, several locations had relatively high gross beta activities at one sampling depth and relatively low activities at the next lower sampling depth. This trend suggested that little or no cross contamination occurred between the two sampling intervals. Safeguards to minimize the potential for cross contamination between sampling intervals include:

An "O" ring seal on the Geoprobe drive point to prevent water from entering the sampler until the desired sampling depth has been reached.

The procedure used for groundwater sampling helped to prevent cross contamination. The probe was advanced 1.5 m below the previous sampling interval, pulled back 0.6 m, then exposed to the groundwater by pushing out the screen. There was a 0.9 m thickness of soil that separated the upper portion of the sampling interval with the previous sampling interval.

COST AND TIME ADVANTAGES USING THE GEOPROBE TECHNOLOGY

Utilization of the Geoprobe system for groundwater sampling and plume/source characterization at WVDP produced a significant cost and time savings over traditional groundwater and sampling methodologies. Table II presents a cost and time comparison of a hypothetical Geoprobe sampling location and the equivalent

monitoring well installation/sampling program. Unit costs and estimated times are based on previous work performed at WVDP. Groundwater sampling intervals for the Geoprobe scenario were assumed to be 5.5 m - 6.1 m; 7 m - 7.6 m; 8.5 m - 9.1 m; and 10 m - 10.6 m. Screened intervals in the four adjacent monitoring well scenario were assumed to be 4.6 m - 6.1 m; 6.1 m - 7.6 m; 7.6 m - 9.1 m; and 9.1 m - 10.6 m. Due to the scope of the Geoprobe sampling program at WVDP, a detailed comparison of subsurface soil sampling costs for drilling and Geoprobe sampling will not be made. A small number of soil samples were collected using the Geoprobe. The relative cost of each Geoprobe soil sample (during the WVDP program) was higher than typical costs for split-spoon samples during drilling.

WASTE MINIMIZATION ADVANTAGES USING THE GEOPROBE TECHNOLOGY

Geoprobe sampling technology significantly reduced the volume of water and soil that would typically be generated during the installation and sampling of monitoring wells. Table III presents a comparison of the waste soil and water generated by each of these methodologies.

SUMMARY

We have found the Geoprobe sampling system to be an advantageous alternative to conventional groundwater and subsurface soil sampling methodologies. The Geoprobe system gave us the opportunity to investigate the groundwater and soil under the Process Building, something that conventional drilling would not have provided. Waste generated was greatly minimized since no cuttings were produced and samples were obtained through smaller boreholes only 0.025 m in diameter. The Geoprobe system was also found to be a very useful and efficient method for defining shallow groundwater plumes, particularly in heterogenous aquifers. Additionally, the Geoprobe sampling system reduced the time and cost of the groundwater and soil sampling program.

We are continuing to explore future uses for the Geoprobe sampling system at our facility.

COAL SORBENT SYSTEM FOR RADIONUCLIDES, HEAVY METALS, AND ORGANIC COMPOUNDS EXTRACTION AND DISPOSAL

Raymond F. Maddalone
Loren C. McClanathan
TRW Inc.

ABSTRACT

Processes involved in current pump and treat systems have led to high treatment costs and the need for complex sludge stabilization chemistries, because they are essentially unit operations and not developed as a unified system for removal and disposal. TRW has developed a system for the removal and disposal of radionuclides, heavy metals, and organics utilizing a coal-based adsorbent, produced by the chemical leaching of ordinary coal using the DOE-sponsored Molten Caustic Leaching (MCL) process. The coal sorbent produced from the MCL process is much like activated carbon with a large internal surface area up to 1000 m2/gram. In addition to its high surface area, the coal sorbent, unlike activated carbon, has inherent carboxyl groups much like ion exchange resins that can remove heavy metals from wastewater. Uranium capacities of 30 mg/g (3%) of coal sorbent have been demonstrated. The coal sorbent could be used as a wastewater treating media to remove both organics due to high surface area and heavy metals due to the carboxyl groups present. Once the heavy metals and organics are adsorbed on the virtually sulfur and ash-free coal sorbent, the spent coal sorbent can be added as a low volume feedstock to existing DOE-developed or commercially available combustion/vitrification processes to encapsulate the metals and destroy the organics. Waste volume reductions as high as 420,000:1 have been demonstrated for uranium from simulated Fernald groundwater at an estimated cost through disposal of $0.001/gallon water treated.

INTRODUCTION

Groundwater under hazardous waste sites and sites used for the processing of nuclear fuels contain heavy metals and toxic organic compounds. Of major concern with groundwater contamination is the potential for contaminating aquifers that supply drinking water or feed waterways. Permanent cleanup of contaminated groundwater requires that the hazardous materials are removed and the resulting waste products are stabilized or detoxified.

The coal sorbent system (CSS) deals with complete end-to-end clean-up, unlike other

processes that deal with simply the removal or disposal steps. For example, ion exchange, due to high resin cost, deals only with the removal of the metal from the waste stream, but does not produce a product that is readily disposed of without additional processing of a liquid waste. In contrast, the CSS process is designed to address the total problem of removing contaminants from aqueous wastes and stabilizing them in an environmentally safe manner.

The CSS process operates as follows: 1) coal is converted to the unique sorbent medium by treatment with caustic at high temperatures utilizing TRW's Molten Caustic Leaching (MCL) Process technology in our existing U.S. Department of Energy test circuit at San Juan Capistrano, California, 2) the product coal sorbent, which is the unique sorbent, is utilized in a portable, fixed-bed processing unit for treatment of contaminated water, reducing heavy metals and radioactive contaminants to parts per billion levels, 3) the loaded sorbent is as combustible as ordinary coal and when burned in a DOE or commercial vitrifier/combustor along with a glass, such as borosilicate, can produce an encapsulated material suitable for storage. Overall waste volume reduction ratios are estimated at up to 420,000:1 while reducing, for example, uranium levels in treated water to below 5 g/L. The basic operations of the CSS process have been reduced to practice under TRW IR&D funds and a patent has been issued ("Improved Metal Ion and Organic Contaminant Disposal," Patent No. 5,169,534 December 8, 1992).

CHARACTERISTICS OF THE TRW COAL SORBENT

TRW's coal sorbent has carboxyl groups providing ion exchange sites for heavy metal adsorption and high surface area for the adsorption of organics. Single point nominal surface areas are in the range of 600 to 1,000 m2/g. TRW has conducted a significant number of laboratory tests of the proposed application using cadmium, lead, nickel and uranium as the test metals and methylene blue as the test organic compound. These removal efficiency tests were initially conducted as batch tests with the coal sorbent in excess. Both the coal sorbent (by titration) and the test solution were adjusted to the test pH (generally between 5 and 7) before they were allowed to contact. Test solutions containing approximately 7,000 mg/L $NaNO_3$ as the background were filtered and analyzed after pH adjustment to ensure that no precipitates were formed prior to contact with the coal sorbent. The filtered sample at the analyzed concentration was then contacted with a fixed amount of coal sorbent in a test tube. Table I shows that the coal sorbent is an effective absorber for solutions of nickel, uranium and cadmium ions. Target uranium discharge concentration for the DOE Fernald, Ohio site is <5 g/L.

Figures 1 and Fig. 2 are the isotherms for nickel and uranium created using a flow-through system consisting of a peristaltic pump, a 0.45 mm filter, and a glass column with a frit. The test amount of coal sorbent (typically 0.1g) is loaded as slurry into the column and is allowed to compact under a deionized water flow. Test solutions and coal were prepared and pH adjusted. The test solution containing the nickel and uranium was pumped through the filter upstream of the coal sorbent bed. A test sample was taken just after the filter to determine the exact concentration passing through the coal bed. In this manner the only removal mechanism would be via ion exchange since any precipitate would have been removed prior to reaching the absorber. Based on these experiments the maximum capacity is 31.3 mg/g (3.1%) in the absence of background divalent ions. In an experiment to determine the capacity of the coal sorbent for uranium in the presence of calcium and magnesium, a solution of calcium, magnesium and uranium at 100,000, 1,000 and 1,500 g/L, respectively, was made. When this solution was pumped through the coal sorbent bed the uranium capacity was determined to be 11.1 mg/g (1.1%). The uranium concentration in the effluent was below the detection limit (0.03 ug/L) of the ICP-MS used to analyze the test solutions.

While TRW's coal sorbent is an excellent ion exchange material, the MCL process also modifies the coal sorbent to produce a material that has many of the properties of an activated carbon. An industry standard test using methylene blue was used to compare the adsorption capacities of TRW's coal sorbent and standard activated carbon. Samples of activated carbon and TRW's coal sorbent were placed in separate test tubes with water. After agitation to thoroughly wet the solids, 0.25 mL portions of a solution of methylene blue (0.15%) were incrementally added to each tube. The tubes were agitated and the disappearance of the blue color was noted after each incremental addition. Approximately 15 minutes elapsed between additions of methylene blue. Under these conditions both the activated carbon and TRW's coal

sorbent adsorbed 93 mg of methylene blue per gram of solid before the color no longer disappeared. In a separate experiment the raw coal did not adsorb any methylene blue. Other tests with coal sorbent derived from brown coal showed higher capacities and faster adsorption rates than the activated carbon.

A direct comparison of TRW's coal sorbent (derived from both brown and black coals) with commercial ion exchange resin and activated carbon is presented in Table II. The data in this table is based on recent tests. TRW's coal sorbent compares favorably with commercial products at a much lower cost.

In summary, these tests with TRW's coal sorbent have demonstrated its effectiveness in reducing uranium levels in laboratory and simulated groundwater matrices with a capacity equivalent to current ion exchange resins used for uranium recovery. Even in the presence of calcium and magnesium at a 100-fold excess, metal ion levels were reduced below target concentrations. An added advantage for water cleanup applications is the affinity of TRW's coal sorbent for organic materials. Ion exchange resins, such as Dowex 21K, have a similar capacity for uranium but typically cost the equivalent of $16,000/ton and are not effective in the removal of organics. Activated carbon products cost from $500 to $2000/ton and, although effective for organic removal, are not effective for heavy metal removal.

COAL SORBENT SYSTEM

TRW's coal sorbent system is a process for removal of heavy metals (including uranium) and organic compounds from wastewaters and groundwater which also destroys the organic compounds and encapsulates the metals for disposal while attaining 4 to 5 orders of magnitude volume reduction. The process employs coal sorbent derived from the MCL process to remove contaminates present in groundwater and then provides a method to combust/encapsulate the coal sorbent with slagging agents to encapsulate the metals and destroy the organics. Contaminated water is contacted with MCL-processed coal sorbent in a continuous fixed bed contactor. The contaminated water is pH adjusted and pumped through the fixed bed unit until the bed reaches saturation of contaminants and breakthrough occurs. At this time the unit is taken off-line and the water flow switched to the readied second fixed bed unit. The cleaned water is filtered for removal of coal sorbent fines and is sent to disposal as nonhazardous waste or pumped back into the aquifer down gradient from the contamination site or injected up-gradient to add additional volume to flush the contaminants from the saturated zone.

To this point the coal sorbent system is similar to most ion exchange processes. However, because the metals and organics are trapped on a low cost, combustible material, a unique and safe disposal process is possible. The coal sorbent is a high energy, clean fuel (no SOx controls required) which can be combusted in a number of way. Because of the low cost of the coal sorbent, the process can be designed as a "once-through" system where the loaded coal sorbent goes directly to a vitrification or combustion plant designed to destroy the organics and encapsulate the metals in an environmentally safe and stable glass. In a proof-of-concept test, a portion of the coal sorbent loaded with uranium was mixed with 10% by weight of ground soft glass and fired in a crucible at 1000oC. Within the limits of the analysis, 100% of the uranium was found in the resulting glass after the coal sorbent had burned off indicating the potential for trapping non-volatile metals in a glassy matrix.

Examples of available vitrification/combustion technologies include:

Combustion in a rotary kiln - the reduced gas velocities will reduce the generation of fine particles and reduce particulate control/costs. A commercial system for non-radioactive waste such as the Waste Technologies System is an example of this type of disposal.

Vitrification - the spent coal sorbent is a low volume feed stream. Conditions and controls in the vitrification process would burn off the carbon matrix and capture the metals in the glass matrix. For radioactive waste, this option can be easily implemented at many of the DOE sites which will have a vitrification process.

Specialized vitrification technologies - for example, Vortec Corporation under DOE sponsorship has developed a fossil fuel fired vitrification process.

The vitrification/combustion step enables the coal sorbent system to exhibit exceptional capability to concentrate metals in a safe disposable matrix. For example, water containing 1,500 g/L uranium can be cleaned to levels below 5 g/L with the coal sorbent retaining up to 30 mg/g uranium. Under these conditions one ton of coal sorbent can be expected to treat from 34,000 cubic meters of contaminated water. This represents a waste volume reduction of 42,000:1. The waste

volume can be further reduced by the vitrification/combustion of the coal under controlled conditions. Glass mineral additives would be used during combustion as a means of vitrifying and encapsulating the waste materials in the slag. Organic materials would be destroyed by the high combustion temperatures. Assuming that adsorbed contaminants, glass mineral additives, and remaining coal mineral matter comprise 10 percent of the coal sorbent, there is a further waste volume reduction of 10:1 for the vitrification/combustion step. This represents overall waste volume reduction of up to approximately 420,000:1 for the complete process. Waste minimization is particularly important for radioactive waste because of the high cost of disposal based on volume and also because of severe limitations on storage area.

COAL SORBENT SYSTEM PROCESS ECONOMICS

Cost studies indicate that TRW coal sorbent can be produced for $330 per ton in a 2 ton per hour MCL plant and at even lower costs for larger sized MCL plants. In comparison, activated carbons for organic removal typically cost on the order of $2000/ton depending on quality and intended application. Unlike the TRW coal sorbent, activated carbon derived from coal contains sulfur which precludes burning without sulfur oxide emissions controls. Activated carbon derived from coconut shells is low in sulfur but is difficult to burn. Although efficient for organics removal, activated carbon is far less effective than TRW coal sorbent for metals (such as uranium) removal from water.

Ion exchange resins used for the removal of heavy metals and uranium from water, such as Dowex 21K, typically cost about $16,000 per ton and a single resin is not effective for the removal of both metals and organics. The high cost of ion exchange resins prohibits once-through use, therefore, ion exchange resins are periodically regenerated in batch operations to elute the contaminants into another aqueous stream which requires additional processing for recovery and disposal of wastes.

For the specific application of uranium removal from wastewater, a process (1) has been proposed based on the co-precipitation of uranyl hydroxide $[(UO2)3(OH)5]+$ with potassium ferrate. The process uses a chemical treatment step to remove most dissolved and suspended solids, radionuclides and priority pollutant metals from aqueous waste streams. Potassium ferrate and magnesium salts are then used to enhance contaminant removal. Magnesium acts as a seed crystal to ensure the formation of colloidal particles and eventual floc formation. Tests to date using the potassium ferrate treatment process allowed 0.5 hour for flocculation followed by 1 hour for the resulting floc to settle. Before the addition of potassium ferrate, the pH of the waste stream was adjusted to the range of 10.6 to 11.2 with sodium hydroxide. From 72% to 86% of the uranium in the wastewater was removed in a once through system. When the waste stream was treated a second time, more than 98% of the uranium was removed.

A comparison of the CSS to the potassium ferrate process was made on a the basis of volume generated (Table III) and the treatment costs (Table IV) for 6.2 million gallons/yr of Fernald groundwater uranium at a concentration of 490 mg/L. In this application of the CSS, uranium contaminated groundwater will be pumped to an agitated tank where it is mixed with a dilute hydrochloric acid solution. The purpose of this step is to remove the carbonate/ bicarbonate from the Fernald groundwater as carbon dioxide. This is essential because in the presence of carbonate uranium forms an anionic complex which would not be adsorbed by the carboxylic acid ion exchange groups on the TRW coal sorbent. The carbonate-free groundwater will then be pumped to a second agitated tank to adjust the pH to ~6. The water then will be pumped at a controlled feed rate to the CSS contactor where uranium and other heavy metals will be removed from the water by adsorption onto TRW coal sorbent. The coal sorbent requirement is calculated assuming a minimal capacity of 0.5% uranium. Laboratory studies have actually shown an uranium ion capacity of 1.1% in the simulated Fernald groundwater (Fig. 2). The encapsulated product quantity includes the 10 weight percent ground borosilicate glass added to the spent coal prior to combustion or vitrification. In calculating the disposal costs for the CSS process, the waste monitoring and disposal charges are assumed to be the same as for the potassium ferrate process on a volume basis. The cost of the combustion/ vitrification operation is based on information supplied by Vortec Corporation which is developing one of the waste encapsulation technologies for spent coal that will be evaluated in this proposal.

Based on chemical costs alone, treating the wastewater with potassium ferrate costs

$0.036/gal. However, when the costs for monitoring, analyzing, treating, transporting, and disposing of the resulting solids are included, the total cost of the potassium ferrate treatment process is $0.08/gal. The total cost of treating the same quantity of wastewater using the CSS process, however, is $0.001/gal. The main cost savings are a direct consequence of the reduced volume of waste generated in the CSS process: 23:1 for wet sludge:spent coal and 244:1 for dry sludge:encapsulated product when compared to the ferrate process.

The CSS process is also less expensive than ion exchange systems requiring regeneration and processing of the regeneration liquor. An estimated operating cost for an ion exchange system for removing uranium from drinking water in Colorado was given at $0.006/gal (2). However, this cost only includes the cost of trucking the regeneration brine containing the uranium to a waste water treatment plant where it is dumped into the process treatment stream. No provision or cost is included for stabilization and disposal.

OTHER APPLICATIONS FOR THE COAL SORBENT

In a broad sense, the CSS process has the unique ability to simultaneously remove both organic compounds and heavy metals from aqueous streams. This is because the TRW coal sorbent has both the high surface areas found in activated carbon and the ionic surface functionalities of ion exchange resins. Because of this dual capability, capital and operating costs of a water treatment facility would be reduced as only a single absorber system would be necessary to remove both types of contaminants. Because TRW coal sorbent is inexpensive and thus can be used on a once-through basis, it may have applications in other areas (e.g., wastewater, process water, acid mine drainage, etc.) where activated carbon or ion exchange would be considered. For example:

The ability to slurry the coal and its affinity for water would enable the TRW coal sorbent to be used as a semipermeable barrier that would retain the metals and organics yet allow the flow of water (uranium mine tailing pond control).

A hybrid system using specialized ion exchange resins coupled with the CSS as the regeneration loop to concentrate and dispose of the metals without the generation of sludge (soil washing systems).

Where favorable economics exist, non-volatile metals can be recovered by roasting the coal to remove the coal matrix and leaving the oxide of the metal. For selected metals the coal sorbent could act as a metallurgical coal and reduce the metal oxides to metal. Because of the low ash and sulfur in the coal sorbent, this can be done without additional pollution controls.

Future applications in acid mine waters will be enabled by a new variant of the coal sorbent having strong acid functional groups added to the sorbent surface. The net effect is a 3 fold or more increase in capacity with a laboratory demonstrated use range down to a pH of 2.8.

TRW has demonstrated mercury vapor capture from a gas stream at flue gas temperatures (250 and 400oF). This opens the use of the coal sorbent as a low cost air emission control material.

SUMMARY

TRW's CSS process is unique as it provides for the simultaneous removal of heavy metals, radionuclides and organics in pumped water and washed-soil leachate, with the additional benefit of providing an effective waste concentration and stabilization method for metals together with thermal destruction of hazardous organic chemicals. Waste minimization is attained by the coal sorbent system in three areas:

The coal sorbent system adsorbs both metals (radionuclides) and organics on a low cost, easy to handle material.

There is no generation of primary wastes such as alkali sludges which are hard to handle and dewater or secondary acid or brine streams derived from the regeneration and elution of ion exchange columns and which require neutralization and precipitation.

Due to the low cost and capacity, the coal sorbent is used as a once-through sorbent.

The coal sorbent has virtually no ash or sulfur and can be destroyed by current combustion/vitrification technologies without any additional environmental emission controls.

Trace metals and radionuclides are encapsulated in the vitrified glass and the coal sorbent while any absorbed organics are destroyed.

Waste volume reductions as high as 420,000:1 have been demonstrated for uranium from simulated Fernald groundwater at an estimated cost through disposal of $0.001/gallon water treated.

REMEDIATION OPTIONS FOR A CHROMIUM CONTAMINATED LANDFILL USING CEMENTITIOUS GROUTS

Marita L. Allan
Lawrence E. Kukacka
Department of Applied Science
Brookhaven National Laboratory
Upton, NY, 11973

ABSTRACT

In-situ remediation of a chemical waste landfill with excessive chromium levels is being investigated as part of the Mixed Waste Landfill Integrated Demonstration. This paper is concerned with the design of advanced cementitious grouts for in-situ stabilization of chromium contaminated soil and in-situ installation of subsurface containment barriers. Grouts have been developed to improve the performance and cost effectiveness of remediation compared with conventional materials. In addition to restoration of chromium contaminated soils, the developed grouts have applications in other environmental operations where superior properties are required.

INTRODUCTION

As part of the Mixed Waste Landfill Integrated Demonstration (MWLID), the authors are developing advanced grouting materials for remediation of a chromium plume resultant from disposal of hexavalent chromium solutions. Further details of the MWLID have been given by Burford et al. (1). The site has an arid climate, a groundwater depth of approximately 160 to 170 m and alluvial type soil. The chromium is present in both the trivalent and hexavalent oxidation states, indicating that some transformation of redox state has occurred since the solutions were disposed. The remediation aims to convert hexavalent chromium into the less mobile and less toxic trivalent state and to contain the contaminated soil through use of subsurface barriers and a surface cover. The Brookhaven research is focused on 1) in-situ solidification/stabilization of the chromium contaminated soil and 2) in-situ subsurface containment barriers.

STABILIZATION OF CHROMIUM CONTAMINATED SOIL

Remediation of the chromium plume requires stabilization of both the trivalent and hexavalent states. Hexavalent chromium requires reduction to Cr(III) before stabilization as Cr(OH)3 (2). For example, Cr(VI) contaminated soil can be pretreated with a ferrous sulphate solution, followed by cement or lime stabilization. However, a concern with this approach for in-situ remediation is that reduction of Cr(VI) may be incomplete and that verification of satisfactory reduction is necessary before proceeding with further treatment. Furthermore, the economics of remediation are detrimentally affected by the need to perform two separate stages.

Research has been directed towards simultaneous reduction of Cr(VI) to Cr(III) and stabilization so that soils contaminated with Cr(VI) or a combination of Cr(VI) and Cr(III) can be remediated in a one step in-situ process. The approach is to use grouts in which ordinary Portland cement is partially replaced with ground granulated blast furnace slag. Previous work has demonstrated reduction and stabilization of Cr(VI) by slag-modified cements (3-5). The low redox potential of slag-modified cements is responsible for the reduction of Cr(VI) (6,7).

The in-situ techniques under consideration for treating the contaminated soil with grout are jet grouting (8-11) and deep soil mixing (2,8,12,13). In these techniques grout is intimately mixed with soil to form soil cement. The choice of technique will depend on ability to meet stabilization objectives and regulatory acceptance, in addition to cost effectiveness for the scope of soil treatment.

Initial research investigated the effects of slag content, water/cementitious material ratio and soil/cementitious material ratio on the leachability, permeability, wet-dry durability and compressive strength of treated soils.

Following successful stabilization of soils spiked with 200 ppm Cr(VI) and Cr(III) and of soil samples retrieved from the landfill under study, further leachability tests were conducted at a higher level of Cr. Additional details of the initial work on stabilization of Cr contaminated soils with slag-modified grouts are available (14,15).

Initial Leach Tests

The grouts consisted of Type I cement, ground granulated blast furnace slag, water, bentonite and superplasticizer. The slag used was ASTM C 989 Grade 100, supplied by Koch Minerals. Sodium montmorillonite type bentonite was added at a rate of 2% by mass of water to improve grout stability. Sodium naphthalene sulphonate formaldehyde superplasticizer with 42% solids by weight was used to enable reduction of the water/cementitious material ratio (w/c) while maintaining fluidity. Superplasticizer was added at a rate of 20 ml/kg cementitious material. Uncontaminated soil collected adjacent to the landfill of interest was spiked with known quantities of Cr and mixed with the grouts.

In the initial studies uncontaminated soil was spiked with either 200 ppm Cr(VI) or 200 ppm Cr(III) and then mixed with grout. The grout was added to soil at soil/cementitious material ratios (s/c) by weight of 1, 2 and 5. The corresponding water/cementitious material ratios were 0.48, 0.72 and 1.40. The concentrations of Cr in the specimens after dilution with grout were 80, 106 and 135 ppm for soil/cementitious material ratios of 1, 2 and 5, respectively. Slag was used at cement replacement levels of 0, 20, 40, 60 and 80% in the grouts. The treated soils were cured by burying in dry soil for 28 days. The objective of the curing was to simulate subsurface conditions under which the extent of hydration is expected to be reduced as compared with conditions where water is readily available. The cured specimens were crushed and subjected to EPA Toxicity Characteristic Leaching Procedure (TCLP) tests. The concentration of leached Cr from stabilized Cr(III) contaminated soil was less than 0.5 ppm for the range of grout slag contents and soil/cementitious material ratios. This compared with 6.3 ppm for the unstabilized soil and the EPA limit of 5.0 ppm. The amount of leached Cr(III) decreased with increasing slag replacement level.

The tests on soils spiked with 200 ppm Cr(VI) showed that the proportion of Cr(VI) to total Cr [Cr(III) plus Cr(VI)] was reduced as the slag replacement level increased. This indicates that reduction of Cr(VI) occurred. The concentrations of total Cr and Cr(VI) in the leachates increased as soil/cementitious material ratio increased. However, at slag replacement levels equal to or greater than 40% the concentrations remained below 0.5 ppm. The untreated soil spiked with 200 ppm Cr(VI) had leachate concentrations of 8.75 ppm Cr(VI) and 9.5 ppm total Cr. Hence, the slag-modified grouts were demonstrated to be potential stabilization agents on the spiked soils.

A significant finding from the TCLP tests on Cr(VI) contaminated soils stabilized with slag-modified grout was that 40% replacement of cement with slag was sufficient to cause reduction of Cr(VI). Studies by Angus and Glasser (7) on slag-modified cements showed that the redox potential was not significantly lowered until slag content reached around 85%. Curing conditions differed from those used in this work, but the curing period was approximately the same. Atkins and Glasser (16) comment that the level of slag replacement necessary for reducing behavior depends on time since more S^{2-} is released as slag continues to hydrate. Thus, the redox conditions in the soils treated with slag-modified grout can be expected to change with time and with the availability of water for hydration.

Leach Resistance with Time

A question arises as to whether the observed immobilization of Cr(VI) with slag-modified grouts is permanent. Oxidation of S^{2-} may occur if oxygen diffuses into the treated soil. Consequently, the reducing characteristics may be diminished. Diffusion of oxygen into the stabilized landfill soil is not expected to be a major concern under subsurface conditions, but requires consideration. The potential deterioration of the reductive capacity of grout treated soil was investigated to determine whether this could result in increased leachability of Cr. Soils spiked with 200 ppm Cr(VI) and treated with grouts containing 40% and 80% slag were crushed as required for the TCLP test and left in laboratory air for periods of 7 and 14 months. The specimens were from the same batches used in the initial TCLP tests and, therefore, should not vary in content or properties except for inherent heterogeneity. At the conclusion of the exposure time the specimens were subjected

to TCLP tests and the results were compared with those collected at an age of 28 days.
The soils treated with the 40% slag grout showed an increase in leached Cr(VI) and total Cr at both 7 and 14 months when the soil/cementitious material ratio equalled 5. At 14 months the material with 40% slag and a soil/cementitious material ratio of 2 had increased leachate concentrations compared to the initial and 7 month values. In contrast, the soil treated by grout with 80% slag did not demonstrate significant increased leachability at any soil content for either of the test periods. The limit of 5.0 ppm leached Cr was not exceeded for either grout and the maximum value for total Cr was 1.0 ppm. The results suggest increased potential for Cr release for soils treated with lower slag content grouts exposed to oxidizing conditions. Higher slag contents appear preferable in this respect and will continue to be monitored.
Leach Tests on 1000 ppm Cr Soil
The initial successful stabilization of spiked and landfill soils with the slag-modified grouts warranted further investigation with higher Cr contamination levels. Two grout mixes were used: 1) 100% cement, 2) 40% slag/60% cement. It is also intended to test grout with 80% slag on higher Cr concentrations for comparison, with emphasis on the long-term immobilization performance. The test specimens had a water/cementitious material ratio of 0.72 and a soil/cementitious material ratio of 2. The grouts were used to stabilize soils spiked with 1000 ppm Cr(III) and with 1000 ppm Cr(VI). Dilution by grout resulted in the Cr concentration of the stabilized soils being 532 ppm in each case.
The results for the leach tests on soil spiked with 1000 ppm Cr are presented in Figs. 1 and 2. The leachate concentrations for the Cr(III) soil illustrated in Fig. 1 were well below the limit of 5.0 ppm and showed enhancement of leach resistance due to addition of slag to the grout. Figure 2 shows that slag decreased the amount of Cr(VI) and total Cr that was leached. At 1000 ppm Cr(VI) in the original soil the grout without slag was unable to comply with EPA leachate requirements. Tests on stabilizing 1000 ppm Cr(VI) soil with higher slag content grouts will determine whether reduction of Cr(VI) to Cr(III) and leach resistance can be improved further.
Fig. 1. TCLP Results for 1000 ppm Cr(III) Soil.
Fig. 2. TCLP Results for 1000 ppm Cr(VI) Soil.
Future Work on Cr Stabilization
The laboratory prepared stabilized soils will be continually monitored for leachability to test that Cr stabilization remains acceptable. The practicality of using slag-modified grouts for in-situ stabilization of the chromium plume at the landfill will be investigated. The planned field trials will involve optimization of grout mix proportions and placement equipment parameters for the site conditions. The properties of the stabilized soil will be tested for leach resistance, durability and physical and mechanical properties. The safety, efficiency and economics of the grout stabilization process will be compared with other in-situ methods.
SUBSURFACE CONTAINMENT BARRIERS
Vertical and horizontal subsurface barriers in uncontaminated soil are required to reduce migration of any remaining leachates and to prevent penetration from external sources. Together with a surface cover, the subsurface barriers will effectively contain the landfill contents. Cementitious grouts containing admixtures have been evaluated for this purpose with the objectives of improving hydraulic and mechanical properties over conventional, high water/cement ratio grouts and producing a more cost effective and reliable solution than polymer or chemical grouts.
Jet grouting and deep soil mixing are under consideration for in-situ vertical barrier placement at the site of interest. Jet grouting can also be used to form horizontal barriers (10,17,18). Permeation grouting is not considered to have a high probability of producing continuous barriers in a controlled manner at the site with cementitious grouts due to the fine particle size and heterogeneity of the soil. Uncertainty of forming continuous barriers at the site is also a concern for claquage, or hydrofracture, grouting.
Two versions of jet grouting are of interest for the barrier construction. The first method is in-situ mixing of grout with soil to form a soil cement barrier. Replacement jet grouting is the second method and involves removal of soil by a jet of water and air, followed by placement of grout in the formed cavity. Of the two, the first method is more readily available and less expensive.
Containment barriers are required to be free from major defects that could give rise

to leakage. Examples of such defects include cracks and discontinuities between successive grout or soil cement columns. The potential for cracking can be minimized to some degree through mix design, such as using minimum water/cementitious material ratio, and through materials selection to reduce shrinkage, increase fracture resistance and decrease thermal effects.

Another concern is that leakage may develop at column joints if the bond is insufficient. Jet grouted or soil mixed columns are usually overlapped and keyed together to form an interlocked barrier. Thus, a mechanical bond is formed. The chemical bond between columns is also of interest since this will influence the hydraulic integrity of the joint, and hence, the overall performance of the subsurface barriers. Studies of the permeability of bonded grouts and soil cements were initiated to examine the interfacial properties. The permeabilities were compared with those of bulk materials.

Bond Permeability Tests

Soil cements and sanded grouts determined to be barrier contenders from earlier property studies are currently being prepared and tested for bond permeability. Soil cements have been prepared from plain and from slag-modified grouts. Sanded grouts containing supplementary cementing materials such as silica fume and slag are being investigated for comparison with soil cements. The results for one soil cement and one grout have been selected for presentation. Both materials contained slag. The same types of superplasticizer and bentonite as used in the Cr stabilization described above were used for the barrier materials. Uncontaminated site soil collected from a location adjacent to the landfill was used. The mix proportions are presented in Table I.

Table I. Mix Proportions of Selected Soil Cement and Sanded Grout used for Bond Studies

Permeability of bonded soil cements and sanded grouts was measured on cylindrical specimens cast in two halves. Wax coated cardboard cylinders 75 mm diameter and 150 mm long were fitted with a vertical insert which had a smooth polyethylene surface. The first half of each specimen was cast, covered with polyethylene sheet and allowed to sit for 24 hours. The insert was then removed and the second half of each specimen was cast. After 24 hours the cardboard mould was removed and the specimens were maintained in water until testing at 28 days age. A total of three specimens per mix were tested.

Figure 3 shows the permeabilities of the bonded materials in addition to the values for bulk materials at the same age and cured under the same conditions. Assuming that the permeabilities are normally distributed, t-tests were performed to determine whether the permeabilities of the bonded and bulk materials were significantly different. It was determined that the permeability of the bonded soil cement was significantly higher than the bulk material at a 5% level of significance. This can be attributed to shrinkage of the second half of the specimen, causing preferential flow to occur at the interface. The permeabilities of the bonded and bulk grouts were not significantly different. This suggests low shrinkage and sound bonding between successive grout batches. In each case, the permeability of the bonded material remained sufficiently low for containment purposes. It is necessary to repeat permeability measurements of column joints produced in the field with full scale in-situ placement equipment and subjected to subsurface shrinkage conditions to test that adequate performance can be achieved.

Fig. 3. Permeability of Bonded and Bulk Materials

The bonded specimens will be subjected to wet-dry cycles and re-measured for permeability to determine the susceptibility to preferential flow at the interface. The permeability under unsaturated conditions is of interest since the barriers will be placed in the vadose zone in this case. The microstructure of the bond will also be investigated to elucidate potential means of improving interfacial properties.

Proposed Field Trials for Barriers

It is proposed to conduct extensive field trials at the landfill site so that the grout proportions, grouting process and barrier performance can be optimized for both vertical and horizontal barriers. Grouting parameters for the unique site conditions require further systematic variation with corresponding evaluation of barrier quality and continuity. The minimization of water/cementitious material ratio while retaining compatibility with the placement equipment is of particular importance since this parameter has the greatest influence on final permeability.

CONCLUSIONS

Slag-modified cementitious grouts have been found to be potential stabilization agents for soil contaminated with up to 1000 ppm Cr(VI). Further tests are in progress to assess the permanence of stabilization. Grouts with enhanced hydraulic, physical and mechanical properties have also been developed and characterized for subsurface barriers. The permeability of joints between barrier materials has been measured and found to be suitably low. The program is now at the stage of demonstrating the slag-modified grouts for in-situ stabilization of chromium plumes and demonstrating superplasticized cementitious grouts for subsurface containment barriers using placement techniques such as jet grouting.

ACKNOWLEDGEMENTS

This work was performed under the auspices of the U.S. Department of Energy, Washington, DC, under Contract No. DE-AC02-76CH00016. Prepared for the Department of Energy Office of Technology Development, Office of Environmental Management. The authors would like to thank Dr. D.A. Bruce, Nicholson Construction Company, for technical information on jet grouting and Mr. J.H. Heiser, Department of Advanced Technology, BNL, for valuable discussions.

IN SITU BIOREMEDIATION: COST EFFECTIVENESS OF A REMEDIATION TECHNOLOGY FIELD TESTED AT SAVANNAH RIVER

Ramiz P. Saaty
W. Eric Showalter
Steven R. Booth

Los Alamos National Laboratory
ABSTRACT
In Situ Bioremediation (ISBR) is an innovative new remediation technology for the removal of chlorinated solvents from contaminated soils and groundwater. The principal contaminant at the SRID is the volatile organic compound (VOC), tricloroetylene(TCE). A 384 day test run at Savannah River, sponsored by the U.S. Department of Energy, Office of Technology Development (EM-50), furnished information about the performance and applications of ISBR.
In Situ Bioremediation, as tested, is based on two distinct processes occurring simultaneously; the physical process of in situ air stripping and the biological process of bioremediation. Both processes have the potential to remediate some amount of contamination. A quantity of VOCs, directly measured from the extracted air stream, was removed from the test area by the physical process of air stripping. The biological process is difficult to examine. However, the results of several tests performed at the SRID and independent numerical modeling determined that the biological process remediated an additional 40% above the physical process. Given this data, the cost effectiveness of this new technology can be evaluated.
INTRODUCTION
The purpose of this report is to study the cost effectiveness of In Situ Bioremediation (ISBR) with horizontal wells as tested at the Savannah River Integrated Demonstration (SRID) site in Aiken, South Carolina. ISBR is an innovative new remediation technology for the removal of chlorinated solvents from contaminated soils and groundwater. The principal contaminant at the SRID is the volatile organic compound (VOC), trichloroethylene (TCE). A 384 day test run at Savannah River, sponsored by the U.S. Department of Energy, Office of Technology Development (EM-50), furnished information about the performance and applications of ISBR.

The overall cost effectiveness of In Situ Bioremediation (ISBR) is based on the cost sensitivity of the biological component; as the biological addition increases, the cost per pound of VOCs remediated decreases.

The short-term cost of ISBR with a biological addition of 40% above the vacuum component is $21 per pound of VOCs remediated. The worse case scenario, ISBR + 0% addition costs $29/lb of VOCs remediated, and is based solely on the vacuum component.

The baseline pump and treat/soil vapor extraction system costs $31/lb in the short-term and has no possibility of a biological addition.

Life-cycle analysis shows that ISBR is more cost effective than the baseline pump and treat/soil vapor extraction system.

As demonstrated, ISBR has a possible savings of $1 million at the SRID site alone.
In Situ Bioremediation is based on two distinct processes occurring simultaneously: the physical process of in situ air stripping and the biological process of bioremediation (see Fig. 1). Both processes have the potential to remediate some amount of contamination. A quantity of VOCs, directly measured from the extracted air stream, was removed from the test area by the physical process of air stripping. The biological process is difficult to examine. However, the results of several tests performed at the SRID and independent numerical modeling determined that the biological process remediated an additional 40% above the physical process. Given this data, the cost effectiveness of this new technology can be evaluated. In addition to calculating the cost effectiveness on the ISBR demonstration at the SRID, sensitivity analysis is conducted in order to determine how the overall cost of ISBR changes in regards to the performance of the biological component. By comparing the overall cost of this system and the price per pound of VOCs remediated against a conventional pump and treat/soil vapor extraction system, we can evaluate the overall cost effectiveness of the alternative technologies.
SYSTEM CAVEATS
The ISBR demonstration at the SRID was set up to address a "hot spot" of an overall larger VOC contaminant plume. The pump and treat/soil vapor extraction system is engineer designed and presumed to perform optimally. Both pump and treat and soil vapor extraction systems have been tested at the SRID. The baseline system (a combination of pump and treat/soil vapor extraction apparatus) is integrated to avoid overlapping of equipment and materials, and is located in an area exactly like the ISBR demonstration in regards to all necessary site characteristics, including overall concentration of contaminants. By designing both the baseline and the innovative systems to handle equal flow and assuming equal vacuum extraction

performance, a level playing field for a cost comparison is created.

ANALYSIS

The data used in these analyses have a "field demonstration" level of confidence and are based on an actual field demonstration. The performance comparison consists of Plan 1, which is based on the new ISBR technology as demonstrated at the SRID, and Plan 2, which is based on "equivalent" conventional technologies, pump and treat/soil vapor extraction, necessary to remediate the contamination problems addressed by ISBR. Plan 2 is constructed so that it remediates the same conditions treated by ISBR at the SRID. In order to be fair to both technologies, equal physical process performance is forced from both Plan 1 and Plan 2. Plan 1 and Plan 2 are compared based on what it costs to operate them over equal periods of time. Performance data indicate that the vacuum component of ISBR destroyed 12,096 pounds of VOCs in 384 days, and an additional 40% above the vacuum component was destroyed by bioremediation. The vacuum component data is used in the pump and treat/soil vapor extraction system, assuming that the equal flow rates will remove the same quantity in an equal amount of time.

The ISBR system, as tested, uses two horizontal wells. The first well is an injection well, 300 ft long and 165 ft deep (about 35 ft below the water table). The second well is an extraction well, 175 ft long and 75 ft below the surface (in the vadose zone). A concentration of methane (between 1% and 4%) and any necessary chemical nutrients (nitrogen in the form of nitrous oxide and phosphorus in the form of triethyl phosphate) are blended into the injected air stream to create a biological element for remediation. The methane provides the necessary material substrate for the indigenous microorganism to produce the enzyme methane monooxygenase which, in turn, degrades the principal contaminant, trichloroethylene (TCE). For the conventional technologies used in Plan 2, four vertical SVE extraction wells are assumed to be equal in area influenced to the one horizontal extraction well of ISBR. One vertical pump and treat well is also used. Volatilized contaminants from both remediation systems are sent to a catalytic oxidation off-gas system where they are destroyed.

Economic comparisons for short-term costs are made by relying on actual field data and using cost sensitivity analysis; life-cycle costs are estimated in relation to possible time to achieve cleanup. The first economic comparison is a calculation of the short-term costs in relation to performance. Short term costs are those expenses incurred during the immediate field test demonstration of the technologies compared (generally about a year). The equipment capital costs are amortized yearly over the useful life of the equipment, which is assumed to be 10 years. All short-term equipment costs are amortized at 7%, which is the interest on the loan.

For ISBR there is a total cost of about $354,000 with total 16,934 pounds of VOCs being destroyed by the vacuum component and biological component, giving a cost per pound of VOCs remediated at about $21. The integrated pump and treat/soil vapor extraction with 4 vertical SVE wells has a total cost of about $380,000. Assuming an equal vacuum extraction performance of 12,096 pounds of VOCs removed, the integrated system has a cost per pound of VOCs remediated at about $31. A ratio of ISBR to the baseline shows that ISBR is 32% less expensive than the baseline.

Next, an analysis of life-cycle cost is conducted. A real discount rate of 2.3% is used to calculate the present value. ISBR, with its combination of vacuum component and bioremediation, costs $1 million and remediates the site in only 3 years. The baseline takes 10 years to remediate the site and costs $2 million. ISBR, therefore, saves $1 million and 7 years of remediation. Even when we assume the baseline can perform at twice the expected time and cleans the site in only 5 years, it still costs $1.4 million. ISBR still beats the baseline by $400,000 and 2 years remediation time.

Where ISBR has the potential to exceed the baseline technologies is its ability to remediate a portion of the contamination in situ, thereby eliminating the need to physically remove the contaminant and process it. Since ISBR relies heavily on the biological component to achieve greater performance, sensitivity analysis is conducted to compare the cost per pound of VOCs remediated versus the performance of the biological component. Of particular interest is ISBR + 0% addition. This is a worse case scenario based on a 0% addition from the biological component. It assumes that all the necessary materials are added to stimulate the biological addition, but no additional remediation occurs. In this situation, ISBR still costs slightly less than the baseline, $29 versus $31, respectively. By adding a percent addition of

pounds of VOCs destroyed by bioremediation in addition to that removed via the vacuum component, we can examine how the cost per pound changes with respect to the biological component. Six hypothetical percentages are used to account for the bioremediation levels: 0%, 20%, 40%, 50%, 70%, and 90%. Figure 2 shows the various hypothetical additions and the decrease in cost per pound of VOCs remediated.
The baseline technologies in Plan 2 have a constant price per pound of VOCs remediated of $31 because there is no biological component. As the biological addition of ISBR increases, the price per pound of VOCs decreases. So, even in the worse case scenario where no bioremediation occurs, ISBR breaks even with the baseline. There is, therefore, no cost risk to run ISBR over the baseline system. The savings, however, are quite substantial when the biological component is stimulated. In order for the biological component to occur, it is necessary to inject methane and nutrients into the system. Without this material, only the physical, vacuum component of ISBR is possible. Because the cost of the biological component is so inexpensive, ISBR only has to remediate an additional 1,570 lbs of VOCs over the 12,096 lbs of VOCs remediated with the vacuum component in order for the system to completely pay for the cost of the methane injection. Any additional remediation is achieved at no extra cost and increases the cost savings of ISBR over the baseline technologies.
Next, the total present value cost for operating each plan for five years, including all necessary equipment, is computed. The total equipment costs are included in the first year so that no amortization is needed. As with the short-term cost, the potential cost-savings for ISBR lie with its ability to remediate VOCs in addition to the physical process, thereby lowering the cost per pound and increasing the total amount remediated over equal time. The same hypothetical percent additions of 0%, 20%, 40%, 50%, 70%, and 90% are used. Table I shows the decrease in price per pound as bioremediation increases. The $38 per pound of VOCs remediated with the pump and treat/soil vapor extraction remains constant because there is no equivalent biological addition.

PERSPECTIVES AND COST DRIVERS

The two largest categories in regards to cost for both ISBR and the baseline system are the costs of consumables and labor. The labor and consumables are greater than 85% of the overall operating costs; therefore, if the overall remediation time of the project is shortened, the cost will drop. This is due to the nature of the labor and consumables which are incurred each day of operation. Since ISBR can significantly decrease operation time, ISBR lowers the overall cost of the remediation effort.

APPLICABILITY

ISBR can be very effective in settings where some interbedded thin and/or discontinuous clays are present. ISBR should prove even move successful than in situ air stripping alone because ISBR contains a biological component as well as the physical air stripping process. A potential concern with the use of ISBR is the possible lateral spread of the contaminant plume. If the geology constricts vertical flow, the injection process can push the dissolved contamination concentrically from the injection point. Thus, it may be advisable in heterogeneous formations to use ISBR in conjunction with a surrounding pump and treat system that provides hydraulic control at the site. Note that the limitations on applicable geologic settings described above also apply to soil vapor extraction and pump and treat systems.

INTEGRATION OF PNEUMATIC FRACTURING AND IN SITU VITRIFICATION IN THE SOIL SUBSURFACE

Ja-Kael Luey
Douglas K. Seiler
Battelle - Pacific Northwest Laboratory
John R. Schuring
New Jersey Institute of Technology

ABSTRACT

Pacific Northwest Laboratory is evaluating ways to increase the applicability of the

in situ vitrification (ISV) process at hazardous and radioactive waste sites. One innovation is the placement of a conductive material that will facilitate initiating the ISV process at a target depth.

A series of laboratory tests performed at the New Jersey Institute of Technology (NJIT) assessed the feasibility of pneumatic fracturing (PF) in the highly permeable soils of the Hanford Site. The NJIT tests included an analysis of Hanford soils, a series of PF injection tests, and a parametric analysis to determine how soil properties affect the PF process. Results suggest that the PF process can be applied to Hanford soils and that dry medium (e.g., conductive material such as graphite flake) can be injected into the fracture.

INTRODUCTION

ISV is a thermal treatment technology, developed by the Pacific Northwest Laboratory for the U.S. Department of Energy, to treat soils contaminated with transuranic elements. The process is traditionally initiated at the soil surface through the use of conductive material placed within an array of electrodes. Heat generated in the conductive material melts the soil. Molten soil conducts electricity and is the heat source for downward and outward propagation of the process. Propagation continues until a target volume has been treated. Operating temperatures in excess of 1400C destroy or pyrolyze organic and inorganic molecules. Heavy metals and radionuclides are immobilized in the final ISV product, a glass and crystalline material that has excellent leach resistance.

Initiation of the ISV process in the soil subsurface: 1) has the potential to increase the applicable treatment depth of the process (demonstrated to 6 m), 2) permits the creation of subsurface vitrified structures, and 3) permits the selective treatment of contamination located at depth. A key step for this ISV application is the placement of a conductive material in the electrode array to initiate the process at a target depth. Murphy et al. (1) identified horizontal drilling, direct injection, and subsurface fracturing technologies as methods to initiate the process underground. In laboratory experiments, Luey and Seiler (2) showed that the ISV electrode array can be connected either by linear paths of conductive material or by a plane of such material. Successful initiation by a plane of conductive material provides the basis for investigating pneumatic fracturing for placement of conductive material at a target depth (fractures typically are horizontal in the soil subsurface).

PNEUMATIC FRACTURING

Pneumatic fracturing enhances the in situ removal and treatment of contaminants in low-permeability soil and rock formations. It was developed at the Hazardous Substance Management Research Center (HSMRC) at the New Jersey Institute of Technology (NJIT). The process generally involves injecting air into a contaminated geologic formation at a pressure that exceeds the natural in situ stresses and a flow rate that exceeds the permeability of the formation. The resultant failure of the medium creates a fracture network radiating from the injection point. The established fractures increase the permeability of the formation, thereby enhancing the flow rate of vapors or liquids for more efficient removal or treatment of contaminants.

The principle objectives of pneumatic fracturing are reduction of treatment time and extension of available technologies to more difficult geologic conditions. It is designed to be integrated with other in situ treatment technologies, such as vapor extraction, bioremediation, and pump and treat. Initial applications focused on enhancing treatment of the vadose zone, but recently the technology has been extended into the saturated zone. The PF system has also been modified to deliver biological supplements (e.g., nutrients, buffers, and microorganisms) directly into the fractured formation to enhance bioremediation.

To date, pilot tests of pneumatic fracturing have been conducted at 10 sites in a variety of geologic formations, including a U.S. Environmental Protection Agency (EPA) Superfund Innovative Technology Evaluation (SITE) Demonstration at a contaminated industrial site in Hillsborough, New Jersey (3). Pisciotta et al. (4), Schuring and Chan (5) and Schuring, Valdis, and Chan (6) have published on PF applications.

Pneumatic fracturing is a patented process (7) and is commercially available from Accutech Remedial Systems of Keyport, New Jersey. Accutech offers a fully mobile, production version called Pneumatic Fracturing Extraction (PFE). PFE is an integrated remedial system for removing and treating volatile organic carbon

molecules from geologic formations of low to moderate permeability.

LABORATORY STUDIES

To support PNL's ISV technology, a series of laboratory tests were performed at NJIT to assess the feasibility of pneumatic fracturing in the highly permeable soils of the Hanford Site. The NJIT tests included an analysis of Hanford soils, a series of PF injection tests, and a parametric analysis to determine how soil properties affect the PF process.

Analysis of Hanford Soils

For a field demonstration of ISV initiated in the soil subsurface, PNL selected a test site on the Hanford Site in south-eastern Washington. The underlying geologic unit is the Hanford Formation, which consists of coarse-grained sands and gravel deposited in a matter of days during cataclysmic floods at the end of the last ice age. The rapid deposition preserved a high ratio of void space between particles. The nature of the Hanford Formation results in high porosity (>30%) and high saturated hydraulic conductivity (0.35 to 3.5 cm/s) (8,9).

Investigators at NJIT tested soil from the PNL test site to determine physical properties of the Hanford Formation. Testing included grain size analysis, Unified Soil Classification System (USCS) classification, Atterburg limit tests, organic content, specific gravity, and the standard Proctor density test. All testing was performed in accordance with the standard methods of the American Society of Testing and Materials (ASTM). The investigators then prepared a surrogate test soil at NJIT to support a series of bench-scale PF injection tests. Table I compares the physical data for the Hanford soils with the surrogate test soil; the surrogate test soil compared well with the Hanford soil and was deemed suitable for bench-scale PF injection tests.

Bench-Scale PF Injection Tests

Bench-scale PF injection tests addressed the application of an integrated PF/ISV system in Hanford-type soils. Bench-scale tests physically simulate the integrated process and thereby permit study of critical soil parameters and their effect on fracture injection behavior. Figure 1 illustrates the key components of the bench-scale system: a test tank with plexiglass walls, an air supply system, a flow-directing injector-nozzle, a venting system, and a dry-media injection system. The plexiglass walls of the test tank permit direct viewing of the results of each injection and permit real-time adjustment of injection pressures and flow rates.

Of the 38 PF injection tests performed, 28 tests were with air alone, 6 with air and silica sand, and 4 with air and ISV conductive material. Soil density for the sessions varied between 1.65 and 1.80 g/cm3; the moisture content was 0.8% to 7.8% by weight. Seven nozzle designs were used during the initial 10 fracture sessions with air alone. A nozzle previously designed for clays and other fine-grained soils (the traditional application of PF) allowed air to escape along the injection pipe. Subsequent designs using discs to isolate the nozzle from the injection pipe provided limited success but erratic results. A design using a disc that provided directional flow was the most effective and was used in most sessions.

Results from the bench-scale tests show that dry density and moisture content of the soils are critical factors in creating and controlling fractures and injecting dry media. The most important factor was dry density. Fractures at a density of 1.7 g/cm3 were successful; inconsistencies were observed at lower densities. A density of 1.7 g/cm3 represents the lower range for Hanford soils. As density increased, the pressure required to initiate fracturing tended to decrease. This effect was accentuated through the use of a surcharge on the soil surface to simulate soil overburden pressure.

Fracturing was generally successful when moisture content exceeded 2 wt%. Fracturing at lower moisture contents was successful if density exceeded 1.7 g/cm3. At densities at or below 1.65 g/cm3 and moisture content below 1wt%, discrete fractures were unattainable.

Table I

Fig. 1

This is attributed to a reduction of interstitial surface tension and the corresponding loss of apparent soil cohesion. The initial pressure required to fracture was not affected by the moisture content, contrary to expectations that the required pressure would decrease with increasing moisture content as apparent cohesion reduced the escape of air.

Results from bench-scale tests involving the injection of dry media (silica sand or

ISV conductive material) showed a significant difference in lens geometry for different materials. Excavation was performed after injection of sand or ISV conductive material. For the sand injection, the lens was nearly continuous from the nozzle throughout the plane of fracture. Injection of sand, which is denser and less viscous than the ISV material, probably enhanced displacement or "cutting" of the Hanford surrogate soils. In contrast, excavation after injection of ISV material revealed a continuous layer at the fracture level, but the lens was not traceable to the nozzle. The ISV material appeared to have traveled upward along the injector pipe to the fracture. The ISV material is less dense than sand and has self-lubricating properties, which may have allowed it to travel along the small annular space between the injector and the soil.

The four tests involving the injection of ISV material were modeled to simulate the integrated PF/ISV process, in which conductivity is measured across the filled fracture and through the graphite electrodes of the ISV process. Results show that pneumatic fracturing can establish a conductive link in the soil subsurface between electrodes. The key to successfully establishing this link will be the formation of the fracture in the Hanford soil.

Parametric Analysis

A modelling study was performed to investigate selected physical processes of the integrated PF/ISV system. This was necessary because there was no previous experience with injecting granular media into a coarse-grain soil formation. The results provided insight into the critical mechanisms of the PF/ISV system and allowed estimates to be made of key design parameters for a field-scale system.

In a radial flow model for pneumatic fracturing, the velocity of the injected air decreased rapidly. Calculations suggest that the effective radius of the PF/ISV system may be limited to several feet in Hanford soil at standard injection flow rates and pressures. This distance is significantly less than the radius of influence typically observed in fine-grained soil and rock formations. The difference is attributable to the high permeability of the Hanford soil and corresponding rapid leak-off. Results underscore the need for proper nozzle design for the field, as well as maximization of system flow rates and pressures.

The critical suspension velocities for transport of the ISV conductive material in the fractures were determined by two different methods: Shields diagram method (10) and dust transport method (11). The suspension velocity determined from these methods was generally less than 0.4 m/s. This relatively low velocity indicates that transport of the ISV conductive material should not be an issue in open fractures; rather, the limiting condition will be the ability to propagate the fractures.

The ability to transport ISV conductive material through the interstices of the Hanford soil was also analyzed with standard published filtration criteria. The results show that interstitial penetration of the conductive material will not be a significant mechanism in the Hanford soil; most of the particles are predicted to strain or cake at the fracture interface. A benefit from this caking may be the extension of the radius of the fracture as caking reduces the permeability of the upper and lower boundaries of the fracture. The reduced permeability extends the fracture by minimizing leak-off from the upper and lower boundaries.

CONCLUSION

Results of bench scale tests suggest that pneumatic fracturing and in situ vitrification can be successfully integrated to expand the applicability of both technologies. The establishment of fractures in Hanford surrogate soils shows that pneumatic fracturing is applicable in soils other than clays and fine-grained soils. Successful injection of ISV conductive material in the soil subsurface to provide a conductive link between ISV electrodes provides a means for initiating the ISV process at a target depth. The consequent increased ISV capability enhances the applicability of the technology beyond current demonstrated depths.

We are integrating the results of the laboratory results into plans for a field demonstration of pneumatic fracturing at Hanford to be performed in the first quarter of 1995 on an uncontaminated soil site. If a suitable conductive path is created, then the field demonstration will continue the ISV process initiated in the soil subsurface.

ACKNOWLEDGEMENT

Pacific Northwest Laboratory is operated by Battelle Memorial Institute for the U.S. Department of Energy (DOE). This work was sponsored by the Office of Environmental Restoration within DOE. The NJIT pneumatic fracturing team supporting this work

included Thomas Boland, Heather Hall, Brian Intindola, Sean McGonigal, and Suresh Puppala, all of NJIT and also John Liskowitz of Accutech Remedial Systems.

ABSTRACT

Commercial applications of the in situ vitrification (ISV) remediation process are underway. The first commercial project was completed in mid 1994, a second project was completed in October 1994, and a third project commenced in November 1994. All three projects involve the treatment of contaminated soil and buried debris. The three projects include:

the Parsons Chemical/ETM Enterprises Superfund Site in Michigan State. The project involved the treatment of 4,800 tons of soil contaminated with mercury and pesticides including chlordane, DDT, dieldrin and aldrin. Buried debris included drum lids, plastic sheeting, concrete, secondary wastes, and automobile tires.

a private Superfund Site in Washington State. The project involved the treatment of 3,100 tons of PCB-contaminated soil and debris with maximum PCB concentrations to 17,000 ppm. Debris included drums and chunks of contaminated asphalt and concrete. This project is serving as the TSCA demonstration project required to obtain a National TSCA Operating Permit for the application of ISV to PCB contaminated soil.

a private Superfund Site in Salt Lake City, Utah. The project involves the treatment of 5,600 tons of soil and sludge contaminated with various organics

including dioxins, furans, pentachlorophenol, xylenes, toluene and pesticides including DDE, DDT, 2,4-D and chlordane. Debris buried in the site includes plastic sheeting, wooden timbers, pieces of clay pipe, investigation derived wastes, and sample bottles.

In addition to these three projects, Geosafe is preparing to conduct on-site treatability tests and intermediate-scale demonstrations involving plutonium and uranium-contaminated debris buried in pits at the Maralinga Test Range in South Australia. This demonstration project is being performed for the Australian Government as part of the Maralinga Rehabilitation Program. The Maralinga Test Range became contaminated from British nuclear weapons tests conducted in the late 1950's and early 1960's. Geosafe's role in the Rehabilitation Program will involve the treatment of burial pits at the Taranaki area; the site's most contaminated area. The burial pits are believed to contain approximately 5 kg of plutonium, about 20 kg of enriched and depleted uranium, and heavy metals such as beryllium, lead, and barium along with massive amounts of debris resulting from the weapons tests.

This paper will present a brief summary of the ISV process, an overview of each of these four projects and present performance results for these commercial applications. Together, these projects demonstrate the capabilities of the ISV process in terms of treating contaminated soil that contains a wide range of contaminant types as well as significant amounts of buried debris.

ISV PROCESS

ISV is an innovative on site and in situ treatment process that involves the electric melting of contaminated soil and/or other earthen materials for purposes of permanently destroying, removing, and/or immobilizing hazardous and radioactive contaminants. ISV was invented by Battelle, Pacific Northwest Laboratories in 1980 for the U.S. Department of Energy. More than 190 developmental tests and demonstrations of the technology have been performed since that time at four scales: bench, engineering, pilot, and large-scale.

The process involves forming a melt at the surface of a treatment zone between four electrodes. The molten soil serves as the heating element of the process, wherein electrical energy is directly converted to heat as it passes between the electrodes. Continued application of energy results in the melt growing deeper and wider until the desired treatment volume has been encompassed. When electrical power is shut off, the molten mass solidifies into a vitrified monolith with unequalled physical, chemical, and weathering properties compared to alternative solidification/ stabilization technologies.

ISV melting typically involves molten soil temperatures in the range of 1600-2000C. This high temperature results in the removal of organics from the treatment volume by vaporization followed by pyrolyzation within the soil closely adjacent to the melt. No organics remain in the melt or the vitrified monolith due to the inability of organics to exist at the temperatures involved. A broad range of organic contaminant types have been successfully treated in various ISV tests and demonstrations, including volatiles (e.g., benzene), semi-volatiles (e.g., pesticides), and nonvolatile organics (e.g., PCBs, dioxin).

The predominant disposition of heavy metal oxides during ISV processing involves physical and chemical incorporation into the vitrified product, which produces a permanent immobilization result. Most species of metals remain as oxides in the melt and are incorporated into the vitrified product upon cooling. However, since ferrous metals do not have a strong affinity for oxygen in an ISV melt, they will remain in a reduced state. Therefore, ferrous metals (e.g., scrap metals, piping, drums) present in the treatment zone typically melt and sink to the bottom of the melt pool where they are encapsulated there by the vitrified product. It should be noted that ISV processes both organic and heavy metal (including radioactive) contaminants simultaneously, which is a capability largely limited to vitrification processes.

ISV is also distinguished by its ability to tolerate debris within the treatment zone. Organic debris materials behave as other organics during ISV processing ... they are destroyed primarily by pyrolysis. Inorganic debris materials are typically incorporated into the melt and the resulting vitrified product. Types of debris previously processed by ISV include: vegetation, wood, plastic, rubber, cardboard, paper, protective clothing, HEPA filters, activated carbon filters, drums, concrete, asphalt, tires, scrap metal, and general construction demolition debris.

ISV results in a 25-50% volume reduction for most soils, and even greater volume reduction for sludges and wastes that dewater and/or decompose during processing.

The volume reduction results in creation of a subsidence volume above the vitrified monolith. In most applications the subsidence volume is filled with clean soil and the monolith is left in the ground since it is no longer hazardous. Sites treated by ISV should be capable of future use without restriction associated with the vitrified monolith.

The ISV process off-gas treatment equipment used for the first three commercial projects includes a stainless steel off-gas containment hood that spans the area being treated; a quencher; a two-stage high efficiency wet scrubber that removes particulates and neutralizes acidic gases; high efficiency air filtration; and thermal oxidation as a final polishing step. The configuration of the off-gas treatment system can be modified to address site specific requirements.

PARSONS CHEMICAL/ETM ENTERPRISES SUPERFUND PROJECT

The Parsons Chemical/ETM Enterprises (Parsons) site represented the first commercial application of the ISV technology. The Parsons site is located near Lansing, MI. The site involved 4,800 tons of silty clay soil contaminated by a variety of pesticides (DDT, dieldrin, aldrin, chlordane), heavy metals (mercury, lead, arsenic), and trace amounts of dioxin. The contaminated soil was present at various locations on the site, and in a drainage ditch about 400-m from the site. To facilitate the melting process, the contaminated soil was excavated and consolidated into nine cells in a 4.9-m (16-ft) deep treatment trench located in a large open area of the site (see Fig. 1). Each cell was 7.9-m (26-ft) square. A significant amount of debris from the site (including protective clothing, roots and vegetation, wood, plastic sheeting, drum lids, and tires) was also placed in the trench with the contaminated soil. Vitrification operations commenced in July of 1993 and were completed in mid 1994. The site conditions posed many challenges that had not been previously experienced with the ISV technology at large-scale. Although these challenges increased the time needed to complete the first few melts, they were all overcome, and the ISV technology is much stronger for the experience. Some of the key challenges associated with the site included the high moisture content of the soil, the added moisture associated with perched water near the surface, and the high sulfur content of the soil which contributed to a non-hazardous sulfur-based odor associated with the off-gas.

A large number of samples were acquired during the project. Preliminary results indicate that the ISV process met cleanup requirements and related ARARs (1). The primary ARAR of concern was the State of Michigan air emissions standards set for this project. Table I presents typical off-gas performance data obtained during the project.

The EPA SITE Demonstration Program monitored the sixth melt. Their results indicate that the cleanup criteria for the contaminants were met (1). A comparison of pre-test and post-test contaminant concentrations in soil is provided in Table II. Analysis of off-gas emissions indicated compliance with Michigan State air emissions standards. The treatment resulted in about a 35% volume reduction of the contaminated soil. EPA has published a Demonstration Bulletin and a Technology Capsule on this demonstration and have also prepared a video describing the Site Program evaluation. Full details of the SITE Program data acquisition and evaluation will be presented in an Innovative Technology Evaluation Report which is presently planned for publication during the first quarter of 1995. Additional sampling of vitrified product and adjacent soil will be performed in the Spring of 1995 when the vitrified product has cooled.

The Parsons project had value for the ISV technology far beyond the meeting of site cleanup and performance objectives. This project was Geosafe's first commercial project and provided an opportunity to prove the ISV technology and Geosafe's capabilities. This was the first large-scale ISV application in a wet clay soil and several site specific challenges had to be overcome. The technology is better for the experience and several innovations implemented during the project have become a routine part of Geosafe's operations. Geosafe acknowledges the support provided by EPA during the project; and notes that such support is critical to the development, demonstration, and commercial implementation of innovative technologies.

TSCA DEMONSTRATION PROJECT

The TSCA Demonstration Project involved the treatment of 3,100 tons of PCB-contaminated soil at a private site in Region X. Geosafe initiated melting operations at the site in June, 1994, and completed the melting operations in October, 1994. In addition to remediation of 3,100 tons of contaminated soil, the

demonstration was performed as required to obtain a National TSCA Operating Permit from EPA for application of ISV to PCB-contaminated sites throughout the U.S. At this time, most of the data has been analyzed and evaluated but surrounding soil sampling activities are on-going.

The demonstration melts were performed in soil and debris containing PCBs to maximum concentrations of 17,000 ppm. The second melt setting was configured with three layers of PCB-contaminated soil with the PCB concentrations in these layers averaging 12,000 ppm with a maximum of approximately 17,000 ppm. The materials were staged for treatment to a depth of 4.9-m (16-ft). In addition to the contaminated soil, some of the melts contained significant amounts of debris, including drums, asphalt, concrete, protective clothing and other secondary waste. Figure 2 illustrates the configuration of the five melts in which the debris content was varied to allow testing of ISV under different conditions of interest.

Geosafe prefers not to treat sites containing sealed containers because the sudden release of gas or vapors from containers can disrupt the melting process. Because the TSCA demonstration site contained sealed drums, a vibratory beam technique was used to breach the drums in situ prior to treatment by ISV. The technique involves using a crane with a vibratory drive attachment to vibrate a beam into the ground in a grid pattern. The vibrating beam has an effective radius of up to several feet and efficiently breaches the drums. This quick and efficient technique effectively demonstrated a means to prepare a site containing drums for treatment by ISV.

The demonstration project was designed to show the efficacy of the ISV technology for treatment of PCB-contaminated soil and debris sites. The process and equipment operated flawlessly during the demonstration and target melt depths were easily attained. Final analytical results of stack samples indicated that the total DRE of the process met Demonstration objectives. DRE data for the second PCB layer of Melt 2 is provided in Table III. Sampling and analysis of surrounding soil samples is on-going and is expected to be finalized within the next one to two months.

WASATCH CHEMICAL SITE PROJECT

The Wasatch Chemical Superfund site is associated with the former Wasatch Chemical Company. Past practices resulted in the contamination of soil and groundwater at the approximate 18 acre site
in Salt Lake City, Utah (2). The ISV remediation involves the treatment of soils, sludges, and debris contained in a concrete evaporation pond. The evaporation pond was formerly used for evaporation of liquid process wastes. These wastes were discharged into the evaporation pond through an underground process drain system that received wastes from several buildings at the site. The pond has a concrete floor that was built approximately 30-cm (1-ft) below grade level. The pond is 38-m by 38-m by 1.2-m deep (125-ft by 125-ft by 4-ft deep). The maximum contaminant concentrations, based on sampling supporting prior ISV treatability tests, are provided in Table IV.

Additional materials from the site have been gathered and staged on top of the sludge and existing earthen materials in the evaporation pond for treatment including various types of debris associated with the on-going site investigation and clean-up. Debris buried in the pond includes plastic sheeting, wooden timbers, pieces of clay pipe, investigation derived wastes, and sample bottles.

Soil and debris staged in and above the pond result in a treatment configuration requiring only 1.8-m (6-ft) to 2.1-m (7-ft) of melt depth. Although configurations involving deeper treatment depths are more economical for the ISV process, it was decided not to restage the material in the pond. Approximately 36 melts are expected to be required to treat the pond area. The final configuration of the pond is shown in Fig. 3.

The groundwater level at the site is typically 1 to 2 feet below grade at the site depending on the season. The groundwater is contaminated with organics in certain areas. Because the water is very near the surface and, at times, can be above the bottom of the pond floor, pumping activities are on-going to temporarily lower the water table to facilitate ISV processing. Although the ISV process can accommodate saturated media as long as the recharge rate is low, the extra water requires more processing time and can result in a larger volume of secondary wastes.

Near the center of the pond area, materials contaminated with high concentrations of dioxin have been staged. This area, referred to as the dioxin cell, will be treated early in the project.

Mobilization to the site occurred in November, 1994. Thus far, three melts have been

completed and the fourth melt is underway. The remediation project is structured to allow the first four melts to be performed in a demonstration mode to so that site-specific process performance data can be obtained and assessed. Variables are being explored during the first four melts. Prior to starting the remaining melts, adjustments will be made as necessary to optimize the process.

During the second melt, it was found that melting into the standing water table was unacceptable, in this case, with the combination of the concrete floor, because it caused excessive melt agitation and overheating of the hood. The transition of the melt penetrating through the floor resulted in a significant amount of water vapor bubbling through the melt. For subsequent melts, Geosafe will limit melt depth, while dewatering will continue to lower the water table to at least one foot below the pond floor.

The third melt was completed without difficulty and the fourth melt is underway. During the third melt stack sampling was performed to verify that stack emissions were meeting ARARs. It is expected that some of the initial performance assessment data including the stack sampling results will be available for presentation at WM-95.

This project is the first to involve the use of two off-gas containment hoods. Since the required melt depths are shallow and the time for each melt is minimal (few days), two hoods are being used so as to minimize the down time between individual melts. Generally, after each melt, the melt is allowed to cool for several hours while the off-gas system is operated before the hood is moved. Then the hood is repositioned, electrical and piping systems reconnected, electrodes installed, and the process reinitiated. With a two hood operation, one hood will be positioned and readied while the other hood is being used for operation. The use of two hoods results in a more efficient and economical operation since down time between melts is minimized.

MIXED TRU-CONTAMINATED BURIED WASTE

ISV has been selected by the Commonwealth of Australia for use on TRU and mixed waste-contaminated burial pits in the Taranaki area of the Maralinga Test Range in South Australia. The burial pits contain contaminated soil and debris resulting from weapons tests conducted by the British in the late 1950's and early 1960's (3). The pits are believed to contain approximately 5 kg of plutonium, about 20-kg of enriched and depleted uranium, and various heavy metals including lead, barium, and beryllium, along with massive amounts of debris.

The ISV process was initially identified by the Commonwealth as the preferred alternative for stabilizing the Taranaki pits in the report by the Maralinga Technical Assessment Group (3). ISV was determined to be the leading candidate for this application because of the ability of the process to immobilize radionuclides in the vitrified product, the associated volume reduction, the ability of the process to destroy organic contaminants, and the improved occupational, public, and environmental safety benefits resulting from the in situ treatment.

Geosafe completed Phase 1 of the initial Maralinga ISV project in mid-1994 and is now preparing to conduct on-site tests as part of Phase 2. Phase 1 involved an initial site assessment and various tests and analyses, including two engineering-scale ISV tests using uncontaminated soil and debris from the Taranaki site. The Phase 1 work was designed to determine key properties necessary to properly apply the ISV technology to the Taranaki pits. Phase 2 is designed to gather comprehensive test information necessary for the proper scale-up of the process and to collect information to support safety assessments. Phase 2 will involve several engineering and intermediate-scale tests performed in situ and onsite at Maralinga. Some of the Phase 2 tests will involve the vitrification of plutonium and uranium contaminated soil and debris. For the intermediate-scale tests, kg-quantities of uranium oxide are expected to be used and a steel plate resulting from the original weapons tests that is contaminated with approximately 3-g of plutonium oxide will be used in the testing.

At this time, plans are being finalized and equipment readied for the on-site Phase 2 testing. The testing will initially involve several engineering-scale tests on small pits constructed to represent the expected configurations of the Taranaki Pits. The engineering-scale tests are being performed prior to intermediate-scale tests to verify immobilization efficiencies of plutonium and uranium using cerium as a surrogate. In addition, the initial tests will be used to determine various operating parameters such as flow rates, process temperatures, particulate loading,

and electrical properties of the melts that are specific to these test configurations. Following the initial engineering-scale tests, a series of intermediate-scale tests will be performed at the Taranaki area. The intermediate-scale tests are anticipated to produce melts in the size range of 3 to 5-tons achieving melt depths of approximately 1.5 to 2-m.
On-site testing should commence by mid-1995. A successful Phase 2 will be followed by equipment design and fabrication for the full-scale remedial operations. It is expected that remedial operations may commence in 1997.

SUMMARY

All of Geosafe's commercial ISV remediation projects thus far have involved the treatment of soils and/or sludges contaminated with all contaminant types (VOCs, BNAs, heavy metals) and containing significant amounts of buried or staged debris. Debris including drums, wood, tires, concrete, asphalt, and various types of investigation-derived wastes have been successfully processed with the ISV technology. As Geosafe gains more commercial experience with sites containing buried and staged debris and as Geosafe progresses with the Taranaki application involving the treatment of mixed TRU-contaminated soil and buried debris, ISV should be considered as a particularly attractive remediation technology alternative for complex sites containing mixtures of contaminant types and debris.
Use of ISV for treatment of buried wastes or staged debris are applications that hold tremendous potential for this very difficult class of remediation problems. The class of buried wastes is a particular remediation challenge because of the difficulty and high cost of retrieving, characterizing, treating and/or finally disposing such wastes. ISV holds the potential to treat the major types of buried wastes onsite and in situ at much lower costs. In some cases of direct in situ treatment of buried waste, ISV will require improved heat removal and off-gas containment and treatment capabilities beyond that of the existing equipment which is designed for contaminated soil applications. Such equipment capabilities are presently being defined and developed.
Alternatively, ISV can presently be considered for those buried waste sites that present too many challenges for direct in situ treatment and cannot be pretreated in situ (e.g., via the vibratory beam technique) or where there are other reasons for retrieval. In these cases, ISV holds promise as a technique for treating the retrieved waste by simply sorting and restaging the debris into treatment cells. In this configuration, materials not suited for direct treatment by ISV could be removed while all other contaminated debris and soil could be staged for treatment by ISV.

INTEGRATED DESIGN PROCESS OF A RADIOACTIVE WASTE FACILITY CLOSURE UTILIZING THREE DIMENSIONAL TECHNOLOGY

Jon D. Blake
William R. Brown
William T. Li
Savannah River Site
Aiken, SC

ABSTRACT

Technological advances in Computer Aided Design (CAD) have allowed engineers to improve the design of manufactured products for many years. This technology is also becoming increasingly more available to engineers concerned about the environment, when performing activities such as modifications of terrain configurations, alterations of surface water hydrology, and isolation of wastes from the biosphere. The purpose of this paper is to describe the process used in a recent low level radioactive waste facility closure design utilizing three dimensional CAD technology. To accomplish this, several aspects of the design are covered including:
existing site conditions and topography

- design considerations and criteria
- electronic surface models
- design interaction and optimization
- drawing compilation and production

This paper presents the design process used, problems and solutions encountered, and the benefits of using a three dimensional computer modeling tool to produce a radioactive waste facility closure design.

INTRODUCTION

The utilization of three dimensional modeling for civil engineering projects, like most recent technological breakthroughs, offers incredible opportunities for waste closure design. Three dimensional modeling provides overwhelming speed and flexibility in developing design alternatives; literally taking seconds to produce what used to take days. The strength of this tool comes from a combination of instant output and feedback, coupled with the ability to make changes and re-perform calculations. Engineers focus their energy on maximizing design efficiency, tweak and pinch alternatives, and produce an optimal design. In addition, powerful presentation tools result in improved client and regulator understanding (see Fig. 1).

The waste facility closure described in this paper provides an overview of the design process for a typical closure project utilizing three dimensional modeling software.

EXISTING SITE CONDITIONS AND TOPOGRAPHY

Just a few years ago, surveyors would document a topographical landscape, recording their findings into a field book, which an engineer could utilize to manually reproduce the field topography onto paper, creating a topographical map. The process, while fairly time consuming, held the advantage of personal interaction. Both the person recording into the fieldbook, and the person reducing the fieldbook onto a set of plans offered human capacity and recognition of obvious error. These positions were eliminated by the invention of a data collector; a device that electronically stores the survey information as it is shot and later transfers the entire record directly into the computer. While saving an enormous amount of time, the data collector does have its draw backs. Surveyors need to account for the lack of human interaction during survey reduction, by enhancing their methods during the field survey. Complex areas require extra shots. A straight retaining wall used to be defined by one survey shot on each corner and sketched in the survey book; the person reducing the survey would understand the wall configuration by the notes and the sketch. Data collectors remove the human interaction, causing far greater challenge to understand what is in the field.

The survey data is imported into the computer where each survey shot becomes a three dimensional point in space. Horizontal and vertical coordinates are relative to the datum established. Each point represents the actual shot taken by the surveyor in the field. Computer software then generates triangles by connecting adjacent points. The result is a three dimensional surface formed by an array of interconnecting triangles, each having a specific size, shape, and plane orientation. This "triangulated model" is the heart of three dimensional surfaces.

Once the Triangulated model is constructed, there are several means to display and analyze the data. Contours can be generated in a matter of seconds. Each triangle is made up of three - three dimensional points, each point having a specific vertical coordinate. For any two points in space, there is a difference in elevation. For example, if a triangle consists of two points at elevation 95.5 and the third at 96.5, it is easy to see that connecting these points, the two vertical segments would have a center at elevation 96.0. For this triangle, a contour at elevation 96.0 would be drawn across the face. Utilizing this principle, the computer draws contours, for any triangulated model. It is important to note that the contours generated for any model are important only for human knowledge. The computer does not require, nor process contour data. (See Fig. 2)

The area being closed was surrounded by existing features, each offering unique design hurdles. An existing road including drainage channels, fence and power poles, an existing closure cap consisting of two feet of cover soil and three feet of Kaolin clay, and an open field. A large amount of the design effort was to make the existing ground triangulated model(s) accurately represent actual field conditions. Existing features such as power poles and fence were not represented three dimensionally, as there would be little gain for a large effort to incorporate this

data. They were always represented two dimensionally (in plan view), so as not to be overlooked during the design process. Concrete drainage channels and other like features were represented three dimensionally (at least the surface of them) because these were critical to the design outcome. The existing closure cap consisted of a two foot vegetative cover and three feet of Kaolin clay.

DESIGN CONSIDERATIONS AND CRITERIA

The waste facility closure "cap" conformed to current EPA regulations for landfill covers, which set final grading of the closure area between three and five percent. The proposed closure cap consisted of (top down) a two foot vegetative layer, a geocomposite drainage layer (GDL), a flexible membrane liner (FML), a geosynthetic clay liner (GCL), and a two foot (minimum) foundation layer with a high strength geotextile reinforcement layer (HSGR) embedded (see Fig. 3). Three aspects of the cover varied from "standard" EPA landfill covers. 1) Most closure covers constructed in the past utilized a two to three foot layer of Kaolin Clay as a barrier material. As mentioned above, the combined layers of GCL and FML are being utilized here. There are many advantages of these materials, among which are resistance to failure during settlements, ease of construction, and cost. 2) There was no biodegradable waste common to municipal landfills within the waste area, and therefore, no vent layer was required. 3) In addition, a typical cover has a one foot foundation layer. This cover has a two foot minimum, which satisfies two criteria; to provide extra protection against radioactive exposure during construction, and provide additional support strength to the GCL and FML layers, i.e. large settlements within the waste area are anticipated.

For the purposes of computer aided design, the cap consisted of two primary layers, the surface of the vegetative layer, and the drainage layer two feet below. These layers impact drainage flow, which is critical for grading purposes. The other proposed layers mirror the drainage layer, and therefore are not considered during the initial grading effort; after the cap is designed these layers will be added to the construction drawings.

ELECTRONIC SURFACE MODELS

The cap design was a trial and error process, beginning from the top down. The waste boundary became the closure cap boundary (plus 1 foot for construction tolerance), defining the area which the top of the closure cap would encompass. Once cap boundary was defined, the existing ground within the boundary was copied four feet higher, and considered a design control surface. That is, since this new surface was exactly the same as the existing ground, but four feet higher, and since the cover section is four feet minimum (see above), this new surface represented the lowest possible design surface. However, this surface still did not meet the slope requirements of 3% minimum and 5% maximum.

Another surface was input into the computer, one which was shaped similar to a gable roof on a house, and met all design criteria. One of the useful design tools on the software package allowed the user to view the design in a plan view (top down) and label the depth between the proposed design surface and the original ground surface in a grid. In this way the depth of additional fill required over and above the four foot design surface was identified. It was quickly seen that in some areas there was over 10 feet of fill between surfaces. Those areas which had large fills were regraded to reduce the proposed grade. Several iterations later the top of cap surface was defined. Once the top surface was approved by the design team, it was copied downward two vertical feet and became the top of drainage layer surface.

At this point the problem of tying the proposed surface into the existing ground, was the next design hurdle. Each of the different conditions which surrounded the closure area required a unique solution. To tie into the existing Kaolin clay closure cover the as-built survey information of the clay was input into the computer, and a new surface created consisting of existing ground/existing clay. In this way one computer generated surface represented two field conditions, the existing Kaolin clay and (where there was no clay) the existing ground. The drainage layer side slope would tie-in to whichever surface it came across.

Utilizing the three dimensional software, a 4:1 side slope was draped from the edge of the drainage layer surface to the existing ground/existing clay surface. Within seconds the proposed surface tied into the existing. However, drainage must always flow downhill; the tie-in had to be checked and modified in those areas where the it formed a low spot. This proved to be fairly difficult along the southern border, where the existing closure cap was sloping downward to the north, counter to the

proposed cap which was sloping downward to the south. At the junction a subsurface swale had formed (the drainage layer is below the cap surface), which had to run longitudinally downhill to the south. This subsurface drainage was outlet into an existing concrete channel. The channel had been used to collect subsurface drainage for the Kaolin clay, so the elevation of the channel was low enough for the new subsurface drainage system to feed into.

Tie-in to the adjacent roadway drainage ditch was less complicated. The proposed side slope tied into the existing ground cleanly, with few modifications necessary. A cursory check proved that the existing ground sloped away from the cap, so that further grading of the existing ground was not required.

DESIGN INTERACTION AND OPTIMIZATION

Many aspects of the design process were enhanced by utilizing three dimensional technology. Cross sections and profiles used for design evaluation and in the final construction drawings were literally cut in seconds. A process which previously would take days was reduced to issuing a command in which several parameters were given; which layers (surface models) to display, where to take the cross section from, and where to place it in the drawing. The ease at which this information could be produced should not be under estimated. The ability to cut sections instantly, allowed the designers the flexibility of cutting them whenever needed. This proved an invaluable tool throughout the design. Temporary profiles and sections were utilized during the design process, to enhance understanding of what was being designed. In other words, in areas in which the design was complex, the ability to display certain information from any perspective allowed the designer to fully comprehend the design three dimensionally and recognize whether an area required modification.

By regulation, slopes were critical to the design. The computer software enabled views of the design, in which slope was represented by color code. Since many areas of the closure cap were actually graded by the computer, this gave an instant view of what grades the computer used in the design. In certain areas the computer deviated from the slopes which were programmed in for the design. This happened due to too many parameters specified for a particular area, which made the design of that area impossible to hold all parameters. In these situations, the computer would hold as many parameters as it could. Unfortunately, these were not always the same as what would be held if a designer were faced with the decision. By displaying the surface slope information by color code, an immediate surveillance of the entire design was visually evaluated, and areas which required attention were flagged.

Earthwork computations are another great example of the benefit reaped from three dimensional design. A process which performed manually would take weeks and have large room for error, was achieved at the push of a button. The process consisted of choosing which layers of material are to be calculated. The computer took approximately a minute, and provided a detailed report, and summary.

DRAWING COMPILATION AND PRODUCTION

The end result of this design was the production of design drawings which were to be used for the construction of the closure cap. The three dimensional software was of great aid in the development of the design but required a fair amount of polishing and embellishment to produce final construction documents. Construction notes, title blocks, legends, details, and labeling are among those items which still require manual input. "Manual input" being a relative term, since even these items are electronically produced on a CADD station, however, they are manual in the respect that they are not automatically produced by software and are created by hand. Figure 4 shows a portion of the final construction drawing plan view as compared to the three dimensional software output, and gives an indication of the type of embellishment required. The final construction drawings set consisted of; cover sheet and index, site map, plan sheets, section sheets and detail sheets. Of these, the plan and section drawings held the greatest benefit from the three dimensional software. The section sheets were almost completely output from the three dimensional software, with minimal embellishment required. Each civil detail was originated by the three dimensional software and manually enhanced.

CONCLUSION

The benefits of utilizing three dimensional software to design a closure cap include flexibility, a host of design tools, output presentation, and most importantly large cost savings. Although, a large percentage of time is required to make sure that existing data is input into the computer accurately. However, the benefit is far

greater than the cost. The process of designing a closure cap has not changed, however the tools to accomplish the design are among those within the high tech. avalanche. As these tools continue to advance, the design method and flexibility will continue to refine saving both time and money. These advancements are not without cost. Each advancement in technology translates into increased costs for hardware and software. A common mistake is to perceive a one time initial cost. In addition, each software advancement requires personal training. Only the passage of time will dictate what the future holds for civil engineering software. In the past, technologies are developed for large budget types of fields, and then adapted to other applications. If this continues to be true, then perhaps one day the civil engineering future, including radioactive waste facility closure design, will contain virtual reality technology or even computer aided construction.

A DECISION PROCESS TO MAINTAIN COMPLIANCE: POSITION DESCRIPTIONS TO TRAINING REQUIREMENTS RELATED TO HAZARDOUS WASTE MANAGEMENT

Rose M. Young
Department of Environmental Management
EG&G Rocky Flats, Inc.
Golden, Colorado

ABSTRACT

Title 40 Code of Federal Regulations Parts 264 and 265 require a written job description for each position at a facility related to hazardous waste management. An operator of a treatment and storage facility of hazardous waste is regulated under the training requirements of Title 40 Code of Federal Regulations (CFR) Parts 264.16 and 265.16, Personnel Training.

Documents reviewed during the development of position descriptions at EG&G Rocky Flats Environmental Technology Site (RFETS) included; (1) the Colorado Department of Health Notice of Violation No. 92-06-17-01, (2) the results of the EG&G Rocky Flats Causal Factor Analysis of Environmental Compliance Violations at the Rocky Flats Plant, (3) the Colorado Hazardous Waste Regulations 6 CCR 1007-3, (4) the State R.C.R.A. Permit ID# 91-09-30-01, (5) pertinent information on the training and qualification history at the Rocky Flats Plant, (6) the Savannah River Site Environmental Training Decision Flow Diagrams, (7) research study on determining position descriptions, and (8) compliance agreements with the Colorado Department of Public Health and Environment for compliance with Title 40 Code of Federal Regulations Parts 264.16 and 265.16 (d)(1)(2)(3).

Hazardous waste worker positions to training requirements for personnel involved with hazardous waste management was reviewed and accepted by the Department of Energy and is in its first phase of implementation at the Rocky Flats Environmental and Technology Site. Facility specific position descriptions and required training for personnel involved in hazardous waste management provide a significant, manageable, and innovative approach for compliance with Resource Conservation and Recovery Act (RCRA) requirements, Title 40 Code of Federal Regulations Parts 264.16 and 265.16 (d)(1)(2)(3) for a hazardous waste facility.

INTRODUCTION

The Resource Conservation and Recovery Act (RCRA), a regulatory statute designed to provide "cradle-to-grave" control of hazardous waste, establishes the national hazardous waste management program (1). Facilities involved with hazardous waste management programs are required to comply with Title 40 Code of Federal Regulations Parts 264 and 265, Standards and Interim Status Standards for Owners and Operators of Hazardous Waste Treatment, Storage, and Disposal (TSD) Facilities.

The Colorado State administrating agency for RCRA is the Colorado Department of Public Health and Environment (CDPHE) under the Colorado Hazardous Waste Regulations 6 CCR 1007-3. Sections 264.16 and 265.16 require that personnel training requirements are identified and outline the hazardous waste facility's RCRA environmental training compliance programs (2).

Pursuant to RCRA, each facility must maintain complete training documents and records. These documents and records include "(1) The job title for each position at the facility related to hazardous waste management, and the name of the employee filling each job; (2) A written job description for each position listed .... (which) must include the requisite skill, education, or other qualifications, and duties of employees assigned to each position; (3) A written description of the type

and amount of both introductory and continuing training that will be given to each person filling a position listed under ... this section"(3)
An ongoing practice for compliance with these requirements has been to provide initial RCRA training and annual RCRA refresher to all employees, also referred to as "compliance madness," at hazardous waste generator and Treatment, Storage and Disposal (TSD) facilities. Although this method was initially accepted, this practice has been identified as inadequate for meeting the regulatory training requirements for maintaining position descriptions related to hazardous waste management.
While some facilities were "training everyone" other, due to widely varying interpretations of the RCRA training regulations, argued that generator training was not required, and therefore maintained that the absence of generator training was not a compliance issue (3). On the other hand, there are facilities where the organizational structure and the tasks and responsibilities assigned to generators dictate extensive training of thousands of personnel to assure compliance with the RCRA regulatory requirements.
Finally, it was noted that while some facilities had training programs in place, the training curricula was inconsistent with the specific needs of the trainees (4). Specifically, the content of the training courses did not include all the topics necessary to meet the tasks of the employees or to ensure a facility's compliance with the requirements of 40 CFR.
Conclusion from initial research indicates a need for a formal process to identify worker positions involved in hazardous waste management and the related training requirements for those positions.

STATEMENT OF PROBLEM

Notice of Violation

On June 17, 1992 the Colorado Department of Public Health and Environment (CDPHE), through the Hazardous Materials and Waste Management Division issued a Notice of Violation (NOV) to the Department of Energy (DOE) Rocky Flats Office (RFO).
The Notice of Violation was based on findings that Rocky Flats had violated the Colorado Hazardous Waste Act, Section 25-15-301 through 313, C.S.R. (1990) and its implementing regulations.
The violations occurred over a period of approximately twenty-two months and demonstrated "systematic problems" with regard to compliance with hazardous waste requirements. Of the fifty-six violations, twenty-eight were in violation of 6 CCR 1007-3, Section 265.16 Personnel Training (5).
Rocky Flats Plant's immediate response to the NOV included a risk assessment through a causal factor analysis and the development of corrective action plans.

Causal Factor Analysis

The causal factor analysis examined the events and conditions that led the Colorado Department of Public Health and Environment to issue a Notice of Violation to EG&G Rocky Flats on June 17, 1992. Of the fifty-six separate violations of the Colorado Hazardous Waste Act, twenty-eight were in violation of 6 CCR 1007-3, Section 265.16 Personnel Training. The CDPHE made a determination that the employees interviewed demonstrated poor knowledge of regulatory requirements in both waste management and production.
Specific to the Resource Conservation and Recovery Act (RCRA) Training and Qualification Program at Rocky Flats Environmental Technology Site (RFETS), the causal factor analysis resulted in a training related problem statement noting "an insufficient cadre of adequately trained, qualified, and accountable RCRA custodians, knowledgeable supervision and knowledgeable support personnel assigned to RCRA-regulated areas across the RFP site" (6).

Status of RCRA Training at Defense Program (DP) Sites

Prompted by the June 17, 1992 issuance of the RCRA Notice of Violation by the State of Colorado Department of Public Health and Environment, a review of the status of RCRA training at Department of Energy Defense Production sites was conducted. The Office of Self-Assessment and the Office of Engineering and Operations Support conducted on-site reviews at eight Defense Programs facilities between November 1992 and April 1993 (4).
The objective of the on-site reviews was to identify systemic weaknesses in the RCRA training programs and to identify weaknesses which leave the complex vulnerable to Federal and State RCRA violations. Findings were categorized into four areas: 1) Programmatic Deficiencies, 2) Federal and State Compliance, 3) DOE Orders and

Guidance Documents, and 4) Other Issues.
The final report identified deficient areas of which some are directly related to adequate selection of hazardous waste workers training requirements. These findings included the following:
1. There are widely varying interpretations of the RCRA training regulations, some of which exclude the training of hazardous waste generators.
2. Formal mechanisms do not exist to ensure that the process used for the identification and training of personnel is functioning.
3. The training curricula at some sites are inconsistent with the specific needs of the trainees. Often, the content of the training courses does not include all the topics necessary to ensure a facility's compliance with the requirements of 40 CFR.
4. Supervisors' RCRA training is often inadequate for them to identify the training needs of their staff and to assess staff's performance at RCRA-related activities.
5. Personnel job titles and duties, and associated training requirements related to hazardous waste management, were not available at some of the contractor sites.
6. The RCRA training records reviewed typically did not contain all the required information, such as position description and introductory and continuing training plans.
Inconsistent interpretations of the RCRA training requirements across the complex was identified as a root cause for these deficiencies.
Recommendations were made for compliance with RCRA training programs to include, as a minimum, documentation for hazardous waste management personnel by employee name, job title, job duties, and required training (introductory and continuing). This documentation is required, as a minimum, for all hazardous waste generators, RCRA Custodians, managers (supervisors), trainers, and course developers. In addition, "the process by which personnel are identified for training should be documented and a formal mechanism established to ensure this process is functioning, such as in a quality assurance plan" (4).
A decision process to determine position-to-training requirements is a critical component of hazardous waste management. Position-to-training requirements ensure appropriate training and qualification based on tasks and duties of the position. The U. S. Department of Energy concluded that a comprehensive decision process resulting in position-to-training requirements must be developed for compliance with 40 CFR and to strengthen the RCRA training program for the prevention of future Notices of Violation (4).
METHOD
Development of a decision process ultimately determined the required training for hazardous waste workers fulfilling compliance requirements of the Colorado Hazardous Waste Regulations 6 CCR 1007-3 Part 264.16 and 265.16 (d)(1)(2)(3) at EG&G Rocky Flats Environmental Technology Site.
This decision process ensured hazardous waste compliance for the facility, and ensured accurate identification of personnel for specific training requirements related to their duty area. This accurate identification also provided significant cost savings by avoiding unnecessary time attending inappropriate training.
The decision process for determining a training path for hazardous waste workers can be modified and made specific for personnel at any hazardous waste facility.
Description of Process; Major Objectives
Major objectives of this process included the following:
1. Thorough research of all applicable federal and state regulations.
2. Interviews with personnel in similar outside industries required to maintain hazardous waste compliance training programs.
3. Identification of the requirements for personnel training documents and records to be maintained at a hazardous waste facility.
4. Analysis which encompassed; (a) identification of existing regulatory requirements for training, (b) identification of personnel who have the potential to be exposed to hazardous waste and hazardous waste management while performing their job duties, and (c) identification of classroom training consisting of applicable regulatory objectives.
5. Development of Hazardous Waste Management Position to Training Requirements Matrix.
6. Pilot study on the use of the decision process and subsequent position descriptions.
RESULTS

The hazardous waste facilities that were contacted and interviewed during the initial research were cognizant of the importance of RCRA regulations and committed to complying with RCRA training requirements. These facilities have expended considerable effort in the development and implementation of their RCRA training programs and contributed invaluable information on maintaining compliance with RCRA regulated training requirements (7).

Position Description and Categories for Hazardous Waste Workers

Position descriptions were developed for positions at the Rocky Flats Environmental Technology Site (RFETS) and grouped into regulatory categories. Position categories were chosen from existing hazardous waste management positions already in place and generic positions identified within DOE guidance documentation. These positions ranged from; 1) senior managers, whose responsibility it is to manage facility programs that involve hazardous waste even though they themselves may never be exposed to hazardous waste or the risks associated with hazardous waste management, to 2) "hands-on" waste handlers, whose responsibility it is to generate, treat, store, or dispose of hazardous waste, to 3) clerical and support personnel who provide administrative support to organizations that deal with the treatment, storage, or disposal of hazardous waste, but, again, are never actually exposed to the risks posed by hazardous wastes. Final documentation identified nine position categories and examples of job tasks and responsibilities that may fall within each category.

Colorado Hazardous Waste Regulatory Matrices

Two matrices were developed for RFETS to show; (1) a relationship between the RCRA regulatory requirements for hazardous waste management and the facility position (based on the job-task-analysis of that position), and (2) a relationship between the RCRA regulatory requirements for hazardous waste management and the facility's training curricula.

Position to Training Requirements Matrix

The Position to Training Requirements Matrix for RFETS was the third matrix in the series of matrices that were developed providing the relationship between a facility position and the required training for that position. This position to training requirements matrix provides an easy reference to determine an individual's training requirements.

Hazardous Waste Worker Training Program

The RFETS official tracking system for training requirements is capable of listing the type and amount of both introductory and continuing training that is available to each person employed in a position related to hazardous waste management. This tracking system is used for identifying a person's training path as it relates to a hazardous waste position. This tracking system is one available reference tool for the immediate supervisor, the trainee, as well as for the training scheduler when determining required training. Importantly, this system ensures that the required personnel training, as indicated, is completed within the required six months (2). In addition to satisfying the requirements of Title 40 Code of Federal Regulations Part 264.16 (d)(1)(2)(3), establishing a process for determining position-to-training requirements for personnel involved with hazardous waste management results in training that is targeted to a specific audience for specific duties and reduces the cost of unnecessary and inappropriate training.

CONCLUSIONS

Development of position descriptions for personnel involved in hazardous waste management is the first step in assuring integral compliance with Resource Conservation and Recovery Act (RCRA) training requirements. A second step is to identify all environmental training requirements applicable to the facility and initiate the same process to assess and identify job duties and tasks, positions, and evaluate specific regulatory driven training requirements for those positions. Once positions, duties and tasks, and required training have been identified, a facility can develop a comprehensive and cost effective environmental training program, meet regulatory requirements and demonstrate compliance.

DEVELOPMENT OF A "SHOULD COST" DATABASE FOR ESTIMATING ENVIRONMENTAL RESTORATION ACTIVITIES

R.D. Williamson
EG&G Rocky Flats
L.J. Ryan
Dames & Moore

ABSTRACT
A new estimating philosophy has been developed at Rocky Flats Environmental Technology Site (RFETS) for estimating the cost of environmental restoration activities. The traditional cost estimating philosophy is to estimate what a task will cost based on the historical cost of similar tasks. This new approach estimates what it "should cost" to perform a task, based on a detailed analysis of the activities and the resources required to accomplish these tasks. A software system has been developed to assemble "should cost" estimates for all environmental restoration activities and generate new estimates for specific projects. Utilization of this software system and the "should cost" approach to estimating can result in significant cost reductions to DOE projects. This paper will discuss the traditional estimating philosophy, understanding the "should cost" philosophy, and how to implement this new approach to estimating.

The Traditional Estimating Philosophy

The traditional estimating philosophy is to estimate what a task will cost given a set of parameters, conditions, and historical cost information. This technique worked well when the goal of the estimate was to establish a budget that had a low probability of overrun. However, this approach often led to project estimates based on the inefficiencies of past performance. Many Department of Energy (DOE) projects are performed by contractors selected for their expertise, with little or no concern for the cost involved. Some projects, especially Environmental Restoration (ER) projects, are performed on a cost-plus fee contract rather than a competitively bid contract. The costs from these non-competitively bid contracts become the historical data used to develop new estimates. These historical costs are then escalated and contingency is added for unknowns. Many of the projects involved extensive overtime costs which also lead to increasingly higher estimates for comparable scopes of work. In short, the old way of estimating costs perpetuates the past instead of improving upon it.

This traditional estimating philosophy has been used to establish DOE budgets that exceed those experienced for similar projects in industry. The ER standdown in January 1994 provided the results of a study by Independent Project Analysis, Inc., that indicate DOE ER projects cost approximately 32% more than similar projects in industry. This 32% above industry cost is a DOE complex-wide average of many projects, with some costing much more than the 32% and others being more comparable to industry. To continue to estimate costs based on project costs that are 32% above industry standards only perpetuates this pattern of continued high costs.

The continual development of inflated estimates leads to a condition where the estimate determines the scope of work rather than the scope of work determining the estimate, e.g., projects are expanded, enhanced, or poorly executed, leading to the utilization of all available funds. These changes are typically not identified in revisions to the estimate basis. Subsequent estimates which are developed utilizing

the historical data, are not based on comparable project scopes. This leads to higher estimates and higher costs.

DOE's New Estimating Goal

Reductions in funding and the awareness that DOE projects consistently cost more than similar projects in industry have forced DOE to change its emphasis on cost estimating and project performance. The emphasis now is to improve performance and reduce costs. The goal is to improve on the past, not repeat it. With this goal in mind, EG&G Rocky Flats assembled a team of experts to improve the approach to estimating projects at the RFETS and advance the philosophy of cost estimating. This innovative new philosophy is called "should cost" estimating and will assist DOE in achieving the goal of reducing costs to a level that is comparable with industry standards. This new philosophy to cost estimating has the following advantages over traditional estimating:

"Should cost" estimating provides the sound basis needed to reduce project costs.

"Should cost" estimating is an improvement on the past, not just a repeat of history.

"Should cost" estimating provides the basis for developing credible and consistent cost estimates for all activities in the ER program, including activities where historical costs are not available or are unreliable.

"Should cost" estimating establishes the benchmarks needed to identify sources of cost reduction, quantify the expected reduction, and improve productivity.

"Should cost" estimating identifies the project cost drivers which are essential for value engineering and other cost reducing exercises.

"Should cost" estimating bases the estimate on the worth or value of an activity, not the average historical cost.

"Should cost" estimating targets project costs at the 100% productivity level. The cost, schedule, and technical risks are addressed separately.

The "should cost" database can provide a resource listing that can be used to level labor requirements.

This new philosophy of "should cost" estimating provides the opportunity for the change needed to reduce ER project costs to industry levels. Estimates can be developed on the worth or value of a task rather than what the task has historically cost. The traditional approach to cost estimating was consistent with DOE policy and procedures in place at the time. The need to improve cost estimating is driven by changing times. By utilizing the "should cost" estimating tool now available, estimators are able to prepare ER estimates that will promote improved performance and cost reduction.

Understanding the New Estimating Philosophy

There are three parts to the "should cost" estimating system at Rocky Flats: the should cost database, the software system that accesses the database and generates new estimates, and the work breakdown structure (WBS). The "should cost" estimating system is organized by the WBS. For the ER program, the WBS is called a Code of Accounts (COA). The Interagency task force, in which DOE participated, developed a complete COA for all ER activities. This COA has been adopted for the ER "should cost" estimating system at Rocky Flats. Additional levels have been added to the COA to establish the base activity level at which the detailed benchmark estimates are developed.

A supplemental COA Dictionary has also been developed which defines the scope of each COA element including scope exclusions. Since the benchmark database is based on the Interagency COA, it can be used throughout the DOE complex and other agencies, if desired. Using a standardized COA allows for a direct comparison of "should cost" benchmarks for similar tasks at RFETS and similar tasks throughout DOE. These benchmarks can then be compared with the Hazardous, Toxic, and Radioactive Waste Historical Cost Analysis System (HCAS) database, which uses the Interagency COA, to facilitate a meaningful comparison with actual historical costs.

The benchmark "should cost" database is the key to the "should cost" estimating philosophy. The benchmarks established in the database are specific for each activity. Where possible, the benchmarks were developed using an industrial engineering approach for establishing performance standards for each activity. Performance standards have been established and used successfully for production work and repetitive tasks throughout industry; however, performance standards have not previously been established for most of the activities associated with the ER program. To establish the "should cost" benchmarks for each activity in the ER

program, an estimate of the worth or value of the activity was developed by professionals experienced in performing each activity. Each benchmark was then reviewed for consistency and credibility before being adopted.
The database of benchmarks for ER activities provides the details needed to support a cost estimate if the specifics are unknown. It also provides the details of what is included, so modifications can be made if project-specific details are known to be different than the benchmarks.
Each benchmark in the database contains the following specific data:

- COA Number
- Name
- Scope of Work
- Basis of Estimate
- Assumptions
- Exclusions
- Notes

The initial set of benchmarks represents a mid-size effort for each COA. Each activity was further defined by the individual tasks required to complete the activity, as well as the specific resources needed to support these tasks. Each activity in the COA is a specifically defined benchmark supported by detailed estimates for what it "should cost" to complete the activity. The COA for developing a conceptual site model, for example, details the activities required to develop the model, i.e., evaluate resources, evaluate exposure pathways, evaluate exposure scenarios, and develop the model. Specific resources required to support these activities are an engineer, physical scientist, and risk assessor. Units required by each resource were estimated and incorporated into the benchmark database.
Additional benchmarks will be added for both small and large efforts for each activity identified in the COA. Parametric modeling can then be used to develop estimates for projects with specific details that are between the benchmarks.
The "should cost" estimating database eliminates two common problems that exist in estimating ER activities. One is understanding and quantifying the work scope of an activity. The benchmarks detail the scope that is included in each COA activity. If project-specific data is not available the benchmarks can be used without adjustment. The second is finding credible historical cost data. The benchmarks replace the need for historical cost data. In the database, the scope, assumptions, and exclusions are well defined for each activity, which greatly enhances one's ability to perform root cause analysis on project cost overruns and initiating corrective action.
The software system is written in FoxPro and provides the user access to the "should cost" database and software required to develop new cost estimates. FoxPro was selected as a cost savings measure to utilize an off-the-shelf item rather than spending funds on development. The database can be accessed by the user but can not be changed by them. The software system also allows the user to assemble information from the database into an estimate. The user has the option to use the benchmarks as they exist in the database or to adjust them to reflect the detailed work scope of a specific project.
The "should cost" estimating software system will automate the formulation, documentation and archiving of cost estimates in such a way that estimates can be created and adjusted confidently using "should cost" benchmarks for COA activities. Cost estimates developed using this "should cost" database template are streamlined, standardized and supported by detailed backup that is defensible and traceable.
The cost estimate database consists of two related although distinct database modules. The first module, the COA activity module, encompasses the entry and maintenance of the "should cost" benchmarks. This involves applying resources and associated costs for what it should cost to support each activity in the COA. The second module supports the development of new estimates based on site-specific activities. The new estimates are developed by using code of account activities as templates for project work package activities. The system allows for easy modifications based on project-specific requirements that differ from the standards defined in the database. As the project manager adds an activity, the software creates a copy of the COA activity and its associated resources into a working estimate. The project manager can then adjust resources and base units from the benchmark considering site-specific complexity and scope requirements. The information contained in both modules is detailed below.

The COA activity module includes the following data fields and outputs:

COA - The codes of account are grouped and organized by likely project activities. The COA includes scope and assumption narratives.

COA Activities - The COA is organized into activities which are basic elements of work composing each COA. Activities have a scope, base quantity (unit of measure), and a complexity factor.

COA Activity Resources - Activity resources are generic resources as they are applied to accomplish activities. The generic resource base costs are stated and the units of the resource are adjusted for the specific activity.

Generic Resources - A library of generic resources is provided with associated base unit cost from which COA activity resources are drawn. A table of standardized costs for each identified resource is included in this module.

A COA Data Sheet compiles data from the fields in the COA module and a report can be printed showing what the activity "should cost." An example of a COA Data Sheet is shown in Table I.

The new cost estimate development module includes the following data fields and outputs:

Operating Units - Operating units are the overall organization of estimate activities.

Work Packages - Work packages are the second level of organization for estimate activities.

New Cost Estimate Activities - Estimate activities are copied from COA activities and can be adjusted to fit the particular requirements of the estimate.

New Cost Estimate Activities Resources - New cost estimate activity resources are attached to the COA activity when the cost estimate activity is added. This resource can be adjusted to fit specific work on the new estimate.

New Cost Estimate Log - Compiles estimates logged by revision number, estimator, revision date, reviewer, and reviewed date.

A Cost Estimate Activity Summary compiles the data from the cost estimate development module and generates a new estimate. An example of a Cost Estimate Activity Summary is shown in Table II.

The software has been designed to offer a variety of report options, including a Summary Data Sheet Rollup (Table III), which can be provided at any level of the COA structure and a Cost Estimate Activity Detail (Table IV).

Implementing the New Estimating Philosophy

The ability to improve on the past and obtain the full effectiveness of the "should cost" estimate philosophy requires the ability to track actual costs in the same format that they were estimated. RFETS intends to enforce utilization of the COA to prepare all ER work packages, to promote a consistency and uniformity in defining the scope of activities that has not existed before. The software system will then feed the "should cost" estimates directly to a cost accountability system for comparison with the actual costs collected in the existing accounting system. Any future comparison of data truly becomes a credible comparison of similar activities with the same scope.

At RFETS, the "should cost" estimating philosophy is being implemented on all projects. Projects at RFETS are categorized into three types: construction projects, maintenance tasks and operating projects. Construction projects include line item projects, general plant projects and maintenance projects that are covered by the Davis-Bacon Act. Maintenance tasks are maintenance projects that are not covered by the Davis-Bacon Act. Operating projects are specific portions of an operating program. The Should Cost Estimating philosophy can be applied to any of these projects because it identifies specific resources to accomplish each activity and assigns a value to each resource. Associated risk is considered for each activity as well as appropriate indirect costs. This results in an all-encompassing estimate for what each activity "should cost."

The "should cost" estimating philosophy at RFETS, along with a cost accountability system that compares the estimated cost to the actual cost, has been fully implemented for all maintenance tasks. The result is exciting reductions in the cost of doing business. This philosophy is currently being implemented on all construction projects. The database of "should cost" benchmarks is nearing completion for the ER program and will be implemented along with a cost accountability system. The full database will be available for use in May 1995.

The development of this "should cost" estimating system was accomplished utilizing a

team of personnel with an extensive background in cost estimating, software design and all phases of ER support. The team consisted of personnel from EG&G Rocky Flats, Inc., Dames & Moore, Inc., The S.M. Stoller Corp. and ICF Kaiser Engineers. EG&G Rocky Flats, Inc. developed the "should cost" estimating concept and provided guidance and oversight to the team. EG&G Rocky Flats, Inc. also provides a review and acceptance of all the benchmarks within the database. After assessing the ER activity at RFETS, Dames & Moore developed a COA and associated dictionary that specifically defines the scope of each COA account. "Should cost" estimates for all RI/FS and remedial design account activities were then prepared by Dames & Moore and reviewed by the team. This process only took six months with a minimal expenditure of funds. In conjunction with this effort, Dames & Moore developed a database program in FoxPro for compiling and reporting "should cost" data. Ongoing efforts include the programming necessary to support the development and documentation of new cost estimates utilizing the "should cost" data files as a template, and accommodating site-specific cost and quantity adjustments. ICF Kaiser Engineers is developing "should costs" for the remediation activities which will be reviewed by the team.

It is obvious that the traditional way of preparing cost estimates does not reduce project costs to industry levels. The "should cost" estimating system is a new tool that, when combined with effective project management, can help project managers move forward and away from the past. The challenge for project managers is to utilize this tool and change the existing culture to attain new DOE goals for cost effectiveness.

THE ROLE AND PROCESS OF INDEPENDENT VERIFICATION OF THE ENVIRONMENTAL RESTORATION OF NORTHWESTERN AREA DEPARTMENT OF ENERGY SITES

Donald Mackenzie
U.S. Department of Energy
Washington, D.C.
John Hollinger
Analytical Services, Inc.

ABSTRACT

This paper describes the Independent Verification program for DOE's Office of Northwestern Area Programs, which has HQ oversight for the environmental restoration activities at the Chicago, Idaho, Oakland, and Richland Operations Offices.

The purpose of the DOE independent verification (IV) program within the Office of Environmental Restoration is to provide an independent assessment of site conditions versus project plans and release criteria prior to project close-out, resulting in a validation of the accuracy and completeness of field measurements and the credibility of the procedures followed.

Both RCRA and CERCLA provide for some degree of verification, usually performed by State or EPA regulators, that planned cleanup levels at environmental restoration sites are achieved. Ultimately, this leads to a certification docket assembled at the completion of the project. However, the processes under RCRA and CERCLA vary from site to site depending on NPL status, state regulations, federal facility agreements and the type of cleanup action.

The need to inform and involve stakeholders in decisions regarding the DOE environmental restoration program has brought a renewed emphasis on the established process of DOE IV. The IV process involves a third party contractor not affiliated with the site who conducts either Type A or Type B verification, depending on the project. Type A verification involves a review of remedial action plans, historical documents, site data, and final surveys in relation to cleanup criteria; Type B verification includes Type A activities supplemented by field measurements, split samples, and other confirmatory activities.

The process is a solid tool for DOE sites to reassure stakeholders that the work to release these sites from DOE control is proceeding according to plans, in a manner which emphasizes the long-term protection of human health and the environment.

INTRODUCTION

The ultimate goal of any environmental restoration cleanup action is to ensure that resulting radiological and (where appropriate) chemical conditions at the site or facility comply with established criteria, standards and/or guidelines and that the public and the environment are thereby protected. For Department of Energy projects

most elements of the completion of a project (i.e. collection of post cleanup data, preparation of documentation, and coordination with state and regional authorities) are implemented by the responsible field organization and the contractor performing the cleanup. As a quality assurance activity, the Department of Energy-Headquarters Office of Northwestern Area Programs conducts independent verification of their environmental restoration activities.

The purpose of independent verification (IV) is to validate the accuracy and completeness of the field measurements and attest to the credibility of the procedures followed during the cleanup operations. While the data collected during independent verification may supplement the data of the cleanup contractor, it is not considered a substitute for complete data from the cleanup contractor. The IV program managed by the Office of Northwestern Area Programs is intended to convey to the public and regulators that the cleanup of these sites and facilities have met established criteria.

NORTHWEST AREA PROGRAMS INDEPENDENT VERIFICATION TASK GROUP

On May 6, 1992, the DOE Office of Environmental Restoration established Independent Verification as a requirement for all Environmental Restoration cleanup projects. In July 1992, the Office of Northwestern Area Programs issued a policy statement containing implementation guidance for IV.

In order to implement IV consistently and efficiently throughout the Office of Northwestern Area Programs it became apparent that additional guidance with input from the Operations Offices was necessary. A task group was formed to develop this guidance and provide recommendations on improving the IV process. The task group is composed of representatives from the Office of Northwestern Area Programs and the Operations Offices: Chicago, Idaho, Oakland, and Richland. Initially the task group determined which types of projects needed IV. A key consideration in this determination was whether projects had sufficient regulatory oversight to render an independent evaluation of the cleanup unnecessary. In these cases the regulator's verification activities fulfilled the need to assure public acceptance of the project.

It was determined during the first meeting of the task group that to function properly, the Independent Verification Contractors (IVCs) who perform the verification activities needed to be included and consulted. It was also determined that maintaining the task group and meeting semi-annually to discuss issues related to the IV program would be beneficial for everyone involved.

The initial findings of the task group are summarized below;

The IV program should be managed from DOE Headquarters (HQ). The task group recommended this approach as the most efficient way to manage the program while allowing the Operations Offices to use it to its fullest extent. The Operations Office representatives on the task group believed that IV should be managed by HQ in order to convey to the public and regulators that DOE is providing independent confirmation that remediated sites and facilities meet the cleanup criteria. The IVCs believe that the management of IV from HQ would assure greater consistency between the different Operations Offices.

Determination of a project's candidacy for IV should be based on 1) the type of cleanup action; 2) future use of the property; and 3) the degree of verification being undertaken by regulators.

The draft procedures should include or address "all hazardous wastes as defined under RCRA and CERCLA that are included in the project plan."

Scoping visits by the IVC and HQ to the site and Operations Office should become a regular step in the IV process. A scoping visit at the beginning of the process provides an opportunity for the personnel involved in the project (the IVC, the Office of Northwestern Area Programs, the Operations Office, and the cleanup contractor) to discuss the project and one another's expectations in the IV process. From this develops a better understanding of the roles and responsibilities of the IVC, cleanup contractor, Operations Office and HQ, contributing to an efficient and complete IV process.

The draft procedures for performing IV should be reviewed, updated, and issued as formal procedures.

Depending on an IVC's level of involvement at a site, the IVC's participation in mid-year and year-end meetings should be considered.

DETERMINATION OF APPLICABILITY OF INDEPENDENT VERIFICATION

The determination of whether a cleanup action should be subject to IV by the Office

of Northwestern Area Programs is based on 1) the type of cleanup action; 2) future use of the property; and 3) the degree of verification being undertaken by the regulators. However, the Operations Office may request IV of any cleanup action, whether or not it is required, if necessary (e.g., to alleviate public concerns). Also, the Operations Office may recommend that IV is not necessary if, for example, there is already a high level of regulator verification activities in a particular project.

To assist both HQ and the Operations Offices the task group produced a matrix for determining which Environmental Restoration projects needed an IV performed (see Attachment 1). One of the more controversial areas of this matrix regards CERCLA and RCRA cleanup actions. The task group concluded that the Northwestern Area Programs should not conduct IV of these actions.

The task group gave the selection of activities that need an IV considerable thought. In order to provide input into the decision, a background paper was written on the verification activities that EPA region and State regulators in the Northwestern Area Programs perform, and sample Federal Register notices stating that no further action is needed were obtained and reviewed. Based on an evaluation of this information and the experience the task group members have had in implementing IV programs and managing environmental restoration projects, the task group concluded that to require the Northwestern Area Programs to perform an IV at either CERCLA sites on the National Priorities List (NPL) or RCRA sites would be a duplication of verification activities performed by regulators.

CERCLA Verification

Under CERCLA, DOE is appointed the lead agency for cleanup activities at DOE owned or operated facilities. DOE is therefore responsible for planning and implementation of removal or remedial actions. This responsibility is subject to EPA and State oversight. In the National Contingency Plan (NCP), authority to enter facilities to conduct investigations of CERCLA action is given to EPA, States, and OSHA (40CFR 300). Beyond this authority, there are other instances throughout the CERCLA process where EPA or the State are indirectly involved in oversight and decisions regarding cleanup actions. EPA and State involvement varies on a site-specific basis, depending on the type of action.

The Close-Out reports constitute one form of third party verification under CERCLA. Their purpose is to clearly demonstrate that activities at the site have been sufficient to meet the completion requirements specified by the Record of Decision (ROD). Close-out reports are prepared by the EPA Regional Administrator and must be approved by both the State and EPA Headquarters. Approval of a final close-out report indicates that the cleanup has achieved levels specified in the ROD, and that the site may be placed in either the "Construction Completion" category on the National Priority List (NPL) or the "no further action needed" category. The Close-Out report correlates to the IVC's final report, as both reports indicate that the cleanup has met the goals stated in the planning stages of the project.

RCRA Verification

For RCRA cleanup actions, it is in the course of a corrective action that environmental restoration activities are most likely to be subject to verification. Although neither EPA nor other party verification of corrective actions is required by law, EPA does administer oversight specific to corrective actions. Facilities are required to demonstrate the effectiveness of corrective actions by establishing a groundwater monitoring program in conjunction with the corrective action. This program must also be supplemented by semi-annual written reports submitted to EPA Regional Administrators. These reports are intended to inform EPA on the effectiveness of corrective actions in progress and can be interpreted as a type of verification activity. Further, RCRA Section 3007 (c) requires the EPA to undertake annual inspections at federal facilities for the purposes of enforcing compliance with RCRA Subtitle C.

The descriptions above illustrate the breadth of compliance and verification activities required under CERCLA and RCRA. For this reason, the task group concluded that the IV of CERCLA and RCRA cleanups would be a duplication of effort.

RESPONSIBILITIES OF PARTICIPANTS IN THE IV PROCESS

Their are four major participants involved in the IV process:

- The cleanup contractor
- The DOE Operations Office
- The DOE-HQ Office of Northwestern Area Programs

The Independent Verification Contractor.

The success and efficiency of the IV of any project is dependent upon the participants knowing what their responsibilities are, and performing their responsibilities in an efficient manner.

The cleanup contractor is responsible for documenting the technical aspects of the project and making them available to the IVC in a timely manner. Whether the cleanup contractor communicates directly with the IVC or provides the information to the Operations Office for transfer to the IVC is determined during the scoping visit. Initially, this information is typically in the form of reports, such as Annual Environmental Monitoring Reports, Characterization Plans and Reports, Decommissioning Plans, and Project Plans.

As the project proceeds through the Operations Phase the information is related more to status and scheduling. The cleanup contractor needs to inform the IVC when the site is ready for verification of interim areas (i.e. rooms, ditches, temporary excavations) and the final survey.

The DOE Operations Office is responsible for coordinating the flow of information on the project between the cleanup contractor and the IVC. Initially, the IVC will rely on the Operations Office to provide the status of the cleanup and background information on the project. The Operations Office is also responsible for evaluating proposed release criteria for soil and/or supplemental limits, and then forwarding these proposals to the DOE-HQ for approval. The Operations Office also must coordinate both the assembly of the Post Remedial Action Report and the closeout of the project.

As stated earlier, the Operations Office may request IV of any cleanup action, whether or not it is required, should the Operations Office believe such verification is necessary (e.g., to alleviate public or regulatory concerns). Also, the Operations Office may determine that IV is not necessary for a particular project. An example would be if the IV would duplicate the regulators' verification efforts.

The management of the IV process by the Office of Northwestern Area Programs provides an additional degree of independence between the Operations Office managing the cleanup project and the IVC, providing assurance to HQ, the Operations Office, the general public and regulators that the resulting radiological and chemical conditions meet the site cleanup goals.

The Office of Northwestern Area Programs is responsible for coordinating the IV Task Group. This group meets every 6 months to review the status and lessons learned from the implementation of IV, and to review and update the status of the projects that are undergoing IV. This group provides participant input into the IV process which is utilized by the Office of Northwestern Area Programs as a basis for decisions.

The HQ responsibilities for cleanup project activity begins with the selection of the IVC for the project. This selection is made with the intent to equally distribute the projects between the IVCs and to establish and maintain current relationships that the IVCs, Operations Offices, and cleanup contractors have established.

The next major responsibility for HQ is the determination of the type of verification needed for the project. HQ relies heavily on the recommendation of the IVC, but is responsible for making the determination (with input from the Operations Office as needed). During the operations phase of the cleanup project HQ monitors the progress of the cleanup and the IV, and assures that the cleanup contractor and the IVC maintain communication about the status of their portions of the project. This monitoring is done through monthly reports, as well as informal communications with the IVC and Operations Office.

When the IVC is preparing to perform a field survey, the Office of Northwestern Area Programs reviews and approves the IVC's survey plan. The review of this plan usually concentrates on whether the scope of the survey plan is sufficient to verify the cleanup, and whether the release criteria that the IVC will be verifying are the release criteria that was stated in the Project Plan. If there are discrepancies between the surveys of the IVC and the cleanup contractor, HQ coordinates their resolution. All discrepancies should be resolved by the time the IVC final report is issued. Discrepancies between the IVC and cleanup contractor, the scope of work for the IV project, and the release criteria are the major items HQ looks for in their review of the final report.

Fig. 1.

The IVC serves as an independent technical expert to the Office of Northwestern Area Programs who confirms the accuracy and completeness of cleanup actions. The responsibilities of the IVC can be segmented into the following phases: Document review and planning, Field work, and Statements and reports.

During the document review and planning phase the IVC is responsible for recommending the type of verification needed for the project and if the cleanup criteria is stated clearly enough to support verification. In the IVC's role as a technical expert, if inconsistencies are noted, or if more efficient means to accomplish the surveys or analysis exist, they should bring this to the attention of the Operations Office or cleanup contractor.

The field work portion of the project consists of performing the on-site surveys of the site. It is often carried out in conjunction with the remedial action contractor in order to limit the amount of time needed before restoration, especially if there is a large turn-around time for laboratory analysis. Background and baseline data must also be gathered at this time for purposes of comparison. Field work is often the most time-consuming part of the IV, as factors such as weather and changes in site conditions can greatly extend the schedule, and large areas require a great deal of radiation scanning and sampling.

An integral part of the IV process is the documentation. The IVC is responsible for producing a report documenting their verification of the project. As soon as the laboratory results are received on the IVC's field work, the IVC should send a letter report to HQ containing the results of the survey, identifying any discrepancies with the cleanup contractors data, and including a statement of whether the IVC's data will verify the cleanup contractor's findings. The IVC should then assemble a final report consisting of field and laboratory analysis results, any discrepancies, confirmation of site compliance with the projects guidelines, and corrective actions for discrepancies.

In addition to the final report the documentation phase includes the archival of representative samples from the remedial action and verification surveys. The samples will be maintained by the IVC over a five-year period, to be held as evidence of the adequacy of the cleanup project and to confirm its close-out. The majority of the samples are to be derived from the IVC field work; however, the samples of the cleanup and radiological contractor may be incorporated as appropriate. Upon obtaining these samples the IVC becomes responsible for their maintenance.

CONCLUSIONS

The Independent Verification process has been found to be a solid tool for DOE to reassure stakeholders that the work to release sites from the Office of Environmental Restoration's control has occurred according to plans, in a manner which emphasizes the long-term protection of human health and the environment. The formation of an IV Task Group has improved the IV process in the Office of Northwestern Area Programs by allowing IVCs, HQ, and Operations Offices opportunities to discuss projects and problems in a non-adversial setting.

Two important lessons learned from the task group have been:

The IV process is greatly improved when the roles and responsibilities of participants are identified and discussed early in the process at a scoping visit.

The earlier the IVC is involved in the project the better. Early involvement lessens the impact of the IVC's comments on the schedule, and allows DOE and cleanup contractors to take advantage of the IVC's expertise in a consulting role as well as a verification role.

Management Systems Engineering Center
Virginia Polytechnic Institute and State University
ABSTRACT
The U.S. Department of Energy (DOE) National Technology Information Exchange (TIE) Workshops are sponsored by DOE Headquarter's Office of Environmental Restoration, Office of Program Integration. The goal of these workshops is to provide a quality forum that promotes the exchange of environmental restoration- and technology-related information across the DOE complex, including information needed to transfer technologies between sites and into DOE from outside sources. A significant percentage of technologies, necessary for conducting restoration activities, already exists. TIE Workshops offer an excellent opportunity and arena for sharing implementation strategies, experiences, and the results of these technologies with those individuals and programs who have a need for this information. Significant savings of time and money have already been realized by the transfer of information, knowledge, and technological solutions among the DOE field offices and sites.
INTRODUCTION
The DOE Office of Technology Development's 1991 midyear review identified a need for improved communications among DOE sites and laboratories regarding availability of both new and existing technologies capable of meeting the needs of environmental restoration programs. The DOE Office of Environmental Restoration initiated the TIE Workshops in response to this recognized need.
TIE Workshops promote teamwork and communication between environmental remediators and technology developers, with the focus on sharing actual field experiences, remediation or demonstration results, and lessons learned (1). The workshops also provide an excellent forum for sharing program needs, project implementation strategies, and information regarding existing and near-term technologies capable of providing solutions to problems. This sharing is accomplished by bringing those who actually do the work together, to interact with one another and to share ideas. This interaction provides an improved planning and communications network, that results in saving both money and time. TIE Workshops offer DOE site representatives an opportunity to learn and share information about solutions to common problems.
OE has also identified the need to recognize fully developed, usable technologies in the private sector and other Federal agencies and to place greater emphasis on transferring these technologies into DOE programs. Subsequent TIE Workshops devoted concurrent sessions on technology transfer barriers and potential solutions to mitigate those barriers.
TECHNOLOGY TRANSFER
TIE Workshops have demonstrated notable examples of technology transfer, with real savings in both cost and time. The following technology transfer examples demonstrate the value of these opportunities to share information between peers and sites.
During the Third National TIE Workshop (hosted by Lawrence Livermore National Laboratory in Pleasanton, California, in November of 1992), a Los Alamos National Laboratory (LANL) participant heard about the "rapid geophysical surveyor," used to locate waste burial pits and shafts. At the time, LANL project personnel were planning to use the "conventional" method, magnetometer surveys, that would have taken up to 2 months to complete the data gathering phase over approximately a 1-hectare area. An engineer from the Idaho National Engineering Laboratory demonstrated the rapid geophysical surveyor technology and capabilities at the LANL site. LANL personnel used the rapid geophysical surveyor to complete the 1-hectare survey to locate the waste burial pits and shafts (even in bad weather) in only 4 days. This survey produced superior data and resulted in enormous cost and time savings for the LANL project.
Rocky Flats Environmental Technology Site (RFETS), under an Interagency Agreement with the Colorado Department of Public Health and Environment and the U.S. Environmental Protection Agency, was required to close and remediate four solar evaporation ponds (Operable Unit 4) in accordance with an approved Interim Measures/Interim Remedial Action Program. An engineered cover capable of protecting human health and the environment for a 1,000-year period was required.

Participants at the Fifth National TIE Workshop, held in Denver, Colorado, and hosted by RFETS, heard about research and design efforts to develop an engineered surface-barrier cover that had been ongoing at the Hanford Site for a number of years.

As a result of this opportunity to exchange information and gain an understanding of each others needs and capabilities, RFETS scheduled a series of meetings with the Hanford Site personnel responsible for the design of the surface-barrier cover. These results enabled RFETS to use the research and design work, which had been completed at the Hanford Site, and apply it to their specific needs for a conceptual design of an engineered cover. This cooperation and information exchange resulted in saving both time and money.

At the Sixth National TIE Workshop (held in Kennewick, Washington, and hosted by the DOE Richland Operations Office in May of 1994), it was reported that the RFETS projected savings of $25 million by using the existing surface-barrier design being developed at the Hanford Site. In addition, significant intangible benefits in the form of time savings (estimated at 5-to-8 years), regulator satisfaction and response, and DOE credibility were gained from the experience.

Individuals from the Idaho National Engineering Laboratory and Sandia National Laboratories proclaimed that the DOE Idaho and Albuquerque Operations Offices may have a similar need for use of surface barriers in the future. If the need arises, TIE participants have an institutional memory of technology applications for various environmental restoration problems. There is always the potential to use information from past TIE Workshops and the TIE Quarterly publication to help sites that may need to address environmental restoration problems at a future date. The TIE workshops are an investment for future needs.

In addition to learning about existing technologies, TIE participants can investigate new technologies developed by industry and discuss strategies for working on common issues. One participant estimated savings of nearly $1.5 million by implementing new techniques (learned at the workshop) to reduce the number of wells at a Southwestern Area Program site.

The benefits of attending the TIE Workshops are many and difficult to quantify. However, numerous participants have gained valuable contacts and information from these workshops. Some additional examples of time and money savings identified from participants who have attended the TIE workshops are

Decontamination and decommissioning activity performed at one site can be performed at others by reusing equipment.

Expedited Exploratory Studies savings at one site will be approximately $250,000.

The Hanford Site saved $10,000 in hotel costs by combining efforts for Environmental Impact Statement preparation and attendance at the TIE Workshop.

Savannah River Site's specifications for decontamination and decommissioning efforts have been shared with others for an estimated savings of 320 work hours and $20,000.

The use of a database developed by HAZWRAP (Oak Ridge, Tennessee) resulted in a developmental cost savings of $150,000.

Long-term savings are anticipated when implementing better technologies.

The TIE Quarterly, a publication that reports on the TIE Workshops, allows for the continuation of information exchange. The TIE Quarterly also reports on current ongoing environmental restoration and technology development activities at various DOE field and site offices. The TIE Quarterly is a tool used to share success, failures, and the introduction of existing and new technologies to help improve communication and to transfer technological solutions throughout the environmental restoration communities of DOE and their contractors.

The World Wide Web (WWW) Internet link provides a means of sharing TIE program information and the use of environmental management technologies within the DOE complex. The WWW TIE web server contains several useful features, including current and past TIE workshop activities; technology contacts made within the DOE complex; and technology updates from DOE Headquarters, Operations Offices, laboratories, and the private sector. The TIE web server is accessible through Mosaic Software. The uniform resource locator is http://www.em.doe.gov.

The TIE Workshops and the TIE Quarterly have provided forums for people to communicate effectively concerning the use of technologies. The Technology Connection (TechCon) Program has used both tools as effective ways to bring problem holders and technology suppliers together in a meaningful way. The TechCon Program

is a DOE environmental restoration effort to identify and support the implementation of existing, usable technologies that have the potential to provide superior performance in solving environmental problems today. The TechCon Program has identified nearly 1,000 sources of technology from domestic and international firms and focuses principally on overcoming obstacles. The TIE Workshops and the TIE Quarterly have provided effective pathways for communications.
Face-to-face interactions, such as those provided through the TIE Workshops, have greatly improved the awareness of resources across the DOE system. Realizing the value of improved communications, an informal group calling itself the EM-40 Technology Network was formed in early 1993. They meet regularly at each TIE Workshop and share insights, challenges, and wisdom. The EM-40 Technology Network would prefer to meet more than once a year.

CONCLUSION

These examples demonstrate the usefulness and need to make available an opportunity to freely and openly exchange knowledge and information so DOE sites can maximize the use of research, technologies, and lessons learned from other DOE facilities. By attending TIE Workshops, participants have transferred technologies and technological information that have saved both time and money. TIE allows participants to build on the experience of others and to network with peers. The goal of the TIE Workshop is to identify and implement the most cost-effective and appropriate technology available to address DOE environmental restoration problems today. On the basis of participant feedback, the TIE Workshops achieve the goal of helping DOE environmental restoration personnel identify and implement the best available, cost-effective, and applicable technologies.

ABSTRACT

Operable Unit No. 2 (OU2) of the Rocky Flats Environmental Technology Site (RFETS), formerly known as the Rocky Flats Nuclear Weapons Plant (RFP), located west of Denver, Colorado, has been the site of extensive environmental investigations related to contamination from past radioactive and chemical waste storage and disposal practices. As part of the OU2 Phase II RCRA Facility Investigation/Remedial Investigation (RFI/RI) process, numerical groundwater flow and contaminant fate and transport modeling using the MODFLOW, MT3D, and ONED3 codes was performed in a simplified manner to support the data needs of the OU2 Human Health Risk Assessment (HHRA). A more complicated three-dimensional flow model using MODFLOW is also being developed to support the OU2 Corrective Measures Study/Feasibility Study (CMS/FS). Characterization of OU2 physical conditions indicates that complex subsurface geologic conditions dominate the hydrogeology and contaminant distribution and transport within OU2. Due to the complex top-of-bedrock surface topography, and the influence of local precipitation as the dominant groundwater recharge mechanism, groundwater elevations and the areal extent of the saturated zone are highly variable during the year, influencing both the extent and migration of contamination. In addition, groundwater flow and contaminant distribution and movement are strongly influenced by interaction between the saturated alluvium and underlying bedrock.
Numerical modeling of the complex hydrogeologic and contaminant conditions in OU2 in a detailed manner to simultaneously meet both the HHRA and CMS/FS needs, although feasible, is costly and time consuming. In order to meet mandatory regulatory

schedules for completion of the HHRA and CMS/FS, separate modeling approaches were developed that addressed the specific data needs of each study. To support the HHRA, it is adequate to limit the degree of model complexity to that necessary to provide conservative estimates of contaminant loading to local creeks, thus resulting in conservative estimates of human health risk. To accomplish this, the complex, multi-layer, highly transient site conditions were simplified to an equivalent, single-layer, steady-state system that incorporated the large-scale behavior of the integrated OU2 system. To support the CMS/FS, it is necessary to preserve the geologic and temporal complexity of the flow system in order to simulate realistic flow system behavior in response to various remedial action alternatives. To accomplish this, a three-dimensional, multi-layer, transient model is being developed to simulate the detailed flow conditions within OU2.

PHYSICAL SETTING

RFETS is a government-owned and contractor-operated facility that was part of the nationwide nuclear weapons complex. The primary mission of the facility from its inception until the late 1980s was to produce metal components for nuclear weapons, including components fabricated from plutonium, uranium, beryllium, and steel. Both radioactive and chemical wastes were generated at the facility, and past waste handling procedures involved both on-site storage and disposal of wastes. In 1992, the primary mission of the facility changed from weapons production to environmental restoration and stabilization of the special nuclear material remaining on site. RFETS is located on a relatively flat, gently eastward-sloping alluvial fan deposit known as the Rocky Flats Alluvium, adjacent to and just east of the Front Range of the Rocky Mountains. RFETS is located in a sparsely populated area about 16 miles northwest of Denver, at an elevation of approximately 6,000 feet above mean sea level. The RFETS area has a semi-arid climate, with an annual precipitation of about 15 inches, most of which falls in the spring. Temperatures are moderate, but the area experiences very strong wind events.

OU2 is located in the eastern buffer zone portion of RFETS, outside the main industrial area. This buffer zone consists of open land in a relatively undeveloped state. Physiographically, OU2 consists of a relatively flat pediment or ridge between two creeks; South Walnut Creek to the north, and Woman Creek to the south (Fig. 1). OU2 includes three major contamination areas. These areas, known as Individual Hazardous Substance Sites Areas (IHSS Areas), include the 903 Pad, Mound, and East Trenches Areas. The 903 Pad IHSS Area includes the 903 Pad, an area previously used to store drums containing spent solvents laced with radioactive metal lathe shavings, and waste burial areas. Leakage of the drums and wastes resulted in soil and groundwater contamination with volatile organic compounds (VOCs) and radionuclides. The Mound Area was also previously used to store drums containing solvents and oils, some of which contained radioactive materials. Leakage of those drums also resulted in soil and groundwater contamination. The East Trenches Area actually consists of two separate areas, the Northeast Trenches and Southeast Trenches, where crushed drums and other waste were buried in trenches. Leakage of residual material in the drums and waste has resulted in subsurface soil and groundwater contamination, primarily in the Northeast Trenches Area.

The hydrostratigraphy of OU2 is complex. Figure 2 is a schematic cross-sectional representation of the subsurface conditions at OU2. The hydrogeologic system at OU2 is comprised of the Upper Hydrostratigraphic Unit (UHSU) and Lower Hydrostratigraphic Unit (LHSU). The UHSU, which is the focus of the modeling studies, is comprised of the Rocky Flats Alluvium and Arapahoe Formation No. 1 Sandstone (No. 1 Sandstone) beneath the OU2 pediment, and the colluvium/terrace deposits on the hillsides of the South Walnut and Woman Creek drainages. The LHSU is comprised of claystones, siltstones, and thin, laterally discontinuous clayey, silty sandstones, and does not appear to be substantially impacted by previous facility operations.

The UHSU flow system is characterized by flow in several directions, controlled by the geometry and physical relationships of the different geologic units, and several topographic features on the top-of-bedrock surface. The UHSU groundwater system is also highly influenced by areal recharge from local precipitation, which is the dominant recharge mechanism, resulting in substantial seasonal variations in groundwater elevations and the lateral extent of the saturated zones. The two most significant shallow permeable geologic units beneath the pediment of OU2 are the saturated Rocky Flats Alluvium and No. 1 Sandstone bedrock.

The principle feature that controls groundwater flow within the Rocky Flats Alluvium is a northeast-trending paleoscour in the underlying top-of-bedrock surface (Fig. 3). Alluvial groundwater collects within this scour and flows northeast along the scour to a point where the scour intersects the south hillside of the South Walnut Creek drainage. The alluvial groundwater then discharges to a major surface drainage gully seep on the hillside.

The No. 1 Sandstone is a paleostream channel laterally surrounded by claystone. Flow within the No. 1 Sandstone bedrock is controlled by the geometry of the sandstone channel and by the laterally intermittent connection with the overlying Rocky Flats Alluvium, which acts as a source of water to the sandstone. The hydrogeologic interaction between those two units is complex and varies both spatially and with time.

Because the Rocky Flats Alluvium and No. 1 Sandstone are entirely truncated by the South Walnut and Woman Creek drainage valleys, virtually all of the groundwater within those units discharges to seeps along the drainage hillsides. Once discharged at the seeps, the groundwater enters colluvium and terrace deposits that mantle the hillsides of OU2, and flows downslope to the creeks (Fig. 2).

Contamination within the Rocky Flats Alluvium and No. 1 Sandstone consists of VOCs and, to a lesser extent, radionuclides. Contamination plumes in the alluvium occur in the vicinity of the 903 Pad Area and extend northeastward along the paleoscour, and southward toward Woman Creek. Contamination plumes within the No. 1 Sandstone occur east of the 903 Pad and in the Northeast Trenches Areas and are related to downward migration from the overlying alluvium. The groundwater chemicals of concern (COCs) used for the OU2 HHRA consist of PCE, TCE, carbon tetrachloride, chloroform, methylene chloride, 1,1-DCE, plutonium, and americium.

As a result of the contamination, a number of environmental investigations have been conducted at OU2. The most recent work was performed as part of the OU2 Phase II RFI/RI investigation. As part of that investigation and ongoing feasibility study work, groundwater models were previously applied in support of the HHRA, and are currently being applied to support the CMS/FS. The HHRA evaluated potential risks associated with the exposure of hypothetical off-site residents to contaminants in surface water in South Walnut and Woman Creeks where they leave RFETS property on the eastern boundary of the facility. The CMS/FS will evaluate several potential remedial action alternatives designed to mitigate the groundwater contamination conditions within OU2.

MODELING

In selecting the appropriate modeling approaches, five general criteria were specified:

The selected models should be able to incorporate key processes and conditions known to occur at the site.

The selected models should be able to satisfy the objectives of the study.

The selected models should be verified using published equations and solutions.

The selected model codes should be complete and well documented and preferably available in the public domain.

The selected models should be practical and cost-effective in terms of actual application as well as resolution of uncertainty.

Initial Modeling Approach

Initially, two levels of model complexity were considered when scoping the groundwater modeling work: Option 1) a simple analytical model designed to assess contaminant concentrations at HHRA receptor locations; and Option 2) a complex three-dimensional, multi-layer, transient numerical flow and fate and transport model to accurately simulate detailed flow conditions, and contaminant transport to receptor locations. Based on assessment of each option relative to the aforementioned criteria, Option 2, the complex three-dimensional numerical model, was initially selected as the modeling approach because it could incorporate most of the complex site conditions and processes, and could simultaneously support both the HHRA and CMS/FS, originally a key objective of the modeling study.

Option 1, use of a simple analytical fate and transport model, was ruled out because it did not meet the criteria of incorporating most of the key processes or conditions known to occur at the OU2 site. These included multiple contaminant source areas, multiple groundwater and contaminant discharge points, complex saturated zone configurations, heterogeneous geologic and hydraulic properties, and variable groundwater flow directions, hydraulic gradients, and contaminant migration

pathways. Option 1 was also ruled out because, although it could support the HHRA needs, it could not support the CMS/FS.

Reevaluation of Project Needs

Approximately midway through the modeling study, the need to compress the project schedule to meet mandatory regulatory schedule deadlines for completion of the HHRA forced a reassessment of project objectives and modeling needs. During several project meetings, each project task was evaluated relative to its potential to affect the project schedule. Because modeling was a critical path item for meeting the project HHRA deadlines, and the application of the complex model involved some uncertainty with respect to the HHRA schedule (i.e., there was some concern that if the complex model encountered difficulties, it could possibly jeopardize the schedule), it was decided to explore simplification of the modeling approach in order to minimize the potential for schedule impacts.

In order to simplify the modeling approach, it was necessary to adjust the project objectives accordingly. A simplified model could not be expected to reliably simulate the details of a complex flow and contaminant transport system, particularly at the level of detail necessary for supporting the CMS/FS. Therefore, it was decided that the project modeling objectives would be limited to supporting the HHRA only, and that modeling in support of the CMS/FS would be conducted later for detailed evaluation of various potential remedial action alternatives.

Revised HHRA Modeling Approach

Given the new modeling objective of supporting the HHRA only, the modeling approach was reevaluated based on the data needs of the HHRA. The HHRA for OU2 addresses a number of potential exposure scenarios. However, the only exposure scenario requiring groundwater modeling involves the migration of groundwater contamination to South Walnut and Woman Creeks, and the subsequent migration of those contaminants in surface water in the creeks to hypothetical receptors at the eastern facility boundary. Direct ingestion of groundwater from an on-site water supply well did not require modeling because current observed contaminant concentrations were used as worst case conditions. Direct ingestion of groundwater at an off-site water supply well was not simulated because virtually all OU2 contaminated groundwater discharges to surface seeps prior to reaching the facility boundary.

The revised modeling approach was designed to simulate reasonable or conservative contaminant mass loading values to South Walnut and Woman Creeks. A separate surface water model then used the groundwater model results as an input parameter, added the estimated mass loading from surface sources via surface runoff processes, and estimated total contaminant concentrations at the receptor exposure points at the facility boundary. Because the HHRA groundwater modeling results were used only as input to the surface water model, the objectives of the HHRA groundwater modeling were selected to meet the data needs of the surface water model. Those data needs were: 1) an estimate of the total annual average groundwater flow into each creek, and 2) an estimate of the total annual average contaminant mass loading to each creek from groundwater. To meet those needs, the following HHRA groundwater modeling objectives were specified:

Simulate reasonable and/or conservative seepage flow rates at the alluvial and No. 1 Sandstone seeps along the south hillside of the South Walnut Creek drainage and the north hillside of the Woman Creek drainage to estimate total annual average groundwater flow to each creek.

Generate a composite groundwater flow field within the OU2 pediment to serve as input to a fate and transport model.

Simulate transport of UHSU groundwater COCs from source areas within OU2 to seeps along the hillsides of the South Walnut and Woman Creek drainages.

Simulate transport of COCs through colluvium/terrace deposits from seeps to discharge points along South Walnut and Woman Creeks to estimate total annual average contaminant loading from groundwater to each creek.

To meet these objectives, a revised modeling approach was selected that incorporated some aspects of the detailed, complex model while simplifying the hydrogeologic conditions, where appropriate, to avoid some of the potential problems associated with the complex model. During the simplification process, the following were considered:

The simplified model should be consistent with the modeling objectives.

The simplified model should be as representative as possible of the long-term overall behavior of the groundwater system at a level of detail consistent with the

needs of the HHRA. For example, because the simplification involved combination of multiple hydrogeologic units, the model should be representative of the equivalent effects at the creeks from flow and transport through the units separately.

The simplified model should be reasonable or conservative in terms of its input parameters and should simulate equivalent or conservative results relative to those that would have been simulated with more detailed and complex models.

Based on these considerations, simplified conceptual and mathematical models were developed. Wherever simplifications were applied, they were judged to be reasonable equivalent approximations of the large-scale behavior of the actual groundwater system, or were selected to result in conservative estimates of contaminant loading to the creeks, so as not to cause underestimates of human health risk at the exposure points.

Three site-specific groundwater mathematical models were used to simulate groundwater flow and contaminant transport; a single-layer, two-dimensional MODFLOW (1) numerical groundwater flow model to simulate the groundwater flow system in the Rocky Flats Alluvium and No. 1 Sandstone; a single-layer, two-dimensional MT3D (2) numerical fate and transport model to simulate the fate and transport of COCs in the Rocky Flats Alluvium and No. 1 Sandstone; and a one-dimensional ONED3 (3) analytical solute transport model to simulate COC migration in colluvium /terrace deposits on the OU2 hillsides from the seeps to the creeks.

The HHRA model domain (Fig. 4) incorporated those portions of the saturated Rocky Flats Alluvium and No. 1 Sandstone important with respect to contaminant transport by including most of the identified major IHSS Areas that contribute substantial contamination to the groundwater system. Boundary conditions were selected to represent seep conditions where they occur on the hillsides of OU2. Some of the major simplifications incorporated in the models included:

Combination of the Rocky Flats Alluvium and No. 1 Sandstone into a single equivalent composite hydrogeologic unit. This simplification was reasonable based on the direct hydraulic communication between the units (where they are in direct contact) and their similar hydraulic properties, and the fact that distinction between alluvial and sandstone seeps was not necessary for assessing total contaminant loading to the creeks.

Simulation of the system under steady-state conditions rather than the actual highly transient conditions. This simplification was reasonable for simulating the long-term average annual maximum concentrations needed for the risk assessment.

Simplification of contaminant source area behavior as constant steady sources or step sources. This simplification was conservative in that it applied worst case conditions over a longer period than is likely to occur in reality.

Simulation of radionuclide colloidal transport as dissolved phase contaminant transport. This simplification was applied using very conservative (i.e., low) estimates of adsorption coefficient so as not to overestimate retardation of the radionuclides.

Simulating one-dimensional transport of contaminants in the colluvium/terrace deposits. This is a conservative assumption relative to probable actual conditions.

Simplification of the geometry of the hydrogeologic boundaries into a rectangular model domain. In applying this simplification, care was taken to preserve the approximate locations of seep discharge areas so as to accurately distribute groundwater flow and contaminant discharge to each creek.

Model Simulations and Results

MODFLOW groundwater flow simulations were run under steady-state conditions and were calibrated against observed site conditions in terms of water levels and flow directions in the alluvium, and hydraulic gradients in the No. 1 Sandstone, and the relative spatial distribution of seeps and their flow rates. The results showed a high correlation with observed conditions in most cases.

MT3D fate and transport base case simulations were run for each COC for a simulation period of 20 years to simulate current conditions. The results from these simulations were then compared to observed contaminant conditions and it was concluded that the model results were similar or conservative relative to observed conditions, and thus, the model was appropriate for simulating reasonable or conservative future contaminant conditions. Predictive simulations were then run for each COC for simulation periods of 150 years for VOCs and 1,000 years for radionuclides. The results of the simulations were then used as input to the ONED3 analytical colluvium/terrace deposit model to simulate fate and transport of the

contaminants as they migrated to the creeks.
The results of the modeling were plotted as predicted curves of concentration versus time at each creek. The maximum concentration values were then converted to contaminant loading values by multiplying them with the estimated groundwater flow rate to each creek. The results indicated that maximum VOC mass loadings would occur to the creeks within the next 30 to 60 years, and maximum radionuclide mass loadings would occur within the next 300 years for americium, but would not occur within the next 1,000 years for plutonium because of its extremely high retardation factor (R=840).
Of note is that even though the groundwater model simulated substantial VOC concentrations (up to 3,100 mg/l, TCE) being discharged to the creeks within the 150 year simulation period, VOC concentrations in surface water at the exposure points at the facility boundary were low (a few mg/L). This is because the surface water model simulated VOC volatilization, reducing VOC concentrations in the creeks to near or below Maximum Contaminant Levels (MCLs) at the receptor locations at the eastern facility boundary.
Corrective Measures Study/Feasibility Study Modeling
Recently, work has begun on development of the groundwater flow model to support the data needs of the CMS/FS. Because the CMS/FS involves analysis of various potential remedial action alternatives within the contaminated portion of OU2, it requires data on the behavior of the groundwater flow system at a greater level of detail than was required for the HHRA. To address the data needs of the CMS/FS, a detailed three-dimensional, multi-layer, transient flow model is currently being developed. This model will simulate groundwater flow within the Rocky Flats Alluvium and No. 1 Sandstone, as separate hydrogeologic units in hydraulic communication. The model will be used to simulate hydraulic responses to various potential remedial action alternatives including no action, groundwater extraction by well array or interceptor trench, reduced groundwater recharge due to placement of a slurry wall or by limiting infiltration, and enhanced groundwater recharge by injection and spray field combinations. The results of the flow modeling will be used in conjunction with detailed contaminant fate and transport modeling to support selection of effective remedial actions for contaminated groundwater at OU2. The approach and results of the detailed flow modeling will be the subject of a future technical paper.
CONCLUSIONS
The effective and efficient application of groundwater modeling to the OU2 project required that the objectives and needs of the different aspects of the project be fully considered, even when those objectives and needs changed midway through the project. The application of separate groundwater modeling approaches has and will continue to allow mandatory regulatory schedule deadlines to be achieved, while meeting the differing technical needs of the OU2 HHRA and CMS/FS. Preliminary review comments received from the involved regulatory agencies indicate that the simplified modeling approach applied in this study for the purpose of supporting the HHRA will likely be accepted. We expect that the agencies will also accept the use of the more complex model to support the CMS/FS. This demonstrates a willingness to consider the project objectives when assessing whether the degree of model complexity is adequate.

ABSTRACT

Uranium plumes, associated with the former USDOE uranium-enrichment metal fabrication plant at Fernald Ohio, have contaminated areas of the sole-source Great Miami Aquifer. CERCLA removal actions on the major uranium plume offsite are utilizing a traditional Pump and Treat well network to arrest plume transport. Restoration of the impacted aquifer to the proposed drinking water standard for uranium (20 ug/l) could require decades unless in-situ recovery methods are implemented. Proposed hydraulic "push-pull" with or without injection of benign lixiviants can enhance recovery significantly. Preliminary laboratory testing and numerical modeling suggests that the major uranium plume in the GMA may be remediated in less than 10 years.

INTRODUCTION

The Fernald Environmental Management Project (FEMP) is located 29 km northwest of Cincinnati Ohio and is managed by the U.S. Department of Energy (USDOE). For almost 40 years, nuclear weapon grade materials and assemblies were produced at this 425 h USDOE complex. Total uranium concentrations in groundwater exceed several hundred ug/l off-site. A major uranium plume (Fig. 1; see (1)) was contained in 1993 with the installation of a 5-well network pumping at an average rate of 1.09E+7 l/d. Over 2.0E+8 liters of uranium-contaminated groundwater are contained offsite within the upper 35 m of a buried glaciofluvial valley (1). The unconfined Great Miami Aquifer (GMA) has weak vertical hydraulic gradients thereby promoting flooring of the uranium plume approximately 30 m below the water table. Horizontal hydraulic conductivity calculated from slug testing and pump testing range from approximately 60 to 200 m/d. Modeled advective groundwater velocities range from 0.33 to 0.95 m/d. Uranium partitioning onto the clay and silt fractions of the aquifer matrix appear to retard locally the transport of the uranium plumes up to 23% (2). Generally though the geochemcial conditions in the GMA are oxidizing and promote the mobilization and transport of U+6 (2;3). Streams and man-made conduits assist the aeration of the glaciofluvial aquifer which is largely dominated by carbonate sand and gravel.

The problem is that present Pump and Treat (P&T) induced zones of capture are not sufficient to recover areas of the plume which are associated with sluggish velocities and/or have weak influence on distal parts of their respective zones of influence. These large diameter wells (>4.7 cm) must pump at least 80 lpm to maintain capture of the plume. A solution is to utilize in-situ recovery (ISR) waterflooding and increase the hydraulic gradient; and hence increase velocities toward the well screens. Simulations by (2) suggest desorption rates of uranium that is adsorbed to "dirty" sands would increase (eg. 3.0 - 6.1 min-1 x 10-4). Additionally dissolved oxygen (DO) as a lixiviant could further enhance recovery rates of FEMP uranium akin to uranium solution mining.

Push-pull (PP) technology is the key ISR component and has been applied successfully for decades by enhanced petroleum recovery operations and is now the method of choice by uranium ore recovery operations. Variations of PP are being utilized to effect extraction of VOC's and LNAPL's in many environmental restoration programs. Assuming of course that the hydrogeologic setting is favorable, the use of injection wells for environmental recovery programs is advantageous.

WELLFIELD DESIGN

Basic wellfield patterns on recovery and injection wells for FEMP are patterned after the uranium solution mining industry. A schematic representation of symmetrical 5-spot well networks is illustrated in Fig. 2. Recovery wells are shown in the center of the grids with injection wells at the corners. In this example the reservoir is injection limited. The induced pressure sink collectively promotes flow inward. In this fashion the plume is concentrated and flow is increased toward the respective recovery wells. The 5-spot is one of the most efficient PP patterns with d/a = 0.5.

Factors influencing the choice of PP networks include:

- Distance between injection and recovery well
- Sweep efficiency
- Pore volumes injected

Recovery capacity
Formation anisotropy
Regional groundwater flow
Chemistry and contaminant recovery

Sweep area per well will vary depending on the well pattern and the distance between each injection and recovery well pair. The sweep efficiency (i.e. percentage of area contacted by injected fluid at a given time) will vary with the number of pore volumes injected. The pattern pore volume is calculated by multiplying the pattern area, thickness of the contaminated zone, and porosity. It is important to note that the areal sweep efficiency does not depend on the magnitude of the flow rate as it is calculated at steady-state conditions.

In addition to sweep efficiency and breakthrough time, the well recovery and injectivity will influence well patterns. If the aquifer is extraction limited as appears to be the case at FEMP, more recovery wells will be needed than injection wells. Anisotropy will influence well placement. Modeling streamline trajectories is useful to initially predict efficient well spacing. Pump tests and other estimates of local permeability changes should assist further ISR well placement. This is crucial if lixiviants are to be injected so as to determine their residence time. For a given formation anisotropy each well pattern (eg. 5-spot) will perform differently in response to directional permeability. For example Table I includes calculations of sweep efficiency (%) for 5-spot and line-drive well patterns per Kx/Ky.

These PP factors can be modeled to approximate an initial wellfield design. As operations proceed on recovering FEMP uranium, wells can be relocated and well hydraulics altered. Design of these wells is not outlined here. Suffice it to underscore that these ISR wells proposed for FEMP are PVC Schedule 40 and 15 cm dia. Compare this to P&T wells at FEMP which are 316 stainless steel and 30.5 cm dia. Standard low flow pumps are installed in ISR wells compared to large flow submersibles in traditional P&T wellfields.

HYDRAULIC PUSH-PULL MODELING

Preliminary two-dimensional steady-state flow governing the ISR modeling of FEMP is:

Eq. (1)

with transmissivity solved as (e.g.):

Eq. (2)

From Eq. 2 the characteristic 2-D equation for a pathline then is

Eq. (3)

and the complex velocity potential for the flow path model analysis is:

Eq. (4)

with:

Eq. (5)

Eq. (6)

The preliminary ISR modeling was conducted with GRANFLOW (4), a FORTRAN code based partly on PATH2D and FLOWPATH. The results (Fig. 3) indicate largely extraction-limited and irregular arrays of wellfield patterns which are superimposed on a 20 ug/l uranium isopleth of the major FEMP plume. The isopleth is contoured from a 1993 sampling event over a short time period. It therefore represents a crude "snapshot" of the uranium contamination in the upper GMA. The "snapshot" is part of a larger time-averaged representation (Fig. 1). Figure 1 illustrates the time-averaged plume(s) over 1988-1993 for the entire FEMP site.

Networks of recovery wells are placed near a major losing reach of Paddys Run (Fig. 3) and were simulated as a continuous array of injection points. The irregular nature of the wellfields is due to the factors of anisotropy and uranium distribution coefficients (Kd). The northern part of the plume outlined in Fig. 3 appears to have more local permeability variability but it is uncertain what the distribution of permeability is in the southern environs.

Although the flow was only modeled in two dimension, the vertical component is believed to be weak based on hydraulic gradient data (1). As a first approximation some cells required only 3 pore volumes to be replaced while others required 18 pore volumes in order to reduce the groundwater concentrations of uranium to 20 ug/l. Bleed rates of approximately 4% were permitted during mass balancing calculations in GRANFLOW between model injection and recovery wells. Operations at solution mining operations typically adjust bleed rates to accommodate local field conditions and economic factors. If lixiviants are not used then there are less variables to

control. The greatest uncertainty in the model runs were the variability of infiltration rates from the local streams and man-made conduits into the aquifer. Paddys Run (Fig. 1), often a losing stream across FEMP, was modeled as a continuous injection gallery.

The location of the P&T wells south of the 20 ug/l isopleth in Fig. 3 appears south of the plume but is an artifact of "snapshot" sampling. Actually the time-average location of this isopleth intersects and is captured by these wells. These wells maintain 80 lpm to effect containment of this major plume. Modeled maximum pumping rates from the ISR wells suggest pumping would be less than 39 lpm and more often near 21 lpm.

No significant excursions were predicted but additional monitoring wells are suggested to guard against errant streamlines. The FEMP site has many monitoring wells which are not shown in Fig. 3. In this model run, approximately 7.8 years would be required to restore the major uranium plume in the GMA to 20 ug/l. Of course it assumes that the uranium sources are removed. During operations, improved field parameter data would afford adjustments in order to further improve extraction efficiency in the wellfields.

LIXIVIANT TESTING

The use of lixiviants may not be necessary as the hydraulic component of PP results in significantly less model remediation times than existing P&T model remediation times at FEMP. However additional removals from higher Kd areas might require lixiviants. Alternatively one could simply exchange more pore volumes until the proposed MCL had been achieved.

Dissolved oxygen is benign and is suitable for the natural geochemical conditions in the GMA. Even entrained air which would occur in the delivery system is conducive for maintaining a mobilizing environment for U+6. An empirical relationship between DO and elevated uranium concentrations in the aquifer, particularly where losing streams across FEMP intersect the aquifer, is observed (2).

Basic reactions for uranium in the UO2 -O2 -CO2 -H2O system in the GMA beneath FEMP include:

Eq. (7)

Eq. (8)

Eq. (9)

Preliminary testing of core materials with dissolved oxygen along with aqueous speciation modeling by (2) using PHREEQE, including updated thermodynamic data for uranium species, suggests that UO2(CO3)3-4 in EQ9 is predominant. The basic DO reaction then is:

Eq. (10)

Laboratory simulation of DO as a lixiviant for injection wells was performed on aquifer solids with a Kd = 23.6. with an initial leachate concentration of 24.1 pCi/l. At 3.6 pore volumes, leaching of uranium was near equilibrium with the column of groundwater solution. At 8.9 pore volumes, two-phase flow began. Saturation with 2 phase flow at unsaturated pressure conditions present in the aquifer medium was 73 mg/l at 25oC.

Modeling a delivery system such as froth flow (5) with DO as the oxidant assumes:

- Radial geometry.
- Porosity is constant.
- Permeability varies in depth only.
- Fluid is incompressible
- Fluid occurs as a single phase.
- Mobility and density of injected fluid and formation fluid are equal and constant.
- Mass transfer rates are large enough such that reactions are kinetically controlled.

The governing equation for DO transport from the injection well into the aquifer is:

Eq. (11)

where the initial and boundary conditions for the injection cycle are:

Eq. (12)

Eq. (13)

Eq. (14)

Solving EQ11 through dimensionless analysis yields:

Eq. (15)

Solution of EQ12 yields a net 41% increase in uranium that is desorbed from the aquifer solids into solution. Desorption experiments are ongoing and it remains

uncertain if residual mass of uranium is significant compared to total uranium in solution. Presently, field investigations support the hypothesis that much of the uranium occurs as U+6 and probably is mobilized in the predominant UO2 -O2 -CO2 -H2O system. Injection of lixiviants while modeled to be significant in enhancing uranium recovery, when residual uranium masses are adsorbed, still may not be warranted if most total uranium is presently mobilized. DO and entrained air in delivery systems would have no adverse impact on the natural geochemistry of the GMA beneath FEMP. Losing reaches of streams aerate upper parts of this unconfined aquifer.

CONCLUSION

A ISR recovery wellfield patterned after uranium solution mining operations could be quite effective at FEMP. Preliminary modeling of hydraulic push-pull techniques suggest a very significant reduction in the time necessary to achieve lower uranium concentrations in the GMA. Compared to existing P&T methodology with or without pulsed pumping (Fig. 4) ISR should be more effective. Operationally, ISR wellfields are less costly to install and allow flexibility in manipulating the local hydraulic conditions to effect capture and recovery rates of the uranium contamination.
ISR could reduce the uranium mass in the major plume in less than 10 years and without the use of injected lixiviants. Favorable hydrogeology and geochemistry in the GMA make FEMP an attractive site for conducting ISR recovery. Ideally then ISR would permit a near zero tolerance discharge to the Great Miami River since the waste water treatment plant would recirculate treated waters to the delivery systems in the wellfields.

ABSTRACT

Methods for chemical characterization of the environment are being developed under a multitask project for the Analytical Services Division (EM-263) within the U.S. Department of Energy's (DOE) Office of Environmental Management. The project focuses on improvement of radioanalytical methods, with an emphasis on faster and cheaper routine methods. We have developed improved methods for the separation of environmental levels of technetium-99, radium, and actinides from soil and water; separation of actinides from soil and water matrix interferences; and isolation of strontium. Among the novel techniques for separation that are being used are element- and class-specific resins and membranes. We have also developed methods for the simultaneous detection of multiple isotopes by using inductively coupled plasma-mass spectrometry (ICP-MS). Because of its mass-selective mode of detection, ICP-MS requires less rigorous chemical separations than does radiochemical analysis. In addition, improvements in the limits of detection, the volume of the sample and the time of analysis were obtained by using other techniques of sample introduction, such as ultrasonic nebulization, automated batch separation and electrothermal vaporization. Investigation of integration and automation of the separation methods with the ICP-MS method using flow injection analysis is underway, with an objective of automating methods to achieve more reproducible results, to reduce the cost of labor, to cut the time of analysis, and to minimize the generation of secondary waste through miniaturization of the process. A solid scintillation device has been developed and tested for measurement and identification of low-energy beta-emitting radionuclides; application of this technique will eliminate the generation of mixed-waste counting cocktails. The final product of all activities will be methods that are available (published in the literature and in DOE's compendium of analytical methods) and are acceptable for use in regulatory situations. Concerted efforts are being made to facilitate implementation of the methods at DOE sites to realize the improvements offered.

INTRODUCTION

Our nation faces a daunting challenge to clean up and protect our environment; but before launching any cleanup, one must characterize the type, concentration, and extent of the contamination. During cleanup, one must monitor the progress; and after cleanup, one must often monitor the site to ensure that the cleanup was successful. Techniques and methods for chemical characterization and monitoring are essential in the execution of these efforts. Research- and-development efforts to improve capabilities can translate into major savings and improvements in environmental cleanups by reducing the unit cost of measurements (e.g., fewer steps in an analysis), reducing the time required to provide the information to the user (e.g., field analysis), or improving the quality of information (e.g., chemical speciation). Radiochemical analysis is of particular concern to the DOE, which expends over $300 million annually on this activity. Unlike organic and inorganic analytes, which are widely found as contaminants, comparatively little effort has been expended on improvements of radiochemical analyses. Desirable characteristics of any new method for characterization of the DOE's radiochemical contamination are the following:

- Faster, to reduce turnaround times
- Cheaper, to reduce the burden on taxpayers
- Better performance, to achieve the desired objectives for data quality
- Less generation of secondary mixed waste through reduction of scale and elimination of steps
- Closer to real-time analysis
- Quicker characterization of sites.

We have developed improved methods for the separation of environmental levels of technetium-99, radium, and actinides from soil and water; for separation of actinides from soil and water matrix interferences and for isolation of strontium. We are also developing methods for the simultaneous detection of multiple isotopes (including nonradionuclides) by using a new instrumental technique, inductively coupled plasma-mass spectrometry (ICP-MS). These accomplishments are discussed in the following sections. Additional research being conducted to improve other aspects of environmental radiochemical analysis is discussed in the section "Ongoing Activities."

RAPID DETERMINATION OF TECHNETIUM-99 IN SOIL AND WATER

Technetium-99 ($t_{1/2}$ = 2.1 x 105 yr) is a pure beta-particle emitter that is formed as a fission product from 235U and 239Pu. Technetium-99 is as abundantly produced as

137Cs and 90Sr. The main sources of 99Tc released to the environment are from the processing of nuclear fuel and the testing of nuclear weapons. Minor contributions come from radiopharmaceuticals and leachates from radioactive waste sites.
In an oxidizing environment, the 99Tc exists predominantly in the heptavalent state as the pertechnetate ion, TcO_4^-, which is soluble in water. Because this solubility tends to make the ion conservative in surface waters and mobile in aquifers, an increasing number of measurements are made each year to monitor technetium in the environment near radioactive waste sites and nuclear processing facilities. Current analytical methods are time consuming and generate a significant amount of mixed waste.
We have developed and validated a rapid, accurate procedure to collect and assay 99Tc in aqueous samples (1). All materials used in the procedure are commercially available. A standard volume (1 L) of sample water or prepared soil extract is passed through two sequential anion exchange membranes (3M Empore Anion Exchange - SR), which extract the pertechnetate anion selectively. Both membranes are then counted directly in a beta counter, and the total original concentration is calculated. Recovery of technetium via the membranes is usually on the order of 99%; but certain interferences, especially nitrate, may reduce recovery to as low as 30%. The preferred way to minimize this interference is to avoid the addition of nitrate to collected water samples. The primary advantages of the method are a short turnaround time (2.7 h) per sample and an average analysis time of 30 min (eight aqueous samples over a 240-min period).
Calculations
The efficiency of the tandem membrane setup was calculated as
$$E = 1 - B/A \qquad (1)$$
where E is the collection efficiency of each membrane, A is the number of beta counts per minute on the first membrane, and B is the number of beta counts per minute on the second membrane. The calculation assumes an equilibrium process and that the membranes are uniform in their functionality. The concentration (Ao) of analyte is calculated as
$$Ao = A/(E \times \text{volume} \times \text{counter efficiency}) \qquad (2)$$
where A and E are as defined previously and where counter efficiency is measured as counts per minute divided by disintegrations per minute (cpm/dpm).
Table I compares our method for analysis of 99Tc with other methods.
RAPID DETERMINATION OF RADIUM ISOTOPES BY ALPHA-SPECTROMETRY
Because radium and its daughters are radioactive and occur naturally in environmental matrices like drinking water, the determination of long-lived alpha emitters such as 226Ra ($t_{1/2}$ = 1600 yr) is very important from the standpoint of geochemical studies and human health. The most frequently used procedure for determining radium is the radon emanation procedure (HASL-300, Ra-03) (2). This technique involves the collection and measurement of 222Rn, a daughter of 226Ra. Large sample volumes, a multiweek waiting period for the ingrowth of the radon, and the absence of internal quality control detract from the utility of this method. Other methods in use involve coprecipitation with barium sulfate followed by counting with a gamma-ray spectrometer, application of thermal ionization mass spectrometry, or electrodeposition followed by alpha spectroscopy. The electrodeposition methods are direct, highly sensitive, and highly specific in comparison with other established procedures. In addition, the electrodeposition techniques decrease the sample size and reduce the turnaround time of the analysis to approximately 24 hr, including counting time.
We have developed an improved method for the determination of low levels of 226Ra and 224Ra in environmental samples by alpha spectrometry (4). A cation-exchange column (1 g. dry resin) is used to separate the analyte from other constituents in the sample (1-50 mL). Optimal separation of the radium isotopes from the matrix is achieved on a cation-exchange column when 100 mL of 1.5 M HCl is used for washing and 45 mL of 6 M HCl is used to elute the sample. After preconcentration and separation, the radium is electrodeposited onto a stainless steel disk from a solution of ammonium oxalate and hydrochloric acid. Electrodeposition conditions are optimal when 400 g of platinum are added, when ammonium oxalate and hydrochloric acid are used as the electrolyte solution, and when an electrodeposition current of 600 mA is used. Radium-224 is used as a yield tracer, through standard addition, to allow assessment of the quality of an individual analysis. Elapsed time for sample analysis is 24 hr, including both analysis and counting times.

Linear responses are greater than two orders of magnitude. The detection limits of the procedure, taken as three times the standard deviation of several reagent blank analyses, are (1.8 + 0.3) x 10-4 Bq and (2.9 + 0.3) x 10-4 Bq for 226Ra and 224Ra, respectively. Recoveries of 226Ra and 224Ra ranged from 90% to 100% when samples of drinking water, well water, and dissolved bones were analyzed. Precision was calculated to be less than 5% for the determination of 226Ra, with a 95% confidence. Matrix effects were studied for the salts of barium, magnesium, iron, and calcium. Future work will focus on preconcentration processes to analyze samples with very low levels of contaminants (e.g., surface water) and on the determination of 228Ra by using beta spectroscopy with the same electrodeposition disk that was used for the 226Ra determination.

DETERMINATION OF ACTINIDES IN SOIL

Techniques such as ion exchange, liquid-liquid extraction, and precipitation have been described for the separation and preconcentration of the actinides, however, these traditional methods are time consuming and generate large quantities of mixed wastes. Newer extraction chromatographic materials such as certain commercially available resins (TruSpec and TevaSpec) and a commercial ion-exchange material (Diphonix) are highly suitable for the concentration and separation of the actinide elements from soil matrices. These materials are highly selective and are the basis for efficient analytical procedures that generate significantly less waste than the more traditional procedures. The goal of our work (5,6) was to develop improved separation methodologies to reduce the manpower and waste costs associated with the laboratory analyses of actinides in soils. The analytical scheme was designed to satisfy the requirements of both radiometric and nonradiometric detection methods. The ICP-MS method requires only a group separation of the transuranics, whereas alpha spectrometry requires the sequential isolation of the actinides. In addition, the schemes for separation were designed to allow analysis of actinides in soils, whether acid leached or totally dissolved through fusion.

Acid Digestion Procedure

TruSpec SPS is used to perform group separations of the actinides, and TevaSpec is used to isolate the trivalent actinides from the lanthanide elements. Thorium and plutonium are individually isolated on a prepacked anion column (Bio-Rad AG 1-X8). Soil samples are dried, homogenized, ashed, repetitively leached with 6 M HCl followed by 8 M HNO3, and taken up in 2 M HNO3-0.5 M Al(NO3)3 after evaporative elimination of the HCl. Ascorbic acid is used to reduce trivalent iron, which interferes with the uptake of americium by TruSpec. The trivalent actinides, including americium, and the lanthanides are eluted from a TruSpec column with 4 M HCl. Plutonium and thorium are removed with 0.1 M tetrahydrofuran-2,3,4,5-tetracarboxylic acid (THFTCA). Finally, uranium is eluted with the addition of 0.1 M ammonium bioxalate. The trivalent actinides are separated from the lanthanides by using TevaSpec resin.

The THFTCA fraction containing the plutonium and thorium can be directly analyzed by ICP-MS; however, plutonium and thorium must be separated prior to alpha spectrometry on an equilibrated, prepacked anion-exchange column (Bio-Rad AG 1-X8).

The ammonium bioxalate fraction from the TruSpec column containing the uranium and residual thorium is dissolved in 8 M HNO3 and passed through an anion-exchange column that retains the thorium. The column effluent containing purified uranium can be directly analyzed by ICP-MS; however, for alpha spectrometry, the solution is treated with aqua regia and then with concentrated HNO3 prior to electrodeposition.

Fusion Dissolution Procedure

Soil samples are dried, homogenized, ashed, fused with flake NaOH, taken up in deionized water, and chemically reduced. The resulting Fe(OH)3, which coprecipitates the actinides, is separated by centrifugation. The Fe(OH)3 is dissolved in HCl, and silica is removed by centrifugation after formation of a colloid with polyethylene glycol. The actinides are separated on a Diphonix (60-100 mesh) column as a group by using 1-hydroxyethane-1,1-diphosphonic acid (HEDPA). The HEDPA solution is decomposed prior to elemental separations with a double-oxidation procedure. Elemental separations are performed as described under "Acid Digestion Procedure."

The extraction chromatographic resins used in the described procedures offer several distinct advantages over most ion-exchange, coprecipitation, and liquid-liquid extraction procedures. Extraction chromatography allows for specific solvent extraction with the convenience of column chromatography. Both the acid concentrations and volumes used in these systems are significantly lower than those

required for traditional methods, thereby significantly reducing waste volumes; however, these lower acid volumes and concentrations make it difficult to maintain large sample sizes, or soils digested with HF, in solution. As a result, Diphonix resin is used to preconcentrate the actinides from larger soil samples that have been totally dissolved by sodium hydroxide fusion.
Results (6) obtained through ICP-MS and alpha spectrometry agree quite well. For analytes present as contaminants (239/240Pu; 241Am), the laboratory results for standard reference materials were in good agreement with the accepted values (5); however, for the acid digestion procedure, the results for matrix constituents (238U, 234U, and 232Th) were quite low, because the silicate matrix was not decomposed. The NaOH fusion technique allows for accurate analysis of both matrix constituents and contaminants.
MEASUREMENT OF LONG-LIVED ACTINIDES BY INDUCTIVELY COUPLED PLASMA-MASS SPECTROMETRY
Inductively coupled plasma-mass spectrometry is relatively new in the radiochemical field and has been shown to be a very rapid technique for the determination of long-lived radionuclides. Quadrupole ICP-MS has been used to determine 99Tc, 129I, and actinide isotopes in environmental samples; however, many investigators have employed ICP-MS solely for the detection of single radioisotopes or radioactive elements. This approach fails to take advantage of the mass spectrometer's capability for rapid sequential analysis.
We have accomplished the determination of long-lived actinides in soil by ICP-MS (6,7). We selected soil samples for this study because of the difficulties inherent in their preparation for analysis. We employed ultrasonic nebulization to enhance the sensitivity of the instrument and used extraction chromatography to eliminate the sample matrix, concentrate the analyte, and separate uranium from the other actinides (to minimize spectral interferences) prior to instrumental analysis. Limits for instrumental detection of the actinides range from 50 mBq/L (239Pu) to 0.002 mBq/L (235U). Alpha-spectrometric determinations of 230Th and 239Pu and the 234U/238U activity ratio in soil leachates compare well with results from ICP-MS determinations.
We also studied hydrogen adducts of the major naturally occurring actinide isotopes, 232Th and 238U, by using ICP-MS and found that these adducts interfere with the determinations of 233U and 239Pu. When the instrumental sensitivity for uranium and thorium was optimized, the 232ThH+/232Th+ ratio was found to be (3.9 + 0.2) x 10-5 with pneumatic nebulization; with ultrasonic nebulization, the ratio was (2.10 + 0.07) x 10-5. Under the same conditions, 238UH+/238U+ ratio was found to be (3.2 + 0.2) x 10-5 and (1.8 + 0.1) x 10-5, respectively, for pneumatic and ultrasonic nebulization. Conditions that reduced hydrogen number density or increased plasma temperature (or both) decreased the hydride/atomic ratio.
ON-LINE LANTHANIDE AND ACTINIDE DETERMINATIONS USING FLOW INJECTION ANALYSIS/ICP-MS
Flow injection analysis (FIA) is a widely used nonchromatographic flow technique for automated quantitative analysis. Control of physical and chemical kinetics in FIA can be used to design powerful systems for environmental trace analysis. We have developed FIA systems that are based on liquid-solid separation and preconcentation for determining lanthanides and actinides in environmental samples. The sample is loaded onto a small column under well-defined conditions. After the sample matrix has been washed away, the solution conditions are altered so that the sample will elute abruptly into a small volume and pass to the detector. The FIA manifolds use off-the-shelf components to permit the precise manipulation of carrier, sample, eluent, and washing streams through column separation modules. The separation modules preconcentrate the sample by a factor of 10 or more and remove the potentially interfering environmental matrix. TRUSpec, a commercially available extraction chromatographic resin that is based on a bifunctional organophosphorus extractant, is packed into a separation column (3 x 50 mm) in the FIA manifold. Detection is performed by using ICP-MS. We have determined 151Eu and 238U in groundwater samples in a low-dispersion (D < 2) FIA system. The extraction column does not degrade when subjected to repetitive injections. A relative standard deviation of <2% was observed for consecutive (n=20) 100-ng/L 238U injections. Carryover between a
100-ng/L and a blank sample is <5% and the total time for analysis of each 5.0-mL aqueous sample is 6 min. We are developing an FIA manifold that allows for the separation of plutonium, thorium, and uranium thereby permitting the minimization of hydride interferences in ICP-MS determinations of actinides. We are also

exploring the use of the FIA approach for uranium preconcentration and matrix removal prior to kinetic phosphorimetric analysis.

ONGOING ACTIVITIES

To build on the accomplishments discussed previously, more research is being conducted to improve additional aspects of environmental radiochemical analysis. We are developing new separations for strontium and cesium, developing new scintillation detectors for alpha and beta emitters, and continuing investigations into applications of ICP-MS to radiochemical analysis. Method integration is key to improvement of efficiency. We are devoting significant effort to the application of FIA techniques to this problem, with an ultimate objective of a continuous-flow dissolution-separation-measurement system. We believe that this fully integrated system of radiochemical analysis is an achievable objective. Initial results indicate that we can achieve significant savings with comparable or even with improved figures of merit when we automate manual methods.

Development of techniques and methods must be followed by validation of the method. For example, a DOE Methods Compedium (8) procedure, we are validating based on extraction chromatography for the measurement of strontium-89 and strontium-90 in water. The validation analyses are being conducted by six commercial radioanalytical laboratories. Results will yield information on the precision and accuracy of the method, as well as an evaluation of the written draft procedure.

CONCLUSIONS

Innovative application of both classic and new techniques to radiochemical analytical methods can provide substantive improvements in the speed, cost, and other performance measures. Improved dissolution, novel separation chemistries and techniques, nonradiometric determination, automation, and waste minimization are some of the generic approaches that have been proven fruitful. A modest research investment has yielded several methods that can be directly applied to both environmental and waste samples and will result in substantial savings for the DOE and other customers.

Numerous additional improvements can be made to other inorganic, organic, and radiochemical methods using similar approaches. Given the projected costs, the increasing needs for real-time data, and the requirements for improved figures of merit, a pressing need exists for continued development of improved methods that can be applied to frequently requested analyte-matrix combinations.

ABSTRACT

A technology demonstration that optimizes sampling strategies and real-time data collection was carried out at the Kirtland Air Force Base RB-11 Radioactive Burial Site, Albuquerque, New Mexico in August 1994. The project, which was funded by the Strategic Environmental Research and Development Program (SERDP), involved the application of a geostatistical-based "smart sampling" methodology and software with on-site field screening of soils for radiation, organic compounds and metals. The software, known as PlumeTM, was developed at Argonne National Laboratory as part of the DOE/OTD-funded Mixed Waste Landfill Integrated Demonstration (MWLID).

The objective of the investigation was to compare an innovative Adaptive Sampling approach that stressed real-time decision-making with a conventional RCRA-driven site characterization carried out by the Air Force. The latter investigation used a standard drilling and sampling plan as mandated by the EPA. To make the comparison realistic, the same contractors and sampling equipment (Geoprobe soil samplers) were used. In both investigations, soil samples were collected at several depths at numerous locations adjacent to burial trenches that contain low-level radioactive waste and animal carcasses; some trenches may also contain mixed waste. Neither study revealed the presence of contaminants appreciably above risk based action levels, indicating that minimal to no migration has occurred away from the trenches. The combination of Adaptive Sampling with field screening achieved a similar level of confidence compared to the RCRA investigation regarding the potential migration of contaminants at the site. By comparison, the Adaptive Sampling program drilled 28 locations (vs. 36 for the conventional investigation), collected 81 samples (vs. 163), and sent 15 samples (vs. 163) off-site for laboratory analysis. In addition, the field work took 3 1/2 days compared to 13 days for the RCRA investigation. These figures translate into large cost savings because 22% fewer boreholes were drilled, 50% fewer samples were collected, and 91% fewer samples were analyzed off-site. Of these costs, the most significant savings involved laboratory analyses which typically cost >$1K/sample. Additional costs associated with the increased level of field screening carried out and costs associated with the use of the Adaptive Sampling software are relatively minor compared to the savings achieved.

During the field demonstration, a SunSPARC workstation containing the geostatistical program was successfully linked via the Internet with an identical workstation at Argonne. In the near future, it will be possible to support real-time sampling decisions in the field from remote locations thousands of miles away.

INTRODUCTION

The Kirtland Air Force Base RB-11 radioactive waste site, located in Bernalillo County, southeast of Albuquerque (Fig. 1A), is a 0.02 sq. km. (4.5 acre) landfill containing nine or ten disposal trenches (the exact number is unknown). Incomplete records suggest that the four earliest trenches located at the southern end of the site (Fig. 1B) are 15 meters (~50 ft.) long by 3 meters (~9 ft.) deep by 0.6 meters (2 ft.) wide and have about 1.2 meters (4 ft.) of earth cover. Two of these trenches are covered with asphalt. The remaining trenches are described as being 30 meters long(~100 ft.), 6-7 meters (20-24 ft.) deep and 2 meters (6 ft.) wide with 1.2 meters (4 ft.) of earth cover.

The RB-11 landfill was used to dispose of laboratory wastes (gloves, wipes, etc.) and animal carcasses that had received varying exposure doses of radiation as a result of military research activities carried out in the 1960s and early 1970s. Most of the radioactivity was in the form of induced activity and short-lived radionuclides. However, based on interviews with former employees who worked at the site, it is likely that several millicuries of radionuclides with longer half lives are present, e.g., 137Cs (t1/2=30 yrs), 90Sr (t1/2=28 yrs). Only a small portion of the waste appears to have been buried in drums. In addition to the radioactive wastes, an undetermined amount of hazardous and toxic liquid wastes may also have been disposed of in the trenches. These included small amounts of acids, mercury, cyanides and silver.

The purpose of this paper is to describe a case study in which traditional site characterization methods currently approved by EPA, such as grid drilling and off-site laboratory analysis, are compared with an innovative approach that combines sample optimization with real-time field screening. The innovative approach achieves similar results but is considerably more cost-effective and time-efficient because fewer boreholes need to be drilled and fewer samples need be collected and analyzed off-site. In addition, the sample optimization strategy employed allows real-time decisions to be made in the field regarding additional sampling, thus obviating the need for more costly supplemental sampling programs during a revisit of the site. Our aim here is to present an alternative site characterization methodology that is equivalent to meeting the information needs of a regulatory-driven program, while being more efficient than traditional methods. We consider the present study to be a first step in demonstrating this new approach. Future, similar investigations will be necessary to demonstrate that data quality objectives (QA/QC), statistical validity, and regulatory satisfaction can be achieved at a broader spectrum of sites.

PREVIOUS STUDIES: KAFB RCRA INVESTIGATION

The U.S. Air Force is responsible for implementing a final remediation action plan for the RB-11 site as required by the Resource Conservation and Recovery Act (RCRA) and under the Air Force Installation Restoration Program. Previous investigative activities at the RB-11 site are summarized in an EPA-approved Stage 2B Work Plan for Kirtland Air Force Base, New Mexico (U.S. Geological Survey, 1). In addition, the RB-11 site was the focus of a minimally intrusive field demonstration of innovative site characterization technologies carried out by Sandia National Laboratories in 1993 (Floran, 2). None of these previous investigations conclusively identified any type of contamination at the site.

In July 1994, the Air Force Environmental Management Division and their contractor, Halliburton NUS, conducted a RCRA Facility Investigation (RFI) at RB-11 to fulfill requirements of their Part B Permit. The results of that investigation (Halliburton NUS, 3) are briefly summarized here.

Conventional geophysical surveys including ground penetrating radar and EM-31/61 electromagnetic surveys were used in the RCRA investigation to define nine irregular trench areas, called "disturbed areas". These data were also used to choose locations for subsurface soil sampling, which was subsequently carried out with a Geoprobe soil sampler. The objective of the sampling was to define the extent of contaminant migration, if any, away from the disturbed areas. As required by the Air Force, sampling locations were carefully chosen so that they were outside of the disturbed zones to prevent penetration of contaminant sources within the trenches. After initial field screening, each soil sample was analyzed in an off-site laboratory for gross alpha and beta radiation; 226Ra and 228Ra; volatile organic compounds (VOCs); semi-volatile organic compounds (SVOCs); cyanide; metals (including mercury); and petroleum hydrocarbons. The RCRA investigation concluded that there has been no significant migration of contaminants (organics, metals, radiation) away from the trenches. However, if a release not detected by field screening had been identified, the Air Force was prepared to revisit the site and conduct a detailed follow-up sampling program.

Over a span of 13 days, 36 boreholes were drilled and 163 soil samples were collected and sent to an off-site laboratory for analysis. These numbers do not include surface soil samples collected, additional drilling and sampling carried out for the EPA, and QA/QC samples that were required by RCRA (duplicates and blanks). If the latter activities were eliminated the total operation would have probably taken about 11 days. It should be noted that the Stage 2D-1 RFI report (Halliburton NUS, 3) revealed that radiation levels averaged slightly above background adjacent to one trench, although the data were insufficient to verify that radiological migration has taken place. In addition, trace amounts of mercury were detected in soil samples near three trenches, suggesting that limited migration of this metal may have occurred at the site.

ADAPTIVE SAMPLING INVESTIGATION

The Adaptive Sampling field demonstration took place during the first week in August 1994, approximately a week after completion of the RCRA investigation. The primary objective was to demonstrate that a "smart sampling" methodology that combines real-time field screening results with sample optimization could do an equivalent or better site characterization than could be achieved by using a conventional

approach. The traditional type of site characterization often involves grid sampling, a heavy reliance on costly off-site analyses, and multiple site visits and sampling programs. To accomplish this objective, the Adaptive Sampling plan was compared with the conventional work plan carried out by the Air Force. To make the comparison as realistic as possible, the same drilling contractors (Halliburton NUS) and the same sampling equipment (Geoprobe) were used in both investigations. Off-site laboratory analyses closely matched those specified in the KAFB Work Plan. The main objective of the analytical work performed during the investigation was to provide data that could be reliably compared with similar data obtained by the Air Force RCRA investigation.

However, there were significant differences in the way the two efforts were carried out. The Air Force followed the required conventional approach of collecting soil samples, conducting field screening (for organics and radiation only), and sending each sample to an off-site contract laboratory for confirmatory analysis as required by EPA in the RFI Work Plan. The RCRA investigation resulted in a four to six-week delay between collection of samples and obtaining analytical results. This time gap was potentially crucial because if any of the samples were found to be contaminated, an expensive follow-up investigation involving a new phase of sampling would have had to be conducted. Although both investigations employed field screening methods, the Adaptive Sampling strategy planned to use these results to obtain additional samples immediately if contamination were encountered, thus saving the added costs of revisiting the site.

A second major difference between the two investigations involved the number of samples collected. The modified RFI Work Plan, which addressed all EPA requirements, called for sampling every 5 feet to the bottom of each trench and then 10 feet below each trench. If contamination was encountered, sampling would continue every 3 meters (10 ft.) until no further contamination was detected. By using PlumeTM (discussed below), a site characterization can be performed quicker and with fewer samples compared to a conventional RCRA characterization, yet achieve a similar level of confidence regarding potential migration of contaminants.

APPLICATION OF THE SMART SAMPLING METHODOLOGY

A geostatistical-based computer program, PlumeTM, and "smart sampling" strategy was used to optimize drilling and sampling locations. PlumeTM was developed at Argonne National Laboratory and is a module of SitePlannerTM, a data management and display program marketed by Consolve, Inc., and currently being used by many government laboratories and private industry. Using PlumeTM, 28 borehole locations were sited adjacent to the disposal trenches. Sampling locations were numbered sequentially from roughly south to north beginning with S1 at the southwest and ending with S28 at the northeast (Fig. 2A). None of the bores drilled directly into the disturbed areas, which was also the case with the conventional RCRA investigation.

PlumeTM combines Bayesian analysis with geostatistics to assist in the location of sampling points. A more complete description of PlumeTM's methodology can be found in Johnson (4). Bayesian analysis allows a quantitative merging of "soft" information for a site with hard sampling data. Soft information can include historical records, aerial photographs, non-intrusive geophysical survey results, etc. This kind of information is used to form an initial conceptual image regarding the probable location and extent of contamination. PlumeTM uses indicator geostatistics to update and refine the conceptual image as hard sample data become available. Indicator geostatistics allow one to interpolate from areas where samples exist to areas where samples are absent. New sampling locations can then be selected so that the uncertainty associated with contamination extent is minimized.

At RB-11, the soft information available consisted of aerial photos; anecdotal information regarding the number, size, location, and content of each trench; and several non-intrusive geophysical survey results for the site. This information was used to construct a conceptual image of the contamination at the site. Figures 2A and 2B show a plan view and cross-section, respectively, of this conceptual image in which soils are gray-scale coded, ranging from white (highly unlikely that contamination is present) to black (contamination known to exist). Most of the site appears as variations of gray, since relatively little hard sampling data were available at the outset.

The conceptual image served as the basis for both the RCRA sampling program as well as the program designed with PlumeTM. The sampling strategy for the two investigations was the same: sample as close to trenches as possible without

actually penetrating them to determine the likelihood that lateral and/or vertical contaminant migration has taken place. In the case of the RCRA sampling program, soil bore locations were based on a modified grid pattern, with one set of soil bores located west of the trenches, four bores to the east of the trenches and the remainder between the trenches (Fig. 2A).

For the Adaptive Sampling program, soil bore locations (Fig. 2A) were selected incrementally with the aid of PlumeTM, so that information gain was maximized. Information gain was defined as maximizing the volume of soil in the vicinity of the RB-11 trenches that could be classified as clean at an 80% certainty level. This definition of information gain was equivalent to the stated objective of the RCRA investigation, which was to determine whether contaminant migration had occurred away from the trenches. RCRA investigations never completely remove uncertainty regarding the nature and extent of contamination. The level of uncertainty that can be tolerated during a traditional characterization activity has not been specified by the EPA. For the purposes of this comparison, an 80% certainty level was chosen. Using the 80% certainty level, the information expected from the RCRA sampling program was evaluated by assuming that the samples would have yielded "clean" results. These samples were used to update the initial conceptual image and measure the volume of soils that would be classified as clean. Locations for the Adaptive Sampling effort were then selected to provide the same information gain, while keeping the number of bores and sampling locations to a minimum. The assumption of clean samples reflects the best possible outcome from the conventional investigation --- confirmation that contaminant migration has not taken place.

In the first phase of the Adaptive Sampling program, enough soil bore locations were selected to provide the same base amount of information as expected from the conventional investigation. Because of the field analytical methods employed by the Adaptive Sampling program, analytical results for radiation and VOC analyses were available the same day that bores were drilled, while most of the metals analyses were available before the end of the first phase. Based on these results, the conceptual site model was updated using PlumeTM. If contamination had been encountered, a second phase of sampling would have immediately ensued, with PlumeTM providing the locations of new bores. Additional soil bores and sampling would have continued until the contamination extent had been fully characterized.

FIELD PROCEDURES

Background Sampling

Prior to the field demonstration, four subsurface soil samples were obtained for background determination of organic compounds, metals and radiation. The samples were collected using a Geoprobe at various depths between 5 and 8.5 meters (16-28 ft.) from areas known to be uncontaminated near the periphery of the site, approximately 90-120 meters (~300-400 ft.) from the ends of the closest trenches (Fig. 1B). These background samples were analyzed on-site by field screening methods and also in off-site laboratories. The data were used to help formulate a sampling strategy for the demonstration.

A procedure was designed to minimize the amount of material needed for both on-site field screening and off-site analysis. Each soil sample was divided into five splits; three of these were used initially for field screening, and two were sent off-site (Fig. 3). In addition, one of the splits used for radiological screening was also sent to an off-site laboratory for isotopic uranium and thorium determinations. This same procedure was followed during the main sampling phase of the investigation in August.

Drilling

During the August demonstration, a total of 81 soil samples were collected at depth using two Geoprobe soil samplers which operated simultaneously in the field (the Air Force also used the same two Geoprobes during their field sampling) . Twenty-two of the 28 borehole locations were sampled at approximately 3, 6 and 9 meters (10, 20 and 30 ft.) below the surface, while the remaining 6 holes were sampled at depths of 3 and 6 meters (10 and 20 ft). Three additional samples were obtained including two field replicates.

Field Screening Methods

On-site field screening of soil samples for radioactivity and volatile organics was obtained within minutes of bringing the samples to the surface. Similar screening for metals took longer but a substantial number of samples were analyzed prior to the end of the field work. Field screening instrumentation included a

photoionization detector (PID) for headspace analysis of organic vapors; a Geiger-Muller (GM) radiation instrument with an internal sodium iodide detector and "pancake" probe for gamma radiation; and x-ray fluorescence (XRF) analysis for metals. Soil samples were also scanned for alpha radiation using a scintillometer and beta radiation using a second GM tube. Field screening methods were employed sequentially, with headspace done first to minimize loss of volatile organics. In addition to headspace and gross alpha/beta and gamma detection, a full gamma-ray spectral scan of a split from each sample to be sent off-site was performed within several hours of sample collection (Fig. 3). Metals analysis by XRF was available within 24 hours. These analyses were done at Sandia in a nearby laboratory three miles away, but for the purposes of this paper, are considered to have been done "on-site". It should be stressed that the laboratory XRF unit is field transportable and could have been operated at the RB-11 site within a mobile lab. During background sampling, which preceded the field demonstration, XRF analyses were obtained in one hour. Quick turn-around time for metals was achieved by eliminating a time-consuming grinding step during sample preparation. Previous results using this innovative method have been shown to be reasonably accurate at identifying anomalous samples during field screening (Floran, 5). Such a rapid analysis strategy ensured quick determination of potential contamination at a particular drilling location.

RESULTS

Field Screening

No elevated values above background readings were obtained. All headspace values were 0 ppm (action levels were set at 10 ppm). XRF results were below RCRA action levels for all metals analyzed. Gamma radiation counts on each soil sample were below background plus two standard deviations, which was the action level used to identify radiological contamination.

Laboratory Analytical Results

Approximately 20% of the total number of soil samples collected were sent to off-site laboratories for confirmatory analyses. These included 15 samples plus two field replicate QA/QC samples. Separate splits of each sample (including background samples) were analyzed for a complete suite of organic compounds, metals and radioactivity. These included 34 volatile organic compounds, 67 semi-volatile species, 23 metals (TAL metals + mercury), three uranium isotopes, two thorium isotopes, cyanide, and pH. In addition, 73 radionuclide species were analyzed in an on-site laboratory at Sandia by gamma-ray spectroscopy. These data are tabulated elsewhere (Floran and Bujewski, 6); only the results are discussed below.

VOCs, SVOCs

Two volatile organic compounds, methylene chloride and toluene, were detected in a majority of the soil samples; acetone was found in just three samples. All of these occurrences were below human health risk based (HHRB) standards, as defined by the Air Force's RCRA investigation (Halliburton NUS, 3). The presence of methylene chloride and acetone are likely to be the result of laboratory contamination. Both compounds were noted in laboratory blanks. In addition, methylene chloride was also found in equipment and trip blanks. Toluene ranged from below detection to 22 mg/kg, well below the HHRB action level of 1.6 x 107 mg/kg.

Six semivolatile compounds were detected in the RB-11 soils, all below action levels. One compound, phenol, was found in every sample and another, bis(2-Ethylhexyl)-phthalate, was detected in most samples. The majority of these occurrences were near or below the reporting limit although in one sample, phenol had a concentration of 1700 mg/kg, and in two other samples, bis(2-Ethylhexyl)phthalate had values of 1500 and 1200 mg/kg. The presence of bis(2-Ethylhexyl)phthalate was noted in the equipment blank. Trace quantities of benzoic acid, chysene and benzo(b)fluoranthene were detected in one sample each, and di-n-ocylphthalate was found in two samples, all at levels below reporting limits.

Metals

Only one metal, beryllium, was detected above its action level. All of the samples exceeded this concentration (0.2 mg/kg), ranging from 0.28 to 0.64 mg/kg. These levels of beryllium are typical of the relatively high background values within the area being investigated (Halliburton NUS, 3).

Other (Cyanide; Soil pH)

No evidence of hydrogen cyanide or any other metallic salts of hydrocyanic acids were found. Two samples reported cyanide concentrations at or slightly above the

reporting limit (0.5, 0.7 mg/kg). The action level for cyanide is 2000 mg/kg. Soil pH ranged from 8.4 to 9.5.

Radiological Compounds

Three isotopes of uranium (233/234U, 235U,238U) and two isotopes of thorium (230Th, 232Th) were analyzed in an off-site laboratory. Ranges for the uranium isotopes were 0.82-4.8 pCi/g (233/234U), 0.021-0.11 pCi/g (235U), and 0.74-4.4 pCi/g (238U). Thorium isotopes ranged from 0.59-1.4 pCi/g (230Th) and 0.54-1.4 pCi/g (232Th). None of these values are appreciably above background values determined for the site (Adams, 7).

Radiological contaminants of concern at RB-11 include the source radioisotopes, 90Sr and 137Cs. 90Sr was not determined. 137Cs was measured during the field screening phase of the Adaptive Sampling investigation but no values above background were recorded. Analysis of these radioisotopes was not required by the EPA-approved Work Plan, although gross beta determinations provided an indirect indication that neither was present above background levels (Halliburton NUS, 3).

Data Transfer Using the Smart Sampling Methodology

A SunSPARC workstation at Sandia National Laboratories, New Mexico, where the geostatistical program resided (four miles from the RB-11 site), was successfully linked to an identical workstation at Argonne National Laboratory via the Internet. Communication between the workstations was instantaneous. Data from the RB-11 site were transmitted to both workstations in minutes using a cellular phone/modem hookup from the field. If contamination had been encountered during the RB-11 investigation, we had planned to use the PlumeTM software at Argonne to suggest additional sampling locations. In the near future, it is likely that these types of real-time sampling decisions in the field will be possible from remote locations thousands of miles away.

COST SAVINGS

Substantial cost savings can be obtained by optimizing the number of samples obtained during a site characterization investigation, as well as by judiciously choosing how many of these should be analyzed off-site. The Adaptive Sampling program resulted in drilling 22% fewer boreholes, collecting 50% fewer samples, and analyzing 91% fewer samples in an off-site laboratory. A synergistic cost savings was possible with the smart sampling approach because fewer samples were collected (compared to the conventional type of investigation) and only a small fraction of the reduced sample set was analyzed. Of these costs, the most significant savings involved laboratory analyses which typically cost >$1K/sample.

For the analyses performed in this investigation, undiscounted prices per soil sample were as follows: VOCs ($295), SVOCs ($585), TAL metals + mercury ($466), cyanide ($65), pH ($25), isotopic thorium ($178), and isotopic uranium ($166). However, discounts of up to 50% are typically available to long-term customers. Actual costs for the types of analyses done here might range between $1K (~50% discount) to $1.8K (no discount) per sample. Thus, there is a tremendous potential for savings in analytical costs if only 20% of the samples collected are sent to an off-site laboratory, as was done in the present study.

Cost savings achieved by reducing off-site analytical costs must be weighed against additional costs associated with the increased level of effort associated with field screening (labor, depreciation on analytical equipment, report writing, expendables, etc.), as well as the costs associated with the PlumeTM software (acquisition, training, personnel required to run the program). In the Adaptive Sampling program, the major additional field screening cost that was not borne by the Air Force investigation was the use of an XRF unit for metals analysis. However, these costs, estimated to be $30/hr or $1,600 for the total project (including labor), were minor compared to the savings in off-site analyses. The cost of the SitePlanner/PlumeTM software, which is now available on a PC, has been steadily dropping; present costs including training are ~$6K.

CONCLUSIONS

The combination of smart sampling with field screening enabled our project to achieve a similar level of confidence compared to the conventional investigation regarding potential migration of contaminants away from the trenches. By comparison, the Adaptive Sampling project drilled 28 locations (vs. 36 for the Air Force), collected 81 samples (vs. 163), and sent 15 samples (vs. 163) off-site for laboratory analysis. In addition, the field work took 3 1/2 days compared to 13 days for the Air Force. These figures translate into large cost savings: 22% fewer

boreholes drilled, 50% fewer samples collected, and 91% fewer samples analyzed off-site. Of these costs, the most significant savings involve laboratory analyses which typically cost >$1K/sample for the type of analyses done in the present study. Despite the large number of samples collectively screened and analyzed in both investigations, no significant contamination above background levels of any kind was found. These results suggest that no gross, systematic migration of contaminants away from the trenches has occurred at the site.

The type of site characterization effort described here, in which geostatistically-based iterative sampling is combined with real-time field screening, is best demonstrated when contamination is present. In such a situation, the value of extensive field screening and avoidance of subsequent sampling phases is more easily quantified. Future demonstrations of the smart sampling methodology at sites with known contamination are planned and will be more rigorously compared with conventional approaches to site characterization.

ACKNOWLEDGEMENTS

This work was funded by the Strategic Environmental Research and Development Program (SERDP), a joint DOD/DOE/EPA initiative to develop and demonstrate innovative methods for environmental site cleanup. We would also like to acknowledge the Mixed Waste Landfill Integrated Demonstration (MWLID) project, which is funded through DOE's Office of Technology Development. The MWLID demonstration at the RB-11 site in 1993 and previous funding of PLUMETM development at Argonne National Laboratory provided the technical foundation and inspiration for the work carried out under SERDP.

INNOVATIVE GROUT RETRIEVAL DEMONSTRATION

Guy G. Loomis
Idaho National Engineering Laboratory

ABSTRACT

This paper presents the results of a field demonstration of an innovative transuranic buried waste retrieval technology involving grouting the buried soil/waste matrix followed by application of demolition grout and then retrieval. By grouting the waste in situ prior to retrieval, the highly mobile transuranic contaminants are locked into a soilcrete matrix, thus reducing the chance of aerosolization during retrieval. In this manner, the technology offers an enhanced contamination control. The demolition grout fractures the soilcrete/waste monolith to facilitate the retrieval process. The technology is applicable for both hot-spot retrieval or full-pit or trench retrieval. The grouting is accomplished using Portland cement and jet grouting directly into the soil/waste matrix at 6,000 psi. Demolition grout involved use of the commercially available product Bristar. Retrieval can be accomplished using standard excavation equipment or remotely controlled equipment. The results presented in the paper include: a) an assessment of the overall efficiency of the jet-grouting operation, demolition grout operation, and retrieval operation, b) an assessment of both the dust spread and rare earth tracer spread during both the grouting phases and retrieval phases, and c) a cost estimate to apply this technology at buried transuranic waste sites.

INTRODUCTION

This paper presents the results of full-scale field evaluation of an innovative retrieval technique for buried transuranic waste. The Idaho National Engineering Laboratory (INEL) has 2 million cubic feet of transuranic waste in shallow land burial (commingled with at least 6 million cubic feet of soil). Retrieval and disposal of this waste is one of the options being considered for this waste. Also being considered is the concept of removing selected hot spots and applying a capping action to the buried waste. Conventional retrieval using off-the-shelf remote excavators for either full-pit or hot-spot retrieval is expected to create considerable dust. Standard contamination control systems involve using misting sprays to reduce aerosolized soils, fixants to maintain the naturally occurring moisture in the soil/waste matrix, and ventilation. Using these conventional mining technologies in a prior retrieval demonstration (1), only a 70% reduction in dust spread was achieved over a baseline case of digging without any contamination control measures applied. During prior dust-control studies, it was identified that a 98% reduction in dust is required to allow for bubble-suited entry in a retrieval enclosure (2). Therefore, any technology that enhances the control over dust spread is mandatory to pursue.

DESCRIPTION OF THE TECHNOLOGY

The innovative retrieval technique involves grouting the buried soil waste matrix with a jet-grouting procedure, applying an expansive demolition grout to the matrix and retrieving the debris. The grouted matrix provides an agglomeration of fine soil particles and contaminants that results in an inherent contamination control during the otherwise dusty retrieval process. The jet grouting was accomplished using a Casa Grande drilling/jet-grouting rig (shown on Fig. 1). The grout was simple Portland cement mixed on a 1:1 ratio based on mass. The 4-9/16 in. drill stem was driven through the waste (consisting of a landfill-type mixture of drums and boxes containing simulated waste material including concrete, paper, cloth, sludge, metal, and wood).

Fig. 1. Casa Grande drilling/jet-grouting rig.

Once fully inserted, the jet grouting began using a bottom-to-top motion of the drill stem. The drill stem was programmed to withdraw in precise increments at a predetermined rate (5 cm every 6 seconds). There was a 2-revolutions-per-second rotation of the drill stem during the jet-grouting operation with two injection points near the bottom of the drill stem located 180 degrees opposite each other facing outward. Using a positive displacement pump, grout was pumped into the waste via the two nozzles at 6,000 psi. Once the jet-grouting operation was completed in any hole, a 2-in.-diameter, thin-walled, spiral-wrapped metal tube closed at the bottom end was inserted into the grouted hole and weighted in place until the grouted monolith was cured. These tubes were used to insert the demolition grout to facilitate the fracturing of the waste. The monolith was evaluated for temperature and once stabilized, the Bristar demolition grout was applied. This Bristar grout is designed to expand upon curing and during field trials near the simulated pit expansions on the order of 1 in. in diameter were observed. Retrieval of the grouted/fractured monolith can be accomplished by standard excavation techniques or using a gantry crane mounted clam-shell/grapple arrangement.

FIELD DEMONSTRATION RESULTS

A full-scale field demonstration of this retrieval technique was performed on a simulated waste pit at the INEL. Reference 3 discusses the important features of this proof-of-concept demonstration including the pit construction, jet-grouting activities, application of the demolition grout, retrieval of the grouted pit, and quantitative evaluation of aerosolized soils and rare earth tracer spread for all phases of the demonstration.

A simulated waste pit 10 ft x 10 ft x 10 ft was constructed using 55-gallon cardboard and metal drums and 4 ft x 4 ft x 4 ft cardboard boxes full of simulated waste. The simulated waste consisted of cloth, paper, metal, wood, sludge, and concrete identical to that which was shipped and buried at the INEL from the Rocky Flats Plant. Each container had a random dump of 200 grams of rare earth tracer to simulate the transuranic contaminant. The pit was built prototypical of pits found in the INEL Subsurface Disposal Area using backfilled lake-bed soil. A large weather shield was erected over the site and air samplers were used for all major portions of the demonstration.

The jet-grouting phase was accomplished with minimal dust spread and no rare earth

tracer spread above background. A total of 36 grout holes placed 24 cubic yards of Portland cement into the pit in a jet-grouting action (at nominally 6,000 psi). The jet grouting was accomplished by first driving the injection bit into the waste and withdrawing the bit in 5-cm increments while applying a slow rotation of the bit. The withdrawal rate was nominally 5 cm per 6 seconds.

The hole spacing was 24 in. on a triangular basis and the process took about 40 minutes to drill, jet grout each hole, and reposition the drill for the next hole. The hole spacing was based on a series of predemonstration field trials in compacted INEL soil in which up to 28-in.-diameter columns were created. After each jet-grouting operation, a bottom-sealed, 2-in.-diameter, spiral-wrapped tube was placed into the drill hole and allowed to cure in place. During the jet-grouting operation, soilcrete and some waste in the form of sludge came to the surface of the pit (in gallon quantities for some holes). Even though this material contained the rare earth tracer, no airborne spread of tracer was found above background on the air samplers spaced strategically around the pit. Figure 2 shows the pit following the grouting operation.

Fig. 2. Grouted pit with spiral wrapped tubes.

The application of Bristar as a demolition grout failed to fracture the waste as planned. The reason the grout did not expand upon curing was that there was an axial temperature gradient in the monolith with up to 60F higher temperatures in the middle regions of the pit than on the ends. This axial temperature gradient was caused by the heat of hydration as the Portland cement cured and the surrounding insulating properties of the soil. As a result, it was difficult to achieve fracturing. The grout appeared to expand at the near surface positions; however, these were the cooler positions. A separate application of the Bristar product in several holes drilled directly into the monolith showed a positive proof of fracturing. For this case, the temperature of the pit was more uniform and reduced from the postgrouting value. An alternative nondust-producing technique to the demolition grout would have been using a hydraulic rock spliter in the spiral-wrapped tubes to fracture the monolith.

Even though the monolith was not fractured by the demolition grout, the standard backhoe bucket with thumb attachment in the belowgrade orientation was successful in removing the monolith. The 10 ft x 10 ft x 10 ft monolith was removed in just under 5 hours of retrieval time. Grouted boxes containing metal pipe, wire, and plate steel caused the most difficulty in retrieval and a larger backhoe or front-end loader would have greatly facilitated the process. The general soilcrete mix was easy to flake off with the backhoe in 1 ft x 2 ft regions. Removal of computer paper resulted in tracer spread as the grout-encased paper easily disintegrated upon retrieval leaving the computer paper intact with visible tracer on the paper. Other waste forms such as pipes and wood also came apart from the grout during retrieval; however, for these materials there was a layer of grout on the surface and in the case of pipes the pipes were completely filled. If the waste pit contained all intact metal drums, there is an indication that this process would result in completely grouted drums including the space between the drum and the drum liner. One such specimen of a metal drum originally containing plastic pipe was completely full of grout and was sectioned for display purposes as shown on Fig. 3.

Fig. 3. Cross-sectional view of grouted drum (jet grouted 10 ft below surface).

The retrieval was accomplished with both overburden included and overburden removed. It was found that leaving the overburden on promotes both dust spread and tracer spread during retrieval. During retrieval with the overburden on resulted in a dust removal over a baseline retrieval case of between 30 and 40%, which compares unfavorably with conventional contamination control cases using misting and fixants where 70% removal was achieved. However, when performing retrieval with the overburden removed, a 90% dust removal was achieved, which compares favorably with the desired dust removal of 98%. During retrieval with overburden on, the airborne tracer concentration was 4,000 times background and with the overburden removed, the tracer concentration was only 1.35 times background. The overburden fell into the pit displacing air, which caused entrained particulate from the debris in the bottom of the pit to travel to the air monitors indicating a spread of contaminant.

In summary, a positive proof-of-concept for a enhanced contamination control was shown during the demonstration. The technology could be applied to buried heterogeneous waste for hot-spot retrieval or full-pit retrieval and could also be applied to contaminated soil zones. It is recommended that the retrieval technology

be further examined to obtain an efficient technique compatible with the grouting idea. For full-scale retrieval this would involve a large 235-CAT class excavator or larger and a large Balderson thumb end effector with companion shears. For this large excavator approach, the abovegrade digging action would pull the waste into the bucket and keep the waste from falling into the pit.

FULL-SCALE APPLICATION AND COST ESTIMATE

To apply this technology to full-scale operations would require very little change to the procedures used in the grouting phase; however, two outstanding questions remain relating to demolition grouting and retrieval of the monolith. The problem areas were stabilizing the axial temperature gradient in the monolith following grouting for application of the demolition grout and using the proper remotely controlled equipment to retrieve the waste. Additionally, it is mandatory to remove the relatively clean overburden prior to removing the monolith.

The cost estimate for this technology is incomplete; however, a first order engineering estimate is given. These costs only reflect the costs of grouting, fracturing, and retrieval. Costs associated with buildings and conveyance equipment, packaging, assay, and disposal would be separately estimated based on risk assessment. To perform grouting and retrieval on a 1-acre site would cost $16 million, excluding costs associated with containment and management of the project. The grouting phase is about half of this cost. To perform a hot-spot removal on a 40 ft x 60 ft site would cost just under $4 million, again neglecting the costs associated with management and containment. For either of these estimates, there are no costs given for treatment and final disposal.

CONCLUSIONS

1) On an overall basis, a positive proof-of-concept for the innovative grout/retrieval technology for retrieval of hot spots and full-scale retrieval has been shown for all major phases of the demonstration.

2) The grouting phase can be accomplished with a simple weather shield and still maintain control over contamination spread. This is based on the measured concentration of dust and rare earth oxide tracer spread during the grouting operation. The airborne tracer spread was measured at background values even though waste material was present in ejected grout/soil material around the drill stem. The simulated contaminants (rare earth tracers) in the "ejected" material was locked up in a slurry mix and did not spread to surrounding regions.

3) The jet-grouting technique created a monolithic block of waste/soil/Portland cement. Although there were striations of soil within the block, there were no continuous regions of soil that would be conducive to water migration through the block. There was no evidence of shadows using the nominal 24-in. hole spacing and all waste material had been encapsulated with the soilcrete mix. Additionally, there was no volume increase in the pit from the jet-grouting activity. There was a mass increase as 24 cubic yards of Portland cement was injected into the pit assessing about 60% voids.

4) It is concluded that the Bristar demolition grout causes extensive fracturing of the monolith if the temperature of the monolith is uniform and the correct product is applied.

5) For excavations involving an access pit [side (digface) retrieval], it is concluded that retrieval of the grouted monolith be accomplished only following overburden removal prior to the retrieval of the monolithic block. Overburden tends to fall into the access pit and cause entrained air to carry contaminants throughout the retrieval area. Comparison of tracer spread with and without overburden removal shows a factor of 4,000 times background of air samplers with overburden and a factor of 1.35 times background without overburden.

STATISTICALLY ROBUST MAPPING OF GAMMA-EMITTING CONTAMINANTS IN THE GROUND

John Conaway
Los Alamos National Laboratory

ABSTRACT
It is common practice at DOE sites to infer the three-dimensional distribution of contaminants in the ground from the analysis of samples from boreholes. In the case of gamma-emitting contaminants, spectral gamma-ray (SGR) borehole logging is sometimes used to augment or replace the sample data. In general, the same SGR analysis technology is used for both laboratory analysis and in situ analysis for gamma emitters. Laboratory spectrometers can give accurate results but the sample size is small. With SGR logging a single measurement represents an analysis of 1000 to 10,000 times as much material as a typical physical sample. Common practice is to make several SGR logging measurements per foot of depth, resulting in overlapping sample volumes and a well-analyzed borehole. Furthermore, while it is generally not feasible to obtain additional samples once the borehole is in place, SGR logging is a cost-effective method for monitoring changes in concentration over time along existing boreholes. Finally, SGR logging is very sensitive, with an estimated detection threshold on the order of 0.1 pCi/g for 137Cs. Typical background concentrations are an order of magnitude higher.
Because the results are not normally quantitative, Los Alamos is modifying and adapting existing data processing techniques developed for uranium exploration and other applications to the problem of assessing environmental contamination. The Quantitative Spectral Gamma-Ray Logging Project is also advancing the state of the art by eliminating limiting assumptions inherent in these existing data processing approaches, in particular the assumption that contaminant distribution varies with depth only. This new approach integrates nuclear geophysics, contaminant transport modeling, and geostatistics. We are developing data quality assurance tools that apply not only to borehole logging but to the collection and analysis of physical samples as well.

INTRODUCTION

Passive spectral gamma-ray (SGR) borehole logging can detect and identify the artificial gamma-emitting nuclides that are found in the ground at some DOE sites as well as natural gamma-emitting nuclides found in most rocks and soils. In addition to naturally occurring potassium, uranium-family and thorium-family gamma emitters, a number of contaminant nuclides can be detected readily with SGR logging (1,2), including 60Co, 137Cs, 152Eu, 154Eu, and 235U. Nuclides with lower energy or weaker gamma-ray lines can also be detected under favorable conditions.
SGR logging is very sensitive, giving an estimated detection threshold better than 0.1 pCi/g for 137Cs, an order of magnitude below typical background concentrations. SGR logging can give a continuous record of concentrations along the borehole and typically analyzes at least 1000 times more material than laboratory sample analyses. Supplementing a reduced sample analysis program with borehole logging can reduce overall costs while enhancing data confidence, as discussed in a General Accounting Office study of the subject (3). In the case of long-term monitoring, in situ measurements are superior to other technologies, offering continuous coverage, large sample volume, sensitivity, and accuracy, combined with the ability to repeat measurements in the same borehole year after year at reasonable cost.
SGR borehole logging services and instruments are available from a number of commercial vendors. The detectors used in SGR borehole instruments are usually low-energy-resolution scintillators (4-6), but a few instruments containing high-energy-resolution, solid-state cryogenic detectors have been built and are in use today. (1,7,8). In the case of low-energy-resolution detectors, full spectral processing is generally needed to identify specific nuclides because the broad photopeaks from different energy lines overlap (2). In the case of high-energy-resolution detectors, overlapping peaks pose much less of a problem, but automatic picking of specific characteristic energy lines from the complicated spectrum is desirable (9,10).
While SGR logging can be very accurate in identifying which contaminants are present, especially when a high-energy-resolution detector is used, the data are not

proportional to the concentrations of contaminants at a given depth except in thick, uniform zones (11). To address this limitation, data processing techniques have been developed for SGR logging, particularly for uranium exploration applications, which can convert the qualitative logs to quantitative concentration profiles for individual nuclides within limitations imposed by well-understood sources of error (12-14). The application of such data processing should make SGR logging acceptable to regulators as a replacement for most laboratory analyses for gamma-emitting contaminants along boreholes; this could yield savings of millions of dollars at DOE sites where gamma-emitting contaminants are a concern (3). In addition to site characterization, the advantages of continuous coverage, large sample volume, sensitivity, and accuracy, combined with the ability to run repeat measurements in the same borehole year after year at reasonable cost, yield a monitoring tool that is superior to all other technologies.

SYSTEM CALIBRATION AND CHARACTERIZATION

A vital step in applying existing borehole techniques to a new application such as environmental restoration (ER) is to calibrate the logging system for the conditions that will be encountered. To understand the scale of the calibration problem it is helpful to draw a comparison with the calibration of laboratory analytical instrumentation. To calibrate laboratory gamma-ray spectrometers, a number of standards must be prepared containing accurately known constituents in the same geometry as the unknown samples that are to be analyzed, and any deviation of the samples from the standards (for instance, different density) must be understood and corrections applied.

Precisely the same calibration requirements hold for borehole instrumentation except standards that simulate the borehole environment are needed rather than small cans or bottles of material. In the case of SGR logging, that typically means a model at least 1 m in diameter by 2 m high with a borehole of the appropriate diameter down the center. As a minimum requirement for quantitative results, the logging system must be calibrated for at least one set of known conditions. Many physical calibration models already exist, including a number in the DOE complex and at other government facilities. For instance, doped concrete models were used extensively in the NURE Program in the U.S. (15) and similar programs in other countries (16), as well as in the petroleum industry (17,18). Quarried rock models have been established at the U.S. Geological Survey in Denver (19), at the Nevada Test Site (20), in the petroleum industry, and elsewhere. In some cases, models are made of loose material encased in a shell of aluminum, plastic, or other material. Suitable experiments or computer modeling can be used to account for the effect of the shell. This approach has been used at the Nevada Test Site (21) and elsewhere.

In the ideal case, the calibration model(s) will mimic field conditions exactly; in practice, that may be difficult to achieve. Therefore, following the basic calibration, correction factors must be determined for field conditions that are different from the calibration conditions, such as a different borehole diameter. This can be accomplished using a number of additional physical calibration models or a combination of physical models and computer simulations. Due to cost and other constraints, the number of physical models available is generally not sufficient to cover all conditions encountered in the field. Computer simulations can be used to supply additional information (22-25). After benchmarking a computer simulation program against experimental data from physical models, other parameters that are difficult or impossible to model physically can be studied using the computer simulations. For instance, it is a relatively straightforward task to evaluate the response of a given logging system in a totally dry physical model and a second model totally saturated with water, but achieving known, intermediate values of saturation using physical models is difficult. However, computer simulation programs, once benchmarked at 0% and 100% saturation, can extend the calibration results to intermediate values. Simulations can also extend the calibration to include such factors as trace elements, different formation densities, and many other real-world conditions that may need to be considered.

QUANTITATIVE INTERPRETATION

Estimates of radioelement concentrations for a homogeneous layer of rock perpendicular to the borehole can be made based on a calibrated gamma-ray or SGR log. Such estimates are derived from the equation (12):

Eq. (1)

where G is the desired average radioelement concentration or weight fraction (the G

represents uranium ore grade in uranium mining), T is the thickness of the bed (meters), A is the area under the recorded gamma ray curve corresponding to the radioelement in question (counts per second times meters) and K is the calibration factor (K-factor) for that logging instrument or tool and that particular radioelement (weight fraction of a given radioelement per count per second). The assumptions upon which Eq. 1 is based limit its accuracy under certain conditions. This has been studied by various authors (12,26). For Eq. 1 to be valid for estimating uranium or thorium concentrations, those elements must be in secular equilibrium with their respective gamma-ray emitting daughters.

Note that the deflection of the recorded gamma-ray curve is generally not proportional to the radioelement concentration at a given depth (Fig. 1a). Only when the tool is in a thick, homogeneous zone (at least a meter or so thick as shown in Fig. 1b) does the concentration become proportional to the recorded gamma-ray intensity, or

Eq. (2)

where I is the recorded gamma radiation intensity for a given gamma emitter (counts per second) at a given depth.

Borehole Effects

Any deviation of the actual borehole environment from the calibration models must be understood and corrections must be applied (27-30). An example of a borehole effect that requires correction would be the effect of steel casing in the hole. If the system is calibrated in a model without casing and then run in a cased borehole, the shielding effect of the casing will cause the radioelement concentrations to be underestimated. A multiplicative correction factor based on casing thickness and composition can easily be applied to compensate.

Figure 1(a) shows the response of a calibrated SGR logging instrument (with detector D) in the vicinity of a thin radioactive bed. Concentration is underestimated and bed thickness is overestimated, but the product of the two is correct. Figure 1(b) shows that instrument response is proportional to concentration near the center of a thick, homogeneous radioactive bed.

Geologic Formation Effects

When an SGR logging tool is calibrated in a model that is different chemically from the lithology to be logged, the resulting calibration factors will not necessarily be correct (31). This could happen if the model is composed of a type of rock different from that encountered in the field, or if there is a different amount of water in the pore spaces of an otherwise identical rock type. Errors resulting from differences in the chemical composition of the matrix material between the calibration model and formations found in the field will generally be small at the higher energies most frequently used for radioelement estimates. Errors can be large at low photon energies when either the calibration model or the field formation contains substantial quantities of heavy elements not found in the other. This is known as the Z-effect, where Z is the symbol for atomic number. The Z-effect results from the fact that at low energies, highly nonlinear photoelectric absorption dominates the gamma-ray interactions, rather than the linear Compton scattering dominant at energies around 1 - 2 MeV.

Conventionally, radioelement concentration is expressed as a weight fraction of the bulk formation including water. This eliminates most of the error associated with varying water content. However, there remains a small, second-order error not accounted for by that convention due to changes in the gamma-ray transport properties of the medium. Results can be improved slightly by applying a multiplicative correction factor (31).

Thin Contaminated Layers

As stated above, data processing techniques have been developed for uranium exploration and other applications that can correct for the errors inherent in logging through thin radioactive layers within limitations imposed by well-understood sources of error. Such techniques are referred to as spatial deconvolution techniques. Spatial deconvolution is not a matter of simple scaling but involves the application of inverse theory to back out the "smearing" effect of the spatial response of the logging instrument. This smearing effect is a non-linear function of a number of borehole and formation parameters including borehole diameter, casing type and thickness, and borehole fluid as well as formation density, porosity, water saturation, and other factors that affect the passage of gamma radiation through matter (13,14). Errors caused by dipping beds can also be

corrected (32).
In an infinitesimally thin borehole using a point detector, the system response function j(z) can be approximated by the equation
Eq. (3)
as given by Davydov (34) based on work by Suppe and Khaykovich (35). In this equation, z is depth along the borehole (the thin zone is located at z = 0) and is a parameter referred to as the shape constant (not the same as the Th/U spectral stripping factor a). The shape constant a can be determined theoretically (36) or experimentally in model boreholes (37). Under favorable conditions a can be determined directly from field logs (37).
Equation 1 describes a double-sided exponential function, which has a corresponding 3-coefficient inverse filter (14):
Eq. (4)
where Dz is the sampling interval along the hole. This digital inverse filter is applied to the digital log using discrete convolution to recover the radioelement distribution information, thereby deconvolving the log. The advantage of the approximation given in Eq. 3 is that it leads to a simple inverse filter (Eq. 4) that may be adapted relatively easily to changing conditions by adjusting a.
In the real case of a finite borehole diameter and detector length, the system response function will no longer approximate Eq. 3 but will appear more rounded in the vicinity of the radioactive zone. Nonetheless, the system response function in these cases will generally approximate the double-sided exponential away from the vicinity of the radioactive zone. For the most part these various distorting effects can be removed from the data separately and in any order (at least to the extent that they can be removed at all). Thus, it is not necessary that the system response function correspond precisely with Eq. 3. The inverse filter may be used to remove the effect of the double-sided exponential part of the total spatial response function, leaving some residual distortion in the immediate vicinity of the thin radioactive zone depending on such factors as borehole diameter and detector length. These effects may also be considered individually using a similar empirical approach, although they are not readily tractable like the double-sided exponential.
The effects of borehole, formation, and instrumental parameters on the shape of the system response function have been considered by many authors (29,36,38,34,14). An increase in the value of the shape constant a indicates a more rapid decrease in radiation intensity with distance from the radioactive zone. This condition can be caused by many factors, including
a) An increase in formation bulk density, including an increase in pore fluid density
(e.g., replacing air with water);
b) A decrease in dip angle between the radioactive zone and the normal to the borehole, until perpendicularity or 0o dip;
c) A decrease in borehole diameter, allowing proportionately less radiation to travel
in the borehole;
d) An increase in borehole fluid density such as from air to water to heavy mud;
e) An increase in the equivalent atomic number Zeq of the formation;
f) An increase in steel casing thickness or density;
g) Restriction of the detected gamma rays to unscattered photons such as the 1.76-MeV 214Bi energy line of the uranium family; and
h) For unscattered gamma rays, a decrease in gamma-ray energy.
Spatial deconvolution techniques, which have proven superior to detector collimation and other approaches, were able to detect substantial errors in the published radionuclide concentrations of a thin-zone gamma-ray logging test and calibration facility at DOE's Grand Junction installation (33) during the National Uranium Resource Evaluation program, as shown in Fig. 2. Those errors, which had gone undetected throughout twenty years of logging instrument tests and calibrations in that model, were confirmed by subsequent physical sampling and laboratory analysis. The concentration values for that model have been corrected and re-published.
Figure 2. (a) Cross-sectional diagram of the mixed-zone model N-5 located at the DOE Grand Junction office. (b) A high-quality, calibrated SGR log from the borehole in N-5 using a small (2.5 cm x 2.5 cm) NaI(Tl) detector. (c) The same data shown in (b) after deconvolution using the inverse filter given in Equation 4. Disagreement with the published concentrations (marked by the arrows in Fig. 2c) caused DOE to

order additional core samples and other samples to be obtained and analyzed. The concentrations were revised based on the log and republished. (d) The deconvolved data compared with the revised published concentrations.

Nonhomogeneous Distributions of Contaminants

Existing approaches to the quantitative interpretation of SGR borehole logs assume that the gamma emitters are distributed in homogeneous layers. This can be a good approximation in some geologic environments such as the sedimentary lithology often associated with oil fields. It appears, however, that contaminants at DOE sites may more commonly be found in complex, three-dimensional distributions. For such cases, an approach is needed that extends the state of the art beyond linear deconvolution. We have proposed an approach which we are calling Optimized Geostatistical Inversion (OGI) that integrates nuclear geophysics, contaminant transport modeling, geostatistics, and other site data such as physical sample analyses. The OGI approach will help explain the relationship between SGR borehole logs and physical sample data, how well the physical sample data and the SGR data predict the actual distribution of contaminants in the ground, and what the trade-offs are among sample density, data quality, and cost. This approach will also provide statistical quality control tools to describe the confidence limits of both SGR logging data and physical sample data. Finally, OGI is a results-oriented approach tailored to each specific location and contamination problem based on a combination of simulations and analysis of field data. The OGI approach may be summarized as follows:

1. Using an available contaminant transport computer model, simulate the general geologic and contaminant transport characteristics of the target environment and use the simulations to gain an understanding of how contaminants of concern move through this type of environment and are deposited along their transport paths. Note that the goal is not to predict or duplicate the actual contaminant distributions, but to use realistic simulated distributions to gain a statistical understanding of the field data.
2. Emplace imaginary boreholes through the simulated contaminant distributions. Using a Monte Carlo radiation transport computer program or other suitable approach, develop synthetic SGR borehole logs based on the contaminant distributions developed in the contaminant transport modeling stage. The synthetic logs should consist of spectra generated at equal depth intervals along the borehole, similar to actual logs.
3. Estimate concentrations of gamma-emitting contaminants based on an analysis of the synthetic borehole gamma-ray spectra using the same procedures as will be followed for real data.
4. In the same imaginary boreholes, determine contaminant concentrations based on physical samples representative of typical sampling protocols. By repeating this for many sample depths and borehole locations, a geostatistical model of the sampling process can be developed.
5. Repeat steps 2-4 for other imaginary borehole locations to develop a geostatistical model of SGR logging and physical sampling for the target environment.
6. Compare the known simulated distribution of contaminants in the subsurface developed in step 1 with estimates that would be obtained by in situ SGR measurements and physical sampling (steps 2-5). In comparing the results of borehole sample analyses and SGR logs, it is important to remember that these samples and in situ measurements investigate two mutually exclusive but related volumes of material. The sample from a particular depth is a small volume of material, perhaps a few cubic centimeters, removed during the drilling process. The SGR measurement at that same depth represents a weighted analysis of perhaps 105 cm3 of material, including all of the material in the region around the borehole sensor except the physical sample itself and other material removed by the drilling process. Thus, in an inhomogeneous medium such as found at Hanford and other DOE sites, it may be expected that the physical sample data and SGR data will rarely agree in a point-by-point comparison. To assure an acceptable level of data quality it is essential to understand the statistical distributions involved in these analysis processes. This approach allows such an understanding to be developed cost-effectively.
7. Finally, using actual SGR data and physical samples from field boreholes, perform a geostatistical comparison of physical sampling and in situ measurements. Compare these results with the statistical distributions developed during the simulation

phase of the project. In this step, inconsistencies in the synthetic data can be identified and the model refined, if required.

Figure 3. The cutaway diagram of the borehole environment (a) shows two identical point gamma-ray sources located at different distances from the borehole. The resulting log (b) indicates that two very different spatial responses would result from the two sources. The gamma-ray energy spectra recorded at the center of the anomalies from sources 1 and 2 are shown in (c) and (d), respectively. The spectrum corresponding to source 1 shows a small peak-to-continuum ratio and lower overall intensity (notice the different intensity scales on the two plots). This information can be used to distinguish between 3-dimensional source distributions and layered distributions.

The simulation approach described above is important because a plausible distribution of contaminants is known completely and accurately, along with the other properties of the media that affect the accuracy of the contaminant estimates. Analysis of the detailed simulated data sets will lead to a detailed understanding of the problem that could otherwise be developed only by examining massive amounts of experimental data, a much more expensive procedure. Using simulation, the groundwork is carefully laid by developing a robust geostatistical framework in steps 1-6, into which the borehole data are folded in step 7.

ACKNOWLEDGMENTS

This project was supported by the United States Department of Energy under TTP Nos. AL931001, AL131004, and AL031001. We thank Caroline Purdy, Bill Haas, Dave Roelant, and Paul Hurley for their support and encouragement. This work has been greatly aided by discussions with a number of people, especially John Hoopes, Chris Murray, John Brodeur, Carl Koizumi, and Tim Scheibe.

INNOVATIVE DESIGN AND CONSTRUCTION SOLUTIONS TO REMEDIATE RADIOLOGICALLY CONTAMINATED RESIDENTIAL COMMUNITIES IN ESSEX COUNTY NEW JERSEY

Michael S. MacIndoe P.E.,
Robert T. Johnson P.E.
Stephen G. Wilkinson P.E.
Bechtel Environmental, Inc.

ABSTRACT

The Montclair/West Orange and Glen Ridge Superfund Sites, located in Essex County, New Jersey, are contaminated to varying degrees with radioactive materials. Both sites are listed on the Superfund National Priorities List (NPL). The waste materials originated from radium processing facilities prevalent in the area during the early 1900's. The design for remediation of these sites is performed by Bechtel National, Inc. on the behalf of the United States Army Corps of Engineers (USACE) Kansas City District, which administers the project through an Interagency Agreement with the United States Environmental Protection Agency (EPA) Region II.

This paper will describe each part of the remedial design process: design field investigations, preparation of designs, final evaluation of designs, and actual construction using these designs. The paper will discuss the relationship between the interpretation of data and the remediation methods and technologies used for the remediation of structures by underpinning basements, on-grade structures, and chimneys; removal of contaminated material below supporting elements without resorting to underpinning; and demolition and reconstruction of basement foundation walls (where contaminated) without use of traditional "cribbing" methods.

SITE DESCRIPTION AND LOCATION

The two sites consist of 773 residential and commercial properties having a combined land area of approximately 210 acres. The Montclair/West Orange radium site covers approximately 120 acres and includes 297 properties in the Town of Montclair and 200 properties in the Town of West Orange. The Glen Ridge radium site covers approximately 90 acres and includes 276 properties in the Town of Glen Ridge and 32 properties in the City of East Orange.

The houses within the sites are generally wood-framed, multi-story with below ground basements, front and back porches, and detached garages. The architecture of the homes is typical of the 1930's era. The size of a property usually ranges from one-sixteenth to one-eighth of an acre.

SITE HISTORY

Radium research and processing facilities were prevalent in Northern New Jersey from the early 1900's to the late 1920's. The processing facilities produced luminous paint for watch dials, surveying equipment and airplane instruments; and later extracted the radium for research and medical applications. By the early 1930's, the effects of excessive exposure to radium were discovered, which subsequently caused an end to the processing facilities. However, the discarded processing waste materials from these facilities were left behind. While some of these materials remained at the facilities, various waste materials such as sand tailings, coal ash, bottles, etc. were disposed of in rural areas surrounding the facilities. Eventually, as these areas were developed with residences, commercial buildings, roadways, parks, etc. the contaminated material was moved to fill low-lying areas or mixed with uncontaminated soil and fill material. In many cases the contaminated material was mixed into concrete and mortar and used in the construction of buildings.

NATURE OF CONTAMINATION

The contamination at the Montclair/West Orange and Glen Ridge Radium Sites consists of elevated concentrations of radionuclides in the soil. The radionuclides present in the soil at these sites are primarily from the uranium-238 decay chain. Contaminated properties in the Montclair/West Orange and Glen Ridge sites have elevated levels of gamma radiation from radionuclides decaying within the soil and building materials, and alpha radiation emitted from radon and radon decay products.

REMEDIAL DESIGN FIELD INVESTIGATIONS

The primary methods used to perform the field investigations on each property included:

- Exterior/Interior gamma radiation surveys
- Subsurface Investigations

Exterior/Interior Gamma Radiation Survey

The exterior and interior gamma radiation surveys were conducted across an entire property (outside the home and on the lowest floor elevation of a home and garage) to locate areas of elevated gamma radiation and map out areas where potential soil contamination existed. Gamma readings were measured using a very sensitive gamma measurement instrument (gamma scintillometer) oscillated approximately six-in. from the ground surface across 6-ft. x 6-ft. grid blocks. This instrument was used to detect general areas where the radiation was above background.

The gamma survey and the readings recorded during the survey were used as indicators to proceed with one of two investigative strategies. The first included subsurface investigations by drilling; the second included a repertoire of investigative methods to classify a home as either "clean" or requiring additional field investigation. Only strategy one is relevant to the Remedial Design (RD) process.

Subsurface Investigations

A subsurface investigation was performed for all properties which exhibited elevated surface gamma radiation measurements. Drilling locations were selected after evaluating surface gamma radiation measurements, noting areas of elevated measurements and noticeable trends of contamination. Consideration was also given to the field investigations performed during the RI/FS; data results from contiguous properties; and any significant or noticeable features or trends observed from work in the immediate area.

Generally, the quantity of boreholes drilled was limited to minimize cost. Therefore, the drilling approach varied for each property and was usually dependent on the apparent extent of contamination as ascertained from the gamma survey and as the need to clarify some aspects related to the engineering design solution of the remediation.

Drilling

The drilling techniques used depended upon the depth of anticipated contamination; physical access onto a property; and the type of soil material that might be encountered.

The drilling was performed using the following types of drilling equipment:

- Skid Mounted Drilling Rig
- Tripod Mounted Sampling Rig
- Hand Augers

With drilling depths of up to 10 ft. several of the holes were drilled with a truck-mounted drill rig. Since soil samples were also taken, a 3-in. diameter split spoon sampler was used.

Due to the limited physical access to many properties by even the smallest drilling rigs, the great majority of boreholes were hand augered. As drilling proceeded for each borehole, a descriptive log of the material encountered in each 6-in. increment of drilling depth was documented. The soil was described by type and color. This information often helped to identify lenses of material that were frequently found to be contaminated.

Borehole Gamma Logging

When a borehole was drilled and all spoil material removed, the hole was gamma logged at every 6-in. increment to determine the rate of gamma radiation at varying depths. Gamma logging was accomplished by inserting a gamma radiation sensing probe into the borehole to determine radiation levels. The radiation measurements recorded during gamma logging were used as precursors for selecting soil samples to analyze and as indicators for depth of contamination.

Soil Sample Collection and Analysis

Soil samples were taken for each 6-in. increment of borehole drilled. Soil samples were selected to isolate the boundaries between contaminated and clean soil. Normally samples were taken after the downhole gamma logs were evaluated and soil samples were screened. Field screening of samples allowed for a quick count gamma measurement and comparison to the downhole gamma log to ensure that the sample is representative of the area and was not contaminated by material falling into the hole during the drilling. Soil samples were analyzed for Radium-226, Radium-228, Uranium-238, Thorium-230, Thorium 232 and Potassium-40.

REMEDIAL DESIGN

Designs were prepared to remove all material exceeding criteria. Preparation of remedial designs required the collective interpretation of gamma radiation surveys, downhole gamma logs and soil sample analysis.

A remedial design for a property included preparation of an excavation plan, restoration plan, sections, landscape schedule and subsurface borehole profiles. The excavation plan outlined the lateral limits of excavation and the depth of excavation; the restoration plan showed features which were to be restored by a contractor; sections of the excavation areas were taken to show actual depth of excavation in relation to existing ground lines; landscape inventories identified trees and shrubs which were to be restored; and borehole profiles showed the type of soil material encountered during drilling.

Excavation Plan

When defining the contamination boundaries, all data gathered during the RD field investigation were considered. The walkover gamma radiation surveys were used as guides in establishing the horizontal limits of contamination. In many cases, contaminated areas were delineated by elevated surface readings and were used to establish design excavation limits.

A detailed civil survey drawing was prepared for each affected property. Civil survey work consisted of preparing grid, contour, boundary and planimetric surveys. The excavation plan showed areas of known contamination exceeding cleanup standards. Excavation was designed to be conducted in two stages - stage 1, defined as primary excavation, and stage 2 as secondary excavation. The secondary excavation cut line represented the anticipated limit of material removal, to be verified by instrument readings during excavation. This cut line was controlled by the depth of contamination detected in boreholes.

Cross Sections

Cross sections were taken across areas of excavation to show depth of excavation in relation to the existing ground line. The sections consisted of the following elements: existing ground line, primary excavation line, and secondary excavation line.

Sections were always cut to intersect boreholes. This was necessary since the borehole data was the baseline for preparing the secondary excavation cut line. The secondary excavation cut line was created by drawing a line through the bottom of contamination (BOC) elevation in each borehole. The primary excavation line was then delineated within the secondary line to define the amount of contaminated material that could be removed before beginning the more time consuming excavation guided by instruments.

Restoration Plan

A restoration plan was developed for all properties disturbed by excavation. Restoration of a property required the replacement of features such as demolished structures (garages), driveways, sidewalks, curbs, lawns, trees, shrubs, and all other disturbed features.

Restoration plans were created to require a contractor to restore the property to preconstruction conditions. In virtually all cases, the appearance of the restored areas was superior to that of the preconstruction conditions because of the contractor's workmanship.

STRUCTURE REMEDIATION

The objectives of the design process were to develop innovative designs to eliminate the need and expense of demolition and cribbing methods while exploring the most cost effective and practical techniques of remediation.

Basement remediation, by common construction methods, would require support of a house by cribbing and demolishing the basement foundation walls, footings, and slab. Deep excavation to remove contamination beneath on-grade structures (e.g., porches, decks, or add-on rooms) typically requires demolition of the structure. However, the

use of innovative underpinning designs allowed remediation of structures and surrounding soils while limiting the required restoration.
Underpinning residential structures offered many challenges, both in RD and Remedial Action (RA). A pre-design reconnaissance consisting of inspecting the structural elements to determine their condition, size, and configuration was mandatory for a successful design effort. Since the construction, configuration, and condition of structures can vary greatly, the designer had to approach each structure as a new and separate problem. On the other hand, it is advantageous to develop solutions based on common elements that can be easily adapted for many structures in order to simplify construction.
Basement Remediation
The houses on these sites are typically wood-framed, multi-story construction resting on concrete masonry unit (CMU) basement walls. The method used to remove contamination from basements depended on the source and location of the contamination as well as the configuration and condition of the structure. Contaminated fill material was usually found either along basement walls or beneath slabs and footings. Remediation in these cases rarely required demolition of structural elements other than the basement floor slab. As previously noted, one of the primary contaminants at the sites was an ash fill. This ash was often used as backfill material and, on occasion, used as an admixture for concrete and mortar. These contaminated building materials were used in the construction of some residential structures.
Removal of the basement floor slab due to inherent contamination or to allow access to contaminated subgrade material proved to be the simplest of the required designs. The interior tubular supports often were founded on the slab itself, necessitating use of temporary supports while the existing supports were removed.
When the source of contamination was fill material, it was not unusual for that contamination to extend to a depth greater than the bottom of footing (BOF). Provided that the foundation or the basement wall was not contaminated, it was possible to remove the material under the footings without demolishing the walls. This was accomplished by excavating a series of alternate three-foot long trenches beneath the footing, while always leaving two trench lengths between open trenches. The trenches were excavated to BOC, then a concrete pier was poured beneath the existing footing to create a new foundation bearing at BOC. This method was used for trench excavations up to 3 ft. deep.
When it became necessary for a partial or entire wall to be demolished, there were many solutions that could have been used. Simplicity, cost, and safety were the driving forces in developing the most practical method for each house. When a major support wall (i. e., one carrying loads from the first floor joists) was demolished, the simplest underpinning method was to provide alternate temporary support for the joists.
For minor support walls (i.e., carrying only loads from upper story walls) and when framing configurations prohibited transfer of wall loads to joists, it was necessary to develop an alternate method. In these cases a concrete lintel was constructed over the walls to be demolished. Although this method can be labor intensive, the lintel allows demolition of large sections of wall.
On-Grade Structure Remediation
The variation in the construction of on-grade structures prohibited many generic solutions. Increased difficulty of structural characterization, magnitude of loads, and depth of anticipated remediation led to a comprehensive design approach to the support of add-on rooms.
Original methods developed required the excavation of shored pits. Once constructed, timber columns and wood needle beams were installed in place of the existing support system. The temporary supports and needle beams removed load from the piers. As design methods were continuously analyzed and improved, a new system was developed using augured piles with I-beams in place of the shored pits. Use of this method should be cheaper and safer than the shored pit method.
PROCESS EVALUATION
Throughout the remedial design process, the methods used to obtain data, interpret data, apply the data to design, and prepare the RD were evaluated to ensure the methods were appropriate.
The investigatory process used to obtain data (i.e. Exterior/Interior Gamma Radiation Surveys, Subsurface Drilling, Borehole Gamma Logging and Soil Sample

Collection and Analysis) has been successful. These data proved to be predictive when used to determine the presence of contaminated material and to define vertical and lateral boundaries of contamination. However, these methods of investigation were not successful in locating contaminated basement foundation wall footing material. When an interior gamma scan was performed across the basement slab, elevated gamma readings were attributed to and usually verified by soil sample analysis to be either a contaminated concrete slab, contaminated subgrade material beneath the slab, or a combination of both. RA work has shown that some foundation wall footings are also contaminated, presumably from using contaminated sand in the concrete mix. Subsequent interior investigations included use of other test parameters, such as interior radon working levels, as indicators to target potential sources of contamination. In addition, methods to investigate existing footings were employed. This was accomplished by core drilling a 12-in. diameter hole in the basement slab adjacent to a foundation wall. The subgrade material beneath the slab core was removed by hand until the footing was exposed. Once the footing was exposed, the footing was scanned for gamma radiation and a sample taken. This procedure has been successfully executed by field personnel.

Another area of investigation that evolved throughout this project was interpretation of data results from foundation wall gamma scans. In some cases, the elevated wall readings were attributed to shine from elevated slab readings, elevated exterior material backfilled against the wall, or a combination of both. To verify if the wall material itself was contaminated (wall material is typically concrete masonry block with mortar joints), a hammer drill was used to core a 2-in. diameter sample. Analysis of the sample confirmed if suspect building material was contaminated.

The methods for removal of material within basements, on-grade structures, etc. were used successfully during RA. The contractor was able to utilize the systems without incident. The support methods that used steel instead of timber members proved to be more cumbersome to construct than expected due to confined work areas and weight of materials.

The wall demolition methods (concrete lintel and joist support) have worked well. Entire and partial foundation walls were demolished with these systems in place. When full height wall demolition was required (i.e. from top of slab to bottom of joist) the exposed footings were often found to be structurally unsound for use. As a result, the contractor usually had to remove the footing section corresponding to the demolished wall section and reconstruct the footing and wall section. Subsequent design work anticipated existing structural conditions that were not suitable for restoration of structural elements.

IDENTIFICATION OF MICROBIAL BYPRODUCTS INVOLVED WITH TRANSPORT OF URANIUM IN SATURATED SOIL

Mark Delwiche
Gretchen Matthern
Idaho National Engineering Laboratory
PO Box 1625
Idaho Falls, ID 83415-2203

ABSTRACT

Filtrates from Aspergillus niger and Penicillium simplicissimum mold cultures can remove 80-90 % of the uranium in Fernald soil when used in a soil washing process. Analyses of the mold filtrates were done to determine the basic components responsible for the uranium transport. High performance liquid chromatography analysis of the mold filtrates showed the primary organic acid components to be

citric, gluconic, oxalic and malic. Uranium removal was correlated with individual acid concentrations and gluconic acid showed the strongest correlation (.56) of any of the single acids. Slightly stronger correlations were shown for all acids combined (.62) and gluconic and citric acids combined (.61). Similar experiments using solutions made to contain 0.1% of individual acids in DI water showed in decreasing order malic, citric, gluconic, and oxalic to be effective in removing uranium. Solution filtered from soil washing experiments was separated by ultrafiltration (3000 dalton) to determine the contribution of small organic molecules to uranium transport. Preliminary results indicate 60-80% of the uranium is in the less than 3000 dalton fraction which contains the organic acids. The 20-40% of uranium which did not pass through the filter suggests that additional compounds other than organic acids are involved in uranium transport from soils. These data will be used to further develop and optimize the soil washing process and provide insight for transport phenomenon important to risk assessment strategies.

INTRODUCTION

The Biotechnology group at Idaho National Engineering Laboratory has been developing a bioprocess for removal of uranium contamination in soil at a former feed-metals plant near Fernald, Ohio (1). In light of the large volume of soil and low level of contamination at Fernald, a large-scale on site washing plant has been proposed. The process uses a solution of metabolic by-products filtered from broth cultures of common molds (referred to as mold filtrate in this paper) to wash the soil. Compounds in the mold filtrate compete with soil particles to form a mobile complex with uranium which moves with the liquid wash phase which is removed from the soil by filtration. This soil filtrate solution can then be treated to remove and concentrate the uranium. Advantages of the system are that it does not subject the soil to extremely acidic or basic conditions, so soil structure is preserved and it uses biodegradable mobilization agents.

Experiments conducted at INEL have shown filtrates from Aspergillus niger and Penicillium simplicissimum mold cultures grown in malt glucose solution are effective at mobilizing uranium from the Fernald soil (See Table I). Remaining to be resolved in the proposed system are issues of separation of complexed metal from solution, optimization of process, and development of waste treatment facilities to handle residual biological oxygen demand created in treatment. This paper addresses the question which is key to all of these issues: Which compounds in the mold filtrate are responsible for mobilizing the uranium?

Several different factors are involved with complexation of uranium in soil treatment. The fact that microbial activities may increase mobility of metal ions has been well documented (2,3,4). Microbes excrete a wide range of biochemicals that may complex with metals. Some of these are "chelating" agents which specifically increase metal concentration in solution and thus increase availability of trace metals necessary for growth (5). Other excreted chemicals may be simply by-products and only incidentally form complexes. Additionally, the presence of actively metabolizing microbes has an effect on the local electrochemistry and may change the soil properties such that metals attach to small particles to form micelles which persist in solution (6,7,8). This paper presents work done at INEL in FY 94 directed at separating the filtrate used in soil washing to determine the degree to which different size fractions and chemical components contribute to mobilization of metals.

This work has potential for application in many situations where similar forms of metal contamination are a problem. It also contributes to the growing body of knowledge related to microbial influence in geochemical cycling (9). Perception that these contributions are globally significant has increased very much in the last ten years (11,12). This knowledge has interested the mining industry and has potential as an extractive technology and as a remediation tool (10,11,13,14). Of particular interest for those involved in radiological waste management, the mechanisms discussed in this paper and the related electrochemical phenomena are of great importance in nuclide mobility (15, 16, 17). Understanding of these mechanisms is key to risk assessment, to containment of wastes, and to regulation of remediation.

Materials and Methods

Mold Filtrate and Soil: Aspergillus niger and Penicillium simplicissimum were cultured aerobically in broth initially containing 20 g/l malt extract, 20g/l dextrose, and 1 g/l peptone for 2 to 12 weeks depending on the experiment. The cultures were vacuum filtered to remove cellular material, and the mold filtrate was

collected. The pH of the mold filtrates range from 4 to 6. The initial concentration of uranium in the soil was 500 mg/kg. 20 mg of soil was placed in 250 ml Erlenmeyer flasks and 100 ml of extracting solution was added. The soil/solution mixtures were place on a model G24 Environmental Incubator Shaker (New Brunswick Scientific, Edison, NJ) set at 200 rpm. Experiments were done at room temperature, approximately 22oC; the pH of soil/solution mixtures ranged from 5.5 to 7.0.

Uranium Analysis: Uranium concentration in all soil filtrate samples was determined by inductively coupled plasma (ICP) with atomic emission spectroscopy analysis (Applied Research Laboratories, Sunland, CA). Samples were drawn from experiments and acidified (6.25% HNO3). It was found that filtrate from soil washing using some broth filtrates, particularly those from Aspergillus niger cultures, were extremely difficult to filter in preparation for analysis, and even after filtration these same mixtures could cause obstruction of the ICP burner nubulizer. Therefore, all samples were routinely refluxed with gentle heating for one hour before filtration. Although this process did not improve filterability much, it did eliminate difficulties with the ICP.

Size Separation of Soil Filtrate: Soil filtrate was separated into greater than and less than 3,000 dalton size fractions to determine the contribution of colloid and soil particles in solution to uranium transport. 20 g of soil was mixed with 100 ml of mold filtrate for 24 hrs (see soil and solution mixing section). Two 15 ml aliquots of soil filtrate were removed and spun separately at 1000 G to remove slow settling particulates. The supernatants were then placed in separate Centriprep model 3 (3,000 dalton molecular weight cut-off, cellulose filter) concentrator tubes (Amicon, Beverly MA). The tubes were spun at 3000 G in a Sorvall RC-5B centrifuge with an HS-4 rotor (Newtown, CT) and repeatedly drained until all liquid had passed through the 3000 dalton membrane. These experiments were conducted in duplicate using mold filtrate from four different mold cultures. Penicillium simplicissimum was grown in Difco malt extract broth (Ps 4/9) and glucose/malt sugar broth(Ps 9/27). Aspergillus niger was grown in Difco malt extract broth (An 4/9) and glucose/malt sugar broth (An 9/27). The cultures were significantly different in composition as determined by high performance liquid chromatography (HPLC) analysis, so conclusions could be made for a spectrum of fermentation types. Uranium concentration was determined for the non-fractionated soil filtrate and the filtrate (<3,000 daltons) fraction (see uranium analysis section).

Organic Acid Content of Mold Filtrate: Samples of broth filtrate from mold cultures were taken before application to soil and the small organic acid contents identified by HPLC separation (Alltech 325 pump and Linear UVIS 200 detector (Fremont, CA) set at 210 nm. The column used was an Aminex HPX-87H). Concentration data from repeated HPLC runs and uranium concentrations obtained from ICP analysis of extract from corresponding soil washings were compared by regression analysis (n=16 for oxalic, citric, and gluconic acids, n=2 for malic acid).

Synthetic Mold Filtrate and Soil: To verify correlation of uranium removal with specific acids, synthetic "mold filtrate" solutions consisting of deionized water and acids were made and applied to soil in the same manner as mold filtrate. Citric, gluconic, malic, and oxalic acid solutions at a concentration of 0.1 wt% were prepared. A solution of citric and malic acids (0.1 wt% each) was also prepared. The pH of the acid solutions ranged from 5.5 to 7.8. Acid concentrations were based on the range of those found in mold filtrate to aid in the comparison of results. All soil washing experiments were conducted in shake-flasks using 100 ml of solution and a 20% soil (dry weight) to solution ratio. Flasks were agitated for 24 hours, 200 rpm, at room temperature before sampling for uranium. Experiments were done using single and triple applications of synthetic mold filtrate as per the experiments with mold filtrate. The pH of the soil/solution mixtures ranged from 6.5 to 8.

Results and Discussion

Soil washing is an effective approach for removing uranium from soil, but the chemicals and conditions employed often subject soil to extremes in pH which can damage soil. Soil washing using mold filtrate from Aspergillus niger or Penicillium simplicissimum cultures can remove greater than 90% of the uranium in Fernald soils (initial uranium concentration is 500 mg/kg) while maintaining the pH of the soil in the 6-8 range. No uranium removal was seen when uninoculated broth was applied to the soil. Optimization of the soil washing step and development of the overall uranium removal system requires identification of the active components of the mold filtrate. This work identifies some of the specific active components and provides

evidence of some additional active components that are not yet fully identified. There was no significant difference between mold filtrate from Aspergillus niger and Penicillium simplicissimum in terms of effectiveness of uranium removal or pH of the soil/mold filtrate mixture (see Table I). Multiple applications of mold filtrate are more effective than single applications, although the majority of the uranium is removed by the first application of filtrate. The pH of the soil/solution mixture does not change with multiple applications of the mold filtrate, suggesting that the additional removal is not a pH effect. Aspergillus niger and Penicillium simplicissimum produce a variety of compounds including organic acids that can mobilize uranium from soils. Optimization of the uranium extraction process relies to a large degree on identifying the types of compounds involved in the uranium mobilization.

Separation by HPLC of filtrate from mold cultures before contact with soil showed citric, gluconic, and oxalic, acids to be the primary organic acids present (see Table II). As would be expected, a complex relationship between culture conditions and organic acid production was observed. In future work, culture conditions (pH, EH, dissolved oxygen, etc.) will be controlled to optimize production of desired components. When filtrate was used to wash soil and the results compared with organic acid composition, gluconic and citric acids were found to best correlate with uranium removal rates (see Table III).

Preliminary results from size separation of the soil filtrate indicate that 60 - 80% of uranium in solution is contained in the less than 3000 daltons size fraction(see Table IV). Four different mold filtrates were applied to separate soil samples and soil filtrate was collected from each and separated into two fractions by a 3,000 dalton filter. The organic acids identified in the mold filtrates most likely account the uranium contained in the less than 3,000 dalton fraction of the soil filtrate. The remaining 20 - 40% of uranium in the soil filtrate is in the greater than 3,000 dalton fraction. This strongly suggests that larger organic molecules play a significant role in transport of uranium through soil. The cellulose membrane used in the separation could also account for a percentage of the uranium in the upper size fraction (especially in the samples with a low concentration of uranium in the unfractionated soil filtrate) but would be unlikely to contain all of the uranium in that fraction (0.02 - 0.16 mg). Cellulose filters were used because they do not readily bind most compounds found in biological media. At this point it is not known whether the larger compounds remove uranium directly from the soil or serve as a sort of mobile sponge or capacitor.

Solutions consisting of organic acids (0.1% w/v) in DI water were used to treat soil in the same manner as with broth filtrate. When extract from washing was analyzed for uranium content, it was found that malic and citric acids were the most effective (see Table I). Overall removal rates were equivalent to those achieved with broth filtrate. A combination of malic and citric acids did not remove as much as would be expected from their individual performances but in fact did only slightly better as a pair. This was interpreted as an indication that complexation of different small organic acids takes place with the same mineral form of uranium in a competitive manner. This may explain the discrepancy between synthetic and fermentation solutions. Repeated treatments with combined citric and malic acids gave extractions equivalent to those achieved with filtrate form mold cultures. Oxalic acid was the least effective at removing uranium and presented the same kind of filtering problems encountered with Aspergillus niger extracts. Avoiding fermentation conditions or organisms which produce oxalic acid will yield more easily handled soil filtrates.

CONCLUSIONS

Significant amounts of uranium are transported from soil by solutions containing microbial by-products. Under the current experimental conditions, most mobility was attributed to small organic acids, however higher molecular weight molecules dissolved soil components may account for a significant fraction. Culture conditions effect solution components and can have important effects on mobilization. Mineral form of contamination likely has a bearing on rate and amount of mobilization. These conclusions support the hypothesis that microbial activities play important roles in distribution of metals in the environment. There is a potential to use this knowledge for control and removal of contamination in soil, and the significance for risk assessment is clear.

A LASER INDUCED FLUORESCENCE TECHNIQUE FOR URANIUM TRANSPORT CHARACTERIZATION
David M. Freed
Scott A. Simonson
Massachusetts Institute of Technology
ABSTRACT
The feasibility of using laser-induced fluorescence (LIF) to detect small concentrations of uranium in wet sand was investigated. The application of this technique will be to observe the migration of uranium in saturated and unsaturated flow systems. This would compliment experiments looking at fingered (unstable) flow of water in certain types of unsaturated systems of importance to the Yucca Mountain Site Characterization Project (YMSCP).
Experiments were performed in which a UV laser pulse was used to excite aqueous uranium (as uranyl ion, UO22+) in a wet sand mixture. The characteristic green fluorescence (actually a long-lived phosphorescence) emitted by uranium in the decay transition, filtered with respect to frequency and decay time, was observed as a function of uranium concentration, solution chemistry, and solid-liquid contact time.

The specific goals of this study were to determine the detection limit of uranium in wet sand under appropriate (realistic) conditions, and to explore the feasibility of effective calibration of the LIF signal with uranium concentration at the ppm level. It was found that in addition to interference from autofluorescence of the sand and other materials, a key issue is the effect of the aqueous chemistry on uranium fluorescence strength, particularly with regard to pH. Therefore, quantitative measurements of uranium fluorescence signal strength in aqueous solutions without sand were also conducted, in order to map pH dependence.

Experiments revealed that in nitrate/carbonate solutions, uranium fluorescence goes through a maximum at a pH of 6.0-6.5, and decreases by orders of magnitude at 1.0-2.0 pH units away from this peak. The bright green emission or "superfluorescence" observed in this range is believed to be the result of one or more uranyl complexes. In experiments with wet sand, resolution of 1 ppm uranium from background was achieved.

MOTIVATION

In order to assess the health risk that would result from geologic burial of spent fuel, it is important to be able to predict the travel times for hazardous, long-lived radionuclides from a repository to the accessible environment. The mostly likely release scenario is thought to be groundwater infiltration into the repository resulting in dissolution of the waste form and migration of radionuclides with the water. It is expected that many of the dangerous, long-lived isotopes, particularly uranium and the transuranics, will migrate slowly due to sorption by clays, zeolites, and other sorptive material in the rock surrounding the repository. Connecting fractures of various sizes may be the dominant flow path through the unsaturated layer from the repository to the aquifer, and these fractures are also thought to contain sorptive substances that will retard the movement of the relatively dilute contaminants in the groundwater.

Predictions of radionuclide migration time often take the form of calculating the groundwater velocity and some form of retardation factor for a particular element in a particular ground material. Typically this factor is calculated from a partition coefficient which is found experimentally by looking at the equilibrium distribution between dissolved and sorbed amounts of the element in batch or column systems. Work at Sandia National Laboratory has demonstrated that downward flow under certain unsaturated conditions in a fracture, simulated by crushed rock between glass plates, can deviate strongly from uniform flow (1). When the ratio of total flux to saturated conductivity is less than one, flow instability causes the growth of "fingers" (preferred hydraulic pathways).

Fingered flow results in increased water velocities at the fingertips, and drains the bulk of the flow from the overlying layer. This has implications for the behavior of a contaminant in such a flow system. The question arises as to whether a contaminant would tend to move with the fingers or stay behind with the bulk water front, since "fingered migration" could significantly reduce radionuclide travel time from the repository to the aquifer located beneath.

An experimental technique for detecting minute uranium quantities in a wet sand mixture can be adapted to examine the behavior of aqueous uranium in a simulated groundwater flow system. In particular it could be used to investigate uranium movement in fingered flow; data in the form of uranium concentration profiles at several locations could be taken in conjunction with observations of the flow field, allowing characterization of fingered migration under various conditions of flow rate, pH, ground material, ionic strength, and other key parameters.

LASER INDUCED FLUORESCENCE (LIF) OF URANIUM

While there are many radionuclides of concern regarding long-term geologic burial, uranium was used in this experiment for the following reasons: uranium decay chains include daughters important for health risk assessment, particularly Ra-226 and Rn-222; uranium dissolution and movement in groundwater is thought to be representative of the actinides; under most conditions uranium forms uranyl ion (UO_2^{2+}) in aqueous solution, which can be detected by its characteristic green luminescence upon excitation by ultraviolet light.

The spectroscopic properties of uranyl ion are well known, and several researchers have shown the high sensitivity capable with a fluorescence technique involving intense UV excitation (2-5). One of the most important considerations for achieving this sensitivity is separation of the uranium signal from other induced fluorescence, such as the sample ground material (sand or crushed rock), organic

materials, and structural materials like the sample container. This is accomplished by time-resolution of the signal and frequency selection with a monochromator. Using time-gating, frequency selection, and controlled solution chemistry (acid enhancement), uranium levels on the order of parts per trillion have been detected (2).

Time-resolution is aided by the relatively long excited decay time for radiative transition in uranyl ion, and is the foundation on which the technique is based. Fluorescence lifetimes for most materials tend to be on the order of nanoseconds, while the uranyl phosphorescence decay time is on the order of microseconds. The uranium signal is therefore characterized by a relatively long tail remaining after other fluorescences have died out. The typical uranyl ion emission spectrum has peaks at approximately 494, 516, and 540 nm (3). (Phosphorescence correctly indicates a radiative transition with a much longer mean-life than fluorescence, however the word fluorescence will be used exclusively hereafter for simplicity).

EXPERIMENTAL SETUP

Figure 1 shows a schematic of the experimental setup. The excitation source was a tripled Nd:YAG laser (355 nm) operated at a range of 10-30 mJ per pulse. The sample chamber was black-anodized aluminum which has very low autofluorescence and stray reflection. Samples were held in square quartz cuvets (17 mm inner side length) which had low autofluorescence and minimized beam scatter. Emission light left the sample chamber, passed through a monochromator (5 nm resolution), and was collected by a photomultiplier tube (PMT). Colored glass filters were also used at the ports of the sample chamber for stray light protection. A monochromator setting of 520 nm, which corresponds to the central emission peak, gave the best signal-to-noise response.

The signal from the PMT was sent to a digitizing oscilloscope (20 MHz bandwidth); data acquisition and analysis was performed on LabviewTM for Macintosh. A shot consisted of a single pulse from the laser, which sent a synchronous trigger to the oscilloscope, programmed to wait a specific delay time before data collection.

For shots on sand, the beam illuminated the sample at a spot on one face, with the cuvet oriented at 45o (see Fig. 1). Beam penetration depth was judged to be on the order of a few grain diameters (1-2 mm). Acid-washed Wedron 510 sand of known mesh size was used. Even after HCl treatment the sand was observed to provide noticeable background fluorescence. Wet sand was prepared by adding (typically) 10.0 g of sand slowly to 20.0 ml solution to ensure a well mixed batch with no dry spots. For shots taken through water (no sand), the cuvet face was perpendicular to the beam, so the full path length was illuminated.

Titrations were performed by adjusting the pH of 200 ml solution with sodium hydroxide or sodium bicarbonate and nitric acid, and transferring 20 ml between bulk and cuvet for each fluorescence measurement. In all cases a blank was prepared and tested in a fashion identical to the corresponding uranyl solution, except that instead of uranyl nitrate it contained an amount of nitric acid equivalent to that in the uranyl solution.

RESULTS

We have found that solution chemistry, especially pH in the range 5-8, strongly affects the LIF signal of uranium. This is crucial since the pH range of interest for contaminant migration at Yucca Mountain is about 7-9. The effects of enhancers and quenchers have been extensively reported (e.g. (4,5)), but only for highly acidic solutions, so this phenomenon was unforeseen. (An enhancer is an acid, typically phosphoric, which forms uranyl complexes with ligands that block nonradiative decay. A 10% phosphoric acid solution can increase uranyl LIF intensity by three orders of magnitude. Quenchers, on the other hand, are ions which aid in nonradiative relaxation such as vibration.)

In order to use the LIF technique, either for laboratory or in-situ observations, it is therefore necessary to calibrate fluorescence signal with pH. Due to the buffering and sorptive properties of the sand, it further requires a means by which to measure local pH in a solid/aqueous system. A demonstration of this type of measurement was carried out with fiber optic pH sensors that are currently available but were not obtained for this study.

The calibration of fluorescence with pH, therefore, became a primary objective. Figure 2 shows three fluorescence vs. pH "maps" for 1 ppm uranium; trial 1 (squares) indicates a solution titrated with sodium hydroxide which had been exposed to air for six days, trial 2 (triangles) indicates the same solution after being exposed to

air for three weeks, and trial 3 (circles) indicates a fresh solution titrated with sodium bicarbonate. Each data point in the figure represents the time-integrated average luminescence of ten identical "shots" using the following time-gating: delay time (To) was 10 microseconds, and total scan time (Ts) was 50 microseconds. Background (as tested with blanks) for all these runs provided negligible contribution and was ignored.

Several maps such as these were generated to test reproducibility of the results. It was generally observed that in systems containing uranyl nitrate and sodium hydroxide and/or sodium bicarbonate, uranium exhibits a "superfluorescence" in the pH range 5-8 which peaks at pH 6.0-6.5. As seen in the figure, however, while generally consistent, the maps were not quantitatively reproducible.

It seems evident that CO2 has an effect since, as seen in Fig. 2 from the difference between trial 1 and trial 2, the fluorescence gains as much as an order of magnitude (at pH greater than 6.5) upon additional equilibration with air. Furthermore the well-equilibrated solution data agrees quite well with that containing added carbonate (trial 3). Further increases in carbonate concentration had no effect, however, and the role of carbonate is still unclear. It seems reasonable that CO2 level controls the formation of a superfluorescing uranyl complex containing carbonate ligands.

Calibration could likely be improved by more careful control of the solution chemistry. Careful measurement of key species concentrations in solution should resolve the role of CO2 or any other species which can effect the fluorescence. In many cases pH drift during titration was observed, probably due to CO2 exchange. Another possible source of error is precipitation of uranium compounds, since at pH 7-8 uranium solubility experiences a minimum at the ppm level (or below, depending on CO2 level and other factors) (6).

In order to verify that useful calibration is feasible, experiments were performed comparing fluorescence of solutions at pH 6.5 with 0.5 ppm U, 1 ppm U, and 2 ppm U. The results are shown in Figs. 3a-d, in which each curve is again an average of ten shots. The x-axis in these figures covers a total scan time indicated by Ts; delay time between pulse and the beginning of the scan is indicated by To. The background (i.e. blank) is not shown in these figures as it was very small (less than 0.04 V after 1 microsecond); thus the resolution in this pH neighborhood is considerably better than 0.5 ppm uranium.

As seen in Fig. 3a, 1 ppm U and 0.5 ppm U are easily distinguishable and the 0.5 ppm U signal is quite strong. The initial (first microsecond) shape of the curves is affected by background, after which a long tail persists for more than 50 microseconds, as seen in Fig. 3b. Figures 3c and 3d compare the same short-time and long-time behavior for 1 ppm vs. 2 ppm uranium. Sensitivity is clearly much better than the factor of two concentration differences used here. The integrated signal between 10 and 50 microseconds, as used above, appears to be a useful measure of fluorescence strength.

Preliminary tests with wet sand were made to verify that the uranium fluorescence can be resolved from the background (autofluorescence) imposed predominantly by the sand. Examples of the results are shown in Fig. 4a-d for shots of 1 and 10 ppm U vs. no uranium (blank) in sand. The 1 ppm U data were single shots taken with To=3 microseconds and Ts=10 microseconds; the solution was initially (prior to adding sand) pH 6.6. The 10 ppm U shots, for which the solution was initially pH 7.1, have Ts=10 and To=0 so the entire curve is shown.

Figure 4a shows that 1 ppm U is discernible above background from sand, but in these conditions 1 ppm is probably near the detection limit. Nevertheless it essentially demonstrates the feasibility of taking measurements with shots on sand. Figure 4b shows the difference between sample and blank and indicates an appropriate exponential decay constant of several microseconds. Figs. 4c and 4d show that the difference between sample and blank is considerably more exaggerated for 10 ppm U.

CONCLUSIONS

It has been shown that in systems containing uranyl nitrate and sodium hydroxide and/or sodium carbonate, uranium exhibits a superfluorescence that exists in the pH range 5-8 and peaks at pH 6.0-6.5. Signal calibration is required due to sensitivity to pH, CO2, and possibly other aspects of solution chemistry.

The results of this study indicate that the LIF technique is suitable for investigating fingered migration and for in-situ measurement provided that the local pH is known for calibration of the fluorescence signal. Thus capability for

measurement of pH in wet sand or rock, for which fiber optic pH probes are available, will allow dependence on this parameter to be accounted for.

CHERNOBYL - A SOLUTION FOR THE CLEAN UP OF HIGHLY CONTAMINATED FORESTS AND WOODLANDS

Michel Dubourg
FRAMATOME
Tour Fiat Cedex 16
92084 PARIS LA DEFENSE

ABSTRACT
This study corresponds to a remediation action of contaminated woodlands and forests due to the fall out of radionuclides after the CHERNOBYL accident. This remediation action implies both incineration of contaminated wood products and foliage and the transformation of clean wood into paper pulp for the industry.
Based on existing industrial products, this remediation action can be justified by the sale of by-products such as electricity and card board which can pay for the necessary industrial investment.
The pay back return is estimated to be obtained in about five years.

INTRODUCTION
The purpose of this study is to present an industrial demonstration unit able to process wood contaminated by the fallout of radionuclides, particularly Cesium 137 (half life 30 years) from the accident of CHERNOBYL Nuclear Power plant Unit 4.

50,000 km of contaminated forests have to be cleaned up from cesium, strontium but also hot particles contamination PU241, which present a real danger for the environment,

Contaminated woodland and forests would be cleaned up by cutting up and chipping the contaminated wood or bark, converting it into small-size waste (chips measuring three to five centimeters), and incinerating the contaminated portion to generate steam and electricity in a waste heat recovery boiler associated with the fluidized bed incinerator,

The sound portions of the wood be converted into building materials or wood pulp by twins-crew extruders. These extruders are particularly economical in their use or energy and produce little secondary waste.
Several solutions could be used for treating wodd chips and for removing the residual contaminaton due to the Cesium 137.

PRINCIPLE OF WOOD TREATMENT
The principles chosen for wood treatment will follow the following main schemes:
A. Segregation of contaminated wood from/non contaminated wood,
B. Cutting down of contaminated trees
C. Removal of bark from clean wood

D. Incineration of contaminated bark
E. Transformation of clean wood into wood pulp
The contaminated portion of trees (50 to 100 bq/gr, forage, branches and bark could be processed in a circulating fluidized bed incinerator designed to generate steam in an atmospheric fluidized bed incinerator in order to produce electricity.
Secondary organic wastes resulting from top soil decontaminating processes such as the RESSAC process developed by the French IPSN could also be collected and incinerated in a fluidized bed incinerator in order to produce steam for electricity generation.
The central portion of trunks which generally present low contamination will be chipped into small pieces in a sawmill and will be used as feed for producing wood pulp for the cardboard industry.
FLUIDIZED BED INCINERATION AND STEAM PRODUCTION
The fluidized bed incinerator and the associated steam production unit include the following components see (Fig. 1).
A fluidized bed incinerator into which are injected the wood waste chips, the bark and the contaminated litter and also some refractory powder for the fluidized bed support.
A solids separating cyclone, installed at the furnace outlet in the high temperature gas (870C) permits reinjecting most of the solid particles leaving the reaction chamber into the system, with only a very small fraction of the ash produced released with the smoke. This limits erosion constraints in the down-steam lines.
The recovery boiler where the heat of the off gas stream coming from the cyclone is removed.
An external heat exchanger feed with fluidized solids removed from the bottom of the solids collected from the cyclone and cools it before their reinjection into the furnace. The distribution between hot and cooled recycled solids permits maintaining the desired temperature in the furnace.
The stability of the circulating bed implies maintaining a large quantity of solids recirculating. The quantity recirculated affects the differential pressure between the top and the bottom of the furnace. Controlling this recirculation is obtained either by regulating the rate of removal of the dusty ash or by regulating the wood injection.
For the incineration of contaminated wood and organic wastes, it is assumed that a large scale fluidized bed incinerator (6 tons/hour of contaminated wastes) is necessary.
This incinerator, as defined in Fig. 1, is coupled to a waste heat recovery boiler for superheated steam production which could be used in a steam turbine for electricity generation.
Protection against the dispersal of radionuclides is provided by a bag house filter located on the off gas stream at the outlet of the waste heat recovery boiler.
The bag house filter is equipped with high retention efficiency bags made of GORE-TEX material having an efficiency of 99.9% for particles of 0.2 to 0.3 m. The GORE-TEX felt is able to operate at 240C and the bags are periodically cleaned by pulsed air.
The incinerator operates a slightly negative pressure which is an additional safety feature.
WOOD PULP PROCESS FOR CLEAN WOOD
The twin-extruder contains two intermeshing and corotating screws are identical and consist of a series of modules each module having a conveying section (right-hand thread) and reverse thread (left-hand thread) section retaining the fibrous matter. Slots and windows are cut into these latter sections. The modules are added, one after the other, on two splined hafts which provide the necessary rigidity.
The thread profile, the right and left hand thread pitches, and the number and which of the reverse thread windows are determined in order to achieve gradual defiberization of the chips and to obtain the required pulp consistency.
The chips fed into the extruder are picked up by the first conveying section of the first module. At the first left-hand thread, a "plug" forms which is forced through the windows. The pressure and induced heating involved in this operation cause the defiberization to begin.
For deciduous and coniferous wood chips there are already two units in operation the most recent started up in February 1992 at the P. Jacquemin cardboard factory in the

Vosges, France. This twin-screw extruder has a capacity of 5 tons/hr of wood waste for cardboard pulp as shown on Fig. 2.
This wood pulp obtained from twin screw extruders is then transformed into high quality calibrated cardboard for the wrapping industry by the means of standardized equipment used in this industry, such as high speed refiners, steam dryers and rollers.
The significant advantage of using twin-screw extruders for paper pulp processing is a less energy consumption: 400 kwh saving per ton of paper pulp and a possible recycling of liquid effluent generated. Various low pollution of bleaching agent can be used such as ozone for obtaining high quality paper pulp.

CONCLUSIONS

The main conclusions of this study are that solutions for the clean up of contaminated woods and organic wastes exist:

Incineration of contaminated wood can generate heat recovery and steam production with environmental protection,

Off gas filtration can be achieved with a high degree of environmental protection. Even with high levels of contamination the emission releases are within the authorized limits.

Clean wood or low contaminated wood can be processed into wood pulp with appropriate decontamination and effluent treatment.

Sounds wood can be used also for construction timber.

Generated energy and wood pulp production can solve economic problems.

It seems that using fluidized bed incineration the wood pulp and timber industries can provide substantial benefit and revenues allowing the possibility of investing in equipment for the cleanup of Chernobyl contaminated areas (see Fig. 3).

INNOVATIVE INITIATIVES FOR ENVIRONMENTAL RESTORATION AT U.S. DEPARTMENT OF ENERGY FACILITIES

Richard H. Wilkinson, P.E.
Philip A. Nixon
Peter J. Holland, P.E.
Parsons Engineering Science, Inc.

ABSTRACT

Environmental restoration activities at U.S. Department of Energy (DOE) facilities are typically governed by a compliance agreement between DOE, the U.S. Environmental Protection Agency (EPA), and the applicable state regulatory agency. These agreements outline the structured process and timetable for remedial decisions and actions. Using the compliance agreement at the Rocky Flats Environmental Technology Site (RFETS) for typical examples, potential streamlined approaches for remedial decisions within the regulatory framework are discussed. Successful implementation of streamlined remediation approaches requires close coordination with the regulatory agencies. Application of these streamlined approaches will allow earlier

implementation of remedial actions at DOE facilities, earlier reductions in human health and environmental risks, and cost savings. Cost savings in environmental restoration continue to be a high priority with the increasing pressure on government budgets. These cost and schedule savings will allow continuing progress in clean-up at DOE facilities while meeting the commitments of the compliance agreements.

INTRODUCTION

Environmental restoration activities at U.S. Department of Energy (DOE) facilities are typically governed by a compliance agreement between DOE, the U.S. Environmental Protection Agency (EPA), and the appropriate state regulatory agency. The compliance agreement at the Rocky Flats Environmental Technology Site (RFETS) is commonly known as the Interagency Agreement (IAG). The IAG documents the commitments between DOE, Region VIII of the EPA, and the Colorado Department of Public Health and the Environment (CDPHE) with respect to the strategy and timetable for environmental restoration activities.

The RFETS IAG identifies a structured process for regulatory review and approval of planned remediation, and the schedule for the planned activities related to each Operable Unit (OU). The structured process is a sequential step-by-step approach based on methodical investigation and characterization, baseline risk assessment, and feasibility study to result in remedial decisions. Each step in the structured process includes regulatory review and public review as appropriate. The compliance agreements are also based on DOE development of a proposed remediation, followed by independent regulatory review. A typical timetable for an RFETS OU, as outlined in the IAG, is shown in Fig. 1.

There are opportunities to use streamlined approaches within the regulatory framework, adapted from successful applications at other facilities, to accelerate the selection, review, and approval process for planned remediations. Acceleration will allow earlier identification and implementation of the planned remediations and thereby will more quickly reduce risks to human health and the environment. Streamlined approaches will reduce the costs of investigations, studies, and analyses, and thereby allow a greater proportion of the limited government budgets to be directed toward implementing actions and reducing risks.

Streamlined approaches should include close coordination and interaction with the regulatory agencies for identification of regulatory requirements and interpretations, coordination of the approaches and alternatives to be considered, concurrence with the methodologies for screening, analysis, and evaluation, and development of the details of alternatives and recommendations. The benefit of close regulatory coordination, in early identification of regulatory requirements and issues, has been demonstrated at RFETS and at other facilities. Close coordination also provides a forum for early resolution of issues. Streamlined approaches that should be considered with close regulatory coordination include the "analogous site", "risk-based decisions", and "presumptive remedy" approaches.

ANALOGOUS SITE APPROACH

OUs have been typically identified in the compliance agreements based on functional areas or geographical locations. OUs such as those identified in the RFETS IAG have not been coordinated to consolidate the planned remediations for similar contaminants in common media (soils, groundwater, etc.). The "analogous site approach" makes beneficial and continuing use of the characterization and feasibility study information from earlier OUs, and applies the selected remediation alternative to later OUs determined to have similar contaminants in the same media. Several DOE facilities including RFETS have initiated efforts to develop sitewide Preliminary Remediation Goals (PRGs), to perform sitewide technology evaluations, and to develop a consistent framework for conducting feasibility studies for all of the OUs. A more progressive and streamlined approach would apply the results of early feasibility studies to all OUs with similar contamination.

As an example, an OU with plutonium contamination in surficial soils (within predetermined bounds) could proceed with a planned remediation based on the prior detailed feasibility study, alternative evaluation, and technology selection from an earlier OU. Initial investigation and characterization to select the proper remediation technology would be required, followed by implementation using an "observational approach". The "observational approach" simply applies a procedure of in-process monitoring to determine the extent of remediation. The potential substantial acceleration of the typical remedial investigation (RI)/feasibility

study (FS) process that would result from using the "analogous site approach" is shown in Fig. 2. The extent and efforts required for a feasibility study are significantly reduced. Note that proactive coordination between DOE facilities could ultimately lead to using the "analogous site approach" between DOE facilities, where a successful remedial approach at one facility might be directly applied at a different DOE facility for similar contamination in the same media.

RISK-BASED REMEDIATION DECISIONS

Typical DOE facility compliance agreements, including the RFETS IAG, rely on a Baseline Risk Assessment (BRA) to support remedial decisions. The BRA is generally performed after investigation and characterization of the contamination, and is used to determine the existing risks to human health and the environment, and to determine the remediation objectives. The risk assessment process is well defined and intended to support first the "No Action" alternative, and then to be used as a basis for establishing the PRGs and the Remedial Action Objectives (RAOs). Alternate streamlined risk-based approaches, coordinated with the regulatory agencies, have been successfully used at other facilities to accelerate this process and to provide early determination of the PRGs and RAOs. Once contaminants are identified during early investigation and characterization, or are known to exist based on historical record or process knowledge, risk analyses using conceptual fate and transport models may proceed directly. The Baseline Risk Assessment should not be required if it is known that a "No Action" alternative is not appropriate and that remediation is required. The risk analysis activities can therefore focus directly on determining the PRGs and RAOs based on the promulgated regulatory standards or the acceptable residual risk levels. The "risk-based decision" process makes the basic assumption that remediation will be required, and then determines the extent of remediation to reduce the risks to the acceptable levels.

This streamlining can still support the "No Action" alternative, in that if the risk-based PRGs are higher than the characterized contaminants, then no further action will be required. In addition, the requirements for remediation can be determined before detailed characterization is completed, and alternatives can be considered and evaluated somewhat in parallel to the completion of the characterization. The potential acceleration in the RI/FS process of "risk-based decisions" is also shown in Fig. 2. Acceleration is provided by parallel activities rather than by the methodical step-by-step process typically outlined in the compliance agreements. An iterative approach may also be used to evaluate composite risks from all media if the risk-based PRGs are considered to be too conservative. The risk-based process more directly supports an "observational approach", since determination of the PRGs and RAOs does not require detailed characterization. The development of the PRGs and RAOs relies on identification of the exposure scenarios and the potential receptors in conjunction with a target residual risk level. For example, the RFETS IAG requires a reduction in risk to less than a 1-in-one-million chance of contracting an excess cancer from exposure to the OUs. The exposure scenarios and potential receptors are determined specifically for each OU. Close coordination with the regulatory agencies is important for developing and implementing the "risk-based" approach to remediation decisions.

PRESUMPTIVE REMEDIES

Coupled with "analogous site" and/or "risk-based" approaches, presumptive remedies can also be employed to expedite the start of remediation. Risk-based determinations for contaminants in media generally apply across the facility. Appropriate remediation alternatives, as accepted by the regulatory agencies at an early OU, generally apply for similar contaminants. Historical records and process knowledge provide early evidence of the presence of contamination. Using these sets of information, identification of a contaminant based on historical record and process knowledge leads to an identified presumed remediation alternative with predetermined RAOs. A presumptive remedy can then be initiated while the nature and extent of contamination are being determined.

The potential acceleration of the RI/FS process using a "presumptive remedy" approach is also shown in Fig. 2. Remediation can begin much earlier in the overall timetable. Using "presumptive remedies" in an aggressive manner would more quickly reduce risks, and would reduce costs to allow further actions within the budgetary constraints.

STREAMLINING RISKS

There are inherent programmatic risks in these potential streamlined approaches.

Remediations may be implemented that are conservative, and therefore result in more substantial clean-up then required to meet regulatory, human health risk, or environmental risk requirements. This aspect of the programmatic risk is considered to be small, since remediation requirements at DOE facilities that have thus far been approved by the regulatory agencies have been quite stringent. The benefits of earlier remediation, earlier reduction of health and environmental risks, and reduced remediation costs out weigh the potential risk of overly conservative remediations.

It is possible that early remediations may be initiated that are later determined to be inadequate for ultimate remedies and closures. This represents a programmatic risk which is also considered to be small, since DOE facility remediations are being implemented with regulatory oversight and approval, the clean-up requirements are typically stringent, and most of the potential technologies have been successfully implemented with proven results. These programmatic risks must also be weighed and balanced against the gains of earlier remediations, earlier reductions of health and environmental risks, and cost savings. Close coordination with the regulatory agencies throughout the streamlined remediation process will reduce these programmatic risks.

CONCLUSION

Application of these streamlined approaches at DOE facilities with close regulatory coordination, review, and approval will save time and money. With increasing pressures on government budgets, innovation is warranted to continue to make progress in clean-up at DOE facilities, and to meet the compliance agreement commitments. Streamlining will reduce the cost of investigations, studies, and analyses, and will allow a greater proportion of the environmental restoration budgets to be used to implement clean-up actions and reduce risks. The potential acceleration of the typical IAG timetable for remediation of an RFETS OU using the streamlined "analogous site", "risk-based decisions", and "presumptive remedy" approaches is shown in Fig. 3. Broad application of these innovative streamlined approaches will substantially reduce the overall cost and timetable for remediation at DOE facilities.

Richland, WA 99352

ABSTRACT

Electron beam techniques have been used to characterize uranium-contaminated soils from the Fernald Site in Ohio, and also plutonium-bearing "hot particles" from Johnston Island in the Pacific Ocean. By examining Fernald samples that had undergone chemical leaching it was possible to observe the effect the treatment had on specific uranium-bearing phases. The technique of Heap leaching, using carbonate solution, was found to be the most successful in removing uranium from Fernald soils, the Heap process allows aeration, which facilitates the oxidation of uraninite. However, another refractory uranium(IV) phase, uranium metaphosphate, was not removed or affected by any soil-washing process. Examination of "hot particles" from Johnston Island revealed that plutonium and uranium were present in 50-200 nm particles, both amorphous and crystalline, within a partially amorphous aluminum oxide matrix. The aluminum oxide is believed to have undergone a crystalline-to-amorphous transition caused by alpha-particle bombardment during the decay of the plutonium.

INTRODUCTION

The clean-up of radionuclide-contaminated sites is a major problem facing the U.S. Department of Energy (DOE). Knowledge of the soil and contaminant characteristics can greatly facilitate the identification of suitable remediation techniques during

bench-scale tests, which otherwise must proceed by trial and error. More importantly, detailed characterization can allow the rejection of inappropriate technologies for a particular site on a sound scientific basis. At the DOE Fernald site in Ohio, several characterization techniques have been used to support the remediation efforts at both bench-scale and pilot-scale. These characterizations have described the exact nature of the uranium contamination and the effect that various chemical treatments had on the soil and contaminant (1). The application of electron microscopy in characterization studies at Fernald has been reported elsewhere (2-4). In this paper, further examples of soil characterization are presented, with emphasis on how they can benefit remediation efforts.

EXPERIMENTAL PROCEDURE

Soil characterization by analytical transmission electron microscopy (AEM) with electron diffraction provides the spatial resolution necessary to examine sub-micron phases. Using the combination of electron diffraction, X-ray energy dispersive spectroscopy (EDS), and electron energy loss spectroscopy (EELS), unknown phases can be identified. At Argonne National Laboratory (ANL) we have developed a small particle handling facility and analytical microscopy laboratory for the characterization of radioactive materials, soils, and residues. The facility uses micro-manipulation techniques to mount small particles and ultramicrotomy to prepare thin sections of the particles for AEM examination. The ultramicrotome is specially designed so that radioactive samples can be thin sectioned. A combination of optical microscopy and scanning electron microscopy (SEM) assures representative sampling.

Characterization Protocol

Soil characterization is divided into two tiers. In Tier I, the bulk physical soil characteristics are determined by particle sizing, separation, radiochemical and elemental analysis, optical microscopy, SEM, and X-ray diffraction (XRD). More detailed characterization falls under Tier II studies. Here, the oxidation state and speciation of contaminant radionuclides are determined by techniques such as AEM and X-ray absorption spectroscopy (XAS), and, if necessary, atomic and molecular spectroscopies. Often it is the combination of techniques which provide the most useful information on the soil contaminant.

Analysis of Soil Samples by Electron Microscopy

Radionuclide-bearing soil samples were infiltrated with a water-soluble melamine resin for examination in the SEM. The radionuclide-bearing particles were located by SEM backscattered electron imaging. Individual particles were isolated by trimming away excess material from the SEM mount. Thin sections suitable for AEM examination were prepared by ultramicrotomy (2). The ultramicrotome has been specially adapted to handle radioactive materials. The instrument itself is located inside a hood and the operator is required to wear a respirator during operation. Monitoring is carried out after sectioning to ensure that there has been no contamination. This method of sample preparation allows direct comparison of SEM and TEM images, which enables characterization of TEM samples to be representative of the bulk sample. The samples were analyzed in a JEOL 2000 FXII TEM operated at 200 kV and equipped with X-ray energy dispersive spectrometers (EDS) and a parallel electron energy loss (EELS) spectrometer. Phases were identified by a combination of EDS, EELS, and electron diffraction.

RESULTS AND DISCUSSION

Assisting Remediation at Fernald, Ohio

The uranium processing plant at Fernald, run by the National Lead Company of Ohio, was the starting point for weapons manufacture in the United States during the Cold War years. Uranium ore was brought from mines in North America and from the Belgian Congo for processing at Fernald (5). The soils around the Fernald processing plant have become contaminated with uranium after decades of uranium processing, and efforts are now being made to remediate the site. The plant is located 20 miles northwest of Cincinnati, by the Great Miami River. Radiological surveys of the site, conducted using a portable gamma spectrometer, located the plumes of high uranium contamination, typically around 500 ppm uranium. However, a number of highly contaminated regions were also found, where, in some instances, the uranium content was up to 5000 ppm (6). Efforts have been concentrated at two regions at Fernald; the incinerator site soils and storage pad site soils, as the soils from these regions were considered to encompass the range of contamination at the whole site. These soils all had an average uranium concentration of 500 ppm.

Lee and Marsh (6) identified by XRD the major non-uranium-bearing phases in the

soils, which were quartz, clays, calcite, and dolomite. Buck et al. (2-4) identified the major uranium-bearing phases by AEM as calcium uranyl (VI) phosphate (tetragonal meta-autunite), uranyl (VI) silicate (soddyite), calcium uranium (VI) oxide, uranium (IV) oxide (uraninite), and uranium metaphosphate [monoclinic-U(PO3)4]. The uranium metaphosphate was only found in the incinerator site soils. Bertsch et al. (7) and also Allen et al. (8) have used XAS to determine uranium oxidation state of bulk soil samples from Fernald. A shift to higher energies of the X-ray absorption uranium LIII edge suggested that 80% of the uranium was in the U(VI) oxidation state. Furthermore, micro-beam XAS by Bertsch et al. (7) suggested that the distribution of uranium-bearing particles in the incinerator site soils was inhomogeneous, as indicated by signal varying as the focused beam was moved across the sample. In contrast, in some storage pad soils, uranium appeared to be uniformly distributed through the soil. This observation agreed with radiochemical analysis and particle sizing performed by Lee and Marsh (6) and observations made by SEM and AEM (2-4).

Carbonate leaching has been selected as the most appropriate method for removing the uranium from Fernald soils. However, the U(IV) phases (uraninite and uranium metaphosphate) in bench-scale tests were not removed. Uraninite can be leached by carbonate according to the scheme (9);

$$UO_2 + 1/2O_2 + 3CO_3^{2-} + H_2O \rightarrow [UO_2(CO_3)_3]^{4-} + 2OH^- \quad (1)$$

In other words, as long as an oxidizing agent is present, uraninite will be attacked. Effective oxidation of tetravalent uranium can be achieved with molecular oxygen in carbonate solution, with the rate of oxidation being proportional to the oxygen partial pressure. Chemical methods for adding this oxygen such as hydrogen peroxide and potassium permanganate are either expensive and/or increase the amount of pollution. Permanganate, however, was used in the bench-scale tests, after TEM analysis had shown that uranium(IV) phases were still present in soils that had been treated with carbonate. Addition of the oxidizer was found to improve uranium extraction during carbonate leaching.

The technique used in the mining industry for the recovery of metals, termed "Heap leaching," may be an attractive alternative for introducing oxygen. The nature of the Heap, where soil is heaped (or piled) onto an impermeable pad, can allow some aeration. In the Heap-treated samples (see Fig. 1), there was evidence from TEM of uraninite dissolution (although some uraninite was still present in the treated samples); however, no evidence was found of dissolution of the uranium metaphosphate phase, and a number of uranyl phosphate phases were still present.

Characterization of "Hot Particles" from Johnston Island

Johnston Island, located in the Pacific Ocean, 1330 km southwest of Honolulu, became contaminated in 1962 when the Island was used for launching missiles to test the effects of high-altitude nuclear bursts (10). In a number of instances problems occurred with the Thor missiles and the nuclear devices were intentionally destroyed by chemical explosives. One intentional destruction 59 sec after launching deposited plutonium- and uranium-contaminated debris throughout the atoll, while a second destruct of a missile on the launch pad contaminated a smaller land area but to much higher levels. Plutonium was dispersed by the explosive high temperatures and pressures generated by the explosion. The growth of the plutonium daughter product 241Am has permitted isolation of "hot spots" by gamma detection.

Tier I size sieving studies and radiochemical analysis by Wolf et al. (11) demonstrated that 96.5% of the activity was located in the 2 to 0.063 mm range. Most of the activity was localized in small "hot particles" in the coral sand. Bramlitt has also indicated that some of these "hot particles" were magnetic. This suggests that they might be closely associated with iron (10). A mechanical soil sorting method has been developed by Moroney et al. (12), termed the segmented gate system, that screens out "hot particles" automatically by using NaI gamma detectors. Improvements in this system have helped to reduce the contaminated volume of soil by 98%. The clean soil has a total alpha radioactivity from the plutonium and americium of less than 500 Bq/Kg.

A Tier II study was undertaken to describe the nature of the plutonium and uranium contamination in the "hot particles" present in the contaminated soils, so that the movement of plutonium at Johnston Island can be explained and further dispersion into the environment predicted. In some sites plutonium has migrated to depths over 1.5 m, and the mechanism by which this has occurred is unknown. In addition, the fate of uranium is unclear.

The AEM examination showed that plutonium is not in direct contact with the coral but is present in "sols" of plutonium and uranium (50-200 nm in diameter) within a micro-crystalline (partially amorphous) aluminum oxide, as well as with other components such as iron. Plutonium-bearing iron particles may account for the magnetic effects observed by Bramlitt (10). Beryllium, a typical bomb component, which can be detected by EELS, was found in some samples. Particles enriched in gallium and plutonium and 50 nm in size were also found. Gallium is often alloyed with plutonium, but the levels found in some of the discrete 50 nm particles exceeded normal alloying levels. In Fig. 2, "sols" of plutonium and uranium can be seen contained within the partially amorphous aluminum oxide matrix. The nature of the aluminum oxide is in itself unusual; the amorphization of aluminum oxide may have occurred by the decay of the plutonium. Alpha decay of 239Pu would cause the most damage, though 239Pu with a half-life of 2.411 x 104 years, may have produced the amorphization of the aluminum oxide within 30 years. The plutonium content in the aluminum oxide varied between 0.5 and 3 wt%. This would produce only 1 x 1013 to 6 x 1013 alpha-events/mg. Assuming that each alpha-recoil event displaces 1500 atoms, the dose delivered would be 0.5 x 10-3 to 3 x 10-3 displacements per atom (dpa). Metamictization in some ancient mineral phases typically occurs after >1.0 x 1016 alpha-events/mg (~1 dpa) (13).

The crystalline-to-amorphous (c-a) phase transformation can be induced by variety of processes such as particle irradiation or inter-diffusion reactions. Elastic softening and volume changes of the lattice often results from the loss of atomic order. The softening effect meant the microtome was able to produce large continuous thin sections of the aluminum oxide. A completely crystalline or amorphous material would have exhibited deformation and/or fracturing. Furthermore, if expansion of the lattice occurred in the partially amorphous aluminum oxide, then this might have allowed the entry of carbonate-bearing water. However, no evidence of any carbonate precipitates was detected in the aluminum oxide thin sections. Alternatively, incorporation of plutonium in aluminum oxide may result in a c-a transition through stabilization of the amorphous structure.

We speculate that an explanation for the distribution of radionuclides in Johnston Island soils to be the following. The aluminum and other metals (iron, magnesium, etc.) used in the bomb casing and bomb materials (plutonium, uranium, gallium, etc.) underwent rapid oxidation when the missile firing was aborted. The plutonium and uranium was deposited in the form of fine droplets which became embedded in the larger amount of aluminum and iron components. Some of the uranium crystallized, which may have made it less susceptible to weathering. Over time plutonium was leached in the surrounding matrix, leaving uranium enriched globules surrounded by a matrix of amorphous aluminum oxide containing small amounts of plutonium. This plutonium was then able to leach into the calcium carbonate coral, where it moved rapidly over the coral surfaces.

The Tier II characterization of Johnston Island "hot particles" suggests that the segmented gate system will be effective at removing the plutonium, and that chemical soil washing will not be necessary. Most of the plutonium and uranium is mainly contained in oxide particles, although some plutonium is spread throughout the aluminum phase. In addition, the uranium also appears to be contained within the "hot particles," suggesting that removal of these particles will also remove any uranium in the soil.

CONCLUSIONS

These AEM investigations have shown a large variety of different contaminant phases in examined soils. These variations result from the broad range of sources of uranium and plutonium, and also the different chemical processes employed at sites such as Fernald. The range of uranium-bearing phases at Fernald has impeded the remediation efforts, as no single chemical process has been able to remove all the uranium without totally destroying the soil. However, carbonate Heap leaching has managed to remove a majority of the uranium phases, only leaving the uranium metaphosphate phase.

Removal of uranium from the Fernald soils and elsewhere can be made easier by detailed knowledge of the chemical and physical characteristics of the waste and its environment. A characterization technique must be able to determine the exact nature of the contaminant phase, as incorrect interpretations of data could lead to the selection of inappropriate remediation methods. A technique which provides both compositional and structural data, such as AEM, is advantageous because it can

determine the chemical form of unique phases. At Fernald, the identification of the ceramic-like uranium metaphosphate phase is a good example of this capability. At Johnston Island, AEM studies have confirmed that removal of plutonium using the segmented gate system will be effective and that it will also remove the uranium from the site, as the uranium is contained in the "hot particles." The characterization methods described above, in combination with other techniques such as XAS and radiochemical analysis, allow remediation technology groups to find more efficient ways of removing contamination. Characterization has been criticized as providing esoteric information. However, when used in the role of problem solving, it can provide information which improves the rate at which bench-scale testing can proceed to full-scale remediation.

The small particle handling facility and microscopy laboratory developed at ANL is equipped to handle radioactive materials for soil and residue characterization. The facility also includes radiochemical analytical instruments, inductively coupled plasma-mass spectroscopy for elemental analysis, and secondary ion mass spectroscopy for surface profiling of radioactive materials. We are currently engaged in establishing commercial sector projects for developing and testing soil and residue treatment technologies.

ACKNOWLEDGMENTS

This work is supported by the U.S. Department of Energy, Office of Technology Development, as part of the Uranium in Soils Integrated Demonstrated Program, under contract W-31-109-ENG-38.

INCREASING QUALITY ASSURANCE THROUGH AN INTEGRATED SURVEY SYSTEM

George Harder

Dr. E. Bolch
Rodney Handy
University of Florida

ABSTRACT

The weakest link in a radiation survey is usually the operator. Repetition produces tedium which increases errors. On the other hand, the computer's strong suit is accurately performing repetitious tasks. The computer's role can be expanded from just data handling to one of retrieving the data from equipment. Through a U.S. Department of Energy Health Physics Faculty Research Award Program, the University of Florida, Department of Environmental Engineering and Science is developing an integrated, indoor survey platform. Two hardware aspects of this project are integration with survey equipment and determining positions. The heart of this survey platform is a Notebook computer with a PCMCIA data-acquisition board. Some survey equipment is available with RS-232 ports which can hook up directly to the Notebook computer. For equipment that is not RS-232 compatible, it is still possible, with the help of the manufacturer, to retrieve analog signals and feed them into a data acquisition card. The computer controls the survey equipment and results are displayed for the user and automatically stored in a database. There are limited alternatives for indoor positioning. Sonic rangefinders need a smooth surface to reflect against, GPS is unavailable indoors and tape measurements are tedious. Another alternative is currently being developed using a combination of triangulation and dead-reckoning. Both devices are controlled by the computer and results are displayed to the user and automatically stored in a database. With more computer control of a survey, the operator's responsibility shifts from just taking measurements to one of ensuring quality control.

INTRODUCTION

Quality assurance begins with the operator taking the survey and ends when the survey information is no longer needed. Quality assurance is the most potent at the beginning, during the survey. By ensuring the data is recorded properly, the operator is taking the first steps of quality assurance. But there are situations that lead to poor quality results such as inadequate training of the operator, fatigue as a result of environmental stresses and lack of concentration from performing repetitious tasks. To improve quality, refresher training can be provided, the operator could be relieved often during surveys and the amount of direct supervision could be increased. Another alternative is to provide "smart" instruments and "expert" systems to the operator.

"Smart" instrumentation can be defined as transferring equipment operations from human operators to computer control. This control only applies to the repetitious and routine procedures that are tedious to humans but for which computers are designed. There is a balancing point between how complex an operations will be to program into a computer and the simplicity for a human to perform the same operation. As computer processing speeds increase, they can take more responsibility for a survey. Computers will then be able to compensate for shortages of adequately trained personnel and increasingly stringent worker protection regulations. But, regardless of how "fast" a computer becomes, the higher order thinking processes required in surveys will still rely on human experience.

"Expert" systems can be defined as a "corporate" knowledge base of situations and responses. This knowledge comes from worker experience and will be accessible to all workers. To do this, the experts need to supply answers to questions that a novice may ask. Expert systems are increasingly needed to help cope with shortages of adequately trained personnel, increasingly stringent worker protection regulations, quality assurance and quality control requirements (1). Expert systems will be able to provide limited substitution for experience. A comprehensive system would allow a novice to operate equipment and perform surveys correctly and quickly. By providing a working knowledge of procedures, expert systems can also cost effectively facilitate the documentation of compliance with DOE, federal and state regulations (2). Development of these systems will put increasing pressure on the developers of software and survey systems to make them as user friendly as possible. These systems will require more from the computer and less from the operator. The first step in generating an expert system will result in a "cookbook" which can guide a novice through difficult situations. As knowledge is gained and integrated into the computer, the "smarter" the system will become.

COMPUTERIZATION OF INFORMATION

The first step towards computerization of surveys is to determine the Department of Energy's (DOE) viewpoint. The DOE allows for transferring records to computer storage as long as it is maintained in a retrievable form (3). The DOE recommends controls for indexing, quality assurance and security. A master index is required which lists the files on every disk and the type of information contained within each file. Additionally, the index should identify the program used to create the information and the format in which the information is saved. Most computer programs, such as WordPerfect, Quattro Pro, Lotus, etc., save information in their own format. Having survey results also saved as ASCII text would ensure that any other program can read the information and can also qualify as a backup to the original information. Quality control during data entry and analysis is ensured if the information is transferred automatically from the survey equipment directly into a database. Finally, safety of the information must be assured. Just as in the case for paper records of a survey, the computerized records should be accorded the same security. Theft and/or tampering with the information should be guarded against.

COMPUTERIZE SURVEY

The University of Florida, Department of Environmental Engineering and Sciences was awarded a contract by the DOE Health Physics Faculty Research Award Program entitled An Integrated Environmental Monitoring and Assessment System for the Evaluation of Indoor Remediation Projects." It outlined and contained five main objectives. These were 1) create databases for site information and test results, 2) automate survey equipment, 3) automate position equipment, 4) provide access to modeling programs and 5) provide access to laws and regulations. The intent of this project was to computerize the surveying process to relieve the operator of some of the responsibility during a survey and put this responsibility on the computer.

The computer for this project was a Toshiba T4600 Series Notebook computer with a 33 MHz IntelTM 486SL processor, 12 MByte RAM, 120 MByte hard disk and two Type II PCMCIA sockets. One PCMCIA socket was fitted with a National Instruments DAQCardTM-700. The data acquisition card allows for sixteen analog signals referenced to ground or eight pairs of analog signals referenced to each other, eight digital input and eight digital output lines and three counters.

An appropriate computer environment was needed which could implement these controls and still provide the flexibility for this project. Microsoft WindowsTM was chosen for three main reasons. First, Windows has become a popular and widely used environment that operates on computers that are decreasing in price and increasing in capabilities. A wide variety of Windows software is available for programming, word processing and graphics depending on the user's preference. Once the raw survey data is entered into the computer, the user can chose the programs they are most comfortable with to process the data. Secondly, most Windows programs have a similar texture. They use similar menus, pop-up panels and options which will help shorten the learning curve on new software. Finally, using the Windows environment will take the computer away from being dedicated to just surveys and allow its use in the office. This becomes important to small facilities that do not require frequent surveys and have limited budgets.

This survey program was developed using Microsoft Visual BasicTM. Visual Basic is a powerful programming tool that is designed to create Windows applications. It is hoped that running the surveys on Windows would require less initial training and be more comfortable to operators. The databases used for this program were created to run on the Microsoft AccessTM engine (4). The databases, tables and fields are created within the survey program and does not require the Access software. However, the user has the option of manipulating survey results and floorplan information, independent of this survey program, using the Access software.

Survey Equipment

For this project, the initial survey equipment used was a Ludlum Model 2350 Data Logger. The Data Logger is a portable digital ratemeter, timed counter or integrated dose counter and timer. This Data Logger can have attached a variety of Ludlum Alpha, Beta and Gamma Scintillation detectors. For this project the Ludlum Model 44-10 high energy 2" X 2" NaI(Tl) Gamma Scintillator and a Ludlum Model 43-1 Alpha Scintillation Detector were used. The Data Logger contains an RS-232 serial port which can be used to connect to a computer or a specialized handheld unit. The Data Logger contains sufficient memory to store the parameters for sixteen different detectors. Through a special handheld unit or a computer, the parameters can be read or changed. The Data Logger is also capable of storing up to 250 survey points with

position information or can supply real-time information to a computer or handheld unit. For this survey program, the computer controls the Data Logger and stores results into a database with information on positioning.

Positioning

The primary method of locating positions indoors has traditionally been by manually laying out grids. This alternative will always be available, but less laborious methods were explored. Eight alternative positioning methods were reviewed for this project. 1) The Global Positioning System (GPS) consists of twenty-seven satellites, twenty-four in geo-synchronous orbits with three satellites utilized as spares. At any time and place around the globe, four satellites are visible and can provide triangulation. However, signals from the GPS are attenuated by building materials making them unusable indoors. 2) The Ultrasonic Ranging and Data System (USRADS) uses three or more ultrasonic transceivers which receive a signal from a backpack worn by the operator. Indoors, this system would seem to be hampered by re-radiation of broadcasted signals causing multi-path errors, but currently the USRADS has had some success with indoor positioning. 3) Inertial guidance provides an alternative for indoor positioning by using "dead-reckoning." Starting at a known point within the room gyroscopes and accelerometers measure and compute changes in distances along all three vectors (X, Y and Z). However, this system has problems with gyro drift and accuracy is directly related to cost. 4) Sonic rangefinders provide the simplest alternative for positioning. The distance from walls can provide positioning and the rangefinder's signals can be directly entered into the computer. However, the signals have limited distance accuracy and are best for small, uncluttered rooms. 5) A sonic rangefinder repeater is available with some models. The signal from a sonic rangefinder is sent at one frequency, received by the repeater and retransmitted at a different frequency back to the sonic rangefinder. The biggest benefit with this system is an increased range. 6) A commercial laser rangefinder can provide accuracy to within a fraction of an inch over distances of several hundred yards. However, the cost for this accuracy makes it prohibitive. 7) One alternative developed for this project was the "floor mouse." It uses a known starting point and then dead-reckons on a roller ball similar to a computer mouse. Movement in the X and Y directions are calculated using optical readers and a spoked wheel. As the mouse moves, the spoked wheels rotate. The optical reader records the number of spokes that pass by and calculates the distance traveled. With calibration, the floor mouse can provide over 99% accuracy in determining position within ten feet of the starting point. This alternative is cost effective and the floor mouse can be discarded along with the other contaminated material. 8) The final alternative developed for this program uses an inexpensive laser pointer mounted on a potentiometer. As the laser is rotated from one landmark to another, the voltage across the potentiometer changes. The change in voltage equates to a change in angle. The angle differences between three known points within a room are entered into an algorithm which uses the known locations of the landmarks and calculates the laser's position within the room.

Both the floor mouse and the laser pointer system work individually and a combination of the two provide a viable option. Exact positioning can be determined by the laser pointer system and then the floor mouse can be used to dead-reckon to different points. A sensor attached to the floor mouse frame would indicate when the mouse has been lifted off the ground. This would require the operator to enter a new "fix" or exact position using the laser or from manual measurements. The combination of both systems will still remain cost competitive compared to other methods of indoor positioning.

Software Development

Modeling programs are still in their infancy. Programs that have been used for years were originally written on punched cards. Computer models were written for DOS-based or UNIX-based systems where the primary concern was with processing repetitive equations. The computers that were used were mainframes with several users all vying for computer time. Code had to be written with the emphasis on efficiency and not with the appearance of outputs. Today, desktop computers have the processing power that could rival the mainframes from the past with the benefit of being readily accessible. Programming languages have evolved from assembly language to Graphics User Interfaces (GUI). Code can be written and modified to appeal to a specific user. The learning curve for some programming languages is relatively short. For instance, anyone with experience with Basic would have no problem jumping to Visual

Basic and generating Windows applications. For hardware and software manufacturers, core processing modules can be generated and packaged into custom controls. Users could take these custom controls and apply them as needed for integrated with other applications. Such an example would be National Instrument's NI-DAQ software. Custom controls for Visual Basic are supplied when purchasing a National Instrument's data acquisition card. Instead of learning the intricacies of Standard Commands for Programmable Instruments (SCPI) and IEEE 488.2 standards, the user can hook up an analog signal to the computer and write a couple of lines of code that tells the computer to read the voltage on a certain input line or the state of a digital input line. The signal is immediately available for modeling applications. This level of flexibility allows users to apply their own modeling ideas to measured results.

Laws and Regulations

An informational source of standards & criteria is available from third party vendors. Installing a copy of standards and regulations onto the computer is easily accomplished by downloading from the appropriate Bulletin Board System (BBS). But, these are also available from third party vendors which also provide two additional benefits. First, monitoring the Federal Register for updates and revisions and then entering them into the appropriate regulations or standards is a full-time job. Second, not all the information contained in standards and regulations are applicable to each site. Third party vendors will take the needs of each site and ensure they receive only the pertinent information. These vendors can also provide ongoing support to ensure the user always has the correct and latest information.

CONCLUSION

The potential for human error increases during the process of surveying. There is no relief yet from having to perform surveys, but there are three immediate alternatives to speed up the process. First is to use the computer for data logging. This step alone will remove the redundancy of writing the information on paper and then transposing the results to a database. Computerizing results makes the data more portable. Information is readily available on-site without dragging along reams of paper. Secondly, the survey results can be directly entered into the computer by the survey equipment. The operator will still have the responsibility of entering the position and any comments. Finally, positioning equipment can be connected to the computer and automatically entered into the database. This removes the operator from the loop of entering positioning and survey information. This alone will improve the quality of the data and decrease the time of the survey.

At this time, we are at the beginnings of a paperless society. This process will come about over time, but methods should be explored that can wean ourselves from paper records. This project is a step in that direction by placing more of the responsibility of the survey with the computer and reducing the dependence of paper records.

EXPEDITING ENVIRONMENTAL CLEANUP -- NATIONWIDE STAKEHOLDER INVOLVEMENT IN DOE'S PLUME FOCUS AREA

Paul Longsworth
U.S. Department of Energy

Office of Technology Development
Gretchen H. McCabe
Battelle Seattle Research Center
Patricia J. Serie
Environmental Issues Management, Inc.
ABSTRACT
The U.S. Department of Energy (DOE) has committed to expediting the cleanup of its contaminated facilities. This calls for using innovative technologies that will improve performance, cut schedules, and lower the costs of cleanup compared with using historically available technologies. DOE has organized its technology development and application activities nationwide into five focus areas. The mission of the Plume Focus Area is to enhance the deployment of innovative technologies for containing and cleaning up contaminant plumes in ground water and soil. New technologies must be driven by high-priority needs at the facilities nationwide, maximizing the benefits and widely deploying successful solutions.
The Plume Focus Area has committed to major involvement of stakeholders in its implementation, incorporating stakeholder values and input in identifying and prioritizing environmental management needs. Stakeholders will also participate in identifying new technologies to address those needs, and evaluating the acceptability of those technologies so that deployment decision makers can select remedies that address broad-based stakeholder concerns.
Stakeholders are defined to include technology users, public interest and environmental groups, civic organizations, Native American tribes, elected and appointed officials, and other interested parties. Early and substantive stakeholder involvement will identify information needs and potential obstacles to technology deployment, which can then be addressed through the focus area's technology development and evaluation efforts.
This paper describes the objectives, approach, and challenges of implementing a stakeholder involvement program that also addresses site-specific needs. It outlines the model that is being used, based in part on stakeholder involvement in DOE's Volatile Organic Compounds Arid Sites Integrated Demonstration. It defines near-term and longer-term activities, and indicates how stakeholder input will be integrated with technical, product line, and industry inputs to support a focused, needs-driven decision process.
INTRODUCTION
The U.S. Department of Energy (DOE) faces formidable challenges in remediating contaminated sites nationwide. A key concern is the presence of soil and ground-water plumes, which contain a range of radioactive and chemical contaminants. Today's technologies and approaches will not be enough to meet the technical, regulatory, and management challenges of the 30-year remediation process.
In Fiscal Year 1994, DOE put in place a new approach to develop and deploy the innovative approaches that are so badly needed. The new approach focuses technology development and deployment into five focus areas, including:

- Contaminant Plume Containment and Remediation
- Characterization, Treatment, and Disposal of Mixed Waste
- High-Level Waste Tanks
- Containment of Existing Landfills
- Decommissioning and Final Disposition

Innovative technologies are not worth developing if they are unacceptable to environmental restoration personnel, regulators, and stakeholders. The focus area is designed to cut across all the relevant DOE components, ensuring that technologies that are developed by DOE are actually used by the waste management and environmental restoration programs (EM-30 and EM-40). Furthermore, the focus area is looking for existing solutions to meet site needs that are available within other agencies and industry before deciding to support research and development.
To ensure that the actions of the Plume Focus Area reflect the perspectives of all the DOE sites and of the other groups and individuals in those site areas with a stake in their cleanup, the focus area team includes a sites' coordination function. The Sites' Coordination Team (SCT) develops and supports the implementation of methods for stakeholder involvement throughout all stages in plume technology development and application. This paper describes the objectives, approaches, and challenges of the SCT for the Plume Focus Area, and discusses how it may result in a model for direct stakeholder involvement in technical and highly complex technology

decision making.
PLUME FOCUS AREA ORGANIZATION AND MISSION
Each focus area includes representatives of all the involved elements of DOE. The Plume Focus Area consists of a DOE Headquarters management team, composed of representatives from EM-30, 40, and 50. A lead organization based at the Savannah River Site supports the management team in implementing the national objectives. The lead organization has formed an implementation team, bringing together DOE and contractor personnel from across the field offices who bring to the team specialized expertise in technology development, industrialization, stakeholder involvement, and other functions. Both teams work together to carry out the steps in the technology development/deployment process, incorporating site and stakeholder involvement at each step (See Fig.1). In summary, those steps include:
Identify environmental management needs
Identify potential technologies to meet those needs
Match potential technologies to needs
Verify needs and technology matches at site level
Issue solicitations and calls for proposal for needed technologies
Conduct research, development, and demonstrations of promising technologies
Evaluate research and demonstration results to assess technology performance and acceptability
Make technologies available broadly for deployment to meet environmental management needs
The SCT is involved in all of these steps in order to plan for, support, and coordinate the involvement of site personnel and other stakeholders, to drive technology development through high-priority site needs, and to improve broad acceptability of the technologies for deployment.
BACKGROUND FOR PLUME FOCUS AREA STAKEHOLDER INVOLVEMENT APPROACH
A foundation for the Plume Focus Area's approach to site and stakeholder involvement is a three-year DOE program, that was sponsored by the Office of Technology Development. The Volatile Organic Compounds Arid Sites Integrated Demonstration (VOC-Arid ID) pioneered a stakeholder involvement process that provided for early, meaningful participation in defining, demonstrating, and deploying acceptable technologies for cleanup of VOCs in arid sites' soils and ground water.
In the VOC-Arid ID, a range of "internal" and "external" stakeholders were involved at the site where the demonstrations are being conducted, the Hanford Site in Washington State. With a solid base of Hanford host-site stakeholder input, the ID broadened its efforts to include participation by stakeholders at other arid DOE sites where the technologies may ultimately be deployed. In this way, technologies' acceptability at other locations and in other regions were assessed, and stakeholders gained a better understanding of some of the technologies being developed to address VOC contamination problems at their sites.
What this earlier work confirmed is that technology planners need to consider both generic and site-specific issues when evaluating potential demonstration and deployment decisions. While the majority of stakeholder concerns are common across geographic areas and even among stakeholder categories, there is a significant level of specificity that, if ignored, would place future decisions at risk.
This is the model used as the basis for the Plume Focus Area SCT. While it has provided insights into design of an appropriate strategy, there are clear limitations when applied to a national program. The specific Plume Focus Area strategy has been tailored to the challenges of integrating ten DOE field offices, many with multiple sites, and each site with numerous environmental management needs and programs.
SITES' COORDINATION TEAM OBJECTIVES FOR PLUME FOCUS AREA
In order to achieve the Plume Focus Area mission, the SCT's objectives are integrated throughout. Specific SCT objectives include:
To define desired outcomes for sites and stakeholders to be involved in the focus area's technology evaluations, and provide a model(s) for achieving those outcomes while retaining site-specific flexibility.
To provide national-level strategic planning, guidance, and support to each DOE site to implement stakeholder involvement activities.
To provide the rest of the plume team with products of stakeholder input that are directly applicable to technology demonstration design, evaluation, and deployment decisions, in the formats and level of detail needed to support team decisions and

results.
To mesh these involvement efforts with those of the other four national focus areas and independent programs (e.g., robotics, characterization), with sensitivity to ongoing stakeholder involvement at the DOE sites.
These objectives and the resulting approach reflect a national vision for sites' coordination and stakeholder involvement. The SCT develops and aids in implementing stakeholder involvement throughout the country. Site-specific stakeholder involvement teams are being formed to carry out the strategy at each site, and the teams will coordinate closely with Site Technology Coordination Groups (STCGs) at each location. The SCT is responsible for identifying and working with those site-specific teams, supporting them to the degree needed (e.g., preparing needed guidance and strategies, helping the teams tailor strategies for their sites that meet the overall needs of the focus area), and facilitating inter-site coordination. Results will help in developing national technology acceptance reports on the innovative technologies being funded and evaluated under the Plume Focus Area.
The SCT's responsibility, then, is to serve as the catalyst to bring the site teams together in a national framework. The SCT will work with the site teams to identify required stakeholder involvement outcomes and assist them in achieving those results to support the national mission.
SITES' COORDINATION TEAM APPROACH
In this first year of operating the Plume Focus Area, the transition year, we have asked the sites to define their plume problems in soil and ground water, describe the technologies they are planning to use to address each problem, describe their environmental management needs, and prioritize these needs. Representatives from each of the DOE field offices have or are in the process of providing the Plume Focus Area with this information. The lead organization summarized this information for each site by grouping the problems into several categories: VOC contamination, heavy metal contamination, radionuclide (e.g., tritium) contamination, and dense non-aqueous phase liquid (DNAPL) problems. The matrices also included summary information on site characteristics and technologies currently planned to address site needs. In addition, descriptions of key operable units (OUs) with plume problems have been developed based on needs described by the field operable offices.
Information in the OU template includes:
- Site/OU designation
- Priority level
- OU Manager/address/telephone
- Regulatory and other drivers
- Schedule and milestones
- Overall objective for site/OU
- Performance requirements and goals for technology(s) to meet site objectives
- Current baseline approach/technologies
- Geologic setting
- Contaminant types, concentrations, volumes, and areal extent
- Issues and concerns

After these need sets were developed, the lead organization of the Plume Focus Area scheduled site visits to verify and prioritize the information. The first round of site visits is taking place during January - March, 1995. With the site needs compiled and verified, the goal will then be to match available and developing technologies with those site needs, and to identify problems for which there are no technologies either available or being developed by DOE that will address the problem. The site visits are critical to establishing the baseline program for the Plume Focus Area and building on it in future years. Environmental restoration program managers are being actively involved in order to obtain their perspective as well as their commitment to using the technologies being developed if they perform adequately in demonstration.
The SCT's role is also to ensure that stakeholders, other than DOE program managers, are involved to enhance the design of the technology demonstrations and ultimately the acceptance of the technologies. In support of this role, the SCT will work through the STCGs to help assemble site-specific stakeholder involvement teams. The SCT will also develop and disseminate strategies and guidance for conducting stakeholder involvement at the national and site-specific levels. To accomplish this, the SCT will coordinate closely with the site-specific stakeholder involvement teams, STCGs, and the Plume Focus Area lead organization and management teams, to

ensure that stakeholder involvement activities are conducted to produce the required results.
Again, the success of the SCT is largely dependent on the results of actions taken by the site-specific stakeholder involvement teams. In Fig. 2a,b,c, responsibilities and activities are shown as divided between the focus area team overall (top layer), the SCT (middle layer), and the stakeholder involvement teams and STCGs (lower third). The SCT, with critical support from these site-specific teams, will:

Develop a national strategy for the Plume Focus Area.

Establish tailored approaches to achieving site and stakeholder involvement in focus area activities and decisions.

Work with the sites to involve stakeholders in identifying environmental management needs at their sites, prioritizing those needs, and matching potentially applicable technologies with those needs.

Consult with stakeholders on the development of evaluation criteria and a prioritization process to rank environmental management needs across all sites; and support verification of the prioritization process by involving stakeholders.

Provide input to the focus area product line team on stakeholder concerns, issues, and data needs to help define the functional and technical requirements for the technology product lines.

Work with technology developers to develop information profiles on their technologies and use these profiles to consult with stakeholders on data requirements to include in the demonstration test plans.

Obtain stakeholder review of demonstration performance and results, receive their feedback, and prepare technology acceptance reports for each technology evaluated.

If there is considerable interest, or significant contrasting input on innovative technologies between sites, the SCT may convene regional focus groups with stakeholders from various sites to accomplish a shared resolution of issues. Such forums may be particularly useful to address interstate regulatory acceptance issues and approaches. Technology acceptance reports will support decisions on deployment of innovative technologies, and will be made available nationwide to communicate Plume Focus Area activities and results to a broad audience.

THE VALUE OF ADDING REGIONAL TO LOCAL STAKEHOLDER INVOLVEMENT IN EVALUATING THE ACCEPTABILITY OF INNOVATIVE TECHNOLOGIES

ABSTRACT

Technology is urgently needed to clean up contamination by volatile organic compounds at United States Department of Energy (DOE) sites. In many cases, however, existing technology is too slow, inefficient, or expensive. The record of technology development is, in some cases, similarly disappointing. Remediation technologies developed at great expense and evaluated piecemeal over long periods have not been deployed because, in the end, the public judged them ineffective or unacceptable. The need for successful methods of remediation is too great and resources too limited to continue with ineffective technology evaluation. In order to make good decisions about which technologies to deploy, remedial project managers need to know stakeholders' requirements for the performance of proposed technologies. Expanding stakeholder involvement regionally identifies the concerns of a broad range of stakeholders at arid DOE sites throughout the West - issues that must be taken into account if technologies are to be accepted for wide deployment.

THE PURPOSE OF STAKEHOLDER INVOLVEMENT IN TECHNOLOGY EVALUATION

Volatile organic compounds (VOCs) are the most prevalent hazardous waste contaminants at Department of Energy sites throughout the United States. Effective, economical technologies are needed to clean them up. But innovative remediation technologies have proven difficult to deploy partly as the result of public

opposition, arising in some measure from stakeholders' sense that they have not played a meaningful, timely role in evaluating proposed approaches. Given this history, stakeholder involvement in technology evaluation has three purposes:
To define those stakeholder issues and concerns that must be addressed in order for a given technology to be accepted for deployment. These issues and requests for information ("data requirements") can then be incorporated into technology test plans.
To identify early in the process of technology development those technologies or aspects of technologies that require modification in order to be deployable. This avoids allocating resources to technologies that ultimately will be unacceptable.
To provide stakeholders with the results of technology demonstrations so they can make reasoned judgments about the acceptability of given approaches.
To achieve these purposes, to expedite the deployment of effective technologies, and ultimately to advance environmental cleanup, Battelle, with funding from the U.S. Department of Energy's Office of Technology Development, has carried out a three-year stakeholder involvement program.
EXPANDING STAKEHOLDER INVOLVEMENT
In its first phase this program, part of the VOC - Arid Sites Integrated Demonstration hosted at Hanford, Washington, involved Hanford stakeholders in evaluating six innovative technologies for the remediation of VOCs in soils and ground water. Because a guiding principle of this effort is "Test once, deploy broadly," it was necessary to determine data requirements at the arid sites other than Hanford that must be a taken into account if test plans are to be truly comprehensive and responsive to stakeholders' concerns. In addition, the team conducting the stakeholder involvement program wanted to subject the criteria for evaluating technology (Fig. 1) and the issues highlighted by Hanford stakeholders to a regional assessment. Were the priorities identified by Hanford stakeholders shared across the arid west? Were there site-specific issues that because of their surpassing local importance would determine the deployability of a technology at a particular site? The public involvement team wanted to identify those issues and concerns that must be taken into account in considering any technology for deployment at any site as well as those site-specific issues of overriding local concern.
Figure 1
To this end, the VOC-Arid public involvement team conducted 75 interviews with stakeholders at Sandia and Los Alamos, New Mexico, Rocky Flats, Colorado, and the Idaho National Engineering Laboratory. Those interviewed represented a cross section of the public concerned about the cleanup of particular DOE weapons complex sites in the West, and included local elected officials, regulators, Native Americans and Hispanic community members and representatives of environmental, public interest and civic groups.
Hanford-site Stakeholder Involvement in the Evaluation of Innovative Technologies for the Remediation of VOC Contamination
The foundation and context for these interviews was two years of consultation with Hanford stakeholders. Hanford stakeholders helped develop detailed criteria for evaluating innovative technologies to remediate VOC contamination. By participating in interviews, focus groups, and workshops, they defined data requirements that have been incorporated in the test plans now guiding technology demonstrations. (These data requirements are presented in a series of reports prepared by Battelle on ground water and soil remediation technologies.) Hanford stakeholders stipulated specific standards of performance for technologies. Overall, they have provided a detailed sense of what concerns the public about technologies and what technologies will have to do and be in order to be accepted and used.
Among the criteria for evaluating technologies, issues of technical effectiveness, cost, and time occurred most frequently in the comments of Hanford stakeholders. In addition to data requirements specific to each of the technologies under consideration, Hanford stakeholders identified the following data and performance requirements as pertinent to all the methods being assessed. (Please see Phase II Stakeholder Participation in Evaluating Innovative Technologies: VOC-Arid Integrated Demonstration, Ground Water Remediation System , Battelle Seattle Research Center, April 1994 for data requirements specific to particular technologies.)
1) Define remediation objectives to ensure that the technology truly contributes to the

objectives.
2) Conduct integrated comparisons of an innovative technology to the technology currently in use.
3) Design demonstrations to provide data on performance, cost, and time to reduce uncertainty and better define trade-offs.
4) Demonstrate the technology considering differing site conditions to measure its versatility.
5) Define the demonstration assumptions and expectations about secondary waste.
6) Define the risk management strategy and the elements of and process for assessing operational readiness.
7) Define how effectiveness of the technology, both in terms of its performance and its effect on the environment, will be monitored.
8) Plan for unintended consequences and define and test all potential failure control mechanisms.
9) Define the liability implications and insurance requirements for the deployment of the technology.
10) Demonstrate that future cleanup is not foreclosed by using the technology.
11) Have a credible third party evaluate demonstration data.

RESULTS OF REGIONAL STAKEHOLDER INVOLVEMENT

In expanding consultation to include stakeholders from four other DOE weapons complex sites in the arid west, the stakeholder involvement team intended to test the hypothesis that data requirements different from those identified by Hanford stakeholders will pertain at these other sites given geographic, cultural, regulatory, and institutional differences. The underlying assumption remains that if a technology is to be widely deployable, this broadened set of data requirements must be taken into account.

The regional stakeholder involvement program yielded a number of findings. Foremost is that a technology will be put into use beyond the location of its demonstration only if issues significant at other possible sites are identified and addressed. Failing to identify or address these site-specific concerns during technology demonstration will increase the time and cost of deployment, and could result in the rejection of the technology.

Regional stakeholders validated the criteria developed by the Hanford stakeholders. There was also agreement about which criteria are most important. Hanford and regional stakeholders placed the most emphasis on technical effectiveness. More comments from Hanford and regional stakeholders focused on performance than on any other criterion.

Similarly, regional stakeholders raised many of the same issues and concerns about the six VOC remediation technologies as Hanford stakeholders.

There are, however, certain local concerns that if not addressed in a technology's demonstration will prevent a technology's deployment at a site. These issues will dominate the local evaluation of a technology. Identifying them at the outset is essential to understanding a technology's potential for deployment.

Taken together, these requirements are basic conditions with which stakeholders will evaluate the acceptability of any remedial technology. They should be considered by those responsible for developing and selecting environmental remediation technology in the western states.

Requirements Identified at All Sites

Technologies should destroy contamination on site rather than concentrating it for transportation and destruction elsewhere. Those technologies that meet this requirement will be regarded more favorably than those that do not.

Technologies should not transfer contamination from one environmental medium to another. For example, the action of the technology should not result in moving contamination from ground water into air.

The number of steps in a technology's treatment system should be minimized as much as possible.

Technologies should be able to be operated and maintained by existing staff.

Technologies should be economical, understandable, and robust.

Technologies must be able to treat co-contaminants. In order to be accepted for deployment, a technology must be effective with more than just its target contaminant. Acceptable technologies will have the ability to deal with radioactive

co-contaminants. The inability to do so may be a "showstopper."

Acceptable technologies are those which solve all aspects of a contamination problem, not just part. It is not acceptable to solve one environmental problem only to create another in a different place or in a different environmental medium.

A technology's entire treatment system is important. Stakeholders will evaluate the entire system, not just the most visible or active component. The entire system must be maintainable and economical. Secondary waste from each component must be dealt with safely.

Across-the-Board Requirements with Site Specific Relevance

Certain site-specific concerns will determine the deployability of technologies:

Technologies will be evaluated within the regulatory framework prevailing at a particular site. To enhance a technology's acceptability, the technology and its demonstration must be presented in terms of that site's specific regulatory framework. Applicable regulations vary among states and tribal nations. For example, in New Mexico tribal governments may have more stringent cleanup standards than state government, particularly in terms of water quality. Also in New Mexico, RCRA alone will govern technology demonstration and deployment. At this time, DOE sites in New Mexico have no CERCLA liability. Conversely, environmental regulators in Idaho may use RCRA or CERCLA; for example, VOC vapor may be regulated under CERCLA and VOC liquid under RCRA.

Where a natural resource is considered special, impacts on that resource will determine a technology's evaluation and acceptance. For example, water is extremely important in the arid west. Communities, particularly in the Southwest, are discovering that the quantity of available ground water is significantly less than previously predicted. Therefore technologies that do not remove and reinject ground water are regarded favorably. In another example, the Snake River Plain Aquifer is of such economic, cultural, and political importance to southern Idaho that any proposed technology's impacts on it will take precedence in the evaluation of that technology. Similarly, Southwestern stakeholders prize the clarity of their air, and therefore will scrutinize any proposed technology's air emissions.

Remote sites place special requirements on technologies. These include the ability to withstand vandalism and operate reliably and automatically for long periods. Remoteness raises the question of power supply, an issue involving concerns about the visual impact of power lines and the air emissions from generators.

The ability to operate in locally prevailing weather will determine the acceptability of any technology. Extremes of temperature and humidity, high winds, particularly at Rocky Flats, and deep snows are among the conditions that must be taken into account.

Trade-offs among criteria will vary from site to site. Local conditions will determine how stakeholders weigh the benefits and drawbacks of some of a technology's characteristics in relation to its other capabilities.

Versatility applies to all criteria, not just to performance. To be acceptable, a technology must be versatile and adaptable in terms of all the criteria used to evaluate it. For example, regulatory compliance means something different in each of the states where stakeholders were interviewed.

In conclusion, not considering these issues in designing, demonstrating, and selecting a technology may result in decisions that are delayed or reversed, and technologies that are never deployed.

ABSTRACT

We are currently at a crossroads regarding public funding for remediation of the chemical and radioactive contamination at United States Department of Energy (DOE) nuclear weapons complex sites across the country. Substantial criticism has been focused upon DOE's inability to clean up the widespread contamination at its facilities. And, the fiscal train wreck envisioned with the FY'96 budget has been dramatically elevated with last November's election. Regardless of the validity of the critique of DOE's fifty years of self-regulation, there is one ultimate truth -- the challenge to isolate these materials from the biosphere, regardless of the risk, is enormous.

Perhaps the biggest challenge faced by DOE today is the development of decision-making processes which welcome the views of interested stakeholders and actually use this input to improve both the quality and public acceptance of decisions. Future R & D decisions must convince the Congress and the public that the money invested in technology development has been spent well.

We submit that out experience in the Pacific NW laboratory's Volatile Organic Compound/Arid Lands Integrated Demonstration Project (VOC/Arid ID) has left us hope that R & D decisions can be made within a framework where money can be spent well, appropriate advanced technology developed, results produced and transferred to the private sector in a timely manner. We have concluded that a decision-making process can succeed if it is well conceived, engages and listens to a spectrum of stakeholder interests from its earliest stages, links principal investigators with both stakeholders and regulators, and does not create unrealistic expectations. Additionally, once established, the investigative and public participation processes employed in such a process can be applied to other sites across the complex.

In this paper, we will develop a comparative analysis of two different approaches to innovative technology acceptance, primarily related to Department of Energy Facilities, that have been initiated over the past two to three years. First, we will examine the Western Governors Association Committee on Development of Innovative Technologies (DOIT). The second approach to be examined, one in which both authors have extensively participated, is the stakeholder participation program supporting the Volatile Organic compounds (VOC) Arid Site Integrated Demonstration (VOC-ARID ID) conducted at Hanford, Washington.

Comparative analysis of these two approaches is intended to illustrate that successful development and deployment of technologies can only occur when those technologies, not only perform well during demonstration, but are found acceptable to the people and groups that have a stake in the cleanup process -- the regulators, the public, and the technical and business people. thus, stakeholder acceptance of innovative technologies is a significant existing "barrier" which can only be overcome through incorporation of a meaningful stakeholder involvement process or approach within the technology evaluation process.

INTRODUCTION

The question which is constantly asked in the realm of technology development is: How do we ensure or enhance the acceptability of innovative technologies? Substantial attention has been paid, as it should, to the technical issues associated with innovative technologies. However, little, if any, attention has been focused on the basis for public resistance to innovative technology deployment. It is well established that public stakeholders generally pay for technology development projects, either directly through financial contributions or indirectly via costs to the surrounding environment or loss of political momentum resulting from excess expenditure on "white elephant" projects. And, it is they who will have to live with the technologies once implemented or the slashed funding for remediation projects. Yet, too often effected stakeholders are not meaningfully involved in the process of selection, demonstration and evaluation of proposed

innovative technologies. Instead, they have been relegated to audience or spectator, invited to public meetings and told what technical experts believe are promising or necessary technological solutions to the problems they face and the reasons why the public should consider those proposed technologies acceptable. Not surprisingly, this approach has alienated the public and led to extreme public resistance to technologies which technical specialists conclude should be wholly acceptable.

We are currently at a crossroads regarding public funding for remediation of the chemical and radioactive contamination at United States Department of Energy (DOE) nuclear weapons complex sites across the country. Substantial criticism has been focused upon DOE's inability to clean up the widespread contamination at it facilities. And, the fiscal train wreck envisioned with the FY'96 budget has been dramatically elevated with last November's election. The critique of DOE's fifty years of self regulation has a number of valid points: lack of contractor accountability, minimal contractor oversight by DOE, enormous financial expenditure with little tangible results, an intractable and unresponsive
culture within both the department and its primary contractors oriented solely toward production of nuclear weapons materials, rather than the careful handling, packaging, storage and disposal of these dangerous wastes. Regardless of the validity of the critique, there is one ultimate truth -- the challenge to isolate these materials from the biosphere, regardless of the risk, is enormous.

Only in the past three years has DOE's effort to consider new and advanced technology for investigation and remediation borne any fruit at all. From the viewpoint of an outside stakeholder, the Department has used research and development (R&D) money primarily to enhance political agendas and provide the main contractors with more largesse. From the late 1980's until the end of 1994, much of the public financing has been poured into large white elephant projects like the Defense Waste Processing Facility at Savannah River -- which has yet to have a hot start and is billions of dollars over original estimates. It is obvious that such projects have not been conceived as components of an integrated, strategic, complex-wide effort to understand and then to design the most reasonable approaches to remediation, but as pork to elected officials. Clearly, these white elephants represent orientations and experiences of both the DOE and its contractors which may have made sense in the 1940's and 1950's but NOT today.

Perhaps the biggest challenge faced by DOE is to develop decision-making processes which welcome the views of interested stakeholders and actually use this input to improve both the quality and public acceptance of decisions. Obviously time and patience are required for members of the public to understand technical problems and options for solving them. Nevertheless, the time must be invested, for today the success of a decision is judged by its cost-effectiveness, its ability to address identified cleanup needs, and the investment of political support from a broad spectrum of stakeholders, (including the public). Thus, while public acceptance is inherently and ultimately a political issue, its value to federal agency decision-making cannot be understated. Future R & D decisions must convince the Congress and the public that the money invested in technology development has been spent well.

We submit that our experience in the Pacific NW Laboratory's Volatile Organic Compound/Arid Lands Integrated Demonstration Project (VOC/Arid ID) has left us hope that R & D decisions can be made within a framework where money can be spent well, appropriate advanced technology developed, results produced and transferred to the private sector in a timely manner. We have concluded that a decision-making process can succeed if it is well conceived, engages and listens to a spectrum of stakeholder interests from its earliest stages, links principal investigators with both stakeholders and regulators, and does not create unrealistic expectations. Additionally, once established, the investigative and public participation processes employed in such a process can be applied to other sites across the complex.

Of course, the front end investment of time for such a process is considerable -- the VOC/Arid ID took two and a half years between initiation and the demonstration phase. And, such projects are not a panacea for DOE's technology development or remediation needs. But, it is our belief that, within the VOC/Arid ID Pacific Northwest Laboratory (PNL), the stakeholders and the principal investigators have broken new ground. Consequently, it is critical that the funding for such projects continue either at current levels or increase. DOE must ensure that the early work at Hanford provides beneficial results throughout the complex. To indiscriminately

slash the Department's EM budget when it is about to make real headway is to "throw the baby out with the bath water".

To better illustrate our point, within the remainder of this paper we will develop a comparative analysis of the VOC/Arid Id with that employed by the Federal Advisory Committee to Develop On-Site Innovative Technologies for Environmental Restoration and Waste Management (DOIT) -- a program which cannot claim equal success. Comparative analysis of these two approaches is intended to illustrate that successful development and deployment of technologies can only occur when those technologies are developed in conjunction with a "meaningful" public participation processes which effectively and systematically involve a spectrum of stakeholders, including the regulators, the public, and the technical and business people.

THE FEDERAL ADVISORY COMMITTEE TO DEVELOP ON-SITE INNOVATIVE TECHNOLOGIES FOR ENVIRONMENTAL RESTORATION AND WASTE MANAGEMENT (DOIT)

In 1991 the Western Governors Association (WGA) entered into a Memorandum of Understanding (MOU) with the Department of Energy (DOE), the Department of Defense (DOD) and the Department of Interior (DOI) creating the Federal Advisory Committee to Develop On-Site Innovative Technologies for Environmental Restoration and Waste Management, commonly referred to as DOIT. Pursuant to its Charter, DOIT is to recommend a program to implement the tasks of the MOU, which include:

identifying technology needs at Federal facilities in western states;
identifying and assessing emerging technologies in Federal and private sectors;
assessing the effectiveness of technology selection processes;
identifying regulatory, institutional or other governmental barriers to technology development;
identifying work force planning/education requirements; and
identifying new approaches to more expeditiously overcome the barriers and get better technology into industry to expedite cleanup.

(Charter, Federal Advisory Committee to Develop On-Site Innovative Technologies for Environmental Restoration and Waste Management, Dec. 10, 1992, pp. 1-2).

As envisioned within the MOU, DOIT was the vehicle by which the signatories could establish a more cooperative approach to the development of technical solutions to environmental restoration and waste management problems shared by states, commercial entities and the federal government. Moreover, this regional approach would serve as a demonstration of principles and practices which could be adopted nationally. (Memorandum of Understanding, July 22 1991, at p. 1). The objectives of the MOU are laudable. However, the mechanism used to involve the public in this process has left much to be desired.

The DOIT charter contemplates the appointment of individuals to "technical workgroups (sic)". Work groups are to be used for any purpose consistent with the Charter and are intended as fact-finding bodies providing information to be used in preparation of an annual report addressing the enumerated tasks of the MOU.Individuals appointed to these Work Groups were to represent "an appropriate mix and balance" of representatives of state government, federal agencies, tribal governments, public interest groups, environmental groups, the waste cleanup industry, the waste cleanup support industry, federal laboratories, academia and other interested and affected parties. (Charter, Federal Advisory Committee to Develop On-Site Innovative Technologies for Environmental Restoration and Waste Management, Dec. 10, 1992, pp. 2-3).

Working groups were created by the DOIT Committee, without interaction or input from stakeholders, in 1991. They include the Mixed Waste, the Mine Waste, the Munitions Waste, and the Military Bases working groups. They were formed with little consideration of the objectives of the process, the proper mix of stakeholders required to meet the objectives, or the end product desired. Moreover, once formed, working group members failed to address vital process issues. Neither the decision-making processes nor the responsibilities of either DOIT Committee or Working Group members were ever defined. Not surprisingly, the working group quickly became different things to different stakeholders.

An appropriate understanding of the weaknesses in the approach to public participation employed by DOIT is best illustrated by examining the operation of one of the DOIT working groups. Since the authors' have extensive personal knowledge of the functioning of the Mixed Waste working group (MWWG), the following discussion will, in large part, be restricted to the functioning of that Group. However, the reader should be aware problems exist throughout the entire DOIT process.

Despite the stated objectives of the MWWG and/or the statement of tasks in the original MOU, the focus of the MWWG, and thus its effectiveness, has been extremely limited. For instance, MWWG fact-finding was initially confined to a review of eighty of the most "promising demonstration projects", largely sponsored by large Management and Operating contractors or DOE laboratories, already under consideration within DOE's "funding pipeline". Nine of those eighty technologies were endorsed by the working group for "demonstration" to allow "regulators and stakeholders to evaluate whether a technology is worth being considered for actual application, permitting or commercialization". Despite references to "selection" and/or "endorsement" for "demonstration", the activities of the MWWG were actually limited to enhancement of existing demonstrations through the addition of approaches to proactive stakeholder participation, existing regulatory barriers, and barriers to commercialization. (See, Id. at pps. 20-30).

The limitation of MWWG review to technologies within the existing funding pipeline caused much concern among public interest/environmental community representatives/members. They felt that "continued reliance on traditional DOE contractors [might] foster the promotion of traditional technologies.(Id. at 21). Concerns voiced by these members were met with assurances that the limitations were necessary if the MWWG was to "generate immediate and important technical and stakeholder participation results. (Id. at 16.) Additional concern was raised public interest/environmental community representatives when it became clear that a large percentage of the technologies being "endorsed for demonstration" by the MWWG were thermal technologies. These concerns were largely ignored. In fact, no mention of any opposition to thermal technologies by public interest\environmental representatives was noted in the 1993 Annual Report of the MWWG. As feared, the absence of opposition to thermal technologies within the 1993 Report was subsequently used by DOE as justification for its continued emphasis on thermal technologies in the face of continued public opposition.

Members representing the public interest/environmental community also questioned continued DOE requests for MWWG assistance in the development of a "proactive stakeholder process". Everyone agreed that effective stakeholder participation in DOE decision-making is important. However, DOE had already invested monies in the development of a credible and highly successful model in PNL's VOC/Arid ID. Many members felt that efforts in this regard were, therefore, duplicative and a waste of scarce resources. At the same time, participants in the VOC/Arid ID regularly questioned the relationship between PNL's effort and the DOIT process.

Complaints from MWWG members were not limited to the technology selection and enhancement process. Common complaints included the lack of a clear definition of the function of stakeholders within the process, and, for that matter, a total absence of any process by which stakeholders were assured that their input was communicated to the DOIT Committee, and/or response to that input received from that Committee. Serious questions also arose regarding the membership of the MWWG. Rather than seek to ensure a balanced membership, representatives of various interests had been invited to join in a hodgepodge fashion. Differences between public interest organizations and environmental groups were ignored. Additionally, the national, regional, and local nature of various environmental and public interest groups were never considered. Similarly, little or no effort was expended in the recruitment of representatives of Native American Tribes. Finally, DOIT Process Administrators had failed, even when questioned, to consider potential MWWG member conflicts of interest. Thus, members representing Management and Operating contractors or DOE laboratory proponents of technologies could not be excluded from Working Group decisions regarding those technologies.

So serious were stakeholders' concerns that they began to question the value of their continued participation in the process. Ultimately various public interest and environmental group representative/members of the MWWG, as well as other Working Groups, called for a roundtable to discuss stakeholder enhancements at demonstration sites. In response an "Implementation Guidance Roundtable" was convened in March 1994 to address "stakeholder" concerns. However, discussions at this roundtable revealed that the real concerns of Working Group members related to the structure and process DOIT was using to conduct its business rather than the implementation of stakeholder involvement processes at demonstration sites. Accordingly, DOIT agreed to hold a new roundtable to address structural and process concerns of the stakeholders.

In the interim, continual public interest/environmental concerns voiced within the Mixed Waste Working Group precipitated a crisis of sorts. In June, 1994, in response to rising levels of member frustration, the MWWG recommended the preparation of report assessing the concerns and recommendations of stakeholders. Paul Robinson, Research Director for the Southwest Research and Information Center was contracted to prepare the report. Interviews were conducted with eight members, representing tribal, public interest and environmental perspectives, and a report submitted on September 2, 1994. Upon completion, the report was presented to and discussed by the Working Group. In response, the MWWG developed a Management Plan. The Working Group also drafted work plans for its two phased analysis of technology demonstrations -- something the MWWG had never done before. It is noteworthy that unlike Phase I, the Phase II work plan more closely parallels the original objectives set forth within the MOU -- seeking to develop a model solicitation for mixed waste technology intended to identify and address barriers to technology development. (Work Plans for Phase One and Two are Appendices) (Contact the author for a copy of the Appendices)
The process followed by the MWWG was ultimately used a the framework for a Stakeholder Roundtable held September 28-30, 1994. Approximately eighty people attended the Roundtable and developed the following general recommendations, followed by specific recommendations and proposed action deadlines, for improvement of the DOIT process:

Improve the diversity and balance of participation
Clarify purpose, structure, and process of DOIT Committee Initiative;
Seek funding and improve access for a wider range of stakeholders to participate;
Link the initiative more directly to the decision-making process; . Develop a communications and outreach plan;
Develop a strategy to address education and training issues.

(DOIT Stakeholder Roundtable Report, Dec. 5, 1994 at pps. 4-9). (A copy of the Report can be obtained by contacting the author)
Needless to say, as originally implemented the DOIT initiative was not an effective public involvement effort. The DOIT process is not yet considered credible and remains seriously flawed. Much time and effort, which should have been spent addressing barriers to technology development, has instead been required to address problems with the process which could have been avoided.
This is not to say that the DOIT initiative is not a worthy effort and/or is not salvageable. The DOIT Committee apparently heard the message voiced initially within the Mixed Waste Working Group and then even more loudly at the Stakeholder Roundtable. As a result, the DOIT Process Administrators and the DOIT Coordinating Group are seeking to address the issues raised at that Roundtable. The remaining three Work Groups have been tasked with drafting management plans, patterned on that drafted by the MWWG. Moreover, the DOIT Committee itself is attempting to revise its Management Plan to address the concerns voiced at stakeholders. Thus, two years into the process DOIT and its Working Groups may are investing substantial time in an attempt to create a credible stakeholder process for achieving their objectives. As to the success of these efforts, only time will tell.*
What is evident to all concerned is that the key procedural issues which formed the basis of many stakeholder complaints should have been addressed, with the full participation of all stakeholder groups, at the beginning of the process. Moreover, to garner credibility and stakeholder support, working group members should have been: presented with a clear statement of the purpose and goals of the DOIT initiative and of each of its working groups; given ownership of and involved early and often within the process, and should have received frequent feedback from the DOIT Committee and/or the Coordinating Group about the input they provided.
PACIFIC NW LABORATORY'S VOLATILE ORGANIC COMPOUND/ARID LANDS INTEGRATED DEMONSTRATION PROJECT (VOC/ARID ID)
The VOC/Arid ID, in contrast to the DOIT Program, invested considerable time and energy at its inception to develop a coherent program that involved the spectrum of people and organizations who had a stake in the remediation of the Hanford site. The investigation had two phases. In the first phase, PNL identified a small cluster of potential new technologies; used Comprehensive Environmental Response Compensation and Liability Act (CERCLA) regulations to establish initial criteria for acceptability; developed an interactive computer program called ProTech to provide a visual representation of the site to be investigated, and identify the specific site location of carbon tetrachloride contamination and the initial technologies to be

evaluated.
Using this information, PNL and its subcontractors sent out approximately three hundred letters to people who had shown an interest in the Tri-party Agreement (the Agreement governing cleanup at Hanford) in particular and the cleanup at Hanford in general. Follow-up phone calls were then made to secure or verify participation. The staff then sought to interview forty individuals and organizational representatives with some stake in the outcome of remediation at Hanford. Stakeholders interviewed by the staff included public and environmental interest groups, regulatory agencies, Federal state and local governments, Native American tribes, Business, Labor, Education, retired Hanford workers, and DOE site contractors/technology users. ProTech was used by PNL during the interview process and considerably enhanced, for the stakeholders, the initial interviews. Interview results were then incorporated by PNL into a refined ProTech program.
Next, stakeholders were asked to assess PNL's draft criteria for the evaluation of technologies. Input obtained in individual interviews and small focus group meetings, was used by PNL to expand the criteria. In this way, the varied concerns of the many different stakeholders were used to create an expanded matrix for technology evaluation, referred to as Criteria Matrix. Although some significant additions were made to the initial list of criteria, the stakeholder input mainly consisted of refinement of existing criteria. It is important to note that the key program staff from PNL were involved in each of these efforts and were diligent in their efforts to incorporate the concerns and/or suggestions voiced by stakeholders. Once completed, the Criteria Matrix served as the basis for technology profiles used in subsequent meetings with stakeholders. The Matrix was also used to organize conceptual test plans being developed by the principal investigators, designing and testing innovative technologies. As stakeholders began to see their suggestions reflected in the succeeding documents, trust in the process began to develop.
Completion of the Criteria Matrix and the publication of a report entitled "Phase I Involvement for Potential Stakeholders of the VOC-Arid Integrated Demonstration" (December 1992) signaled the end of Phase One and the beginning of Phase Two of the program. Although many different stakeholders participated in Phase One and Phase Two of the program, a consistent but diverse set of stakeholders participated in all of the meetings. The continuity of participation and perspectives by this set of stakeholders enhanced the discussions and expedited the process. In other words, consistent participation by the same stakeholders prevented the need for a return to zero, on the learning curve, at every meeting. Phase Two of VOC/Arid ID began in early 1993 with the preparation of technology profiles and fact sheets for four innovative technologies to remediate VOCs in groundwater: sonic drilling, in-well vapor stripping, membrane separation and in-situ bio-remediation. These profiles, as well as profiles of baseline technologies, were sent to stakeholders. Stakeholders were then brought together in three focus groups, one for regulators, one for public and environmental interest groups and elected officials, and one for principal investigators and other technologists. The purpose of these meetings was application of the Criteria Matrix to the four groundwater remediation technologies slated for demonstration. Focus group summaries were subsequently prepared and provided to participants, as well as other stakeholders. Review of these summaries, and subsequent revisions to the technology profiles and fact sheets, incorporated stakeholder comments. Thus, stakeholders were pleasantly surprised by the responsiveness of the program. Efforts by PNL to incorporate stakeholder input made stakeholders feel that they were an integral part of the process, thereby increasing their trust in the process and support for the technology demonstration.
In early 1994, PNL convened an integrated workshop to bring together the regulators, principal investigators, and stakeholders. The principal investigators and the stakeholders engaged in a day long dialogue concerning the incorporation of the Criteria Matrix into test plans for the proposed technologies.* Stakeholders were then asked to review profiles and fact sheets for three additional technologies: tunable hybrid plasma (THP), passive soil vapor extraction using borehole flux (PSVE), and freeze wall barrier technology. During the summer of 1994, PNL also expanded its outreach efforts and conducted interviews with stakeholders from the other arid DOE sites, including: Sandia and Los Alamos National Laboratories, Rocky Flats, and Idaho National Engineering Laboratory concerning all six of the innovative technologies under investigation at Hanford. As a result, the Criteria Matrix representing data requirements was again expanded and the potential for

replication of the Arid Lands Program increased.
The process has now reached Phase Three, the demonstration phase. Stakeholders have been assured that data requirements set forth within the six test plans address concerns voiced by stakeholders within Phase One and Two. Upon completion, data from those demonstrations is to be provided to the stakeholders for review.
It is important to note that throughout the VOC Arid Program, stakeholders were kept informed, their advice sought and incorporated into the ongoing development of the Criteria Matrix, and public and environmental interest representative afforded full participation with the regulators and principal investigators in the evolution of the program. If PNL had a motto for this program, it must have been "Early and Often". The investment of time and resources from the inception of the program, while slowing down field demonstrations has enhanced the prospects for success of the VOC/Arid ID.

CONCLUSION

As we began to consider submission of this paper to Waste Management '95, the contrasts between the DOIT Program and the VOC Arid ID Program came into sharper focus. While the PNL effort had a clear, understandable design, a well-defined and focused stakeholder participation component, and a realistic scope of investigation, the DOIT initiative has been seriously lacking in all three. Additionally, despite the shared goals of the two processes, there has been no attempt to integrate them. PNL staff have been included as members of the MWWG and/or participants in DOIT activities. Yet, in most instances their input has met with systematic resistance, especially on the part of DOE staff, and the integration of the two processes intentionally thwarted. Instead, reliance for input on public participation has been placed on a process delineated in a report of the Colorado Center of Environmental Management -- a process which has received little, if any, support from the public interest/environmental communities.
The message which we wish to leave you with is this: acceptance and continued public funding of technology development efforts cannot and will not occur without "meaningful" stakeholder involvement process. "Meaningful" stakeholder involvement requires substantive involvement of interested/affected individuals in the very earliest decisions about technology suitability. Stakeholder input must be accurately incorporated into test plans and evaluation criteria. Additionally, stakeholders must be shown how their advice and guidance is actually used at each stage within the process. Although requiring a significant investment of time and resources, "meaningful" stakeholder involvement efforts, such as the VOC Arid ID, will ultimately facilitate rapid acceptance and implementation of appropriate technologies.

28-4

INNOVATIVE ADMINISTRATIVE, TECHNICAL, AND PUBLIC INVOLVEMENT APPROACHES TO ENVIRONMENTAL RESTORATION AT AN INACTIVE LEAD-ZINC MINING AND MILLING COMPLEX NEAR PECOS, NEW MEXICO

Wm. Paul Robinson
Southwest Research and Information Center
P. O. Box 4524,
Albuquerque, NM 87106

ABSTRACT

This paper will summarize innovative regulatory, technical, and public involvement activities associated with the investigation and remediation of lead and zinc ore mining and milling waste sites near Pecos, New Mexico. Resulting from unreclaimed mining operations conducted in the 1920s and 1930s, the site has been prominent during the past decade due to related fish kills in the Pecos River fish kills, state's role as a responsible party, potential for Superfund - CERCLA listing of the site, and state participation in funding of the multi-million dollar restoration effort.
The administrative framework and reclamation technology at the mill and tailings portion of the site, El Molino, is reviewed with an emphasis on potentially transferable innovative methods. The administrative framework responds to a local interest in a "Superfund level of cleanup without the perceived cost and delay problems of Superfund" and includes an administrative order on consent and statement of work which substitute for parallels within the Superfund process. This innovative approach provides a model of state enforcement of Superfund level remediation, if

the completed restoration efforts are fully effective and timely. The administrative process includes strong stakeholder involvement initiatives such as technical assistance and community relations contractors and informal technical review meetings to enhance and focus affected community participation. Technology innovations include site characterization techniques such as heavy metal analysis using x-ray fluorescence, and remedial design techniques such as subsurface flow cutoff trenches integrated into a surface flow diversion channel, construction of replacement wetlands, and a lined, multilayer tailings cover system.

INTRODUCTION

Successful environmental restoration of industrial waste disposal sites provides employment and post-restoration land use opportunities, as well as long-term human and ecological risk reduction. Attaining a goal of successful and sustainable environmental restoration requires effective and lasting solutions to the unique complex of administrative and technical problems presented by the individual sites. Environmental professionals seeking to effectively restore waste disposal sites can benefit from an understanding of successful approaches used for other wastes and at other sites in order to broaden the range of proven effective approaches available for consideration at sites of concern. Experience of this type, at restoration projects outside the radioactive waste management arena where innovative technologies and administrative solutions have been demonstrated, is particularly important for radioactive waste managers. Such sites provide excellent examples of effective solutions which are applicable to radioactive waste problem sites. They also offer a much wider set of cases and methods to learn from than the very limited number of completed radioactive waste sites restorations. Since the range of radioactive waste forms, sites and administrative settings is so wide due to the uniqueness of each site, the opportunity to apply experience from one radioactive waste problem to another may be very limited. Conversely, effective approaches from problem sites without a radioactive waste component but facing similar administrative and environmental restoration standards may be directly relevant. A prime source of such transferable restoration technology is the mining sector where large volume, heavy metal-laden wastes present complex, multi-pollutant problems where governmental and owner-operator roles are poorly defined and affected communities are actively involved in the restoration policy and design proceedings. Many mine and mill sites involve resolution of complex regulatory, technology and public involvement concerns in rural areas, often in the western US, but certainly found in other parts of the country and in every region around the globe, which are similar to the maze of decision-making and environmental technology design problems facing radioactive and chemical waste managers.

The environmental restoration process for lead-zinc mine and mill wastes near Pecos, New Mexico offers a wide array of specific examples of effective and innovative technologies and administrative and public involvement approaches potentially transferable to a variety of radioactive, and other large-volume, long-lived, chronic-hazard sites. Particularly relevant waste forms include those with dispersed heavy metal contamination, such as uranium extraction, processing and fabrication sites; low-level, buried and mixed radioactive waste sites; as well as other hard rock mining and milling and mixed metal-organic chemical sites.

BACKGROUND

The spectacularly beautiful Upper Pecos River Valley of northern New Mexico lies 20 miles west of Santa Fe. The valley is the setting for the Village of Pecos, an abandoned Pueblo Indian community now protected at Pecos National Monument, heavily used recreational attractions associated with enjoyment of the world-renowned Pecos Wilderness and other areas in the Sangre de Cristo Mountains within Santa Fe National Forest and the high-quality fishing and camping opportunities along the river. It is also the site of a long inactive mine and mill complex which produced some 2,200,000 tons of lead-zinc ore between 1926 and 1939. The mine site at Terrero (a Spanish term for mine dump) is well known by many of the 3,500 local residents and area visitors. It borders the highway which provides access to the high country of the Pecos Wilderness and is found at the mouth of Willow Creek, a local tributary to the Pecos River. Sixteen miles downstream of the mine site is the 50 acre mill and tailings complex - known locally as "El Molino" - which covers approximately one-half mile along, and with, the streambed of the Alamitos Creek. The southern end of the El Molino site is less than one-half mile from residences in the Village of Pecos and the Village's elementary and high school complex. Since state acquisition

of the surface rights to the mine and mill sites in 1950, portions of the highway, mine and mill wastes have been hauled off-site for use in construction at several nearby state and federally managed campgrounds and a state fish hatchery. This complex of mine and mill sites are titled the "Upper Pecos Site" and are being managed as five units: the Pecos Mine, El Molino, State Recreation Use Areas, State Highway 63, and the Lisboa Springs Fish Hatchery.1 This paper will focus on the El Molino unit, as the unit with the largest volume of waste, the unit closest to a residential community and the unit with the most advance environmental restoration program as of January 1995.

Though active mining ceased before World War II, substantial data is available on the nature of the materials handled at the mine and mill including the mill tailings. The ore body is reported to have been discovered in 1881, but not brought into production until 1927 by American Metals Company of New Mexico, The multi-mineral ore averaged 10.6% zinc, 3.3% lead, 0.5% copper, 2.8 oz./ton silver and 0.1 oz./ton gold, and was processed at a 600 ton per day selective flotation mill until "water problems, labor disputes and bad ground at depth contributed to the mine's shutdown in 1939". Ore was transported to the mill and tailings site, the area of the El Molino unit, via a 12 mile aerial tramway. (2) Following removal of values, mill tailings were discharged into two impoundments behind embankments across Alamitos Canyon. The Canyon is drained by Alamitos Creek, an intermittent stream which flows through the Village of Pecos before reaching the Pecos River and capable of generating substantial seasonal flows from snowmelt and peak precipitation runoff events. A third impoundment was constructed downstream of the other two dams, presumably to contain eroding tailings from the upstream dams, approximately one mile from the confluence of Alamitos Creek and the Pecos River in the Village of Pecos. See Fig. 1 Location Map for orientation.

In the tailings disposed of into the creek downstream of the mill site, concentrations reported for key metals and other contaminants include: 2800 to 10,000 ppm - lead; 150 to 5500 ppm - copper; 130 to 13,000 - ppm zinc; 15 to 20 ppm-silver; and 2.7 ppm - cyanide. (1)

Process chemicals used in the mill include: 1) in the mica circuit - Cresylic Acid - 0.175 lb/ton of ore; 2) in the lead circuit - Lime - 0.574 lb/ton, Potassium pentasol xanthate - 0.161 lb/ton, Zinc Sulfate - 1.395 lb/ton, Cyanide - 0.060 lb/ton; and 3) in the zinc circuit - Lime - 1.848 lb/ton, Copper Sulfate - 0.783 lb/ton, Sodium ethyl xanthate - 0.500 lb/ton, Pine oil- 0.151 lb/ton. (1)

In addition to the characterization of hazardous constituents in the tailings, extensive heavy metal contamination at the sites has been well documented by New Mexico state agency and operator investigations, though a range of specific data gathering activities are on-going. By the end of 1991, the following data had been developed.

Surface water samples from Alamitos Creek showed concentrations of: lead (ranging from <0.01 to 4.1 ppm), cadmium (<0.001 to 0.022 ppm), iron (<0.1 to 67 ppm) and manganese (<0.05 to 1.4 ppm) in excess of New Mexico Water Quality Control Commission (NMWQCC) standards (Pb - 0.05 ppm, Cd -0.01 ppm, Fe - 1.0 ppm, Mn - 0.2 ppm) and United States Environmental Protection Agency (EPA) Maximum Contaminant Levels (MCLs) - (40 CFR 141: Pb - 0.05 ppm, Cd - 0.01 ppm; 40 CFR 143: Fe - 0.3 ppm, Mn - 0.05 ppm).

Filtered ground water samples showed concentrations of sulfate and manganese as well as total dissolved solids (TDS) in excess of NMWQCC standards (SO4 - 600 ppm, Mn - 0.2 ppm and TDS - 1000 ppm) and EPA MCLs (40 CFR 143: SO4 - 250 ppm, Mn - 0.05 ppm, and TDS - 500 ppm).

Soil data showed significant contamination for lead (background 5 -30 ppm, tailings 2800 - 10000 ppm, downstream of tailings - 1400 ppm), zinc (background 30 - 60 ppm, tailings 190 - 13000 ppm, downstream - 350 ppm) copper (background 9 - 20 ppm, tailings 150 - 5500 ppm, downstream - 290 ppm) and iron (background 13000 - 17000, tailings 44000 - 51000 ppm, downstream - 31000 ppm). (1)

Though the mine and mill complex were privately operated, the State of New Mexico acquired the sites, except for mineral rights, in 1950. At that time, the New Mexico Game Commission purchased the mine and mill site from Pecos Estates, Inc., the corporation to which the mine operator American Metals of New Mexico had transferred the real property and minerals from the Pecos Mine and El Molino sites in 1939 after shutdown. American Metal Company Limited of New York was the majority shareholder in American Metal Company of New Mexico. The recently formed Cyprus-Amax Minerals

Company is the successor corporation to American Metals Company. (1) In addition to contamination at the state-owned mine and mill sites, other State Game and Fish Commission lands, and land administered the New Mexico State Highway Department and United States Forest Service lands were impacted by the use of mine waste in construction, off site uses which occurred after state surface rights acquisition. At various times since state acquisition, mine waste has been removed from the mine and mill areas for use as construction or maintenance materials within the Pecos River floodplain between the Village and the mine including state highways, building pads, government -owned campsites and the state's Lisboa Springs Fish Hatchery. (3) The Village of Pecos is governed by a mayor -council system typical of small incorporated rural communities in the West, with the Mayor serving as chair of the Village of Pecos Board of Trustees. Local community organizations have been active and visible in the consideration of environmental and natural resources issues in the Valley. La Gente del Rio Pecos, an organization addressing community development and natural resource protection concerns (and a successor to the earlier Upper Pecos Association), includes members active in raising the initial concern about contamination, assuring legislative support for state funding of cleanup, educating residents and reviewing site plans. Southwest Research and Information Center has served as a technical assistance provider for La Gente. A local People for the West chapter, including the store manager at Terrero, remedial contractor employees and other residents has also participated in many site decision-making activities. Individual local residents have verbally indicated that mine and mill waste has been transported to home sites for construction and yardfill use and selected residents report that children play, and they as children played, in the colorful tailings residue along Alamitos Creek. Active local resident use of the tailings area also include extensive shooting practice and off-road vehicle play, leading to potential lead exposure and on-site vandalism. A County Road which crosses the upper end of the tailings impoundment is the only road access to several private homesites upstream of the tailings.

While some hard rock exploration activity had occurred in the upper Pecos watershed in recent years, (4) American Metal and its successor AMAX had long since left the area except for mineral ownership and historical linkage to the Pecos Estates, Inc. When clean up concerns were raised in the 1980s, New Mexico had no "State Superfund" or an inactive hard rock mine reclamation program to define a regulatory framework for site management. Initial studies where funded by federal funds provided to the state through the Environmental Protection Agency to support site characterization and ranking activities pursuant to the federal Superfund legislation and associated program implementation.

Environmental investigations by the New Mexico Environmental Improvement Division, now the New Mexico Environment Department (NMED), at the site began with preliminary site assessments in 1985-6, (1) with NMED and Cyprus-AMAX staff and consultants conducting site characterization and design studies since that time. While Pecos Valley resident concerns about mining and water quality have periodically been raised during the 1980s, significant public involvement in the Pecos site contamination and remediation date from the Spring of 1991. In March of that year, spring snowmelt carried contaminants into the Pecos River, killing 90,000 fish. Two campsites where mine waste was used in construction were closed due to contamination and the drop in the number of Pecos area visitors dropped off significantly, hurting the local economy. Though state studies to develop contaminant distribution and hazardous ranking data were available to the public and AMAX unveiled a "remediation plan" in May 1991, no administrative framework had been adopted to allocate financial responsibility and define clean up standards at that time. (5)

INNOVATIONS IN THE REGULATORY AND ADMINISTRATIVE FRAMEWORK FOR SITE RESTORATION

Since that time, major hurdles in site administration, restoration standards setting and remedial design and construction have been crossed, and at a relatively fast pace. Less than five years have passed between significant public recognition of to the installation of an effective, at least in the short to medium range, pollution control and source containment system at El Molino. While different positions continue to be expressed as to the long-term adequacy of the remedy selected, and currently being implemented; many of the public policy steps, in terms of specific administrative and public participation measures, provide a use set of program elements for consideration at other environmental restoration site. Including sites like the Pecos complex, which at one time, appeared to have no clear administrative,

funding or design solution.
Following the fish kill in March 1991, a public meeting was convened in Pecos on May 22. In an innovative effort to work cooperatively with community interests, the meeting was convened not just by government officials but actively in conjunction with the most visible local non-governmental community-based organization, the Upper Pecos Association. Concerns raised at that time were well documented and continue to be reflected in site restoration activities. Citizen concerns included potential impacts on ground and surface water quality, active interest in prompt clean up, the need to reclaim sites for aesthetic and recreational uses, lead clean up standards and processes, downstream impacts, natural resource damage fishery impacts and use of local contractors. Parallel to the citizen concern for prompt clean up, both state officials and AMAX representatives expressed a perception that the area could be cleaned up more quickly, economically and correctly if EPA could be prevented from including the site on its Superfund (National Priority) List. (5) This "threat of Superfund" served as a common point of concern for the parties involved in the development of an "Administrative Order on Consent (AOC)" which defined the administrative and financial responsibility of the site owners and their successors, which include both the State of New Mexico and Cyprus-Amax (through its Amax Resource Conservation Company unit). The AOC was signed on December 2, 1992 by three representatives of the State of New Mexico - NMED, NM Game and Fish Department, and NM State Highway Department -each signed, as well as AMAX. (6)
The Pecos Administrative Order on Consent (7) has proven to be an effective and innovative approach to inactive waste site remediation decision-making in several critical ways. Firstly, it created an administrative framework for remediation and inter-agency communication where none had existed in state law; a framework within which governmental and private organizations agreed to share responsibility (without any party acknowledging their role in creation of the problem as stated in many "settlement" type agreements). Secondly, it contributed to the impressively strong and diverse support for appropriation of the $5,000,000 by the New Mexico Legislature, for the states on-fifth share of the estimated cleanup cost. Thirdly, the AOC has also been recognized outside New Mexico, where it has served as a working model in Idaho at the Triumph Mine site - also an inactive mine waste site with both state government and private participants and a common interest in avoiding Superfund Listing - where it has been a valuable example used in restoration decision-making by the responsible parties and local residents. (8)
The AOC, with its two attachments - a "Cost Allocation Agreement" and "Statement of Work" - establishes a site specific remediation program which is designed to provide a functional parallel to Superfund with respect to clean up criteria, remediation funding, timely performance and public involvement. The AOC and attachments restate directly and by reference the full range of Superfund criteria and criteria from other applicable state and federal requirements to be attained by the parties . Thus the AOC serves as a jointly-agreed upon demonstration to state and federal regulators that the remediation process will be at least as effective as a Superfund program, since all important Superfund milestones are incorporated in the AOC. This restatement of Superfund criteria allowed the responsible parties to provide EPA an enforceable foundation for successful site remediation without final Superfund listing, as long as substantial progress towards Superfund-level goals is maintained. An important benchmark for the responsible parties in their effort to accomplish reclamation outside the Superfund process was a Memorandum of Understanding between EPA and NMED which describes the cooperative roles of the agencies in the oversight and enforcement of response activities at the Terrero Mine Site. This cooperative role provides for implementation of the restoration program under the AOC, with EPA oversight to assure that site restoration is as effective as it would have been were Superfund, and other relevant federal laws, applied. (9)
Innovative elements in the Administrative Order on Consent include:

A Cost Allocation Agreement which establishes a commitment to fund the remediation with a cost sharing ratio of 80% Amax and 20% State funds, if the State of New Mexico appropriates it share of the funds through its legislative allocations. This condition was an effective incentive for New Mexico legislators to make a $5,000,000 special appropriation in 1993.

A Statement of Work (10) which provides for implementation of a schedule of itemized milestones including of health and environmental risk assessments, community relation plans, remedial investigations, feasibility studies, natural

resource damage assessments, long-term operation and maintenance plans and other performance objectives "in accordance with CERCLA and the National Contingency Plan (NCP) and shall meet the requirements and goals of a CERCLA RI/FS and RD/RA, ... Community Relations Plan consistent with the NCP", and technical assistance grants including reference to EPA guidance documents .

A set of numerical Applicable or Relevant and Appropriate Requirements (ARARs) to guide investigations and remedial design and demonstrate Superfund level remediation as well as compliance with other state and federal requirements;

Establishment of a document repository for all project materials in Santa Fe and Pecos;

Requirements for Site Health and Safety and Quality Assurance Plans, to meet federal standards for all site workers and data gathering activities;

A basis for selection of long-term remedial actions which demonstrate (among other criteria): long-term effectiveness and permanence; compliance with applicable public health and environmental standards; cost-effectiveness and an ability to be implemented; reduction of toxicity, mobility, and volume, and community acceptance.

A schedule, in the SOW, which outlines a timetable for development and implementation of Decision Documents for each of the five operable units including preparatory studies leading up to the selection of remedial action in the Decision Documents (DD).

A Dispute Resolution Process for the AOC parties to provide a mechanism for addressing disagreements without abandoning the overall framework.

Limitations in the AOC are also apparent, limitations which have partially undercut the achievement of timely and effective remediation. These include: 1) a lack of an explicit role in decision-making for affected community residents and organizations, interests who have continued to be active in the restoration process since the initial recognition of the problem and identification of issues to address during reclamation; 2) a lack of clarity in the roles and funding for the state agencies, which include both regulatory roles in the Environment Department, and "site owner" roles for both the in the Game and Fish and the Highway Departments; and 3) a lack of a clearly defined role for the state Office of the Natural Resource Trustee, an organization which had no operating experience prior to the AOC and which was lead by an individual with multiple roles in the AOC (the State Natural Resource Trustee was also the Chair of the state Game and Fish Commission).

INNOVATIVE PROCEDURAL AND DESIGN ELEMENTS IN THE FINAL DECISION DOCUMENT AND REMEDIAL DESIGN FOR THE EL MOLINO SITE

The transition from the need to reclaim a site to actual reclamation on the ground can be so problematic that simple attainment of successful progress toward overall reclamation goals is often the best measure of whether innovative actions taken are effective. Using this criteria, the progress to date at the El Molino site demonstrates broadly successful application of innovative environmental technology, though initially anticipated schedule dates have often proven to be unrealistic. The sequence of activities from the AOC stage through to the development and implementation of the site specific El Molino Decision Document provides extremely useful experience for interests attempting to identify successful cases of applied reclamation. These activities at El Molino are all the more notable in light of the limitations in the AOC that could have made El Molino reclamation particularly difficult. First off, El Molino became the testing ground for the AOC as the milestones set out in the SOW for the El Molino Site resulted in that site being the first site to be addressed by a remedial action Decision Document (DD). Second, El Molino initially was not recognized to be as major contamination and remedial design problem as its location and size merited, due to the press and responsible party focus on recreational and fishery impacts in the Pecos River near the Pecos Mine site.

These concerns led to public concerns about the timing and implementation of the DD, surfaced with the distribution of an original DD in April 1993. This interim Decision Document (11) identified a selected remedial design with conditions, presented updated contamination data a detailed set of Applicable or Relevant and Appropriate Requirements (ARARs), and a set of Statutory Determinations which concluded that "actual or threatened releases of contaminants and hazardous substances from this site, if not addressed by implementing the response action selected in this [DD], may present an imminent and substantial endangerment to public health, welfare or the environment" and that "community and state acceptance

is favorable to this remedy in comparison to other alternatives presented to the public."
The interim DD was responded to very strongly by La Gente del Rio Pecos, which asserted that the development of the document had been a very closed process limited to AOC parties with no effective opportunity for public comment, along the lines of the public meeting, workshops and newsletter which typify Superfund community involvement efforts when NCP guidance found in the AOC is followed. No public meetings had been scheduled prior the issuance of this "first final" DD. La Gente also raised a substantial array of procedural and design concerns with NMED including the failure of NMED to provide any basis for the conclusions that either the statutory requirements or community involvement requirements in the AOC and SOW had been meet. (12) The AOC included, directly and by reference, clear requirements for public meetings and a contractor-based community relations plan, including direct reference to NCP guidance, before issuance of a final DD. These were critical concerns for the residents who face the site-based risks daily and yet are provided no role in the AOC process other than through comment period opportunities and the (still anticipated) community relations plan.
NMED Secretary Judith Espinosa and staff responded positively to these concerns. They rapidly agree to meet with La Gente representatives and responded to the comments by agreeing to hold a public meeting in Pecos and extend a comment period after the meeting to allow additional written comments prior to the publication of a Final DD. This meeting of June 15, 1993 was advertized with bilingual flyers in local mailbox and hosted by the Village of Pecos attracted almost 100 attendees. The public meeting and extended comment period provided by NMED were important results of community-based stakeholder involvement in the reclamation process. The on-going benefits of these processes included heightened local community and local government involvement in the process, in addition to continued La Gente involvement, and significant improvement in the final DD issued in September 1993. (1) Village of Pecos involvement has been dramatically enhanced as a result of increased elected official involvement and the technical efforts of Village's technical assistance contractor on the Upper Pecos Site, New Mexico Engineering Research Institute. The Village was allocated $50,000 by the 1993 New Mexico Legislature for the technical assistance contractor, to provide a rough parallel to the Superfund Technical Assistance Grant (TAG) available for up to $50,000. In a twist from the Superfund framework though, the New Mexico Legislature provided the funds to a unit of local government, not a independent non-profit corporation, in sharp contrast to the Superfund framework which does not allow TAGs for municipalities and requires an independent non-profit as a grant recipient. Improvements in the September 5, 1993 Final DD were incorporated into the statutory determination and design condition portions and are reflected in the summary of the Final DD below.
The Final DD reviewed site contamination data and summarized six alternatives remedial designs, selected a preferred alternative and identified 19 additional items or conditions related to the NMED approval of the preferred alternative. The preferred alternative - called "Flood Conveyance Through a Channel"- was selected over the other five titled "No Action", Institutional Controls", Flood Conveyance Through a Pipe with Flood Attenuation", Flood Attenuation with Multiple Upstream Dams", and "Reprocessing of Tailings Either On- or Off-site". Design elements in the selected alternative, including the additional items include:
Consolidate all tailings and contaminated soil with lead concentrations above the health based risk level (set at 500 parts per million) into [the two largest] tailings ponds;
Convey surface water through tailings ponds 1 and 2 via a lined, stable channel designed for a 6-hour 100-year storm event;
Reinforce side drainages leading into the main channel to minimize erosion and design for a 10-year 24-hour storm and a safety factor of 1.5 for drainage bottoms and banks;
Cap tailings ponds to minimize erosion (to less than 1/16" per year) and ponding and revegetate with native plant species;
Stabilize dams to meet state embankment engineering standards;
Regrade and revegetate with native species all borrow areas;
Replacement of wetlands lost during remediation at an appropriate location within Alamitos Canyon;

Install piezometers in tailings ponds 1 and 2 and monitor along with existing and new ground water monitoring wells until compliance with ARARs for eight consecutive quarterly samples is approved by NMED;

Evaluate potential contamination of downstream water courses and agricultural fields near the site, including soil and tissue sampled, as part of Health and Ecological Risk Assessment, required before final approval of the remedial action;

Develop, install and maintain measures to protect newly reclaimed areas and prevent vandalism;

Conduct computer modelling of ground water flow and contaminant transport, develop contingency plans to protect community and private wells, and replace two existing private wells;

Develop and implement programs to assess effectiveness of the remedy including but not limited to assessment of moisture and metals movement from the tailings ponds, revegetation success, channel system and liner stability, tailings cap stability, wetlands replacement success, and surface and ground water quality;

Develop a long-term operation and maintenance plan to be approved by NMED upon attainment of ARARs and Remedial Action Criteria in the SOW, to be subject to review every five years.

INNOVATIONS IN SITE CHARACTERIZATION, REMEDIAL DESIGN AND CONSTRUCTION AT THE EL MOLINO SITE.

Site remedial design and construction activities have been conducted by Cyprus-Amax and their primary contractors on the project, Kenneth R. Paulsen Consulting, Woodward-Clyde Consultants and Daniel B. Stephens and Associates. All project costs are subject to the 80% Cyprus-Amax-20% New Mexico cost sharing arrangement in the CAA, resulting in Cyprus-Amax's consultants being subject, in part, to acceptance of their work products by the state as a condition of payment. This role of private contractors receiving payment from public funds appears to have enhanced the responsiveness of project contractors, as their staffs have continually recognized their responsibility to both their private contractor and the public, who through the state are also paying the consultant's bills. A full range of tailings, soil, water, and air quality sampling and analysis activities have been conducted at the site and documented in NMED-maintained document repositories in Pecos and Santa Fe.

Two innovative aspects of the site characterization efforts are notable, though highly accurate and reliable data gathering and analysis methods have been used throughout the project. A first key innovation in the process has been the early acceptance by the responsible parties of a Quality Assurance Project Plan (QAPP); a plan developed pursuant to the AOC and in conformity with EPA guidance documents identified in the SOW. The QAPP was prepared by Cyprus-Amax consultants and approved by NMED shortly after completion of the AOC. The early acceptance of this Quality Assurance Plan had several important results. The acceptance of the QAPP demonstrated that the parties could reach agreement on technical matters in addition to the administrative framework and allowed the cooperative approach to site characterization and reclamation to be further reinforced. Acceptance of the QAPP insured that all parties, including AOC parties and the public, would be able to rely on a common data base with results including reduced costs as redundant "competing data costs" were largely eliminated, allowing technical reviewers to focus on what-the-data-means, rather than was-the-data-accurate questions.

A second innovation has been the use of x-ray fluorescence (XRF) techniques for soil and tailings characterization for heavy metals, particularly lead. Public concerns for lead contamination and clean have lead to a need for the accurate mapping of the distribution of lead contamination and associated considerations of lead cleanup levels and clean up costs. The XRF method has been used to characterize lead levels at the Terrero Mine and El Molino Units in much greater detail and much faster than conventional techniques, such as off-site laboratory based inductively coupled plasma (ICP) and atomic absorption spectrometry (AAS) methods, due to the relatively low cost per sample, without sacrificing accuracy. NMED research shows a good correlation (correlation coefficients for lead and zinc comparative analyses were 0.70 and 0.74, respectively) between ICP and XRF data at the Terrero mine. (13) On-site chemical analysis using portable instrumentation, with essential real time data production allows up to 100 samples or more to be analyzed at the El Molino site. (14) Additional advantages to XRF include improved worker safety resulting from elimination of acid digestion steps in conventional analysis and the nondestructive nature of the method, which leaves samples and standards available

for future investigation. (15) XRF data has been used to develop 200 ppm, 500 ppm, and 1200 ppm contours for lead concentrations in soil at the El Molino site relying on several hundred individual data points.
The remedial design characterized in the Final DD has evolved in several important and innovative ways as a result of restoration designers effectively incorporating both new information gathered during investigation as well as construction and technology improvements identified though public comment and agency review. Key motivations for these design enhancements are technical comments provided by the Village of Pecos, La Gente del Rio Pecos and their technical assistance providers. Both parties have raised concerns about the long-term, the hundreds to thousands of year time, durability of the existing diversion channel, and ground water flow under and through the tailings as placed. (16) While this site is designed to pass surface water generated by a nominal 100-year event, substantial concern among residents has resulted in the Village of Pecos having passed a resolution recommending removal of the tailings to a "out of creek" site for permanent disposal, and consideration of the existing diversion mechanism as an interim, multi-year but not-multi-decade solution. (17) La Gente concerns have also included the need to insure that long-overdue health and ecological studies and community relations and long-term operation and maintenance plans are completed before, rather than after, the final remedial design is approved. These concerns for the reliability of the diversion channel concept was heightened when a leak of acid water from the tailings into the diversion channel shortly following liner installation was observed by Village and legislative committee representatives in the fall of 1994. (18)
These potentially volatile differences have been address substantively in an innovative approach to intergroup communication. The AOC and the public participants have maintained regularly, approximately monthly, working meeting with an informal yet technical detailed discussion focus using a consensus agenda and supporting technical working documents tone. These meetings have been held in response to La Gente and the Village Mayor's concerns expressed at Village of Pecos Board of Trustees meetings; initially at the invitation of Cyprus-Amax at the site, and most recently in Santa Fe hosted by NMED. Specific design elements of note include upgrade of the diversion channel liner and cutoff trench system, replacement wetlands plans and the long-term performance of the tailings cap.
A major environmental protection milestone achieved at El Molino is the control stabilization and control of off-site movement of tailings by embankment repair and construction of a 40-mil PVC and rip-rap lined diversion channel to carry surface water above the tailings. Engineered concrete cutoff trenches, footed into excavated bedrock according to the installers, complement the system by providing a barrier to subsurface flow in the Alamitos Creek alluvium and serve as a anchor for segment of the welded PVC liner. However the liner leaked within months of installation. (18) Cyprus-Amax and the state's response has been three- fold: 1) raise the channel base above the water table within the tailings (considered to the source of the leak); 2) maintain design flow volume by widening the channel; and 3) installing a horizontal piezometer and additional vertical piezometers at the cutoff trench site where the leak occurred. Benefits of this design modification are considered to be: reduced risk of leakage by locating the channel and liner above the local water level; availability of a drainage mechanism to prevent leakage even if the water table in the tailings again rises; and a more comprehensive groundwater monitoring network for the overall design.
Wetlands replacement is an integral part of the El Molino DD and is considered an important part of the plan by all parties. While debate continued on the acreage of wetlands replacement needed, initial construction of a wetlands has begun at the south end of the site, were previously deposited tailings have already been removed. Initial Cyprus-Amax plans includes a cattail dominated wetlands system utilizing seepage from the lower tailings dam site as a water source. Recent informal working group discussions has focused on the need for wetlands restoration to replace pre-existing subsurface flow-, rather than surface flow-, dominated wetlands as originally found at the site and the recognition of the uncertain volume and quality of the tailings dam seepage flow. The working group has also used pre-reclamation plant species list to establish revegetate planning and survival criteria. Design criteria and performance specifications for the replacement wetlands are currently being developed. (19)
The tailings cap has also been the subject of substantial working group discussion.

The original proposal of a 15 inch cap of borrow soil, with agricultural limestone and a bactericide below and revegetation by shallow-rooting plants was determined to be "inadequate, ... at the least, an additional layer must be added that will act as a barrier for water, plant roots systems and burrowing animals". (20) In response Cyprus-Amax proposed, in January 1995, a typical cap section which added a 30-mil PVC liner overlaid by a geoweb drainage mat with a fabric cover below the 15 inch soil cap. Public and regulatory agency review of this proposal were in process as this paper was prepared. While the design modification responds to agency and public concern for more effective barriers layers, documentation of the relative permanence and long-term operation and maintenance aspects of the design have yet to be distributed.

As a final element in the set of effective innovations at El Molino, construction activity at the site has relied heavily on local, meaning Pecos-area, construction contractors and heavy equipment operators. This reliance on a local workforce, can be considered innovative, as it responds to a strong community-based concern and has not been mandated by project decision documents.

CONCLUSION

This overview identifies a wide array of innovative approaches to environmental restoration currently being applied at a complex heavy-metal contaminated waste site. This "effectiveness-based-on-experience" measure of success provides a potentially more valuable assessment of specific innovations than, determinations of technical merit isolated from real world application. This transfer from proven model to full-scale application is so extremely difficult because site specific conditions, rather predetermined and controllable design conditions, usually dominate environmental restoration decision-making. As a result, the identification of effective innovations which are transferable among environmental restoration projects requires a clear understanding of the administrative, public policy and technical aspects for both the innovative demonstration setting and the potential transfer site.

Few if any sites are amenable to single step, "magic bullet" type of restoration decision-making and environmental restoration. Recognizing that full long-term restoration is accomplished in a step-by-step way allows site managers and technicians to focus on innovation designed to achieve the sequence of incremental milestones necessary to achieve site-wide goals. This summary of innovative aspects of the Upper Pecos Site, El Molino Unit demonstrates how well-prepared site specific solutions can lead to substantial environmental restoration progress on a broad front by carefully tailoring the application of design innovation to the full range of site concerns. The creative solutions at the Pecos site, offer a full range of innovative concepts and designs for resolution of site-specific waste management dilemmas, including radioactive waste sites, in many places.

The author wishes to acknowledge the many participants in the El Molino cleanup process. This includes Cyprus-Amax and their consultants, the State of New Mexico representatives, Village Trustees and their consultants, and in particular, La Gente del Rio Pecos and the residents of Pecos, who will depend on the environmental restoration of the El Molino site for the foreseeable future.

TECHNOLOGY CERTIFICATION AND TECHNOLOGY ACCEPTANCE: PROMOTING INTERSTATE COOPERATION AND MARKET DEVELOPMENT FOR INNOVATIVE TECHNOLOGIES

Bradley R. Brockbank
Senior Project Manager
Denver Projects Office
Pacific Northwest Laboratory

ABSTRACT

In the past two years, public and private efforts to promote development and deployment of innovative environmental technologies have shifted from the analysis of barriers to the implementation of a variety of initiatives aimed at surmounting those barriers. Particular attention has been directed at 1) streamlining fragmented technology acceptance processes within and among states, and 2) alleviating disincentives, created by inadequate or unverified technology cost and performance data, for users and regulators to choose innovative technologies. Market fragmentation currently imposes significant cost burdens on technology developers and inhibits the investment of private capital in environmental technology companies. Among the responses to these problems are state and federal technology certification/validation programs, efforts to standardize cost/performance data reporting, and initiatives aimed at promoting interstate cooperation in technology testing and evaluation. This paper reviews the current status of these initiatives, identifies critical challenges to their success, and recommends strategies for addressing those challenges.

Introduction

Public and private efforts to promote the development, deployment, and commercialization of innovative environmental technologies have accelerated in the past two years. During this recent period, the focus of federal, regional, and state

activities -- as well as the involvement of the private sector -- has shifted from the analysis of barriers to the selection of innovative technologies to the development and implementation of initiatives aimed at surmounting those barriers. Other published documents have catalogued and analyzed these barriers in some detail; that is not the focus of this paper*. Rather, this paper describes the status of several recent initiatives at the federal, regional, and state levels which attempt to address two of the most critical barriers identified by this earlier research. Specifically, these initiatives focus on:

streamlining fragmented technology acceptance processes within and among states; and

alleviating disincentives, created by inadequate or unverified technology cost and performance data, for technology users (e.g., engineering consulting firms, remedial project managers) and regulators to choose innovative technologies.

Fragmented technology acceptance processes within and among states, created by varying regulatory and procedural requirements as well as by differences in the values, interests, and influences of local community stakeholders, have the effect of fragmenting markets for environmental technologies. Markets are also difficult to assess and penetrate because acceptance of a technology for full-scale deployment depends upon the availability of credible technology cost and performance data, which is often insufficient in the eyes of users and regulators who are not generally rewarded for taking risks with new technologies.

Historically, technology vendors and developers seeking commercial acceptance of their technologies have been forced to adopt a strategy of conducting repeated treatability studies and technology demonstrations in multiple jurisdictions or markets. Eventually, sufficient experience with the technology is accumulated in enough separate locations that the technology becomes more readily accepted by users and regulators. This appears to have been the pattern with technologies such as soil vapor extraction and certain bioremediation techniques, which are now in such widespread use that the term "innovative" may no longer be entirely appropriate to describe them.

However, the time and cost burdens required by this approach have been identified by technology developers, especially small companies, as a major obstacle to innovation and a source of often unbearable financial strain on commercialization efforts*. Likewise, venture capitalists have indicated that the fragmentation of markets created by multiple state approval requirements and the uncertainties such repetitive demonstrations create for estimating return on investment significantly inhibits capital investment in environmental technology companies, further threatening small companies' financial viability*.

RESPONSES TO THE PROBLEM

Recent efforts at the federal, regional, and state levels to address these problems are of three types:

state and federal government certification or verification/validation programs, aimed at providing credible cost or performance information that users and regulators in multiple jurisdictions can use to make more certain judgments about the application of innovative technologies;

interstate regulatory cooperation initiatives ranging from multi-state involvement in individual technology demonstrations to more ambitious regional and national efforts to streamline permitting for innovative environmental technologies; and

federal and regional initiatives aimed at standardizing cost and performance data reporting protocols.

Programs and initiatives in these three areas are described below.

Certification and Verification/Validation Programs

While the U.S. EPA has conducted focused verification programs in a few select technology areas for several years (e.g., the SITE program), the agency has recently embarked on an ambitious new initiative -- EnTICE -- to extend validation of cost and performance to environmental technologies in more than a dozen technology categories. Beginning with a few pilot efforts, EnTICE will develop standardized testing protocols with the assistance of stakeholder advisory groups. Those protocols will then be used by a variety of selected verification entities (e.g., universities, federal labs, private testing firms) to verify the cost and performance of interested vendors' technologies.

In a related initiative, EPA's Environmental Monitoring Systems Laboratory has joined in a partnership with the Department of Defense, the Department of Energy,

the Department of Commerce and the Small Business Administration to form the Consortium for Site Characterization Technology. The agencies will collaborate on field demonstrations and evaluations of site characterization technologies, including a third party verification. One planned project involves DOE's Sandia National Laboratory, which will develop a field demonstration workplan for the U.S. Navy to test its Cone Penetrometer Laser-Induced Fluorescence technology (also known as SCAPS -- Site Characterization and Analysis Penetrometer System) in accordance with EPA guidelines for verifying effectiveness.

At the Department of Defense, the Environmental Security Technology Certification Program was initiated this fiscal year to help get technologies out of the laboratory and into the field with the help of third party validation of cost and performance data generated in demonstrations. The goal is to provide data that DOD users and federal and state regulators can accept so that repeated demonstrations of technologies can be avoided. Next year, the program plans to collaborate with the Department of Energy to test DOE technologies at military sites, with DOD providing the independent assessment and validation.

The State of California last year began a pilot program to certify the performance of hazardous waste technologies. Twelve technologies have been certified to date, based on reviews of existing test data submitted by applicants. The program, which operates on a fee-for-service basis, is partly intended to streamline intra-state regulatory acceptance by providing verified technical data for use by local and regional regulatory jurisdictions within the state that may not have the resources to validate vendor's claims. The local and regional entities could then focus their resources on assessing technologies against local or site-specific acceptance criteria.

Forthcoming regulations will also create a second type of certification -- regulatory certification -- that will streamline regulatory requirements for applicants by qualifying the technology for regulation under one of the less stringent tiers of the state's tiered hazardous waste permitting program.

California also is exploring the possibility of reciprocal arrangements with other states, whereby California's certification could be used by other states in their regulatory decisions and California, in turn, might accept cost and performance data generated under similar certification programs in other states. At this time, California is the only state with such a program. The State of Washington recently authorized the creation of a certification or validation program, in conjunction with Oregon and British Columbia, to promote streamlined permitting among those jurisdictions. In addition, the initiative will explore a linkage to DOE's Hanford site that would provide for technologies certified under the program to receive preferred status in procurements*.

Interstate Regulatory Cooperation Initiatives

The "DOIT" (Develop On-Site Innovative Technologies) initiative, a joint program of four federal agencies and the Western Governors' Association, began in December 1992 to expedite cleanups on western federal facilities and support the commercialization of new environmental technologies. Fourteen sites were chosen in 1994 to test the effects of specific demonstration process enhancements on federally funded technology demonstrations planned for 1994 and 1995. Several of the proposed DOIT demonstration enhancements involve regulators or other stakeholders from other sites in the region in demonstration planning or execution, with the goal of streamlining regulatory acceptance of the technologies in future applications:

Demonstration plans for a low temperature thermal desorption technology at DOE's Rocky Flats site in Colorado were discussed with regulators from five other interested states. Representatives from Kentucky, Ohio, New Mexico, Texas, and California were asked to supply information about regulatory requirements in those states that may be compared against performance measures to be assessed in the demonstration.

For DOIT demonstrations of off-gas treatment technologies at McClellan Air Force Base and the SCAPS technology at Port Hueneme Naval Base in California, CalEPA has invited other sites to participate in the design or review of demonstration plans and results.

In New Mexico, the demonstration of advanced landfill cover designs for mixed wastes at Sandia National Labs will incorporate review and comments from seven states on the demonstration design and acceptance criteria.

Information on bioventing demonstrations at DOD sites across the country will be

compiled by Hill Air Force Base in Utah for use by regulators in multiple states.
In December 1994, western governors charged the DOIT initiative with developing by June 1995 a framework for interstate cooperation on permitting innovative environmental technologies. Governors asked that the framework be operational by June 1996. According to Jim Souby, Executive Director of the Western Governors' Association (WGA), three possible levels of cooperation are being considered:

broader adoption by states of a Permit-By-Rule system, possibly patterned after California's, that would allow technologies meeting certain criteria to be permitted in states more expeditiously;

joint permitting activities, such as those currently being tested in some DOIT demonstrations, where multiple states would participate in a demonstration at a host site; and

cooperation based on common cost and performance protocols that would expedite subsequent state acceptance without active participation by those states in demonstrations themselves*.

Another outgrowth of the DOIT initiative is a proposal by the Western Governors' Association, which DOE has agreed to fund, to hire a regional "circuit rider" to assist western states with innovative technology issues and promote broader regional acceptance.

Elsewhere, the Southern States Energy Board, with DOE and EPA support, has initiated a pilot program with South Carolina and Georgia to streamline the permitting process between the two states on for technologies addressing contamination plumes. The pilot will also investigate the use of data management and integration technologies. If the pilot is successful, SSEB intends to expand the program regionally on a state-by-state basis*.

Finally, in an effort to share the experience of all of the above approaches and to identify additional strategies for states across the U.S., the states of California and Texas, WGA, SSEB, EPA and the Association of State and Territorial Solid Waste Managers conducted an interstate cooperation meeting February 7-8 in Denver. Participants, mostly state and federal agency representatives, discussed their activities and interests in promoting innovative environmental technologies and developed some initial action plans for facilitating interstate cooperation. Some of the specific strategies discussed by the group included:

EPA's Technology Innovation Office will establish a file in their CLU-IN electronic bulletin board for sharing information on technology demonstrations and other issues of interest to the group.

A task force formed by the group will develop summaries of interested states' regulations , standards, policies and other requirements governing the development, demonstration, and application of specific environmental technology types. A list of technical parameters for those technologies will also be developed and reviewed by participants in specific demonstration projects. The information will then be used to develop protocol templates for use in future applications of the technologies.

Another group will compile case studies, if available, on which innovative technologies have reached commercialization, which have not, any why, with recommendations for next steps.

Standardization of Cost and Performance Data Reporting

A number of groups have attempted, in various fora, to develop standardized cost and performance reporting formats for innovative environmental technologies. An effort led by the Western Governors Association last year generated a list of detailed questions to be addressed in technology demonstration reports.

In addition, an ongoing effort focused reporting data on full-scale technology applications by federal agencies is being pursued by the Federal Remediation Technologies Roundtable. The Roundtable issued a document last year describing the format, and representatives of the participating agencies will meet in Atlanta later this year to share examples of reports using the common format.

SOME CHALLENGES COMMON TO NEW INITIATIVES

While all of these related initiatives hold some promise in addressing barriers to innovative technology development, deployment, and commercialization, they also face several common underlying challenges. Research on regional stakeholder involvement in technology demonstrations conducted by Battelle, the Pacific Northwest Laboratory, and Environmental Issues Management, under the Department of Energy's VOCs in Arid Soils Integrated Demonstration Program, has shed new light on these challenges*.

First, no single, pre-defined set of technology acceptance criteria -- whether applied as part of a certification or validation program or utilized operationally as a testing protocol -- will address the full scope of data needs, institutional prerogatives, or implementation issues that decision makers, including communities, use to evaluate technologies, even within focused technology categories. Although some participants in regional discussions have openly wished for formal interstate reciprocity -- meaning acceptance by one state of another state's regulatory permitting decision -- most players in this debate recognize that the most realistic outcome is to identify a core set of data needs that are held in common by technology decision makers in multiple states. Then, perhaps, after a preliminary demonstration at one site successfully captures these core data, more streamlined and less costly demonstrations can be conducted at subsequent sites to address local or site-specific acceptance criteria.

Even so, a second challenge is that the proportion of the total scope of acceptance criteria can be captured in this core data set is uncertain. PNL's research indicates that considerable commonality exists among the general criteria most often raised by stakeholders from site to site; not surprisingly, technical effectiveness and cost factors are almost always mentioned. However, there is some evidence to indicate that greater specificity in the types of technologies being assessed (e.g., in situ bioremediation technologies) generates more specific, idiosyncratic data needs on the part of interested regional stakeholders. A greater focus on single technologies also creates another challenge to broader acceptability: for most stakeholders, acceptance decisions are not focused on single technologies, but on the entire technology system that is required. Thus, the acceptability of soil vapor extraction, for example, will probably be a function not only of the cost and performance of the extraction system, but the associated off-gas treatment technology as well.

A third challenge to technology acceptance is that the relative importance of different acceptance criteria will vary from locale to locale. In some cases, critical "deal-killers" may be criteria idiosyncratic to state- or site-specific concerns and not be captured in a core set of criteria. For example, while the creation of hazardous secondary wastes is an important evaluation criterion for treatment technologies everywhere, this criterion may receive primary consideration at sites, such as Rocky Flats, where storage capacity is a critical problem. This challenge creates a difficult dilemma for initiatives aimed primarily at promoting interstate regulatory cooperation, since many of these idiosyncratic, but "deal-killing" criteria are likely to be a function of public values and preferences not enshrined in regulations or policy.

Thus, the relationship between certification, or validated demonstration of a core set of cost and performance data, and the predictability of commercial deployment -- a key criterion for investors -- is not yet established.

A solution to these challenges may be found in combining a certification program like California's or EPA's with a planned outreach effort involving decision makers (and decision shapers) in targeted markets and designed to identify potential "deal-killers" in specific application settings as well as validate assumptions about the weighting and scope of acceptance criteria. Regulators and other stakeholders influencing technology acceptance may find greater assurance in both the validation provided by a regulatory body and the availability of credible data addressing their site-specific or local concerns.

Another method which could have value in promoting interstate cooperation and market definition is for more states to consider certification or validation programs similar to California's. The unpredictability of technology acceptance that is a major inhibitor to commercial investment could be significantly improved, at least in the short run, to the degree that such programs require states to more explicitly document the criteria that lead to market acceptance in their jurisdictions.

More generally, the growth in interest in this area is generating more information about acceptance criteria that, eventually, may be transformed into more robust assessments of technologies' maturity and commercial potential. That, in turn, will stimulate greater investment in these important technologies, allow users and regulators to tailor demonstrations and applications more appropriately to the capabilities of the technologies, and reduce the risks that make technology decisionmakers reluctant to employ them.

Session 29 -- Rules and Regulations

Germantown, MD 20874
ABSTRACT
DOE's mixed wastes have not been completely characterized, facilities for waste treatment were not built and operated, and few mixed wastes have been disposed. As a result, DOE has upwards of 600,000 cubic meters of mixed waste (HLW, TRU, and LLW) in inventory, with additional quantities of waste expected to be generated by D&D and waste cleanup activities.
The 1984 RCRA amendments require waste to be treated to EPA specifications before being disposed of. Waste treatment requires a permit (issued by a State or by EPA), and regulators can attach a variety of conditions to the permit when it is issued. Some of these conditions are nowhere to be found in regulations, nor are they specifically authorized by law. Rather, regulations, can rely on a general grant of authority to protect public health and the environment.
This broad grant of authority to the regulators, together with the 1992 Federal Facility Compliance Act, gives the States an unprecedented opportunity to plan for mixed waste management. Of course, any plans will have to be reviewed by the Congress, as DOE is not allowed to spend funds that Congress has not appropriated.
HISTORY
For several years after the 1980 RCRA hazardous waste regulations were promulgated, until the 1987 byproduct rule, DOE maintained that its mixed wastes were not subject to State or EPA regulation as hazardous waste. (Until 1984, DOE maintained that all of its wastes were not subject to hazardous waste laws.) A DOE order, since rescinded, required DOE units to obey the substantive standards set forth in the environmental laws, but not comply with administrative provisions (permits, inspections, etc.).
Since 1987, and until 1992, DOE claimed to be subject to both the administrative and substantive provisions of the environmental laws (in other words, DOE facilities apply for permits and allow inspectors on site), but not subject to the sanctions of fines and penalties. After the Supreme Court agreed with DOE on this point, the Federal Facility Compliance Act was written to require DOE (and other federal agencies) to be subject to fines and penalties as well.
One consequence of this history of seeming immunity from RCRA is that mixed wastes were not completely characterized, facilities for waste treatment were not built and operated, and few mixed wastes were disposed of. The emphasis at DOE during this time period was still one of nuclear materials and weapons production. The legacy for those of us in the waste management arena is upwards of 600,000 cubic meters of mixed waste (HLW, TRU, and LLW) in inventory, with additional quantities of waste expected to be generated by D & D and waste cleanup activities.
Now that DOE has this waste, it needs to plan for its management and eventual disposal. WIPP (the Waste Isolation Pilot Plant) was designed and built for safe disposal of transuranic mixed waste. DOE is investigating whether Yucca Mountain is an appropriate site for a repository for DOE and civilian high level waste and spent fuel. The remainder of DOE's mixed waste inventory, the low level mixed waste, also needs a disposal site or sites.
The 1984 RCRA amendments required waste to be treated to EPA specifications before being disposed of. They also required that storage be only for the purpose of accumulating quantities for proper treatment. No longer could hazardous (including mixed) wastes be lawfully stored indefinitely without proper treatment and disposal. Permits are required before anyone treats, stores, or disposes of RCRA hazardous waste, including mixed waste. Permits contain specific conditions for the operation of RCRA permitted units. Some DOE RCRA permits, for example, contain specific prohibitions against importing wastes from other sites.
RECENT COURT DECISIONS

In 1994, the Tenth U.S. Circuit Court of Appeals decided (U.S. v. New Mexico) that states are pretty much free to set whatever permit conditions they desire, so long as they are related to protection of human health and the environment. States are not required to first establish objective standards (by regulation) and then write detailed permit conditions to achieve the objective standards. Rather, a permit condition will be allowed so long as it appears calculated to achieve the goals of the RCRA statute. In this decision, the court followed the 1994 Supreme Court decision in the PUD No. 1 v. Washington Department of Ecology (114 S. Ct. 1900) case that stated criteria "are often expressed in broad, narrative terms, such as "there shall be no discharge of toxic pollutants in toxic amounts.'"

In this specific instance, the LANL incinerator applied for a hazardous waste permit. As permit conditions, the State required LANL to survey hazardous waste for radioactivity, to monitor radioactive emissions, and to shut down the incinerator if radioactive emissions exceed background by more than 10%. Although no New Mexico regulations require such actions, the permit writer felt that these conditions were necessary to protect human health and the environment.

Since neither DOE, nor NRC, nor any other agency has established a lower limit on what can be properly called "radioactive," state agencies (such as New Mexico's Health and Environment Department) can limit hazardous waste management facilities' receipt of mixed waste containing any detectable radioactivity. Rather than states simply regulating the management of hazardous constituents in hazardous waste, and leaving the management of any radioactivity to management under the provisions of the Atomic Energy Act, New Mexico has successfully asserted control of management of radionuclides under authority of its hazardous waste laws.

This decision injects even more uncertainty into RCRA permitting than existed before 1994. Courts are showing increased deference to EPA and state regulators, and allowing delegation to regulatory officials with lower and lower levels of responsibility. No longer will applicants be able to depend on the presence (or absence) of regulatory provisions that establish numerical (or even narrative) standards. Permit writers will be able to add requirements that are nowhere found in regulations, leaving applicants little written guidance as to what will be expected of them, and even less leverage for negotiation of permit conditions.

EPA and the States refer to the so-called "omnibus" provision of RCRA 3005(c)(3), that requires permit writers to include whatever provisions are protective of health and the environment:

Each permit issued under this section shall contain such terms and conditions as the Administrator (or the State) determines necessary to protect human health and the environment.

EPA has recently advised its permit writers and the states to use this authority to implement proposed regulations that have not yet been promulgated. Clearly, this provision affords permit writers much latitude: they are not constrained by promulgated regulations. Nor, according to the Tenth Circuit, must regulations be proposed. Rather, the permit writer need only find some relationship between the permit conditions and protection of human health and the environment.

FEDERAL FACILITY COMPLIANCE ACT

The Site Treatment Plan (STP) process required for DOE mixed waste facilities under the Federal Facility Compliance Act (FFCAct) provides even more State leverage with respect to permits. DOE submits STPs to the states, which can approve, disapprove, or modify the plans. DOE is required to develop treatment capacity according to binding orders to be issued by the States as part of the STP approval process. Since this treatment is regulated by RCRA, permits will be required before construction of the facility. Thus, while it is incumbent on DOE to construct the facility, it is incumbent on the States to issue the required permits.

Since the FFCAct requires facilities to be built and permits to be obtained, States will have a great latitude in determining which facilities to be built and the conditions of operation of the facilities. Both the recent United States v. New Mexico court decision and the FFCAct give great flexibility to the States to determine how wastes are treated. DOE has correspondingly lesser power to determine whether, where, when, and how its mixed wastes will be treated.

This STP process provides an unprecedented opportunity for DOE and the affected states to discuss the management of mixed waste. DOE has proposed treatment plans to the states; the states' responsibility is to now approve, disapprove, or modify those treatment plans. While it is clear that DOE will have to abide by approved or

modified plans, it is less clear what DOE's responsibility will be if a plan is disapproved.
Compliance orders issued by the states must be obeyed by DOE. Clearly, these orders must be limited to what is feasible. DOE should not be expected to comply with an order that, for example, directs it to do something that is impossible. While the authority of the states is great, it is not absolute. Congress will decide whether to appropriate all funds for compliance with state orders. DOE is subject to the same fiscal constraints that other federal agencies are; DOE managers can't obligate DOE to spend money that Congress has not appropriated. It is up to DOE and the states to ensure that the STP process results in a pragmatic approach to managing mixed waste that will result in Congressional appropriation of the funds necessary to implement the plans.

AN OVERVIEW OF THE CORRECTIVE ACTION MANAGEMENT UNIT AND TEMPORARY UNIT REGULATIONS

U.S. Department of Energy*
ABSTRACT
In February 1993, the U.S. Environmental Protection Agency (EPA) promulgated the corrective action management unit (CAMU) and temporary unit (TU) regulations as 40 CFR Part 264, Subpart S. These regulations are intended to foster the selection of protective and cost-effective remedies for the restoration of sites contaminated by hazardous substances, hazardous wastes, and hazardous waste constituents by removing certain regulatory impediments to implementing those remedies, most notably those of the land disposal restrictions (LDRs). This paper provides a brief overview the CAMU and TU regulations.
REGULATORY OVERVIEW
The Resource Conservation and Recovery Act (RCRA), as amended by the Hazardous and Solid Waste Amendments (HSWA), established a broad new mandate for EPA and the States to implement corrective action at hazardous waste treatment, storage, and disposal facilities (TSDFs). RCRA 3004(u) requires that permits issued to such facilities address corrective action for all releases from solid waste management units (SWMUs) at the facility and RCRA 3004(v) established the authority to compel remediation of releases that have migrated beyond a permitted facility's boundary. Under RCRA 3008(h), EPA may issue administrative orders to compel corrective action at interim status facilities. RCRA 7003 provided EPA authority to require corrective action whenever a release of solid or hazardous waste poses an imminent or substantial endangerment to human health or the environment .
On July 27, 1990, EPA published a proposed rule under these authorities to establish 40 CFR Part 264, Subpart S, a comprehensive regulatory framework for implementing RCRA corrective action. The proposal establishes detailed technical requirements and administrative procedures for investigating and responding to releases of hazardous wastes and hazardous waste constituents at RCRA facilities. The proposed Subpart S regulations also contained two provisions, the requirements for establishing CAMUs and TUs, intended to address some of the unusual problems associated with the management of wastes generated during environmental restoration activities. Based on public comments, EPA recognized the need to revise the proposed CAMU and TU regulations and to expedite their promulgation. As a result, EPA revised the regulations and published them as a final rule on February 16, 1993 (see 58 FR 8658).
The proposed Subpart S rule is a significant step toward a comprehensive set of regulations addressing corrective action; however, because EPA has not finalized the bulk of the Subpart S proposed rule (even though it is used as guidance by EPA), 40 CFR 264.100-101 (which essentially codified the statutory provisions) remains the governing regulation. An amendment to 40 CFR 264.101 promulgated in the CAMU and TU rule did, however, create a link between the general requirements of 40 CFR 264.101 and the specific requirements of the CAMU and TU regulations. Thus, it is necessary to make clear that until the balance of the Subpart S proposed rule is promulgated, 40 CFR 264.100-101 and the CAMU and TU regulations together are the regulations

governing corrective action under RCRA 3004(u) and (v), and RCRA 3008(h).
WHAT IS A CORRECTIVE ACTION MANAGEMENT UNIT?
The definition of a CAMU, found at 40 CFR 260.10, is "... an area within a facility that is designated by the Regional Administrator [RA] under Part 264 Subpart S, for the purpose of implementing corrective action requirements under 40 CFR 264.101 and RCRA 3008(h). A CAMU shall only be used for the management of remediation wastes pursuant to implementing such corrective action requirements at the facility." Note that the definition does not explicitly state that a CAMU must involve land-based units (e.g., landfills, land treatment units, surface impoundments, waste piles); this is however implied, in that it is most likely that a CAMU used to manage remediation wastes would be some form of land-based unit.
In some cases, land-based waste management activities within a CAMU that may otherwise be subject to unit-specific standards under 40 CFR Parts 264 or 265 may be incorporated into a CAMU rather than remaining a distinct and separate unit. For example, wastes are often excavated and staged in piles before being transported to a treatment unit. Under the approach outlined by EPA, the area where the wastes are piled would not be considered a separate "waste pile" unit for RCRA purposes. In this case the RA would specify technical standards for that area of the CAMU (e.g., liners, wind dispersion controls, closure requirements) according to the decision criteria in 40 CFR 264.552(c). Similarly, areas of a CAMU could also be used for land-based treatment processes, such as bioremediation systems that involve structures or equipment to maintain optimal treatment conditions.
One significant change between the proposed and final CAMU regulations merits special mention. Under the proposed regulations a non-land-based unit could not be physically located within the boundaries of a CAMU. This requirement was changed in the final regulations. Now a non-land-based unit (e.g., a tank) can be located within the boundaries of a CAMU, but that unit will not actually be a part of the CAMU; it would maintain its separate regulatory identity, and all applicable Subtitle C requirements (e.g., design and operation requirements under 40 CFR 264) continue to apply to that unit and to the wastes managed in that unit. This scenario, where a hazardous waste management unit lies within the boundary of a CAMU but is not a part of the CAMU, poses a significant compliance challenge to facilities operating under such conditions. Clearly, additional waste tracking and segregation practices would be required to ensure compliance with the applicable regulations.
WHAT IS A TEMPORARY UNIT?
Under the final regulations, a TU can only be a tank or container storage unit (so long as the unit does not require permitting under 40 CFR 264 - Subpart X) located at the facility conducting corrective action and which are used solely for the short-term treatment or storage of remediation wastes. A TU has an operational life of up to one year, with a one-year extension available at the RA's discretion. Tus can be located either inside or outside the physical boundaries of a CAMU and such location will not affect the requirements that apply to the TU; however, a TU must be located within the boundary of the facility. This requirement ensures that the regulatory agencies maintain a direct oversight of the unit and that the alternate standards specified for the unit by the RA are appropriate given the context of the site-specific assessment. Because of the narrow scope of the TU definition, Tus are used when there is a need for temporary relief from the compliance requirements of 40 CFR 264 applicable to these types of units. Tus cannot be used for the management of "as-generated wastes," cannot be any other type of unit (e.g., a waste pile, incinerator), are limited to a one-year operational life (with a single one-year extension available at the RA's discretion), and must provide the same degree of protectiveness under the alternative design, operational, or closure requirements as would be achieved by full compliance with all applicable Subtitle C requirements.
WHAT WASTES MAY BE MANAGED IN A CORRECTIVE ACTION MANAGEMENT UNIT OR A TEMPORARY UNIT?
Only remediation wastes can be managed in a CAMU or TU. Remediation wastes are defined at 40 CFR 260.10 as "... all solid and hazardous wastes, and all media (including ground water, surface water, soils and sediments) and debris that contain listed hazardous wastes, or which themselves exhibit a hazardous waste characteristic, that are managed at a facility for the purpose of implementing corrective action requirements under 40 CFR 264.101 and RCRA section 3008(h). For a given facility, remediation wastes may originate only from within the facility

boundary, but may include waste managed in implementing RCRA 3004(v) or RCRA 3008(h) for releases beyond the facility boundary." Wastes generated as part of the site investigations (e.g., drilling muds) are also considered to be remediation wastes. In addition, remediation wastes must have originated from corrective action at that facility, but does include those wastes generated as a result of RCRA 3004(v) or RCRA 3008(h) corrective action activities to address a release that has migrated offsite when the waste is returned directly to the facility for subsequent management. The definition of remediation waste excludes "new" or as-generated wastes (either hazardous or non-hazardous) that are generated from ongoing operations at a facility. In limiting remediation wastes to those that have "originated" from the facility, it should be made clear that this term refers to wastes that originate from remedial activities at the facility, rather than applying to the "as-generated" wastes that created the problem. For example, some facilities may have accepted wastes from offsite, and these wastes have subsequently contributed to contamination problems at the facility. Such waste would be considered remediation wastes for that facility when they are managed in the course of conducting corrective action under 40 CFR 264.101 or RCRA 3008(h).

Notwithstanding the example cited above, if wastes are transported to the facility from an outside source, they would not be considered remediation waste for that facility, regardless of whether those wastes were the result of some type of remedial action conducted at another facility. Similarly, wastes that are excavated, transported to an offsite treatment facility, and returned to the facility are not remediation wastes under these regulations.

The requirement that CAMUs and TUs be used only for the management of remediation wastes is of particular importance. Only wastes that are generated as a result of implementing environmental restoration activities at a facility can be managed within a CAMU or TU. These units cannot be used to manage "as-generated" hazardous wastes; that is, those wastes generated from ongoing production processes or other industrial activities. Further, CAMUs should be limited to the management of wastes that are, or are contaminated by, listed hazardous wastes (i.e., wastes that have "F", "K", "P", or "U" hazardous waste codes). This is because it is these types of wastes that present the greatest challenge when compliance with the full range of the RCRA Subtitle C regulations, most notably the LDR, is required. EPA has suggested that whenever possible, remediation wastes that exhibit only a characteristic of a hazardous waste (which usually do not pose as significant an LDR compliance challenge as do remediation wastes contaminated by listed wastes) and all non-hazardous solid wastes should not be managed in a CAMU, since there are other waste management alternatives that would conserve the capacity in the CAMU.

THE ADVANTAGES OF USING CORRECTIVE ACTION MANAGEMENT UNITS AND TEMPORARY UNITS IN ENVIRONMENTAL RESTORATION ACTIVITIES

There are two advantages to the designation of a CAMU. The first is that remediation wastes generated at a facility and managed in a CAMU (subject to certain restrictions regarding offsite transportation) are not subject to the LDR. This applies to remediation wastes generated during corrective action at any location within the boundary of the facility; that is, remediation wastes may be consolidated from several locations at the facility into a single CAMU. Further, lateral expansion of an existing unit designated as a CAMU, or other activities related to the construction and operation of a new CAMU, are exempted from the minimum technology requirements (MTRs) (e.g., liners, leachate collection systems); however, as a practical matter, these design features may be required by a regulator. The use of TUs during environmental restoration activities allows the RA set less stringent design and operating standards than otherwise required under 40 CFR Part 264 for the temporary operation of tanks or container storage areas used to manage remediation wastes, so long as the alternative standards provide adequate protection of human health and the environment.

In addition, the use of CAMUs may reduce the cost and/or enhance the environmental effectiveness of closure of hazardous waste management units under the provisions of 40 CFR Part 264/265, Subpart G. For example, a unit that would otherwise be capped with the untreated waste left in place could be incorporated into a CAMU, the waste excavated, treated to reduce the toxicity, mobility, or volume of the contaminants, the treatment residues returned to the unit, and the unit capped, all without having to meet the burdensome requirements of the LDR. Another advantage to the use of CAMUs is that remedies selected under the CAMU alternatives would likely be more

acceptable to the communities in the area surrounding the facility relative to those selected that do not include a CAMU, due to reduced reliance on incineration and/or off-site transportation and disposal. This potential for greater acceptance by the surrounding community would be of benefit not only in the context of RCRA corrective action, but extends to the evaluation of remedial actions under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA).

IMPLEMENTATION AUTHORITY

The final CAMU and TU regulations apply to interim status facilities undergoing corrective action under RCRA 3008(h) authority, as well as to permitted facilities conducting corrective action under RCRA 3004(u) and (v). Although the original proposed regulations for CAMUs did not explicitly state that CAMUs could be implemented under RCRA 3008(h) orders, EPA intends that the Subpart S regulations, when promulgated, would be implemented at interim status facilities as well as at permitted facilities. In order to clarify this point the final regulatory definition of a CAMU contains explicit reference to their use under RCRA 3008(h) orders. Further, at the RA's discretion, a CAMU or TU may be used in a response conducted under RCRA 7003 authority (i.e., imminent hazard authority) even if the response is not at a facility subject to 40 CFR Parts 264 or 265. In addition, the CAMU regulations are an applicable or relevant and appropriate requirement (ARAR) at sites being addressed under CERCLA.

The CAMU and TU regulations provide the RA with the authority to designate and approve such units for the purpose of managing remediation waste. While a facility owner or operator may request designating an area as a CAMU, or may request permission to use a TU, the decision rests with the RA but within the context of the RA's authority, there are limits which merit special mention. For example, the RA can, under 40 CFR 264.552(b), designate a "regulated unit" as a CAMU, or include a regulated unit as part of a larger CAMU. This authority does, however, have two important limitations: (1) only closed or closing units could be so designated, and (2) such a designation may only occur if doing so will enhance implementation of an effective, protective, and reliable remedy for the facility. The first limitation excludes operating regulated units, including regulated units continuing to operate under delay of closure provisions (in 40 CFR 264.113 or 40 CFR 265.113), from being eligible for designation as CAMUs because such units will continue to receive and manage "as-generated" wastes.

CONSIDERATIONS FOR DESIGNATING AN AREA AS A CORRECTIVE ACTION MANAGEMENT UNIT

With the exception of the limitations discussed above, 40 CFR 264.552(c) specifies seven decision criteria applicable to CAMUs which form the basis for designating an area as a CAMU. The RA will review the documentation supplied by the owner or operator and consider each of these decision criteria below in designating a CAMU.

Decision Criterion One: Facilitation of Reliable, Effective, Protective, and Cost-Effective Remedies

The first decision criterion [see 40 CFR 264.552(c)(1)] is that the CAMU will facilitate the implementation of a reliable, effective, protective, and cost-effective remedy. Under this criterion, a CAMU is not intended as a mechanism that will undercut the protectiveness of remedies; rather, CAMUs will facilitate the implementation of more reliable, effective, protective, and cost-effective remedies. If an owner/operator cannot provide information to support their claim that designating an area as a CAMU will result in remediation activities with these qualities, then that area will not be designated as a CAMU. In the preamble to the final CAMU regulations, EPA states that evaluation of this CAMU decision criterion will not necessarily require a detailed cost/benefit or other quantitative analyses to support this claim; however, this type of information, as well as other protectiveness, effectiveness, reliability, and cost information, would probably be necessary for the evaluation and should be provided with the submission to the RA.

Decision Criterion Two: Risks During Remediation

The second decision criterion [40 CFR 264.552(c)(2)] specifies that remediation waste management associated with CAMUs cannot create unacceptable risks to human health or the environment from exposure to hazardous wastes or hazardous waste constituents. This provision is intended to ensure that remediation waste management activities are conducted so as to control the short-term risks arising from environmental restoration activities. For example, corrective measures often involve management of large volumes of wastes that could potentially lead to exposure from windblown particulates, air emissions during excavation and transportation, or other

short-term risks. Other considerations include situations where waste characteristics are such that risks to workers are high and special protective measures are required to minimize this risk. Evaluation of this criterion requires that potential short-term risks from remediation activities be carefully examined prior to, and carefully controlled during, implementation of the corrective measure. As with the first criterion, although the regulations do not require a quantitative risk assessment, one probably will be necessary for the evaluation.

Decision Criterion Three: Uncontaminated Areas

The third decision criterion [40 CFR 264.552(c)(3)] requires the RA ensure that uncontaminated land will be included within a CAMU only if remediation waste management at that area will be more protective than at already contaminated areas of the facility. Although it would generally be inadvisable to establish a CAMU in an area that was not contaminated, it will not always be possible to avoid incorporating uncontaminated areas into the CAMU. For example, small uncontaminated areas often exist within an area broadly contaminated by releases of hazardous wastes or hazardous waste constituents, and to simplify the delineation of the areal extent of the CAMU, these uncontaminated areas would be included in the CAMU. Another case is that it may be appropriate to include small portions of uncontaminated land within a CAMU when the remediation activity cannot be conducted on or within the contaminated area itself. For example, it might be necessary to include in a CAMU for a surface impoundment where wastes are being excavated, a small parcel of uncontaminated land adjacent to the impoundment where excavation equipment can be located. In those cases where uncontaminated land is included in a CAMU, the RA will generally include in the permit or order conditions requiring the owner or operator prevent contaminating the uncontaminated parcel during the remediation activities. As with the first two criteria, while the regulations do not require formal risk assessments or other quantitative analyses be performed, such analyses are likely to be necessary in order to demonstrate compliance with this standard.

Decision Criterion Four: Minimizing Future Releases

The fourth decision criterion [40 CFR 264.552(c)(4)] specifies that areas within a CAMU where wastes will remain in place after closure of the CAMU are to be managed and contained so as to minimize future releases, to the extent practicable. This decision criterion closely parallels the closure provision for CAMUs, and is intended to make clear that the RA must consider at the time of CAMU designation whether long-term reliability and effectiveness of the remedy will be ensured through the implementation of a CAMU, particularly when it is necessary to leave wastes in place. Any CAMU recommendation by the owner or operator or designation by the RA must consider, as a primary objective, the long-term (i.e., post-closure) reliability and effectiveness of CAMU-related remediation actions.

Decision Criterion Five: Timing

The fifth decision criterion [40 CFR 264.552(c)(5)] specifies that the CAMU will expedite the timing of remedy implementation, when appropriate and practicable. The use of CAMUs is encouraged when doing so will eliminate unnecessary delays and will encourage more rapid implementation of corrective measures. However, it should be understood that CAMUs may not always result in a more rapid implementation of the corrective measure, or in complete remediation of a unit. By allowing for onsite waste management and encouraging the use of innovative technologies, the resulting corrective measures selected by the regulatory agency may take longer to complete than other options. For example, excavating all wastes and transporting them to an offsite commercial treatment or disposal facility can be accomplished quickly, but optimization of an onsite bioremediation system can take considerably longer, particularly if the system has not yet been used for a full-scale operation. Thus, as provided in the final regulations, this decision criterion only requires that a CAMU expedite remediation of the unit only when it is appropriate and practicable, in consideration of the technological limitations of the selected treatment option and other remedial objectives for the facility.

Decision Criterion Six: Enhancing Long-term Effectiveness

The sixth decision criterion [40 CFR 264.552(c)(6)] requires the use of treatment technologies to enhance the long-term effectiveness of the corrective measure by reducing the toxicity, mobility, or volume of wastes that will remain in place after closure of the CAMU. Long-term reliability and protectiveness is directly tied to the effective treatment of wastes that pose a potential for a future release. This

criterion does not preclude consideration of alternatives that do not employ treatment, as long as they are capable of ensuring long term effectiveness. As a general rule, however, treatment provides greater long term effectiveness than containment, but in certain circumstances containment may be sufficiently effective. In making this evaluation, there is no preference between toxicity reduction, mobility reduction, or volume reduction.

Decision Criterion Seven: Minimizing Land Areas Where Wastes Will Remain in Place

The seventh decision criterion [40 CFR 264.552(c)(7)] requires that the designation of a CAMU minimize the land area where wastes will remain in place after closure, to the extent practicable. CAMUs, by their very nature, promote consolidation of remediation wastes into smaller, discrete areas of the facility suitable as long-term repositories for the wastes. Such units can be effectively managed and monitored over the long term. This criterion of minimizing the land area where remediation wastes will remain in place after closure of the CAMU ties in with the overall goal of achieving effective, protective remedies with long-term reliability. In addition, as a practical matter, development of the facility property (for future beneficial uses or by the owner/operator) may be less constrained if a relatively small area of the facility were dedicated to continued long-term containment of remediation wastes than if remediation wastes were managed at or near their point of generation. This is particularly true for Federal facilities which often cover extremely large tracts of land that could be used for other purposes once the operating agency no longer needs use of the land.

DOCUMENTING A CORRECTIVE ACTION MANAGEMENT UNIT DESIGNATION

Documentation of CAMU decisions is analogous to the documentation the EPA must currently make to support the selection of a RCRA corrective measure or a CERCLA remedial action. Therefore, if a CAMU is selected as part of a final remedy under RCRA corrective action authorities, such an explanation will need to be incorporated into the Statement of Basis [a document analogous to a Record of Decision (ROD)] for the RCRA permit, corrective action order, or RCRA permit modification or order to require implementation of the selected alternative. If a CAMU is to be designated as part of a remedial action under CERCLA, an explanation of this designation will need to be documented in the Proposed Plan and included in the ROD.

In designating an area as a CAMU, the RA will review the documentation supplied by the owner/operator and consider each of the seven decision criteria discussed above. Based upon this review, in accordance with 40 CFR 264.552(f), the RA will document the rationale for designating the CAMU and will explain the basis for such designation. Such rationale will be incorporated as part of the RCRA permit or corrective action order, or in the remedy selection documentation (e.g., the ROD) for that facility, and will be made available to the public. The rationale given for a CAMU decision in the supporting documentation will generally address only those criteria that are considered important to a given CAMU designation. For example, when a CAMU includes uncontaminated land on which remediation waste management will occur, the rationale supporting this inclusion will be specified. However, if remediation wastes will only be managed on contaminated land, this criterion need not be specifically addressed.

CONTENTS OF INFORMATION PACKAGES REQUIRED FOR DESIGNATING A CORRECTIVE ACTION MANAGEMENT UNIT

Under 40 CFR 264.552(d), the owner/operator typically will be required to submit all the necessary information and documentation, such as the results of a RCRA Facility Investigation, Corrective Measures Study (CMS), or other site-specific analyses, for the RA to use in assessing the decision criteria discussed above. Therefore, it is in the interest of the owner/operator to ensure that the documents supplied to the RA address each of the specific decision factors in sufficient detail to allow an informed decision. Further, the facility should also consider how best to integrate the analysis of the specific criteria for selecting a corrective measure under RCRA and the criteria for CERCLA remedial actions with the documentation required for a CAMU. These analyses, while not identical, do share common elements, and careful integration of the evaluation processes may provide a significant savings in the level of effort required.

CAMU designations made through the permit process will generally be approved (or denied) according to the EPA-initiated permit modification procedures under 40 CFR 270.41, or the Class III permit modification procedures under 40 CFR 270.42. Class III permit modifications are similar to EPA-initiated modifications in terms of the

amount and type of public review and comment that are provided. Typically, an EPA-initiated permit modification requires compliance with 40 CFR Part 124 provisions for public notices, comment periods, and a public meeting. Class III modifications require similar actions such as publication of a public notice, a comment period, and public meetings, if requested. In the case of a CAMU implemented through the use of a RCRA 3008(h) order, the order would generally require that the same information be provided as for permitted facilities under 40 CFR 264.552(e). Therefore, the need to approve a CAMU early in the process (e.g., to support an interim measure or "stabilization" action) will pertain to facilities subject to RCRA 3008(h) orders, as well as RCRA-permitted facilities. Thus, to implement a CAMU under an existing RCRA 3008(h) order, the order may need to be amended to reflect the addition of the CAMU.

In 40 CFR 264.552(e)(1), EPA states that the RA will specify in the permit or order the actual areal extent or configuration of the CAMU. Because permits and orders will generally identify the physical boundaries of CAMUs on a facility map, together with a specific description of the physical boundaries or dimensions of the CAMU, the owner/operator should supply this information in the documentation supplied to EPA. 40 CFR 264.552(e)(2) states that the permit or order must specify how remediation wastes will actually be managed in, or as part of, a designated CAMU, including specification of design, operating and closure requirements. For example, if wastes were to be excavated and bioremediated in an enclosure located within the CAMU, the permit or order would specify the requirements for the bioremediation technology, the design and operation of any structures used for the bioremediation process, the disposition of the treatment residuals, and other associated requirements for those wastes and the areas of the CAMU to be used in managing them. Again, it is incumbent on the owner/operator to supply this information to the RA. Under 264.552(e)(3), the permit or order must also establish the groundwater monitoring requirements for the CAMU. Because CAMUs will typically be implemented following studies to determine the extent and nature of surface and subsurface contamination, in most cases groundwater monitoring systems will already have been installed to characterize releases to groundwater. 40 CFR 264.552(e)(3) is intended to guarantee that the owner/operators continue to monitor groundwater quality in the vicinity of the CAMU to ensure that any releases of contaminants from the CAMU are detected and addressed. It is important to note that the groundwater monitoring requirements specified in the final regulations are not detailed, specific requirements and in no way addressed the numerous technical elements of installing and operating an effective groundwater monitoring system. Instead this requirement provides only a general performance standard, leaving the detailed specifications and performance standards for a groundwater monitoring program to be developed based on site-specific information and conditions, and then be specified in the permit or order. Also, at 40 CFR 264.552(e)(4), the final regulations for CAMUs promulgate those provisions addressing closure and post-closure requirements for CAMUs that must be incorporated in permits or orders. These requirements address the inclusion of such closure activities as excavation, removal, treatment, capping or containment of wastes, capping of areas where wastes will remain in place, and removal and decontamination of equipment, devices, and structures used for remediation waste management in the permit or order.

DECISION FACTORS FOR DESIGNATING A TEMPORARY UNIT

40 CFR 264.553(c) specifies seven decision criteria that will be used by EPA to evaluate TU designations. The RA will review the documentation supplied by the owner/operator and consider each of these decision criteria in designating a TU. According to 40 CFR 264.553(c), the RA shall consider the following factors in establishing standards to be applied to TUs: 1) length of time the unit will be in operation; 2) type of unit; 3) volumes of waste to be managed; 4) physical and chemical characteristics of the wastes to be managed; 5) potential for releases from the unit; 6) hydrogeological and other relevant environmental conditions at the facility which may influence the migration of any potential releases; and 7) potential for exposure of humans and environmental receptors if releases were to occur from the unit. It is incumbent on the owner or operator to supply all the necessary information to support such a designation, and to recommend the alternative design, operational, and closure standards for the TU.

DOCUMENTING TEMPORARY UNITS DESIGNATIONS

Documentation of TU decisions is analogous to the documentation required to support

the selection of a RCRA corrective measure or the designation of a CAMU. Therefore, if a TU is incorporated as part of a corrective measure, an explanation would be incorporated into the Statement of Basis for a permit modification or a new or revised RCRA 3008(h) order. Under 40 CFR 264.553(g) the RA is required to document the rationale for designating a TU or granting a time extension for a TU, and to explain the basis for such a designation.

As required under 40 CFR 264.553(d), the RA will specify requirements for TUs in the facility's operating permit or in a RCRA 3008(h) order. The requirements specified will include the design, operating, and closure requirements for such units, and will reflect the decision factors described above. This section of the permit or order will also specify a one-year time limit for operation of the TU. At the end of the specified time limit for a TU, or at the end of an extension granted by the RA, the owner/operator will be required to cease management of remediation wastes in that unit and initiate the closure requirements prescribed in the permit or order. Incorporation of a TU designation into an existing permit will be conducted in accordance with the procedures for EPA-initiated permit modifications under 40 CFR 270.41, or the owner/operator of a permitted facility may request approval for a TU through a Class II permit modification. Class II owner/operator initiated permit modifications follow the procedures set forth in 40 CFR 270.42. In both cases, there are requirements for public notices, comment periods, and public meetings, if requested.

EXTENSIONS TO SPECIFIED OPERATING TIME LIMITS FOR TEMPORARY UNITS

In some cases, due to unexpected circumstances, a TU may have to remain in service beyond the one-year time limit. 40 CFR 264.553(e) specifies the criteria the RA will consider prior to approving an extension to the time limit originally specified. If such an extension is requested, the RA will have to determine that continued operation of the unit will not pose a threat to human health and the environment and that continued use of the unit is necessary to ensure the timely and efficient implementation of corrective measures at the facility. Upon approval of an extension, the RA will identify the specific time limit for the extension in a modification to the permit or order. As mentioned above, 40 CFR 264.553(g) requires the RA to document the rationale for granting a time extension for a TU and to explain the basis for such designation. The rationale for such decisions will be incorporated as part of the Statement of Basis in a permit or order modification. Approval for extensions for TUs that are not addressed under a Class III permit modification or that are not part of an EPA-initiated permit modification will be processed as Class II permit modifications, subject to the somewhat less stringent requirements of 40 CFR 270.42. In cases where it is necessary or desirable to continue the waste management activity that was conducted in the TU, the owner/operator will be required to retrofit the unit to meet the applicable standards specified in 40 CFR Part 264 or Part 265 for that type of unit, arrange for an alternative unit in which to continue conducting the activity, or otherwise modify the waste management practices so that the unit is no longer used as a TU. If the owner/operator chooses to retrofit the unit, but such changes to the unit cannot be made before the end of the extension period, the owner/operator will be required to cease management of the waste until the retrofitting has been completed. Changes to TUs (e.g., retrofitting) or to other remediation waste operations at the end of the operating time limit for a TU will be subject to approval through modifications to the permit or order.

INTEGRATION WITH STATE LAWS AND REGULATIONS

Under RCRA 3006, EPA may authorize States to administer and enforce the RCRA program within the State. Following authorization, EPA retains enforcement authority under RCRA 3008, 7003, and 3013, even though authorized States have primary enforcement authority. Under RCRA 3006(g)(1), as amended by HSWA, new requirements and prohibitions imposed under HSWA authority take effect in authorized States at the same time that they take effect in unauthorized States. EPA is directed to carry out these requirements and prohibitions in authorized States, including the issuance of permits, until the State is granted authorization to do so. Since the CAMU and TU rule was promulgated pursuant to RCRA 3004(u) and (v), and RCRA 3005(c) (i.e., interim status), all of which are HSWA provisions, EPA intends to implement the CAMU and TU provisions immediately in all States and territories in which the EPA now administers the RCRA 3004(u) and (v) corrective action authorities. Thus, the rule takes effect immediately in: (1) States that are not authorized for the RCRA base

program; and (2) States that are authorized for the RCRA base program, but are not yet authorized for the HSWA corrective action program. These regulations do not, however, automatically apply in States that are authorized for the HSWA corrective action requirements.
A complicating factor is that under RCRA 3009, States may impose more stringent or broader regulations than are included in the Federal program. Because the CAMU and TU regulations reduce regulatory requirements for certain types of waste management conducted during corrective action, EPA considers them to be less stringent than, and to reduce the scope of, other existing Federal corrective action requirements. Therefore, the CAMU and TU regulations will not apply in those States authorized for corrective action, until those States have adopted comparable provisions under their own State law. Furthermore, because the rule is less stringent than other existing corrective action requirements, authorized States are under no obligation to adopt these regulations, and States not yet authorized for corrective action are not required to include these provisions in their programs when they seek authorization.
Another complicating factor is that many States have laws and programs to address environmental contamination problems that are not addressed under RCRA or CERCLA authorities. As a general rule, since CAMUs are defined as units to be used in connection with 40 CFR 264.101 or RCRA 3008(h) actions, they can be employed only at a facility regulated under Subtitle C of RCRA, or at CERCLA sites where the CAMU or TU provisions are determined to be ARARs. Therefore, sites being addressed under State laws may not be able to have an area designated as a CAMU or TU.
In sum, although the CAMU and TU provisions have been adopted by EPA, these provisions may not necessarily take effect due to the specific requirements of State implementation of the Federal RCRA program, and of other State environmental laws. Thus, a facility may wish to designate an area as a CAMU under the Federal program in order to gain relief from some regulatory requirement (e.g., the RCRA LDR), but be prohibited from doing so under State law. It will be incumbent upon the owner/operator to determine the applicable requirements under both the Federal and State programs, assess how the use of CAMUs or TUs integrates with those requirements, and successfully demonstrate to the agencies concerned that their proposed CAMU or TU will meet those requirements. It may be possible that the use of a CAMU or TU to gain relief from a more stringent regulatory requirement is not possible due to a conflict between Federal and State regulations.
SUMMARY
The CAMU and TU rule finalizes provisions of the proposed Subpart S regulations for CAMUs and TUs. Both of these units function solely to manage remediation wastes that are generated at a RCRA facility during corrective action or by a CERCLA response action (if determined to be an ARAR). These units cannot be used to manage "as-generated" hazardous wastes from ongoing production processes or other industrial activities. In adopting these regulations, EPA has provided added regulatory flexibility in order to expedite and improve actions to address releases of hazardous wastes or hazardous waste constituents. For example, the final CAMU and TU regulations provides a means of gaining relief from the LDR and MTR requirements for wastes managed in a CAMU. Although these regulations provide additional flexibility when selecting a corrective measure, it is extremely important to recognize that other requirements, policies, and guidelines for establishing site-specific cleanup goals and for selecting remedies under both the EPA- and State-administered programs remain in effect, and may significantly influence the usefulness of the CAMU and TU provisions.

29-7
DEVELOPMENT OF THE EPA RADIATION SITE CLEANUP REGULATION
Amy Newman
United States Environmental Protection Agency
Office of Radiation and Indoor Air; Radiation Studies Division
ABSTRACT
The United States Environmental Protection Agency is developing a proposed rule that will establish a uniform standard for cleaning up radioactively contaminated sites. The rule will apply to federal facility sites and to sites licensed by the Nuclear Regulatory Commission or an Agreement State. The cleanup standard must be met if a site is to be released for public use. The regulation will not mandate the cleanup of any sites or provide remedy selection criteria on when cleanup is appropriate.

EPA has coordinated the development of the rule with a wide range of governmental organizations and affected groups. A regulatory impact analysis of the rule's economic effects is underway, and the Agency plans to develop implementation guidance to help agencies responsible for radiation site cleanups meet the cleanup standard.

This paper discusses the latest technical and policy developments for the radiation site cleanup rule. The information presented is preliminary in nature and is subject to change as the regulatory development process continues. It is intended to be used primarily to maximize discussion and comment with interested parties.

INTRODUCTION

The United States Environmental Protection Agency (EPA) estimates that there are approximately 5,000 sites known or presumed to be contaminated with radioactive material in the United States. Currently, radiation site cleanups are regulated or managed by several federal agencies, including EPA, the Nuclear Regulatory Commission (NRC), the Department of Energy (DOE), and the Department of Defense (DoD).

The lack of specific cleanup standards for radioactive materials has been a major impediment to progress in cleaning up many contaminated sites. Under current procedures, sites are evaluated on a site by site basis to determine the appropriate cleanup level. This process has caused delays and uncertainty in the cleanup of sites, as well as large costs due to legal disputes over determining an acceptable cleanup level. To address these concerns, the Agency is developing a radiation site cleanup regulation which will establish a health-based cleanup standard that will reduce the costs and delays in determining the level of cleanup to be achieved at contaminated sites. EPA anticipates publishing a proposed radiation site cleanup rule in the Federal Register during the summer of 1995.

Coordination Of The Rulemaking

The radiation site cleanup rule has generated extensive interest among a variety of constituencies, so EPA is coordinating its development with several organizations and groups. These include federal agencies such as DOE, DoD, and NRC; state and local governments; Native American tribes; and organizations representing environmentalists, industries, and other affected groups. The Agency also strongly encourages members of the public to participate throughout the process to ensure that their concerns are understood and addressed.

As part of its coordination effort, EPA has established a radiation site cleanup subcommittee under the National Advisory Council for Environmental Policy and Technology (NACEPT).a The subcommittee provides advice on issues related to the formation of the radiation site cleanup standards and helps foster scientific and technical objectivity and public openness. To ensure balanced representation and a wide range of viewpoints, the NACEPT subcommittee includes representatives of state and local government agencies, industry, and Native American and public interest groups. The meetings of the subcommittee are open to the public and provide opportunity for public comment.

The Agency is coordinating the development of the rule with state officials through the Conference of Radiation Control Program Directors (CRCPD), in particular with the CRCPD Committee on Decontamination and Decommissioning, which is examining similar technical issues. In addition, the Agency is exchanging information with other state organizations such as the Association of State and Territorial Solid Waste Management Officials.

EPA is coordinating with DOE, DoD, NRC, and EPA program offices through an Interagency Steering Committee and interagency workgroups. The Steering Committee was established by EPA to ensure that the radiation site cleanup rulemaking effort receives appropriate resources and priority. The interagency workgroup examines specific technical issues related to developing and implementing the radiation site cleanup standards.

The Agency also is working closely with the NRC on the Commission's development of separate regulations governing the decommissioning of NRC-licensed facilities. EPA and the NRC regularly share information that pertains to their respective rulemaking efforts, and EPA participated in the NRC's Enhanced Participatory Rulemaking Workshops. EPA and NRC believe that this parallel approach to rule development will ensure that EPA's cleanup regulation and NRC's decommissioning standards will be consistent, fully protective of public health, and issued in a timely manner.

Responsibility of EPA

In developing the radiation site cleanup regulation, EPA plans to exercise its authority under the Atomic Energy Act (AEA), which sets forth the Agency's responsibility and authority to promulgate regulations to protect people and the environment from the harmful effects of ionizing radiation. The Agency also has the authority to prepare radiation guidance documents. Under Executive Order 10831, the EPA Administrator is charged to "advise the President with respect to radiation matters, directly or indirectly affecting health, including guidance for all federal agencies in the formulation of radiation standards and in the establishment and execution of programs of cooperation with States."
Reorganization Plan No. 3 of 1970 transferred from the Atomic Energy Commission (AEC) to EPA the authority to establish standards for the protection of people and the environment from the effects of all radioactive material. It should be noted that EPA is not the only federal agency to derive its authority to regulate radioactive material from the AEA; the NRC and DOE do as well. However, these agencies must implement EPA's generally applicable radiation standards.
OVERVIEW OF REGULATION
Purpose of the Regulation
EPA's goal in the development of the Radiation Site Cleanup Regulation is to establish clear, consistent, and protective health-based cleanup standards that are implementable. By doing so, the Agency will facilitate the cleanup of radioactively contaminated sites and promote the beneficial reuse of land. The Radiation Site Cleanup Regulation will not, however, mandate the cleanup of radioactively contaminated sites.
Applicability Of The Regulation
The regulation will apply to sites contaminated with radioactive material that are under the control of a federal agency, such as DOE or DoD, and to sites licensed by the NRC or an "Agreement State."b The regulation may also apply to Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA)/Superfund sites as a potential applicable or relevant and appropriate requirement (ARAR). The cleanup regulation will set a standard that must be met if a site is to be released for public use. The standard will limit radiation exposures from all sources, including soils, ground water, surface water, air, and structures.
The proposed rule will specifically exempt the following facilities/sites from coverage:
Any uranium mill tailings pile after it has been disposed of under 40 CFR Part 192, Health and Environmental Protection Standards for Uranium and Thorium Mill Tailings.
CERCLA sites that have been cleaned up under 40 CFR Part 300, the National Contingency Plan, with signed Records of Decision as of the effective date of the rule.
EPA may exempt NRC and Agreement State licensees from the cleanup regulation if the Agency finds that the decommissioning standards being developed by NRC are sufficiently protective of human health and the environment. This is in accord with a Memorandum of Understanding (MOU) between EPA and NRC (57 FR 54127, November 16, 1992), which discusses how the agencies will avoid overlapping regulations.
Health-Based Dose Limit
The current staff working draft of the radiation site cleanup rule limits total exposures from residual radiation at a site to 0.15 mSv/yr (15 mrem/yr) above background radiation levels if the site is to be released for public use. To ensure protection of underground sources of drinking water, EPA also plans to set a separate standard for ground water based on the Safe Drinking Water Act (SDWA) standards. In order for a site to be released, compliance with these standards would have to be demonstrated for a period of 1,000 years.
The annual committed effective dose limit of 0.15 mSv/yr (15 mrem/yr) above background corresponds to a lifetime excess cancer risk level of approximately 3 x 10-4 over 30 years of exposure. A 3 x 10-4 risk is generally consistent with other environmental cleanup programs, as well as other radiation protection standards. Because many radionuclides are long-lived, EPA believes it is important that compliance with the standard be demonstrated for a 1,000 year period.
Use of Active Control Measures
Achieving the health-based cleanup level established by the proposed rule would permit the release of a site without the use active control measures and would ensure that individuals located at the site would not be exposed to radioactive

material at levels above 0.15 mSv/yr (15 mrem/yr) in excess of background radiation. The term "active control measures" means measures that control radiation dose or prevent exposure to members of the public by methods other than physical removal of radioactive material. This definition includes, but is not limited to, deed restrictions, deed notices, and the plugging of existing ground water wells.
EPA recognizes that some sites cannot be cleaned up sufficiently to allow such release due to technological limitations, worker safety, ecological concerns, or other factors. In these cases, active control measures can be implemented to ensure that members of the public do not receive doses over 0.15 mSv/yr (15 mrem/yr) in excess of background radiation levels. The active control measures would also have to ensure that exposures to the public from contaminated ground water do not exceed the ground water standard. The active control measures must be selected through a public notice and comment process which involves individuals potentially affected by site cleanup activities. In addition, sites that employ active control measures will be re-evaluated every five years to ensure that the active control measures are still working properly.
EPA also is proposing an annual committed effective dose limit of 0.75 mSv/yr (75 mrem/yr), in excess of background radiation levels, in the event that all active control measures fail at a site. While EPA fully expects implemented controls to be effective, this additional requirement provides assurance for cases where the effectiveness of controls must be projected well into the future.
Public Participation
The draft radiation site cleanup rule enumerates five situations in which implementing agencies will be required to provide public notice and opportunities for public comment. The public notice and comment requirements would apply whenever any of the following occurs:
The implementing agency determines that a site, or any portion thereof, will be evaluated for remediation for release from under the control of the implementing agency or its licensee.
The implementing agency proposes its plan for achieving compliance with the radiation site cleanup regulation, including:
-Whether remediation will occur, the nature of the proposed remediation including the selection of any active control measures, and the anticipated future land use for the site, or
-That the land will not be released for public use.
The implementing agency remediates a site and intends to release it within 60 days.
For sites that use active control measures, the implementing agency verifies whether the controls are continuing to function.
The public notice and comment procedures are similar to those required by Superfund when proposing to list a site on the National Priorities List, proposing a remedial action prior to the signing of a record of decision (ROD), and when a fundamental change occurs to the remedy selected in a ROD. These procedures include notification to EPA; State, local and Tribal governments; and other communities that may be affected by site remediation (such as communities along a corridor for waste transport), as well as publication in the Federal Register of a notice with request for comment from affected parties. The proposed rule also requires the implementing agency to establish and maintain an information repository containing relevant site remediation documents for accessibility to the interested public.
The draft rule's public participation requirements are intended to be flexible. In all cases, there is a requirement that the public be informed of the relevant action, decision, or proposal, and have an opportunity to provide a response. Agencies may provide additional opportunities for public information and participation, such as public meetings, announcements, fact sheets, and other measures as appropriate under the circumstances. The rule does not require a response by the agency, but EPA anticipates that agencies will choose to provide responses in many cases, either because they are required to do so by other laws, or because community support is a practical necessity before property can be released. The purpose of the public participation requirements is to make the public aware of cleanup decisions, and give the public an opportunity to provide information that may assist the agency in conducting an evaluation or in carrying out the release of the property.
EPA has been working with other federal agencies and the public to develop

innovative methods for involving communities in the cleanup process. To this end, EPA established the Federal Facilities Environmental Restoration Dialogue Committee (FFERDC), whose members represent 40 federal agencies, tribal and state governments and associations, and local, national, environmental, community, and labor organizations. The FFERDC's mission is to develop consensus policy recommendations aimed at improving the FFER decision-making process to ensure that cleanup decisions reflect the priorities and concerns of all stakeholders.

One recommendation of the FFERDC is the establishment of site-specific advisory boards (SSABs) at federal facilities. SSABs would assist in providing:

Consistent opportunities for affected stakeholder involvement in federal facility cleanups,

Regular, early, and effective public participation in federal cleanup programs, and

Consolidation of the many public involvement initiatives addressing cleanup.

Although EPA is not requiring the establishment of SSABs, the Agency strongly encourages the use of SSABs (or similar mechanisms) and believes that they would promote early, direct, and meaningful participation through the cleanup process. The Agency believes that such participation is consistent with the goals of the AEA and other environmental statutes.

OVERVIEW OF ANALYSES PERFORMED IN SUPPORT OF THE RULE

In order to evaluate options for the cleanup standard, EPA has been conducting technical and economic analyses in support of this rulemaking.

Risk Analyses

Like metals, radioactive wastes cannot be destroyed by treatment techniques such as incineration or chemical reaction. Many radioactive wastes remain hazardous for long periods of time. Consequent ly, radioactive site cleanup means reducing the long-term risk to people who live on or near a contaminated site, often by excavating the waste and moving contaminated material to a disposal facility. Cleaning up and transporting radioactive waste, however, may lead to short-term risks, including increased traffic fatalities, that are nonradiological in nature. Therefore, EPA is assessing the net health impacts resulting from remedial activity by subtracting the short-term risks due to remedial activity from the fatalities averted due to the reduction in long-term risks as a result of remedial activity. The risk analyses evaluate the net health impacts at various cleanup levels and under various cleanup scenarios.

EPA used computerized models to assess the potential radiation doses and associated risks to the public from all significant exposure scenarios, media, and exposure pathways. The risk analysis focused on estimating: (1) the change in risk to an individual under reasonable maximum exposure (RME) conditions, and (2) the number of cancers per year in the exposed population. The methodology is consistent with that described in the EPA Risk Assessment Guidance for Superfund (RAGS) for baseline risk assessments.c

Mathematical models also have been used to estimate, based on RME assumptions, the cleanup levels of radionuclides in soil to be achieved under rural residential and commercial/industrial exposure scenarios. The scenarios address land-use and exposure situations expected after the cleanup of sites covered by the proposed rule.

The rural residential exposure scenario addresses long-term risks to individuals expected to have unrestricted use of a site after cleanup. It assumes that individuals live on the site and are constantly exposed, both indoors and outdoors, to residual concentrations of radionuclides in soil through the maximum number of exposure pathways, including:

External radiation exposure from photon-emitting radionuclides in the soil,

Inhalation of resuspended soil and dust,

Inhalation of radon and radon decay products from soil containing radium,

Incidental ingestion of soil containing radionuclides,

Ingestion of drinking water containing radionuclides transported from soil to potable ground water sources,

Ingestion of home-grown fruits and vegetables contaminated with radionuclides taken up from the soil,

Ingestion of meat or milk containing radionuclides taken up by cows grazing on contaminated plants and fodder, and

Ingestion of locally caught fish containing radionuclides.

The commercial/industrial exposure scenario addresses long-term exposures and risks

to commercial or industrial workers assuming a site was released with a restriction allowing only commercial or industrial development. Under this scenario, the model assumes workers would be exposed to residual levels of radionuclides in soil during an average eight-hour workday, both indoors and outdoors, at a site. This scenario does not consider exposures to site cleanup workers or to construction workers, nor does it address risks to workers from contaminated structures or building materials.
Five pathways were evaluated under the commercial/industrial exposure scenario:
External radiation exposure from photon-emitting radionuclides in soil,
Inhalation of resuspended soil and dust containing radionuclides,
Inhalation of radon and radon decay products from soil containing radium,
Incidental ingestion of soil containing radionuclides, and
Ingestion of drinking water containing radionuclides transported from soil to potable ground water sources.

Regulatory Impact Analysis

As required under Executive Order 12866, the Agency is developing a Regulatory Impact Analysis (RIA) to estimate the anticipated economic effects of the proposed radiation site cleanup rule. The RIA estimates the incremental cost of the proposed regulation by assessing two of the regulation's cost impacts. First, the establishment of a uniform cleanup standard is expected to provide cost savings through:
Streamlined site assessments,
Reduced legal costs associated with selecting a cleanup risk level, and
Reduction of market barriers that inhibit the use of existing waste minimization technologies.

Second, to the extent that the rule establishes a level of cleanup that is more stringent than what would be achieved without the regulation, the proposed regulation will cause an increase in costs.

To assess these cost impacts, EPA has developed a computer-based cost model that estimates the change in costs arising from the new regulation compared to a baseline case, which assumes no new rule for radiation site cleanups. To do this, the model computes the cost of cleaning up each of 16 reference site categories that are representative of the universe of federal facility sites to be remediated. EPA's computer model calculates cleanup costs under baseline conditions (i.e., no new EPA cleanup rule) and under alternative dose limits considered for the proposed rule. Summing the cleanup cost estimates for all 16 site categories provides estimates of national-scale impacts.

There are five major components of total cost associated with the cleanup of radioactively contaminated sites that are estimated in the RIA:
The cost of precleanup activities, which includes initial site characterization and legal costs,
The cost of cleanup,
The cost of transporting, by rail or truck, the contaminated soil excavated from a site to a disposal facility,
The cost of disposing of contaminated materials, and
The cost of verifying that a site cleanup has been successful and the target risk level has been achieved.

CONCLUSION

The Agency plans to publish a proposed rule in the summer of 1995, and a final rule is expected a year later. The publication of the proposed radiation site cleanup rule is expected to generate a great deal of public interest, and EPA looks forward to receiving additional comments at that time. The Agency believes that by involving all interested parties and by examining comments and information from a wide range of viewpoints, the rule will be consistent, implementable, and protective of human health and the environment.

29-8

ACHIEVING INDEPENDENT EXTERNAL REGULATION OF DEPARTMENT OF ENERGY ENVIRONMENTAL MANAGEMENT: TWO ALTERNATIVE MODELS

Dr. Martin G. Seitz
United States Department of Energy
Office of Facility Transition and Management
Adam R. Lipinski, J.D.
BDM Federal

ABSTRACT
In its strategic plan, Fueling a Competitive Economy,(1) the Department of Energy commits to developing external regulation of its environmental management activities. The Department, in fulfilling this commitment, developed two models that reveal the merits of alternative regulatory structures. This paper describes the results of applying the models to develop external regulation at the Rocky Flats Environmental Technology Site and other environmental management sites of the Department. The linear model relates each activity at a site to the multiple regulators prescribed by law. Results show that the Department can work most efficiently with regulators to eliminate overlapping requirements with the regulatory structure of the linear model. Also, the Department can enhance efficiency by customizing communications for efficient information transfer to the regulators.
The integration model, the second model, groups responsibilities under one regulator. To implement the structure of the integration model for external regulation, the Department must work with the regulator that monitors compliance prescribed by law. The Department can eliminate conflicting requirements to gain credible regulation and uses a dispute resolution process to resolve jurisdictional issues efficiently. With attention to the structure developed for regulation, the Department can operate effectively in the regulated environment and achieve its strategic goal of credible, external regulation.

Background

In the strategic plan the Department of Energy recognized the importance of increasing external regulation of its environmental management operations. The fruition of this process will be increased stakeholder knowledge of the ensured safety and health of workers and the public, and restoration of the environment as the Department transfers facilities from production to reuse or ultimate disposal. The Department has incorporated this goal throughout its operations and has identified critical success factors to measure the process' rate of achievement. The Strategic Plan commits the Environmental Quality business area to the following:

> Achieve independent and credible regulation of activities and facilities, and eliminate conflicting requirements.

In meeting the goal of the Strategic Plan, the Department must operate within several parameters such as federal laws, regulations, and court orders to attain external regulation. However, the Department maintains flexibility in establishing the regulatory structure in several ways. For example: the Department negotiates authority and scope of activities with various regulatory agencies; the Department regularly proposes and agrees to specific arrangements for regulation; the Department establishes stakeholder groups, initiates public hearings, and conducts the National Environmental Policy Act (2) process for public reviews. Finally, the Department proposes to the Administration legislation for efficient external regulation. Through these activities, the Department helps form the regulatory structure.

The Department recognizes the merits of a thorough analysis of the shift to external regulation of environmental management activities. The Department has a strong interest in external regulation that ensures responsible management and operation, and instills public confidence. In an evaluation of regulatory responsibility, the Department works to coordinate regulations to improve its cleanup activities.(3) Generally, the Department has retained internal orders and procedures. The Department has developed a basis for external regulation in the Standards it maintains for its self regulation function.(4) However, the Department is evolving from a position of self regulation to external regulation through interaction with regulators, such as state and federal agencies, stakeholders, judicial orders and decrees, and through Congressional mandates. Unfortunately, this process has produced procedures for environmental management overlap and often conflict. This paper examines two models which have been used to help implement the goal of external regulation. The models are presented from the perspective of a user that can be the regulator, the regulated entity, or other stakeholders. The models are tools for the user to conceptualize a particular regulatory environment, for example; once the goals of the regulator, regulated, and stakeholders are identified. Alternatively, the models can be tools to examine a regulatory process and to understand the consequence of establishing specific regulatory relationships. The application of these models is particularly useful during negotiations, in

developing regulatory relationships, and in fostering public understanding of the regulatory structure.
The first model, called the Linear Model, seeks to identify a diverse set of regulators for all environmental management activities. The user of the model groups expertise and activities to minimize the overlap among regulators. The user concludes with details that identify the existing and required external regulators.
The second model, called the Integrated Model, seeks to direct responsibility to principal regulators. The user of the model attempts to gain efficiency by focusing all regulation to a few parties. The user concludes with a structure that minimizes the number of regulators.
The Department has applied the mechanisms of both models implicitly and to expand the roles of regulators in such circumstances as interagency agreements and plans under the Federal Facility Compliance Act.(e) The models can be used to identify beneficial approaches in the negotiation of these documents. This paper will demonstrate the beneficial application of these models to the development of external regulation at the Rocky Flats Environmental Technology Site (RFETS).
Descriptions of the Models
Linear Model: Activities Correlated to Individual Regulators
The Linear Model links each activity at a site with specific regulations. The first model can be implemented as follows:
To achieve independent and credible regulation, the user identifies the relationships of activities to current regulations, and proposes additional relationships. The user then examines the current and proposed regulation in terms of comprehensiveness and reduced overlap.
1. Assessment of the status of the existing regulatory environment
The first step in application of the Linear Model is to assess the status of existing regulations. This assessment requires identification of existing external regulators for activities at the site, identification of appropriate regulations, assessment of the credibility of existing regulations, and identification of overlapping and conflicting requirements.
2. Development of a systematic process and development of initiatives
The second step in this model is to associate the appropriate regulatory agencies with activities. Individual regulatory responsibilities for specific activities must be identified to assure that each activity has a recognized regulator. Both employees and the public must recognize the independent regulator for specific actions.
Once the relationship between activity and the appropriate external regulator is identified, then an analysis of appropriate initiatives can be started. This will require identification of the existing parameters within which the model must operate such as legislation, court orders, and existing agreements with regulators and stakeholders. Initiatives can then be proposed to modify the regulatory environment towards that identified in the model.
Integration Model: Activities Integrated Under One Outside Regulator
The second model integrates regulatory responsibilities under one regulation and a single external regulator.
The mechanics of this approach can be illustrated by an example. The user of the model identifies one statute as the integrating vehicle for the site. The agency authorized to enforce the statute acts as a gatekeeper regulator and, through negotiations, determines the appropriate level of external regulation. If the gatekeeper regulator determines the regulated entities existing regulations and procedures are sufficient, then the regulated entity continues its management of activities. If, however, the gatekeeper determines that the regulated entities management is insufficient then the gatekeeper retains jurisdiction or, if other regulations are appropriate, the gatekeeper assigns the activity to another regulatory entity.
1. Identification of the Appropriate Vehicle and Regulator
The first step requires the user to identify the appropriate statute to act as the vehicle for regulation of the activities at a site. This selection is weighted toward regulations that are established within a regulatory agency with the resources and a technically-experienced staff. Of course, the regulatory agency must have appropriate jurisdiction. Therefore, the selection favors an external regulatory agency with access to a vehicle which gives it jurisdiction over the site or a group of activities at the site. The gatekeeper agency may also be limited to

certain activities. Therefore, this step of the model requires recognition of existing parameters within which the regulated agency must conduct its activities as in the previous model.

2. Determination of Appropriate Level for Operation

In this step, the user establishes a level of regulation that will meet the regulator and stakeholder expectations. The user can conduct the minimum level of regulation from existing controls such as Standard Operating Procedures (SOPs) for the site, standards and safety rules developed by the regulated agency. Often these standards and rules are published in the Code of Federal Regulations published in the Federal Register. Existing controls which have had the most extensive public review and have been implemented successfully should be given the most deference.

3. Assignment of Activities to Appropriate Regulatory Agencies

In the third step of the model, the user assigns activities to the gatekeeper regulator. With this assignment, the gatekeeper would review the activity to determine if they are being implemented by the regulated entity.

If the gatekeeper's review determines that the activities are being conducted within the acceptable regulatory limits, then the activity continues under the regulated agency. If, however, the gatekeeper determines that there is a unacceptable level of risk involved, then it is incumbent on the gatekeeper to review other potential regulatory vehicles to determine whether the activity could be regulated by another agency. In a situation where the gatekeeper agency determines that another agency exists and has jurisdiction, the gatekeeper agency would notify the other agency of the need to regulate the activity.

If the gatekeeper agency determines the site is not operating within acceptable regulatory levels and is not within the jurisdiction of another regulating agency, the gatekeeper regulator imposes requirements to address the deficiency. As part of this step, the gatekeeper agency must review the rules and regulations of other agencies to determine if jurisdiction exists. However, the point of demarkation for a gatekeeper's jurisdiction and another agency's jurisdiction may be uncertain and the gatekeeper's determination of an inadequate regulatory posture by the site should be resolved through an established dispute resolution process. Once the gatekeeper establishes the regulatory relationship, he must establish mechanisms that will prevent conflicts with each regulator's jurisdiction. Therefore, critical to the success of regulation, success of regulation structured by the model is a dispute resolution process that can efficiently resolve jurisdictional issues.

Application of the Models

The two models described above have been applied to environmental management activities of the Department of Energy. Applications described in this section are analyses of possible regulatory structures at the RFETS. The work was conducted principally to develop a headquarters perspective in support of the negotiations of the Rocky Flats Cleanup Agreement. The applications were developed for a specific site but are appropriate to most Department sites with environmental management activities.

Application of the Linear Model

Step 1. Assessment of the Status of the Existing Regulatory Environment

In most cases, the existing regulations of environmental activities are comprehensive and potential regulators are independent of the managing office. For example, at a site with environmental management activities, projects for downsizing, dismantlement, deactivation, restoration, managed for environmental remediation construction, operations, maintenance, production, maintenance, operation and construction projects proceed simultaneously.(6) However, there are several areas where conflicting requirements may exist. Conflicting requirements originate from requirements and responsibilities as defined in DOE Orders and Procedures, multiple external regulators and stakeholders, judicial orders and decrees, and specifically legislated Congressional mandates.(7)

Step 2. Development of a Systematic Process and Development of Initiatives

Figure 1 suggests appropriate regulators for several activities within the different projects. The Fig. exhibits major regulators within projects to illustrate the one-to-one relationship of regulator to activity. The results exhibit gaps and overlaps in the external regulation of site activities. One systematic process that can be used by the Department to gain comprehensive external regulation is to map every activity in the site budget to an independent regulator.

Fig. 1.

Initiatives can be undertaken to address specific issues identified in the analysis. For example, in the experience of the authors the credibility of regulations is degraded by: regulations and Orders that have evolved over time without attention to redundancies; reduced budgets that preclude compliance; uncertain regulators for specific activities; and poorly defined responsibilities. For example, cleanup activities and decontamination, decommissioning, deactivation, and dismantlement activities at Department facilities are covered under overlapping requirements of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA),(8) the Atomic Energy Act of 1954 (AEA),(9) and the Price-Anderson Act Amendments (PAAA).(10) Analyses using the models can be used to demonstrate to the public or regulators that existing or even reduced regulations can lead to desired remedied conditions.

Application of the linear model requires a review of laws from which the Department derives its authority. The analysis identifies some of the limitations on external regulation that must be addressed through legislation. For example, under the current legislation, certain regulations can only be developed by the Department. This is the case for activities prescribed by the AEA or the PAAA. The AEA defines the responsibilities of the Department in managing certain types of nuclear materials. The AEA, therefore, may limit the ability of the Department to achieve external regulation without legislative action. In the law, there is evidence that Congress intended to make the Department's authority exclusive in activities dealing with Special Nuclear Material (SNM). Congress limited the Department's ability to enter into agreements with a state that would discontinue the Department's regulatory authority over SNM materials in at least two instances. The first instance is section 274 (b) of the Act which explicitly prohibits the Department from entering into agreements with states to discontinue its regulatory role in cases where quantities of SNM are sufficient to form a critical mass. Another instance is found in Section 274 (c) which requires the Department to retain authority and responsibility with respect to regulation of operation of any production facility.

Another limitation on external regulation of the Department can be found in the Price-Anderson Act Amendments (PAAA), passed in 1988, which requires that the Department enter into agreements for indemnification with those conducting nuclear activities that present a liability to the public. The mandate from Congress required the Department to develop an enforcement program. Subsequently, the Department will promulgate many Department Nuclear Safety Requirements in the Code of Federal Regulations (CFR). The (proposed) Department Final Rule makes it clear that Department will assess civil penalties for any violation of: 1) any Department Nuclear Safety Requirement set forth in the CFR, 2) a violation of a Compliance Order, or 3) any program or plan explicitly required by a provision of the CFR or by a Compliance Order.(11) The PAAA also gives the Department the authority to issue fines and penalties for failure to operate facilities safely as well as to forward evidence of potential criminal violations to the Attorney General of the United States.

Initiatives can be identified that resolve identified issues. In this regard, conflicting regulations can be eliminated by encouraging regulators to focus on specialized areas consistent with their resources. Tools to accomplish this step are risk measures to identify priority actions, models comparing alternatives to reveal equivalencies, and other analyses to demonstrate resolution of conflicting requirements. For example, in order to expedite cleanup, the Department should review the benefits of legislation modifying the restrictions on SNM so that this material can be regulated by another federal agency, a federal agency in coordination with state agencies, or a state.

Another initiative that the Department could undertake to increase credibility of regulation is to assure that information is transferred consistent with the resources of the regulators and stakeholders. This is especially true in instances where the Department is mandated by Congress as the regulator. For example, the Department can work with regulators such as state agencies to develop resources and expertise in the nuclear field. Another example is the Department lessening the burden on citizen groups in the regulatory process. As with all entities, the public has limited time and resources to support regulatory activities. Upon implementing the linear model of regulation, the Department must use efficient mechanisms to transfer information to the public and the regulators. In addition, a systematic

periodic review of the external regulation should be conducted by the Department to meet the regulated goal of the Strategic Plan. This will serve as an important measure of the regulatory structure for both the public and regulators as well as the Department.

Application of the Integration Model

1. Identification of Appropriate Vehicle and Regulator

Many sites of the Department of Energy with environmental management activities are in the Environmental Protection Agency (EPA) National Priorities List (NPL). One consideration is that CERCLA is an appropriate vehicle to manage the Department's environmental management activities. For this consideration CERCLA would give the EPA overall jurisdiction at the site and, therefore, CERCLA is the appropriate integrating vehicle at these sites. This argument has validity in the sense that under CERCLA Section 104, the Administrator has very broad reaching jurisdictional authority and is directed to promulgate regulations establishing reportable quantities:

> Whenever (A) any hazardous substance is released or there is a substantial threat of such a release into the environment, or (B) there is a release or substantial release into the environment of any pollutant or contaminant which may present an imminent and substantial danger to the public health or welfare.

In conflict with this consideration are the restrictions found in parameters mentioned in the linear model. Any scheme established under an integrating gatekeeper agency must accommodate the Congressional mandate of the AEA and Department regulation through the authority of the PAAA.

2. Determination of Appropriate Level of Operation

During the negotiations of the Cleanup Agreement, the parties attempted to establish appropriate standards for operation for meeting state and Federal requirements. This was to be based on a compromise between the state's authority to enforce the Resource Conservation and Recovery Act (RCRA)(9) and the EPA authority under CERCLA. The state's standard was to be based on the RCRA operating permit for the site while an alternative standard for other activities was the the EPA determination of a substantial threat of release to the environment. Federally permitted releases which under the integrating vehicle of CERCLA provide exclusions to CERCLA requirements would be recognized as operating within adequate regulatory levels. For example, emissions that are within the permitted limits of a National Emissions Standards for Hazardous Air Pollutants(m) (NESHAPS) would not be categorized as a substantial threat of release to the environment.

3. Assignment of Activities to Appropriate Regulatory Agencies

In specific instances at sites with environmental management activities such as RFETS, limitations on the jurisdiction of the regulator depend on whether the facility is surplus or operational. Two types of facilities must be considered at environmental management sites: operating facilities which consist of facilities involved in maintenance of special nuclear material, waste storage, waste treatment, infrastructure support, and maintenance of resources; and surplus facilities which have been designate as surplus and are ready for decommissioning, deactivation, and dismantlement. Regulatory authority under CERCLA for environmental restoration may not apply to a facility that is operational. In such a case, regulatory jurisdiction may exist in a state RCRA operating permit, DOE Orders, or other outside regulations. Figure 2 illustrates the application of the integration model.

Fig. 2.

RESULTS

Use of the models reveals relationships of activities and external regulation that can be achieved at an operating site. The models highlight the impediments and changes required to achieve external regulation. The application of these models to regulation at sites with environmental management activities revealed three topics of major concern. First, current regulatory constraints limit external regulation and challenge the full implementation of external regulation. The review of the current regulations as required by both models reveals constraints to external regulation. Consequently, many regulations can only be developed by the Department. This is the case for activities prescribed by the AEA or PAAA. Several changes were recommended in the previous section which could reduce these constraints.

To achieve its strategic goal, the Department can either support legislation to transfer this regulatory authority to other agencies or oversee these activities in a manner credible to stakeholders. The Department should participate with other

agencies to identify conflicting requirements and to develop the specific delegation of responsibility. Where appropriate, recommendations and draft language should be submitted jointly to Congress so that legislative actions can be initiated. The legislative action must clearly define participation of the external regulator.
The second topic of concern revealed by the model is conflicting regulations. Conflicting regulations are easily recognized by application of the models and can be eliminated. Left unaddressed, conflicting regulations reduce the efficiency of operations and add to the cost of external regulation. The models recognize conflicting or overlapping regulations by the relationships of each activity to the external regulators. Conflicting regulations can be eliminated by encouraging regulators to focus on specialized areas consistent with their resources. Tools to accomplish this step are risk measures to identify priority actions and equivalencies as revealed by the models. In this regard, the Department can review the benefits of modifying the restrictions on SNM so that this material can be regulated by another federal agency, a federal agency in coordination with state agencies, or a state agency.
A final concern the models address is the development of functional relationships between the regulators and the regulated entity. An initiative identified by the models is transfer of information consistent with the resources of the regulators and stakeholders. A regulatory structure based on the linear model requires attention to information transfer to serve the many regulators of the Department's diverse activities. The efficient transfer of information is one key to successful working relationships in regulation. Broadcasting information is inefficient since each regulator must discern the relevance of all information to its responsibilities. The Department must be prepared at all times to respond to information requests. The regulators can participate effectively using published notices, draft findings, hearings, formal question response procedures, and other planned media to communicate.
The DOE has success with efficient and focused information transfer of benefit to the regulators. For example, in administering the National Environmental Policy Act, the Department lessens the burden on citizen groups by communicating information at planned intervals and concluding public interactions with summaries of concerns and responses. The summaries form the basis for advancing in the regulatory process. To implement external regulation, the Department must ensure that the regulators understand the methods of communication.

SUMMARY

The models presented in this paper represent a conceptual archetype. In actuality, the relationship between the regulator and the regulated identified by the user may be a hybrid of both models.
After the models have been applied, the user can evaluate the success of proposed initiatives by examining specific figures of merit. Suggested figures of merit include the independence of regulation, credibility of the regulation experienced by the public, the reduced conflict and overlap of the regulation, and the cost to implement the regulation. The evaluation of the models should also consider a cost benefit analysis to evaluate options. Effective parameters for a cost benefit analysis include the marginal benefit obtained in terms of additional safety to the public and workers compared to the marginal cost of implementation of the new regulatory structure. Figure 3 assesses the value of both models.
Fig. 3.

CONCLUSION

By developing external regulation that is credible and efficient, the Department can proceed in a coherent fashion to achieve the regulatory goal of the Strategic Plan. The Department can judge the potential of actions to support the goal of external regulation using two models. The linear model uses the complexity of existing regulatory structure to develop credible external regulation. Using the linear model, the Department must achieve efficiency through tailored communication to each regulator. The integration model minimizes the complexity of regulatory structure, but requires that the Department nurture an effective dispute resolution process to treat jurisdictional issues efficiently. Certain actions support the goal as revealed through application of the models and can be implemented. Other actions could detract from the goal and can be avoided. With attention to the structure developed for external regulation, the Department can operate effectively in the regulated environment and achieve its objectives within environmental remediation.

ABSTRACT
The Fast Flux Test Facility (FFTF) is a 400 MWt sodium-cooled research reactor owned by the U.S. Department of Energy (DOE) and operated by the Westinghouse Hanford Company (WHC) on the Hanford Site in southeastern Washington State. The decision was made by the DOE in December, 1993, to initiate shutdown of the FFTF. This paper describes the FFTF Transition Project Plan (1) (formerly the FFTF Shutdown Program Plan) which provides the strategy, major elements, and project baseline for transitioning the FFTF to an industrially and radiologically safe shutdown condition. The Plan, and its resource loaded schedule, indicate this transition can be achieved in a period of six to seven years at a cost of approximately $359 million. The transition activities include reactor defueling, fuel offload to dry cask storage, sodium drain and reaction, management of sodium residuals, shutdown of auxiliary systems, and preparation of appropriate environmental and regulatory documentation. Completion of these activities will involve resolution of many challenging and unique issues associated with shutdown of a large sodium reactor facility. At the conclusion of these activities, the FFTF will be in a safe condition for turnover to the Hanford Site Environmental Restoration Contractor for a long term surveillance and maintenance phase and decommissioning.

INTRODUCTION

The FFTF, located on the DOE Hanford Site near Richland, Washington, is the largest, most modern sodium-cooled test reactor in the world. Originally constructed to support the U.S. Liquid Metal Fast Breeder Reactor Program, the 400 thermal megawatt reactor began operation in 1980, and was ordered to shut down in December, 1993, when the DOE concluded there was no possibility of financial viability and the reactor was no longer needed to support its missions. The DOE requested WHC to develop a Plan to transition the FFTF to an industrially and radiologically safe

shutdown condition in approximately five years.
The decommissioning process for the FFTF, and other major transition facilities on the Hanford Site, will be accomplished in three phases: Phase I (Facility Transition), Phase II (Surveillance and Maintenance), and Phase III (Disposition). The FFTF transition phase started with termination of operations and includes those activities required to place the plant in a safe, stable and environmentally secure end-point condition with reduced risk to plant workers, the public, and the environment. Present planning is that FFTF will be unoccupied and locked, with the exception of maintaining a minimal amount of lighting, fire protection equipment, inert gas supply to the drained sodium systems, and ventilation required to support routine surveillance. The goal is to achieve this low cost surveillance and maintenance state as quickly as possible so funds can be redirected for higher priority environmental restoration activities at the Hanford Site.
At the completion of the Phase I activities, the FFTF will be turned over to the Hanford Site Environmental Restoration Contractor under the guidance of the DOE Office of Environmental Restoration (EM-40) for an extended surveillance and maintenance phase (Phase II) prior to the disposition phase (Phase III). During the surveillance and maintenance phase, the plant will be routinely monitored until decommissioning is completed. The DOE is currently developing a long-term facility decommissioning plan covering all key Hanford transition facilities. This decommissioning plan will facilitate integration and prioritization of the decommissioning activities with other Hanford cleanup efforts.
SCOPE OF THE FFTF TRANSITION PROJECT PLAN
The Plan provides the major elements and project baseline for completing Phase I transition activities and was the basis for development of a resource loaded schedule. The major activities include: reactor defueling, fuel offload to dry cask storage, sodium drain and storage, management of sodium residuals, shutdown of the auxiliary systems, and preparation of the appropriate environmental and regulatory documentation. When the transition end-state is achieved, the irradiated fuel will be washed and located in storage casks at the Interim Storage Area in the northeast corner of the FFTF complex, the approximate 260,000 gallons of sodium coolant will be drained and stored in the new Sodium Storage Facility adjacent to the reactor complex, the frozen sodium residuals remaining in the plant will be maintained under an inert gas blanket, and the auxiliary systems will be drained and deactivated.♀
Preliminary transition phase end-point criteria was developed for the FFTF early in the transition process. A detailed end-point criteria document is being developed to define the physical state of each plant system at the conclusion of the transition phase. This document will require extensive interaction between the FFTF staff, DOE, Environmental Restoration Contractor, and the regulators (i.e., State of Washington Department of Ecology and the U.S. Environmental Protection Agency). Once the transition phase is complete, the plant will remain in the low cost surveillance and maintenance phase for possibly decades before the start of disposition activities. Therefore, the plant will be configured with only a minimal number of operational systems.
The transition activities will be managed and directed utilizing a projectized approach for control and reporting to achieve the best schedule and cost effectiveness. The Resource Loaded Schedule (2) indicates that completion of the transition phase will require approximately six to seven years, at a cost of approximately $359 million. The summary schedule for the FFTF Transition Project is graphically shown in Fig. 1. The DOE goal is to accomplish the transition in approximately five years. The transition schedule extends beyond this goal due to many unique challenges associated with completing the sodium drain, fuel offload, and integrating these activities with shutdown of the plant's auxiliary systems. These challenges will require innovative engineering solutions and new and complex plant evolutions. During the first 4 years of the transition, approximately 90 percent of the plant systems are required to support hot sodium circulation. The minimum level of funding necessary to maintain the FFTF in a safe and stable condition prior to the sodium drain is estimated to be $32 million per year. Clearly, an expeditious completion of the transition will result in significant cost savings. Therefore, efforts are focused on accelerating the sodium drain and other critical path transition activities to the maximum extent possible, within budgetary and regulatory constraints in order to achieve schedule compression and the associated major cost reductions.

The key transition activities and associated issues are discussed in the following sections in the order depicted in the Fig. 1 summary schedule.

Reactor Defueling

The reactor vessel is currently being defueled to Interim Decay Storage and the Fuel Storage Facility using standard FFTF refueling equipment and operating procedures. The Interim Decay Storage vessel is located in-containment adjacent to the reactor vessel and is designed to provide temporary storage in a liquid sodium environment for new components en route to the reactor, and for irradiated components removed from the reactor. The Fuel Storage Facility is a separate building adjacent to the Reactor Service Building, and is designed to store spent fuel in a liquid sodium environment.

As each fuel component is removed from the reactor vessel, it must be replaced with a non-fueled component in order to maintain the upright geometry of the core necessary for the in-vessel handling machines to remotely grapple remaining core components. Initial shutdown planning called for inserting simulated core components that were used during the pre-critical checkout of the reactor system during this defueling evolution. An innovative approach was implemented to use the irradiated non-fuel core components (e.g., reflectors, control rods, etc.) that would have been excessed in order to maintain the necessary geometry. When defueling is complete, most of the non-fuel core components will be consolidated in the reactor vessel. This use of non-fuel irradiated hardware will result in waste minimization and circumvent the associated washing (removal of sodium from) and disposal costs for this hardware, culminating in a cost avoidance of $38 million. At the completion of reactor defueling, there will be 243 non-fueled components in the reactor vessel, 112 fueled components in the Interim Decay Storage and 258 fueled components in the Fuel Storage Facility. The milestone for completion of reactor defueling is September 6, 1995; however, the activity is ahead of schedule and is expected to be complete several months early.

Environmental Compliance

Significant activities are required to achieve compliance with the environmental regulations which impact the Phase I transition activities. The major regulations include the National Environmental Policy Act of 1969 (NEPA), Resource Conservation and Recovery Act of 1976 (RCRA), Clean Air Act and Amendments of 1990, Toxic Substances and Control Act of 1976, and National Historic Preservation Act of 1966. In addition, environmental restoration activities at the Hanford Site are governed by negotiated milestones established in the Hanford Federal Facility Agreement and Consent Order (Tri-Party Agreement).

Fig. 1.

Summary Schedule

The January 1994 amendment to the Tri-Party Agreement, required DOE to enter into negotiations with the State of Washington Department of Ecology and the U.S. Environmental Protection Agency, Region 10, to establish milestones for major Hanford Site facilities undergoing the decommissioning process. These milestones are legally binding and subject to judicial enforcement. A tentative agreement was signed by the three parties on January 17, 1995. The agreement includes milestones for transition of the FFTF corresponding to the critical path transition activities. The tentative agreement will undergo a 150 day public review and comment period prior to finalization. The goal of the FFTF agreement is to ensure that the facility completes the transition phase as expeditiously as possible so that funds can be redirected to higher priority environmental restoration activities at the Hanford Site.

The appropriate level of NEPA documentation required for the transition activities was determined to be an Environmental Assessment (EA). An EA was prepared and, following appropriate WHC and DOE review, was submitted to the affected states and Indian Nations on January 11, 1995 for a 30 day public review and comment period. The transition activities specifically delineated in the EA cannot commence prior to completion of the NEPA process. The associated constraints are depicted in Fig. 1, the most immediate being construction of the Sodium Storage Facility and initiation of fuel offload. The DOE-Richland Field Office recently received delegated authority from the DOE-Headquarters to approve NEPA documentation. This has expedited the EA approval process and removed it from the critical path. Following resolution of any comments, the Finding of No Significant Impact (FONSI) is anticipated by the end of February, 1995.

RCRA establishes requirements for the management of hazardous waste. The State of Washington Department of Ecology administers the requirements of this Act through the "Dangerous Waste Regulations" contained in the Washington Administration Code 173-303 (WAC). If a future decision is made to dispose of the approximately 260,000 gallons of FFTF sodium coolant as waste, management of the material would be regulated pursuant to these requirements. Currently, the sodium provides cooling for the irradiated fuel components. Although this inventory of sodium will not be needed for cooling after the fuel is removed, a new purpose for the sodium has been identified by the Tank Waste Remediation System (TWRS) Program at the Hanford Site. The TWRS Program plans to use the sodium, converted to sodium hydroxide, for caustic washing as part of the high level waste tank sludge pretreatment process. The TWRS process requires 21,000 metric tons of sodium hydroxide. Sodium hydroxide produced from the sodium metal at FFTF represents approximately 8 percent of this requirement. The sodium will be managed as product material for use at TWRS until an evaluation is completed in June, 1998, to confirm the final sodium disposition and form (i.e., product or waste).

In the interim, activities have been initiated to provide RCRA and WAC compliant storage for the sodium in the Sodium Storage Facility and treatment in the Sodium Reaction Facility, in the event the 1998 evaluation determines the sodium use at TWRS is not viable and the material must be managed as dangerous waste. A Notice of Intent for the new sodium facilities was submitted to the public for a 150 day public review/comment period. Following this period, a Part A Permit Application will be submitted to the State of Washington Department of Ecology.

A Notice of Construction is being prepared according to requirements of the WAC 246-247, "Radiation Protection - Air Emissions" and 40 CFR 61 Subpart H for the Sodium Storage Facility. The Notice of Construction is scheduled for submittal to the Washington State Department of Health by February 1, 1995 and approval is required to initiate construction of the Sodium Storage Facility.

IEM Cell/Fuel Offload Washing

The highly-radioactive fueled components will be moved to interim storage at the Interim Storage Area. The fueled components that are currently stored in a sodium environment will be transferred one at a time to the Interim Examination and Maintenance (IEM) Cell for washing, utilizing existing fuel handling equipment. The fuel is subjected to a moist argon atmosphere (within a closed sodium reaction system) to slowly react residual sodium in a controlled manner. The initial reaction is followed by several water rinses and, subsequently, the fuel is dried. The cleaned fuel is loaded into a Core Component Container in the IEM Cell, inerted, sealed and then transferred to the Reactor Service Building Cask Loading Station for placement into an Interim Storage Cask for transfer to above-ground dry cask interim storage at the Interim Storage Area. The cask is designed for storage up to 50 years pending a decision on final disposition (e.g., repository emplacement).

The rate at which fuel can be transferred to the IEM Cell, washed, dried and transferred into a Core Component Container and an Interim Storage Cask is limited by the time it takes to wash the assemblies. Fuel washing operations will be continuous (round-the-clock) seven days per week during the offload period. Since these IEM Cell activities, i.e., transfers, washing, and drying, have been performed routinely as part of the experiment processing cycle, rate estimates are presented with a high degree of confidence. Assuming a conservative availability factor of 50% for the entire fuel offload process, the current inventory of fuel assemblies and pin containers (371), which also includes 32 unirradiated assemblies and some special assemblies that will be stored at other locations, can be washed in approximately 2.8 years.

Several enhancements to the IEM Cell and cask loading station are in progress to support the fuel offload process and are scheduled for completion by September, 1995. An ion exchange system is being installed in the radioactive liquid waste system to essentially eliminate the waste that is currently generated during use of the sodium removal system (approximately 500 gallons/wash). This represents a significant waste minimization effort that will reduce the radioactive liquid waste that would have been generated from approximately 185,000 gallons to less than 1,000 gallons. The savings in radioactive liquid waste disposal costs are expected to be greater than $2 million.

There are two intact assemblies that produced a delayed neutron-monitoring signal while in the reactor, which indicates that a breach occurred in the fuel cladding.

These assemblies will be disassembled in the IEM Cell. The failed pin(s) will be identified and encapsulated, placed in pin containers with the remaining pins and dispositioned as the highly-radioactive fuel discussed above. Additionally, several fuel assemblies are known to have pin hole cladding failures which resulted in release of fission gases only while in the reactor; these assemblies will be processed last to minimize the consequences of potential contamination release and resultant deposition in the sodium removal equipment, which would make equipment maintenance more difficult.

While the modifications are being completed in the IEM Cell, selected fuel pins and ducts will be washed and transferred to off-site facilities (i.e., Idaho [Hot Fuel Examination Facility] or Pacific Northwest Laboratory [300 Area, Hanford Site]) for further examination. These materials were irradiated in the FFTF under the terms of a Specific Memorandum of Agreement between the DOE and the Power Reactor and Nuclear Fuel Development Corporation of Japan (PNC). Planning shows that this activity can be completed by the end of Fiscal Year 1995 without affecting the transition project critical path. Funding for this work will be provided by PNC.

Interim Storage Casks

The Core Component Container accommodates six or seven fuel assemblies or pin containers and will ultimately be stored in an Interim Storage Cask. In addition to providing the primary confinement boundary for the 50-year design life of the fuel dry storage system, the Core Component Container provides the necessary handling capability for transfer operations. The fabrication contract for fifty Core Component Containers was placed on January 13, 1995.

The Interim Storage Cask design and fabrication contract schedule is a critical path element for successful completion of the FFTF transition. Initiation of fuel washing activities is dependent on having storage available. Above ground, dry cask storage is currently used both nationally (e.g., by Virginia Power at the Surrey and North Anna plants), and internationally (e.g., nuclear power plants in Canada and Europe). The concept has been thoroughly studied and documented [additional details pertaining to this mode of operation for interim storage may be found in the Final Version Dry Cask Storage Study (3)].

The Interim Storage Cask design is a passively ventilated concrete and steel shielded cask with a stainless steel secondary confinement boundary. The maximum weight of the cask, with the 5,000 pound Core Component Container payload, will be 114,200 pounds. The Interim Storage Cask design is modeled after an approved U.S. Nuclear Regulatory Commission (NRC) design and meets the general licensing provisions of 10 CFR 72 for storage of commercial fuel. Provisions have been incorporated into the ISC design to accommodate the possibility of future on-site fuel transfers; however, this unit is a storage cask, not a licensed transportation cask. Fuel transportation casks are typically large, involve complex loading and transfer operations, and are very expensive. Design, procurement, and licensing of the 50 to 60 Interim Storage Casks required for storage of the FFTF fuel to meet requirements for off-site shipping would be cost prohibitive and inconsistent with industry practice.

The purchase order for the design and procurement of the first ten Interim Storage Casks was placed with General Atomics on September 16, 1993 at a cost of $4.7 million. After the first cask is received and tested, the purchase order for the remaining forty casks will be placed by September 1995. Original planning was to place six fueled components into each Core Component Container. However, an alternate loading configuration is being evaluated in which seven assemblies would be placed in each Core Component Container. This would reduce the number of Core Component Containers and Interim Storage Casks needed from 57 to 50. This approach would result in a substantial cost savings to the Project on the order of $2.6 million. There would also be additional cost savings achieved as a result of fewer cask loading/handling operations.

The Interim Storage Area, located in the northeast corner of the FFTF complex, will be surrounded by a fence with locked access to permit controlled loading, unloading and inspection of the Interim Storage Casks. There will be overhead lighting and crash barriers installed, as required. The design and construction of the Interim Storage Area is estimated at $300,000 with a construction schedule as depicted in the Fig. 1 summary schedule.

Unirradiated/Low-radioactive Special Nuclear Material (SNM)

Eleven slightly irradiated fueled components will require additional safeguards and

security measures because there will be insufficient radioactivity levels for the assemblies to be self-protecting. By the year 2030, seven assemblies will be classified as slightly-radioactive, and the remaining four will be moderately-radioactive. The current approach is to place the seven future low-radioactivity fuel in a single Interim Storage Cask and ship it to the Hanford Plutonium Finishing Plant (PFP) for storage in their existing protected area. The four future moderately-radioactive fuel would be intermixed (one each) with five or six highly-radioactive components and stored at the Interim Storage Area.
The fuel offload also involves sending 32 unirradiated fueled assemblies to the PFP for storage. As with irradiated fuel, the unirradiated assemblies will be washed in the IEM Cell. An engineering study is evaluating the preferred storage option at PFP. At present, the lowest cost option appears to entail loading the fuel into Interim Storage Casks for transfer and storage of the fuel on a storage pad at the PFP protected area. Before the Interim Storage Casks can be shipped to the PFP, a Safety Analysis Report for Packaging (SARP) must be prepared to allow the Interim Storage Casks to be transported across the Hanford Site. An estimated $5 to $7 million savings over earlier storage options could be achieved by this approach.
Sodium Storage Facility
The metallic sodium coolant will be maintained in a molten state until the fuel assemblies are removed from their respective storage location (i.e., the reactor vessel, Interim Decay Storage, or the Fuel Storage Facility) and the sodium transferred to the new Sodium Storage Facility. The Sodium Storage Facility will be designed and constructed adjacent to the FFTF complex to support the sodium drain operations and will house the FFTF primary (140,000 gallons), secondary (66,000 gallons), Interim Decay Storage (23,000 gallons) and Fuel Storage Facility (31,000 gallons) sodium inventories.
A detailed review of the design and construction schedule for the Sodium Storage Facility indicated that a six month acceleration could be achieved, contingent upon availability of appropriate funding, and would culminate in a substantial savings to the Project of approximately $3 million for every month the project is completed early. Detailed planning and supporting activities are proceeding accordingly on an accelerated basis. The Fig. 1 summary schedule reflects this acceleration. The conceptual design was approved on December 16, 1994 with a total project cost of $10.4 million (including required transfer piping). Project authorization was received from RL on December 30, 1994 for $5.2 million in Fiscal Year 1995 to complete the definitive design, site preparation work, and contract award for starting construction on/or before the end of the fiscal year.
Conceptually, the Sodium Storage Facility will be a concrete building approximately 110 feet long by 170 feet wide. Because of the uncertainty in the final sodium regulatory designation, and the fact this is a new facility, the Sodium Storage Facility will be designed and constructed to meet Resource Conservation and Recovery Act of 1976 (RCRA) requirements, as implemented by the WAC 173-303, Dangerous Waste Regulations. This will eliminate modifying the facility to meet WAC 173-303 storage requirements following the 1998 TWRS evaluation should the sodium designation change to waste. Four sodium tanks (three 80,000 gallon and one 52,000 gallon capacity), originally procured for the Clinch River Breeder ♀
Reactor Project, will be installed in the facility. The tanks are currently stored at the Hanford Area's 300 Area. Each tank is expected to require a separate move, using a crawler type transporter. A large, portable crane at each end of the move will be required to handle the tanks. An access route to the Sodium Storage Facility site will need to be cleared (power lines moved, fences removed/installed, underground utilities protected from weight, etc.). The facility will provide shielding to reduce radiation levels to acceptable limits outside the building walls. Radiation levels at the top of the tanks will be approximately 85 millirem per hour.
Piping will be provided from the FFTF sodium systems to the new Sodium Storage Facility. Insulation and trace heat will be added to maintain a 300F to 400F temperature during the sodium transfer. The tanks will be inerted prior to transfer of the sodium and an inert gas blanket will be maintained over the sodium during storage. The sodium will be pressure transferred to the facility, and subsequently allowed to cool and solidify. The sodium will be stored in a frozen state pending the decision on final sodium disposition and form (product or waste). The sodium would not be converted to sodium hydroxide until closer to the TWRS projected need

date in the year 2008.
Sodium Drain
Approximately 90 percent of the plant systems are required to support hot sodium circulation at an estimated minimum surveillance and maintenance cost of $32 million per year. Therefore, efforts have been ongoing to attempt to accelerate availability of the Sodium Storage Facility, as discussed above. An innovative approach will be implemented to transfer the secondary sodium loops to the three in-plant storage/drain vessels on an expedited basis prior to the availability of the Sodium Storage Facility (April, 1997). This secondary sodium transfer will be initiated after the reactor core has been defueled, and two immersion heater assemblies have been installed in the reactor vessel fuel transfer ports. This transfer sequence is estimated to save approximately $2.6 million resulting from reduced electrical power costs and elimination of related equipment maintenance and surveillance. The primary system will be drained when the Sodium Storage Facility is available followed by the Interim Decay Storage and Fuel Storage Facility drain when all the fuel has been removed.
Every reasonable effort will be taken to remove as much of the sodium as practicable from the plant. However, sodium residuals (approximately 3,000 to 4,000 gallons) will remain within the systems at the conclusion of the transition phase. It is planned to maintain an inert gas blanket over the frozen residuals to minimize any chemical reactions during the long-term surveillance and maintenance period. This will provide the greatest flexibility for later decommissioning activities. A small quantity (600 gallons) of sodium-potassium (NaK) alloy exists in specialized cooling systems within the plant. Chemically, NaK is more reactive than sodium, especially when exposed to air, and can become shock sensitive. As a result, we believe it is expedient not to leave Nak residuals in the plant. An innovative approach is being evaluated that includes cross connecting appropriate sodium and NaK piping systems and using the sodium to flush the NaK into the bulk sodium. The total NaK inventory is a small fraction of 1 percent of the sodium volume, and sodium properties (e.g., freezing point) would not be measurably affected by the presence of this small quantity of NaK. This option will require confirmation by the TWRS Program to ensure the potassium impurity would not impact the proposed use of the FFTF sodium in the tank waste pretreatment process.
Due to the relatively simple secondary loop layout and component design, most of the sodium in the secondary loops will drain by gravity. However, the Intermediate Heat Exchangers will not drain completely. Each Intermediate Heat Exchanger will have approximately 1500 gallons of secondary sodium remaining in the tube sides of the units following the gravity drain. This sodium must be removed by cutting into the boundary at the top of the inlet pipe of each unit and installing a special dip tube through which the sodium can be removed. This activity must be performed within the primary Heat Transport System cells inside containment where the Intermediate Heat Exchangers are located.
Drain of the primary system provides a unique challenge. With the exception of the reactor vessel, all of the plant sodium systems are trace-heated and system temperature can be maintained while draining. The reactor vessel is currently maintained at temperature by heat transfer into the primary system from the secondary loops (which are heated by pump work and/or oil fired preheaters). As soon as primary flow is stopped, the reactor vessel will start cooling. The reactor has no permanently installed heaters and there is virtually no temperature instrumentation on the vessel itself. During original preheat during the sodium fill, two temporary heating units were utilized to preheat the reactor vessel. Only one of these units is still available, the Nitrogen Blower Heater Unit. This unit circulates heated nitrogen around the bottom of the reactor vessel through a permanently installed piping manifold within the guard vessel. In addition, electrical immersion heaters are being purchased and will be installed through the fuel transfer ports to provide a redundant heating mechanism.
The three primary loops, the upper portion of the reactor vessel, and the reactor overflow tank can be drained. At the point where the reactor vessel outlet nozzles are uncovered, circulation will stop and the sodium will begin a slow cooldown if auxiliary heating is not provided. At this point approximately 51,000 gallons of sodium will remain in the reactor vessel and all vessel heat will come from the Nitrogen Blower Heater Unit and immersion heaters. Sodium draining can continue through the cold leg piping until the sodium level is reduced to the vicinity of the

reactor inlet nozzles. However, drain of the reactor vessel below the level of the inlet nozzles is precluded by design. Approximately 16,000 gallons of sodium will remain in the vessel at this point. An access hole will be drilled through the core basket and the wall of the low pressure inlet plenum to permit installation of a dip tube directly from the top through the reactor vessel head. This will require design and fabrication of remotely installed drilling equipment over forty feet long for drilling under sodium.

The Interim Decay Storage vessel has an installed drain line to the bottom and can be drained. The drain will be complicated by the time consuming task of removing sodium from the Core Component Pots within the vessel, either by siphoning or displacement. The Fuel Storage Facility vessel drain will also have to utilize a dip tube. In addition, the Fuel Storage Facility is not cross-connected with the rest of the FFTF sodium systems, and approximately 400 feet of sodium line will have be installed to connect to the Sodium Storage Facility.

General Plant Support/Auxiliary Systems Shutdown

The level of general plant support for the FFTF during the first four years of transition will be comparable to that required for hot standby because approximately 90% of the plant systems are required to support hot sodium circulation prior to sodium draining. Some reduction will result from the planned early drain of the secondary sodium systems. Future efforts will focus on compressing the logic for shutdown of the auxiliary systems. Disposition of the polychlorinated biphenyl transformers following the completion of the sodium drain was a major contributor to the two year extension to the transition schedule. Emphasis is being placed on integrating this activity earlier in the transition activities by shifting plant power loads as possible to free up transformers for removal. This effort is expected to result in compression of the overall schedule.

As the plant systems become available for shutdown, there will be a corresponding reduction in the need for general maintenance and plant support. As the level of required support decreases, the displaced resources will then be available to assist in configuring the plant for turnover to the Environmental Restoration Contractor. The required level of support will be minimal after fuel offload and sodium drain and cooldown to ambient temperature. Essentially all of the plant systems will be deactivated. Actual facility support will be limited to minimal maintenance, inert gas system positive pressure checks, and facility walkdowns. The cost for the facility in this low cost surveillance and maintenance state at the completion of the transition phase is expected to be approximately $1 million per year.

Minimal monitoring will also be required for the Sodium Storage Facility up to the time it is drained and the sodium is processed through the Sodium Reaction Facility. Fire detection will be required in both facilities where storage of sodium and processing will be centralized.

Sodium Reaction Facility

The Sodium Reaction Facility will be constructed as a separate building near the Sodium Storage Facility. Since the FFTF sodium may not be required by the TWRS Program until 2008, for planning purposes the construction of the Sodium Reaction Facility is being deferred, since the long term storage of solidified sodium is preferred to the long term storage of sodium hydroxide. The Sodium Reaction Facility schedule depicted in Fig. 1 presents the schedule that would be pursued if the sodium has to be disposed of as waste. It is retained on the schedule to maintain visibility for the project. The technical baseline for both the TWRS and FFTF Programs is to utilize the sodium, converted to sodium hydroxide, for the high level waste tank pretreatment process.

The sodium reaction process utilized by Argonne National Laboratory-West currently forms the technical baseline for the Sodium Reaction Facility. Pending operational verification of the Idaho unit, a duplicate processing facility will be constructed at FFTF, thus reducing development and design costs. The process consists of injecting molten sodium and water into a reaction vessel partially filled with 30% to 50% sodium hydroxide at about 240F. The vigorous reaction produces more sodium hydroxide and hydrogen gas. The gas is swept out of the vessel by a nitrogen cover gas purge and ♀
maintained at sufficiently low dilution so as not to be flammable when mixed with air. The FFTF sodium metal will be processed in two years, assuming a plant efficiency of 70% at a throughput of about 30 gallons/hour. If disposal of the sodium as waste is required, the sodium hydroxide solution would be reacted with

sulfuric acid to produce sodium sulfate. The sodium sulfate would be dried and collected into containers and transported to a Hanford Site disposal facility.

Documentation

The FFTF Transition Project Plan will be maintained as a living document that will be updated as the FFTF transition progresses in order to provide the current logic and project baseline. Implementation of a Technical Specification Reduction Project eliminated 79% of the current Technical Specifications and provided a new, cohesive safety basis for the FFTF deactivation (estimated savings of $1.1 million). Revisions will be required to reflect new plant evolutions (i.e., fuel offload and sodium drain) and evolving plant conditions as the transition phase proceeds. The End-Point Criteria Document will define the actions required prior to turnover of the FFTF to the Environmental Restoration Contractor and the Surveillance and Maintenance Plan will address the requirements for the Surveillance and Maintenance Phase.

CONCLUSION

To date, the Transition Project has been extremely successful and continues to be ahead of schedule and under cost. Challenging and innovative work is in progress to resolve technical issues and to support efforts to compress the transition schedule. The erosion of experienced FFTF staff, from natural attrition and the recent early retirement incentive, has begun to be felt and dwindling resources will make achievement of the aggressive transition schedule a challenge.

PUREX/UO3 PLANT DEACTIVATION PROJECT STATUS: THE TRANSITION TO DECONTAMINATION AND DECOMMISSIONING

S.K. Barnard
W.G. Jasen
Westinghouse Hanford Company
P.O Box 1970
Richland, WA 99352

ABSTRACT

The U.S. Department of Energy's Plutonium-Uranium Extraction (PUREX) Plant came on line in mid-1955. The PUREX plant extracted plutonium and uranium from spent nuclear fuel for use in the nation's defense program. The plutonium was sent to the Plutonium Finishing Plant, and the uranium was sent in liquid form to the Uranium Trioxide (UO3) Plant. At the UO3 plant, the liquid was converted to a solid uranium oxide powder that was then shipped to other Department of Energy defense sites. Now, Hanford's mission has changed from making plutonium to environmental cleanup. The Department of Energy shut down the PUREX plant in 1990 and the UO3 Plant in 1993. The two plants are to be deactivated--brought to a state where they can be maintained with minimal surveillance while awaiting final deposition.
Deactivation begins the transition of a nuclear facility to decontamination and decommissioning (D&D), the final phase of a facility's life cycle. The goal of deactivation is to place the facilities in a safe and environmentally secure configuration. The five-year PUREX/UO3, Deactivation Project Management Plan (Project Management Plan) outlines the proposed methods by which that goal is to be achieved. The Project Management Plan is being reviewed by the Washington State Department of Ecology, the Department of Health, the U.S. Environmental Protection Agency, citizens and interest groups effected by Hanford cleanup decisions. Their input helps decide how cleanup will proceed.

DEACTIVATION

Deactivation activities include eliminating or reducing the plants' major chemical

and radioactive hazards. The bulk of the equipment and the structural components will remain, and some contamination will remain on surfaces within the plants. Such contamination is fixed in place or isolated, to keep it away from people and the environment.

When deactivation is complete, the buildings will be unoccupied and locked, and will be monitored and inspected periodically. The PUREX and UO3 plants can remain in this safe condition for many years, until final D&D takes place.

WHY DEACTIVATE?

The Department of Energy wants to deactivate the PUREX and UO3 plants in order to progress with Hanford cleanup and to save money. Surveillance and upkeep alone for these two plants costs about $34 million per year. Deactivation activities are expected to cost between $10 and $16 million each year of the five-year deactivation project. Once the plants are deactivated, expenses will decease to less than $2 million annually.

THE DEACTIVATION PROJECT MANAGEMENT PLAN

In December 1992, planning was initiated for deactivation of the PUREX and UO3 Plants. The objective was to identify the activities needed to make both plants safe and environmentally secure until their final disposition.

The PUREX/UO3 Deactivation Project Management Plan describes the proposed deactivation approach and the estimated supporting technical, cost, and schedule baselines. For planning purposes, an option was chosen for each deactivation activity so that cost and schedule estimates could be developed for the project. However, other public interests and values may be associated with deactivation. Interested public parties, the Department of Energy, and Westinghouse Hanford Company and its regulatory agencies will all define together how the PUREX/UO3 deactivation project will proceed.

The objects of the Project Management Plan support the Department of Energy's goal to develop swift, uniform methods for deactivating facilities similar to PUREX/UO3. The objectives are:

Establish a safe and environmentally secure configuration of the plants that can be maintained for at least 10 years

bring yearly surveillance and maintenance costs to less than $2 million

Use a cost-effective, innovative approach to achieve and maintain deactivation

Comply with environmental, safety, and health codes and standards

Involve interested groups, citizens and affected parties in major policy decisions during development and execution of the Project Management Plan

Upon completion of deactivation, help the PUREX/UO3 workforces find new jobs

Apply lessons learned from commercial deactivation experience

Establish the PUREX/UO3 Deactivation Project as a model for other Department of Energy facilities.

ISSUES CONFRONTING PUREX/UO3 DEACTIVATION

Several issues challenge the PUREX/UO3 deactivation project. The project management plan explains how Westinghouse Hanford Company proposes to deal with these issues; however, public values will play an important role in making the final decisions. Some of the issues are:

Spent Fuel Storage

When PUREX shut down, it had not processed all the spent fuel in the plant. The remaining fuel must be moved and stored safely. The department of energy's current plan is to move the PUREX spent fuel to the 100 Area K Basins, where it will be encapsulated and stored with other Hanford spent fuel.

Nitric Acid

Contaminated nitric acid is a byproduct of the PUREX process. Approximately 200,000 gallons are stored at PUREX. One option is to reduce the quantity and concentration of nitric acid by a process called sugar denitration. This process would discharge nitrogen oxide gases to the air through the PUREX main stack. The preferred option is to re-use the nitric acid product at an off-site facility. Current plans are to send the acid to a facility in England.

Reducing Waste Volume

Large volumes of liquid waste will be generated from process flushing during deactivation. This waste will be transferred to the Hanford Site waste storage tanks. The amount of waste transferred can be significantly reduced by operating a PUREX concentrator that would create non-contaminated steam condensate, which would be disposed of in the 216-B-3 Pond System.

Plutonium/Uranium Solutions

There are approximately 6,000 gallons of plutonium/uranium solution in tanks in the PUREX canyon. The preferred alternative is to neutralize the solution and send it to the Hanford Site Tank Farms' double-shell waste tanks, where it would be mixed with similar waste.

Effluent Path

Currently, the PUREX ventilation system operates 11 stacks. The current planning basis option is to consolidate all the ventilation systems in the 202-A Building into a single effluent path. This action would reduce the volume of air discharged and the amount of stack surveillance required. Another option is to completely shut down the ventilation system.

Development of End States for Turnover to D&D

For each of the facilities' systems and spaces, a logical process is being followed to determine a satisfactory end state. The end state is the condition the system or space will be left in when deactivation is complete. The process looks at the objectives, tasks and expected later uses for that system or space. The end states are developed in successively more detailed levels, until each task necessary to achieve a satisfactory end state has been defined.

CONCLUSION

The PUREX/UO3 plants have had a long and productive history. Deactivation begins the transition of a nuclear facility to decontamination and decommissioning and is an important step in achieving a safe, stable condition that minimizes surveillance and maintenance costs. Deactivation also brings to an end a historic phase in the lives of the PUREX/UO3 plants.

30-3

DEACTIVATION AND CLEANOUT OF THE 308 FUELS LABORATORY AND THE 232-Z INCINERATOR AT THE HANFORD SITE

R.J. Bliss
M. S. Gerber
Westinghouse Hanford Company

ABSTRACT

This paper describes the deactivation and source term reduction activities conducted over the recent past in two plutonium-contaminated Hanford Site buildings: the 308 Fuels Development Laboratory and the 232-Z Incinerator. Both of these facilities belong to the U.S. Department of Energy, and the projects are unique success stories carried out in direct support of EM-60 functions and requirements. In both cases the buildings, for different reasons, contained unacceptable amounts of plutonium, and were stabilized and placed in a safe, pre-D&D (decontamination and decommissioning) mode.

The concept of deactivation as the last step in the operating life of a facility will be discussed. The need for and requirements of EM-60 transition between operations and D&D, the costs savings, techniques, regulations and lessons learned also will be discussed. This paper describes the strategies that led to successful source term reduction: accurate characterization, cooperation among different divisions within DOE and the Hanford Site, attention to regulations (especially unique in this case since the 232-Z Incinerator has been nominated as a Historic Structure to the National Register of Historic Places), and stakeholder concerns involving the proximity of the 308 Building to the Columbia River. The paper also weaves in the history, missions, and plutonium accumulation of the two buildings. The lessons learned are cogent to many other present and future deactivation activities across the DOE complex and indeed across the world.

DEACTIVATION ACTIVITIES AT THE HANFORD SITE

The Hanford Site, located in southeastern Washington state, was one of America's primary arsenals of nuclear defense production for nearly 50 years beginning in World War II. Approximately 53 metric tons of weapons grade plutonium, over half of the national supply and about one quarter of the world's supply, were produced at Hanford between 1944 and 1989. Today, many Site buildings are undergoing deactivation, an EM-60 activity that is a precursor to decontamination and decommissioning (D&D). The primary difference between the two activities is that equipment and structural items are not removed or torn down in deactivation. However, utilities are disconnected, and special nuclear materials (SNM) as well as hazardous and pyrophoric substances are removed from structures undergoing this

process.

308 FUELS DEVELOPMENT LABORATORY

Deactivation was completed as of March 31, 1994 at the Hanford Site's 308 Fuels Development Laboratory (FDL), a 94,000-square foot structure that opened in 1960 to support fuels diversification and modeling in the pre-breeder reactor era. Throughout its active lifetime, the 308 Building was the scene of an almost dazzling array of pioneering developments in fuels technology and fabrication. Primarily a non-defense facility, the 308 Building was the Atomic Energy Commission's (AEC - predecessor agency to the DOE) largest research effort to demonstrate the effectiveness of various PuO2 and MOX fuels in the "Atoms for Peace" program.(1) The first fuel mixtures produced in the PFPP (Plutonium Fabrication Pilot Plant - original name for the 308 Building) were metallic, but ceramic fuel blends were being worked in the facility within five years. For a brief time in the late 1960s, neptunium-aluminum alloy fuel target elements and lithium aluminate (LiAlO2) fuel targets were produced in the 308 Building for defense production testing in Hanford's N-Reactor.

However, the building's largest mission came when the Hanford Site was chosen in 1969 as the location for the DOE's prototype advanced sodium cooled reactor (the FFTF) that would develop and test fuels for breeder reactors.

The earliest fuels made in the 308 Building for potential use in the FFTF were vibration packed ("vi-pack") powders, but testing demonstrated a low density. This concept soon was discarded in favor of oxide pellet fuel made in the shape of cylinders approximately 3/10" high and 2/10" in diameter. The 308 Building's last mission was repackaging work involving MOX powders for purposes of consolidation This work took place from late 1991 through early 1992.(2)

The decision to deactivate the structure was driven by a 1980s Department of Energy (DOE) decision that plutonium fuels should not be fabricated in areas near the Site's boundaries, as well as by changing facility structural requirements. The 300 Area is located just four miles north of Richland, along the Columbia River, an area of intense interest and concern to regional stakeholders.

Removal of the building's working inventory of plutonium, used in making mixed oxide (MOX) fuel pellets for the Fast Flux Test Facility (FFTF) and other test reactors, took place over the course of a year beginning in mid-1991. Completed in May 1992, this work decreased the yearly security costs for the facility by approximately $3-million. During the peak of its years as a fabrication facility, the 308 Building held as much as 3 metric tons of encapsulated plutonium and approximately 200 kilograms (kg) of MOX powder.

Inventory transfer has been followed by the cleanout and stabilization of plutonium oxide (PuO2) and enriched uranium oxide (UO2) residues and powders in the facility's equipment and duct work. This additional effort, along with the transfer of all resident personnel from the building, lowered the annual surveillance budget by another $1 million.

ALPHA CONTAMINATION STABILIZED IN GLOVE BOXES AND HOODS

Over the past three years, a small crew, the remnant of a once-large FFTF fuel supply staff, worked in the 308 Building to wipe, spray and seal the 50 glove boxes and six open-faced hoods that are being left inside the facility until complete D&D occurs at a future date. A majority of the glove boxes are standard size, and contain front and back windows, numerous glove entry ports, equipment doorways and ports, and entryways for electrical and fluid/gaseous services. In these glove boxes, MOX powders and pellets were pressed and then sintered into reactor fuel, However, six of the glove boxes are approximately 30' long by 3' wide and 3' high, with 40 entry ports and multiple windows, larger equipment ports, and other penetrations. These glove boxes held the furnaces and other large, pilot equipment pieces crucial in the many fuels fabrication research and development activities that were pioneered in the building. The open-faced hoods are approximately 4' long by 3' wide and 3' high, and stand on legs about 4' high. These hoods, although they accumulated alpha contamination, did not provide the level of confinement of a glove box, and so were used primarily for work with uranium materials and processes.

The deactivation crew, after removing much of the instrumentation and other small equipment from the building, donned special anti-contamination clothing and extracted small equipment from inside the glove boxes and hoods. They then performed multiple wipe-downs of the inner surfaces, using damp rags that later were

dried and disposed as solid waste. Next, they sprayed the insides of the glove boxes and hoods with a modified acrylic latex, contamination fixant that appears cloudy at first but dries to a nearly clear state. Lastly, they covered all of the glove ports with specially fitted metal plates, and placed over them a polyolefin "shrink-wrap" material that contained an adhesive on the inside. The material is the same as that used to protect welds in industrial pipelines. Using a hot air treatment, they activated the tar-like adhesive so that it melted and flowed into all the crevices between the plates and the ports, thus creating a very rugged seal. The plutonium inventory currently remaining ("held-up") in this equipment totals less than 400 grams.

ATTENTION ALSO GIVEN TO DUCT WORK, TEST REACTOR AND OTHER BUILDING COMPONENTS

In the meanwhile, non-destructive assay was performed on 2,000 feet of duct work in the 308 Building. Although only small amounts of contamination were found, the flanges were caulked with silicone sealants. Lastly, the fasteners on the gaskets were painted with a high-grade interior household sealant. Uncontaminated equipment in the building, such as wire-wrap machines used to spiral wrap the outside of each FFTF fuel pin, pulse magnetic welding (PMW) equipment, and profilometers used to make precise measurements of the outside diameter of finished fuel pins, were either excessed or sent to offsite storage.(4)

The deactivation of a 250-KW (kilowatt) TRIGA (Training Research Isotopes, General Atomics)* reactor that was emplaced in Room 162 of the 308 Building's Annex in the late 1970s will occur on a slower schedule. The reactor operated for 13 years to perform neutron radiography testing on fuel pellets and pins, to irradiate materials, and to provide reactor operator training. Currently, the TRIGA's 68 fuel elements have been removed from its core and placed in racks in the water-filled pit or reactor pool. An Environmental Assessment (EA) for the disposition of this spent fuel, which has been irradiated to only a low burnup level (less than 1 percent), currently is under review.

Specially designed irradiated fuel shipping/storage casks are being designed by the staff of the Hanford Site's operating contractor, Westinghouse Hanford Company (WHC). Until the fuel leaves the 308 Building Annex however, regular surveillance of this area will be necessary. Following fuel removal, the control rods, other neutron sources, and some instrumentation will be taken out of the TRIGA and the water pool will be drained. Most of the large, fixed equipment will be left for future D&D.(5)

232-Z INCINERATOR

During 1994 in Hanford's 200-West Area, cleanout of plutonium-bearing equipment, parts and residues took place at the 232-Z Incinerator. Located in the PFP (Plutonium Finishing Plant) complex, the incinerator operated from 1962 through 1973. It was conceived and built as a way to salvage additional plutonium (Pu) that was being buried as residual material on contaminated solid wastes in the late 1950s, a time when the per unit value of plutonium was extremely high.

Candidate wastes for the incinerator included cartons containing contaminated filters, rags, paper, special work clothing, gloves that were not rubber or plastic, and other combustible items used in the PFP and in Hanford's REDOX and PUREX operations. Still more Pu was recovered from non-burnable scrap in one (later two) leach pot(s) in the 232-Z Building. The leachate then was run through solvent extraction processes in the 234-5Z facility to complete the Pu recovery operation.(6)

Preliminary isolation and terminal cleanout activities began in 1982, and continued on a sporadic basis until inspections undertaken in 1989-90 demonstrated the need for more intensive action to stabilize the old facility. At that time, when seismic evaluations demonstrated the 232-Z Building's inability to meet modern criteria, the structure was elevated to high priority status for cleanout. Further, inspections of the duct work and service piping estimated the presence of 848 grams of "held-up" plutonium, levels considerably higher than the "one-third of critical mass" amounts necessary for the facility to be considered "isolated."

The 1994 cleanout was conducted as a joint effort between the WHC Transition Projects and Decontamination and Decommissioning (D&D) organizations. Between January and September, Nuclear Process Operators (NPOs) from the PFP removed moveable equipment, instruments, portions of contaminated piping, duct work and other parts.

At the completion of this effort, the 232-Z Building was left standing, with its

five glove boxes, the scrubber (exhaust filtration) cell, the ventilation system, the in-floor filter and the filter box still in place. Approximately 600 grams of Pu were removed, and the effort cost about $1-million.

USQ DECLARED AND RESOLVED

However, just at that point, NDA (non-destructive analysis) undertaken to ascertain the Pu inventory of the incinerator glove box itself still showed the presence of between 1-10 kilograms (kg). Since the amount at the high end of that scale falls outside the confirmed safety boundaries, a USQ (Unreviewed Safety Question) was declared in late August, and administrative controls (including no unnecessary entries) were placed on the 232-Z Building.

Immediately, two separate criticality analyses were launched, to model the situation in the glove box under worst case scenarios. No conditions that could lead to a criticality event were found. Within just a few days, an extensive, independent re-analysis to better characterize gamma and neutron emissions from the Pu was started by a team of national experts in NDA. The team also looked at attenuation (shielding) factors in connection with the approximately 2,900 pounds of fire bricks in the glove box itself.(7)

Using state-of-the-art neutron detection equipment, as well as the long and careful germanium method of gamma detection, the team placed a highly radioactive cesium-137 source at various points outside the glove box to determine and compare their readings. No intrusive entry into the glove box was allowed. Their findings, released in October, demonstrated the presence of only 1-5 kg of Pu.

At the same time, Hanford Site personnel moved to re-study the structural characteristics of the 1962 concrete block building itself. While re-verification took place, consideration was given to placing a heavy steel shroud around the incinerator glove box itself. However, the re-study showed that such a shroud would not be necessary.

In a parallel path, safety re-analysis was taking place. Accident scenarios ranging up to total collapse of the building (with toppling of the glove box) were studied. The outcome of these analyses demonstrated only a 10 percent "release factor" for the glove box itself, but a 100 percent release factor for the building. In other words, should an earthquake occur, only 10 percent of the material in the glove box would be expected to escape the glove box (through two top glove ports), but 100 percent of that material would be expected to escape the building.

Given this result, no further protective actions were required, but WHC decided to install a special new anchoring system for the glovebox as an added safety measure. This anchor assures that the glove box will not topple over under any foreseeable accident conditions. Design, procurement and installation concluded in December. Meanwhile, the USQ was officially resolved.

232-Z FACILITY HISTORIC

Meanwhile, in mid-1994, the 232-Z facility had been named to the National Register of Historic Places due to its unusual equipment design and first-of-a-kind method of automating and executing the incineration of plutonium-bearing combustibles. Opened in 1963, the 232-Z operation surpassed previous Pu scrap burning efforts at other AEC sites in terms of complexity and automation.

Because of its unique past, the 232-Z facility required thorough historic documentation and photographing under the National Historic Preservation Act. A Historic American Engineering Record (HAER) preservation package was rushed to completion during the hectic days right after the USQ was declared and the criticality analysis was completed. The building is now being readied for final cleanout and eventual D&D.

CONCLUSION

In conclusion, the deactivation work carried out at Hanford's 308 Fuels Development Laboratory and at the 232-Z Incinerator demonstrate lessons that are cogent to many other present and future deactivation activities across the DOE complex and indeed across the world. The lessons in techniques of contamination fixation, cooperation among various organizations, attention to regulations and stakeholder views and priorities can be applied elsewhere to stabilize buildings that may have to wait years for D&D but that must be rendered safe for the interim period.

ABSTRACT

The methodology presented in this report provides a model for estimating the volume and types of waste expected from the removal of equipment and other materials during Decontamination and Decommissioning (D&D) of canyon-type fuel reprocessing facilities. This methodology offers a rough estimation technique based on a comparative analysis for a similar, previously studied, reprocessing facility. This approach is especially useful as a planning tool to save time and money while preparing for final D&D. The basic methodology described here can be extended for use at other types of facilities, such as glovebox or reactor facilities.

INTRODUCTION

Located in the southeastern region of the state of Washington, the Hanford Nuclear Site began chemical processing operations in 1944. Now over five decades later, a number of facilities on the Hanford Site are preparing for final decontamination and decommissioning (D&D). To assure that the necessary resources are available to handle the waste generated as a result of D&D, estimates of the volume and characteristics of the expected solid waste are required.

The Plutonium-Uranium Extraction (PUREX) Plant (Canyon 202-A) is a fuel reprocessing canyon facility that is similar in construction to other onsite and offsite fuel reprocessing canyon facilities. It is also one of the first major facilities that will be scheduled for D&D at the Hanford Site (1). This report presents the methodology used to estimate the characteristics and volumes of equipment and other materials that might be removed and processed as solid waste during the D&D of the PUREX Plant. Comparison of the PUREX D&D solid waste volumes to other canyon facilities yields solid waste estimates that may benefit future waste estimation and decontamination activities at Hanford as well as other U. S. Department of Energy (DOE) facilities.

PUREX PLANT

The PUREX facility consists of a canyon, four galleries, and a service annex. The canyon is a thick-walled, heavily shielded concrete structure that houses the equipment used for radioactive processing. The canyon area is 306.3 m (1,005 ft) long, 9.3 m (30.5 ft) wide, and 31.7 (104 ft) high. A single row of 12 process cells is contained within the canyon (1). The functions of these 12 cells, as well as the equipment they contain, are described in Table I.

A 1.8-m- (6-ft-) thick concrete wall separates the cells from the galleries (1). The storage, sample, pipe and operations, and crane cab galleries parallel the north wall of the canyon and are located at different levels, one above the other. The pipe and operations gallery, located below the crane cab gallery, contains instrument transmitter racks, electrical motor controls, steam and cooling water

supply lines, and the piping and associated valves used for transferring nonradioactive solutions. The next level down is the sample gallery, which contains the remote samplers used for obtaining process solution sampled from the cell equipment. The storage gallery area, the level below the sample gallery, was used for storage of dry chemicals and spare equipment.

The service annex is adjacent to the north of the gallery section and consists of two separate areas (1). The larger, main area houses the maintenance shops, offices, lunchroom, locker room, radiation zone entry, ventilation air and supply room, a switch gear room, compressor room, central control room, and the aqueous makeup facility. The smaller laboratory are contains the analytical laboratory, the headend control room, and a switch gear room.

In addition, PUREX contains two tunnels used for interim storage of failed or obsolete process equipment that was too radioactive or bulky for removal from the PUREX Plant. Since the estimation methodology presented in this report is based on the PUREX canyon cells, more detailed information on the PUREX tunnels is not presented.

In 1956, the PUREX Plant began recovering uranium and weapons grade plutonium from irradiated aluminum-clad uranium metal fuel from the Hanford Site reactors. The plant was modified in 1967, to reprocess zirconium alloy clad fuel from the N Reactor in order to recover plutonium, uranium, and neptunium.

Three semi-distinct operating areas reside within the PUREX Plant: the head end, where fuel elements were chemically declad and the irradiated fissile materials dissolved; solvent extraction, where the dissolved fuel was separated and purified; and the N Cell area, where purified plutonium was either loaded out as nitrate solution or transformed into an oxide.

In October 1990, the DOE - Richland Operations Office (RL) directed Westinghouse Hanford Company to initiate transition-to-standby activities for PUREX. The standby condition was achieved in September 1992. In December 1992, the Assistant Secretary for Environmental Restoration and Waste Management authorized plans to terminate the PUREX Plant and directed DOE-RL to proceed with shutdown planning and terminal cleanout activities (1).

At the completion of the Stabilization Campaign in 1990, the feed stock left in PUREX from the 1988 shutdown had been processed and removed from the plant. Bulk chemicals, solutions used to test the processing equipment, the PUREX process solvent, recovered nitric acid, and a small quantity of pre-1972 reactor fuel were left in the plant. During the subsequent transition-to-standby phase, these materials were left untouched.

The deactivation project will remove, reduce, and/or stabilize the major remaining radioactive sources and hazardous chemicals within the PUREX Plant. Completing these activities will reduce the risk to workers and the public and will allow for a reduced level of the PUREX Plant will be transferred to the Hanford Surplus Facilities Program pending eventual D&D (2).

Final D&D will include closure of secondary containment; the end-state of the equipment, systems and material left in place, including material in the "containment building;" final disposition of the vessels and equipment in the tunnels; and closure of the tunnels (2).

PUREX ESTIMATE

The PUREX Plant contains many process vessels, chemical storage tanks and other types of equipment that are candidates for removal and decontamination. To develop an estimate of the type of waste and volume of removal candidates, it was necessary to obtain information on the size, weight, material of construction, internal equipment and contents/contamination of the canyon process cells.

The large number of items involved and the allowable time precluded a survey of dimensions and weights for each piece of PUREX equipment based on inspection of individual as-built drawings. The as-built drawings represent the most up-to-date information, but would involve a fairly slow process of review and reproduction. For the PUREX estimate, approximately 5% of dimension and weight data were obtained from drawings, and 37% from certified vendor information files (CVI) (1). The only disadvantage is that without the as-built drawings there is no positive verification that the items described in the files are the items actually installed in the plant. Many of the CVI files specifically call out vessel or assembly weights, therefore they were very useful.

The items not identified using prints or CVI files contain estimates based, when

available, on information located in the PUREX Technical Manual (3), or on known values for similar pieces of equipment. Dimensions obtained from the technical manual do not include flanges or connectors or support structures. The technical manual also does not provide equipment weights. An item by item inspection and consultation of prints would be necessary to support actual D&D work.

The following waste types, based on the definition documented in the Hanford Solid Waste Acceptance Criteria current at the time of publication, were recognized in the development of this estimate (4).

Transuranic (TRU) Waste - Without regard to source or form, TRU waste is contaminated with alpha-emitting transuranium radionuclides with half-lives greater than 20 years and concentrations greater than 100 nCi/g of waste matrix. Transuranium radionuclides are radionuclides, radium sources and 233U in concentrations greater that 100 nCi/g of the waste matrix are managed as TRU waste.

TRU Mixed Waste - TRU mixed waste meets the definition above for TRU waste and contains dangerous waste in addition to the radioactive components. Dangerous wastes are defined in the Washington Administrative Code (WAC 173-303-040).

Low Level Waste (LLW) - LLW, as defined in DOE Orders 5820.2A and 5400.3, is radioactive waste not defined as high-level waste, TRU waste, spent nuclear fuel, or by-product material. All LLW is also classified according to Category 1, 3, and greater than Category 3 concentration limits. These limits are based on the waste classification system developed by the Nuclear Regulatory Commission (NRC) in 10 CFR 61; however, it should be noted that these categories are not synonymous with Class A, C, and >C definitions.

Low Level Mixed Waste (LLMW) - LLMW is low level waste that contains dangerous waste, as defined in WAC 173-303-040.

Nonradioactive Dangerous Waste - Any nonradioactive solid waste that has been contaminated by hazardous chemicals, as defined in WAC 173-303, is regulated as dangerous waste.

The goal of the current deactivation effort is to minimize dangerous wastes; therefore, equipment is assumed to be non-hazardous, unless a known hazardous component is present (1). Equipment classified as hazardous or mixed wastes include the dissolvers, which contain zirconium hulls and mercury thermowells, and the silver reactors, which contain silver salts. Nonradioactive, nonhazardous wastes are identified only as solid waste.

The waste volume estimates reflect those expected to be generated by all D&D activities prior to actual building structural component disposal. This includes volumes expected to result from removal of all the process equipment, piping, and fixtures that can be removed with relative ease, such as unbolting or cutting, leaving bare cell and canyon walls.

METHOD APPLICATION

Once a detailed study of a model facility is complete, other similar facilities may be estimated by scale. This methodology can save time and money while providing critical information to support planning activities for current and future solid waste treatment, storage, and disposal (TSD) facilities and operations. In this case, facilities similar in construction and process to the PUREX facility were selected.

The estimates obtained in the PUREX Plant study were applied to several other major canyon facilities located at the Hanford Site to characterize and estimate the volume of solid waste that will be generated during D&D. These facilities include the following: B Plant (221-B), T Plant (221-T), U Plant (221-U), the Uranium Trioxide (UO3) Plant (224-U & 224-UA), the Reduction Oxidation (REDOX) or S Plant (202-S), the Plutonium Concentration Facility for B Plant (224-B), and the Concentration Facility for the Plutonium Finishing Plant (PFP) and REDOX (233-S) (5).

In order to estimate the waste volume, the cells (or process areas) in each facility were matched with the most similar cell(s) in PUREX. Cells were correlated based on knowledge of the equipment present, physical layout, and process history.

To develop the volumetric estimate of waste, similar cell processes were identified, and it was assumed that the density of equipment in the unknown cell was the same as the matching PUREX cell. The volumetric ratios for similar cells were calculated then multiplied by the amounts of solid waste (volume and weight) reported for each of the PUREX cells (1) to yield the estimates for each unknown cell. These cell estimates were summed over the entire facility using the following equations(5):

Eq. (1)

Eq. (2)

where X represents the individual facilities. The same calculation was made for the pipe galleries:

Eq. (3)

Once the volumetric estimation was completed for each of the cells (or process areas) in a given facility, a waste class was assigned to the cell (5). The designation of waste classes was based solely on the best judgement of the authors and was grounded on knowledge of the processes and equipment present in a given cell. The piping in a facility was assumed to be designated in the same waste classes and proportions as the equipment in that facility.

EXAMPLE

The B Plant (221-B) is located in the center of the 200 East Area on the Hanford Site. The B Plant was originally constructed to chemically separate irradiated uranium fuel using the bismuth-phosphate process. The plant commenced operation in April 1945 and continued until 1952, when the bismuth-phosphate process became obsolete with the development of the PUREX method. The plant shut down until the early 1960's, when a series of renovations were made to support the extraction of various fission products from high-level liquid waste (5).

The final renovation, completed in 1968, facilitated a high-capacity solvent extraction and ion-exchange process. The campaign lasted from approximately 1968 until 1985 and resulted in the extraction of over 100 MCi of cesium and strontium (5).

A subsequent and final campaign involved 38,000 L of neutralized current acid waste (CAW) from double-shelled tank 101-AZ. Waste from this campaign still remains in the tanks in B Plant, but will be removed prior to decontamination and decommissioning (5).

Currently, B Plant stores chemicals used to treat LLW generated at the B Plant and the Waste Encapsulation and Storage Facility. It is used for the generation of demineralized water and for the conditioning of water used in heating, ventilation, and air conditioning units (6).

The B Plant is a lightly-reinforced concrete building, approximately 259-m (long), by 21-m (wide), and 23-m tall, covering an area of about 5,370-m2 and occupying a volume of approximately 121,100-m3 (5). The canyon portion is about 247-m long and contains 40 canyon cells in a single row running the length of the canyon. The building is divided into three main areas: galleries (listed from the bottom upelectrical, piping, operating, and crane), canyon deck, and the cells. All interior and exterior walls, roof and floor slabs, and cell dividing walls are constructed of thick concrete to provide shielding from ionizing radiation.

To estimate the volume, weight, and type of solid waste present in the B Plant, the following conditions were assumed (5):

The original equipment used for bismuth-phosphate separations accounted for the bulk of the equipment described in the B Plant Safety Analysis Report (7). This allowed the use of the Hanford Engineering Works Technical Manual (8) to corroborate information and supply missing information.

All process chemicals from separations activities were removed from the plant, either by flushing or by use of the plant for the most recent cesium-strontium extraction process (the neutralized current acid waste campaign).

The B Plant cells, which either performed the same general function or contained the same equipment as the PUREX facility, would produce the same D&D waste volumes. To estimate these volumes, B Plant cells were scaled to PUREX according to the volume of each processing cell and volume of equipment that cell contained.

For example, cell 22 in B Plant was used for vessel ventilation and contains condensers, an ammonia scrubber, filters, heaters and a tank. PUREX cell F is most similar based primarily on process knowledge and supported by equipment similarity. It was used for waste treatment and process ventilation and contains a nitric acid absorber, condensers, pumps, tanks, samplers, concentrators, jets and agitators (see Table I). Cell 28, in B Plant, was used for solvent extraction and contains an ion exchanger column and tanks. PUREX cell G is most similar based on process equipment. It was used for solvent treatment and contains a pulse column and generator, tanks, a decanter, a turbo-mixer, pumps, agitators, and samplers (see Table I). Table II summarizes cells 22 and 28: the use of each cell, the approximate sizes of the equipment within the cells, and the cell volumes (5).

Using the calculated ratios between PUREX cells and similar B Plant cells, an estimate of the volume and weight of equipment considered candidates for D&D was developed for each cell in the B Plant. Results for cells 22 and 28 are given as an example in Table III. The total equipment volume, considered candidates for removal during D&D, of B Plant is estimated at 1,585 m3. Its weight is estimated at 316,816 kg.

Once the volume of equipment was estimated for each cell, the type of waste expected also was estimated. This resulted in a total estimate of the volume and waste type expected from B Plant.

CONCLUSIONS

This study was designed to achieve an initial rough estimate of solid waste that may be generated during D&D from the facilities included in this study. The estimates were not only based on historical data, available documents, and process knowledge, but also a structural or process area comparison of the facilities with the results presented in the PUREX study (1). Although a more detailed study would be required to maximize characterization accuracy, the information presented in this report provides a rough estimate that will help facilitate future planning and activities associated with solid waste treatment, storage, and disposal.

The estimation methodology provides a model for estimating the volume and types of waste expected from the D&D of other similar DOE facilities. The facilities with the greatest similarities to the PUREX Plant include the H and F Canyon Facilities at the Savannah River Site, which also use a PUREX process, and the Idaho Chemical Processing Plant, which uses another solvent extraction process. Although these four facilities differ in their size, capacity, and specific chemistry (due to plant specific feed fuel constituents, cladding, and the final product produced), the methods applied to the PUREX Plant provide a substantial knowledge base for the subsequent deactivation and D&D of these facilities.

The method of volume ratio estimation can be applied to other types of facilities such as nuclear reactors or glovebox line facilities. In fact, a detailed study has been completed for the Plutonium Finishing Plant (PFP or Z Plant) at the Hanford Site (9), which may serve as a scaling standard for other glovebox line facilities.

Parsons Engineering Science, Inc.

ABSTRACT

The U.S. Department of Energy (DOE) has focused internal efforts for the transition of surplus facilities, including nuclear facilities, within the DOE Office of Transition Management (EM-60). This Office has the challenge of transitioning facilities from former operations and production within Defense Programs to an inactive, safely deactivated mode awaiting receipt by the DOE Office of Environmental Restoration and Waste Management (EM-40). The responsibility for delivering nuclear facilities to EM-40 in a `D&D ready' mode (or in a condition that would allow preparation for reuse) has been assigned as a function of EM-60.
As a primary engineering, remediation, and waste management contractor to a number of DOE sites, Parsons Engineering Science, Inc. (Parsons) has provided support for the development and implementation of several site-specific transition, deactivation, and D&D programs. The information provided in this presentation is based on this experience and interactive participation.
The initial phase of facility remediation activities involves the transitioning of surplus DOE facilities from operations (within the mission of DOE Defense Programs) into the DOE EM-60 [Transition Management] organization. This organization is responsible for transition planning and management of initial activities prior to acceptance by the DOE EM-40 Environmental Restoration organization, which is responsible for oversight of decontamination and decommissioning (D&D) operations. Included in this presentation are considerations for transition planning and deactivation of nuclear facilities at the DOE site operations level. A discussion is provided on the establishment of a typical transition management program and `lessons learned' in program development.
The transitioning of D&D facilities to non-operational cleanup programs is a recent development within the DOE, and programs such as transition management and deactivation are not well defined in many cases. This programmatic overview provides some insight into concerns that many DOE sites may face.
This presentation has been prepare for the perspective of anyone involved in DOE waste management, environmental restoration, decontamination and decommissioning, transition management, and/or deactivation programs. Conclusions and suggestions are provided for future programs development. The analysis involved in this presentation indicates that a great deal of preplanning and evaluation is necessary in order to implement a cost-effective, efficient, and functional transition management program.

INTRODUCTION

The Department of Energy (DOE) has a very complex and convoluted mission as it undertakes to disassemble the unnecessary elements of the national nuclear defense program and dismantle surplus nuclear defense production facilities. The DOE nuclear weapons complex involves manufacturing, production, assembly, testing, and research and development installations that may contain a variety of hazardous, toxic and/or radiological materials. Proper planning, staging, transitioning, and management of these surplus facilities is a key element in this mission of remediation and restoration.
The facility transition and deactivation mission has been assigned to the Office of Facility Transition and Management (EM-60). EM-60 functions in an intermediate capacity, receiving facilities from the responsible production program operations office and preparing the facility for future transfer to another organization. In most instances the management responsibility for a facility is transferred to DOE EM-40, the Environmental Restoration and Waste Management organization. However, in some cases, ownership of the facility may be transferred to another organization for future use or may be retained by EM-60 until ultimate disposition of the facility is decided.
Many DOE sites have facilities that currently are in a cold shut-down (transition) mode, and are in the process of developing and implementing program procedures and protocol. The management structure to accomplish transition, deactivation, and implementation of D&D programs and policies, in many cases, is developmental or in a state of reorganization seeking optimal performance. These management programs are being developed to organize, staff, direct, and control activities necessary for managing and implementing transition, deactivation, and D&D program requirements and to assist in site-wide transition efforts. Subsequently, each site will be transformed from its previous operational mode of nuclear weapon components production to a condition of deactivation, decontamination, and environmental restoration.

Since it is not possible for all of the facilities to be transitioned simultaneously, DOE has adopted an overall strategy of deactivating facilities on a priority basis. This program involves selecting facilities for transitioning on a risk-based priority schedule. Once selected, the transition process requires that the selected facility be placed in a condition which provides safety, stability, and minimal monitoring, surveillance and maintenance requirements for an extended period while awaiting final decommissioning. This method was selected in order for DOE to utilize limited resources to accomplish the greatest net gains in facility safety and stability in the shortest time.

THE FACILITY TRANSITION PROCESS

Transition begins with the termination of operations. This phase includes surveillance and maintenance, and terminates with deactivation, the achievement of safe shutdown, and transfer to the future custodial organization. As the program has been conceptualized, the responsible environmental management program for a site is to receive `D&D-ready' facilities from the transition management program. Transition activities include deactivation planning for surplus facilities, placing the subject facility into a `D&D-ready' condition, and application to the environmental restoration program (under EM-40) for acceptance and transition of a facility for reuse or D&D operations. Specific elements of the transition program include shutdown of operations, deactivation of processes, removal of radioactive substances and Special Nuclear Materials (SNM), and placing the facility in a condition where D&D operations may be conducted.

Some of the concerns with transitioning and transfer of DOE facilities to EM-40 are:

The need for accurate preliminary characterization and hazards analysis;
Requirements for establishing an effective surveillance and maintenance (S&M) program;
Initiation of the EM-40 budget cycle (which could require up to three years); and
Achieving compliance with EM-40 acceptance criteria.

This phase ends with the execution of a memorandum of agreement (MOU) and acceptance of ownership by EM-40.

DOCUMENTATION FOR TRANSITION AND DEACTIVATION

The transition and deactivation process requires a great deal of certification, verification, and validation in order for custodial ownership to be transferred. These efforts require the preparation of documentation and reports that protect both the previous and future owners of a facility, and allow the involved parties to estimate the level of funding, risks, and schedules associated with the required deactivation project. This documentation interacts within the responsible DOE organizations at various levels.

Programmatic Documentation

The primary program elements and decisions that interact with the transition planning project phase include:

1) Generating a master list of surplus facilities;
2) Preparing a D&D Project Management Plan;
3) Developing and maintaining a Five-Year Plan; and
4) Providing project authorization (related to fiscal year budgets and the site Activity Data Sheets).

Specific documentation from these activities are:

Master List of Surplus Facilities

DOE Order 5820.2A requires that each DOE field organization prepare and maintain a complete list of contaminated facilities (both operational and excess). This list of facilities is maintained by responsible site DOE field office in order to identify and assign decommissioning responsibility to the appropriate responsible manager.

The surplus facility inventory will be used for developing a master plan for all transition and D&D subprojects (i.e., the phasing of overall D&D activities). The ultimate land use, utilization of facilities to facilitate D&D operations or other restoration programs, and the need to maintain utility services for on-going plant operations must be considered when developing the master schedule.

One component of the surplus facility list is the formal transfer of landlord responsibilities from the specific plant operations manager to transition management. As specified in DOE Order 5820.2A, Chapter V, 3.a.(5), contaminated facilities may be transferred from one program organization to other by mutual

agreement of the programs involved. This agreement typically will involve a Memorandum of Understand (MOU) between the appropriate managers. The transition management organization to which the contaminated facility is transferred is required to accept full responsibility for surveillance, standby operations, maintenance, and deactivation of the facility until a decision is made on the final facility disposition.

DOE-RFO Five-Year Plan

The Five-Year Plan represents the long-range planning action for ensuring the proper allocation of funds. This budget cycle includes establishing and maintaining a master D&D budget, and preparing Activity Data Sheets.

The inventory of surplus buildings and equipment forms the basis for assembling budgets to obtain required funding to execute the transition and D&D programs. The budget cycle is initiated with the development of the Five-Year Plan and is carried forward with the submission of annual budget requests for specific subprojects. The quantity of the information used to develop the budget estimates is a critical factor in ensuring that sufficient funds are available when required and to provide the justification for the funding. Activity Data Sheets will be used as the information resource for developing the budgets. The format and content of the Activity Data Sheets should be supplemented, if required, to ensure that program needs and goals are properly funded.

Project Authorization

Documentation may be required for submittal in support of project/subproject authorization. The DOE Project Management System (DOE Order 4700.1) provides guidance for project authorization documentation. Most deactivation and D&D projects will be managed under the specific requirements established for Major System Acquisitions (in which funding for a project is handled in a manner similar to cost/expense funding). However, the basic information required by the project management system for general project management may be applied. The D&D Manager must determine the level of detail and format appropriate on a task-by-task basis. Factors which determine which organizations or individuals must approve or authorize a transition project include, but are not limited to cost, funding, safety issues, required input from external organizations, schedule limitations, high project risks, and impending regulatory issues.

Project-Specific Documentation

Following the establishment of the program components, the development of plans for implementation of individual transition and deactivation projects can commence. This portion of the process typically includes preparation of plans and completion of activities, including: the Facility Operation History; Baseline Characterization Plan; and Facility Characterization.

The preparation of this information has been handled in a number of configurations by various DOE sites. In some instances, much of the information required for project-specific documentation is obtained by the operating organization prior to transfer. In other cases, the transition management function assumes the responsibility to characterize the facility and to determine the end state of deactivation prior to transfer. In still other instances, it has been the responsibility of the EM-40 organization to obtain the information required to prepare project documentation and to proceed with D&D operations. While the specific terminology may vary from site to site, the following documentation typically is prepared:

Facility Operation History

Information regarding the operational history of the facility will be reviewed to assess the nature and extent required of activities required for deactivation, including worker protection requirements. The goal of this effort has two components. The first goal of the review is to obtain as much information about the facility as possible early in the planning stages to allow the project scope, budget and schedule to be defined. If it is determined that additional information is required, the second goal of the review to identify the data requirements for the development of a Baseline Characterization Plan.

Baseline Characterization Plan

Once the data requirements have been identified, a Baseline Characterization Plan can be developed to obtain the missing information to support implementation of the deactivation project. Depending on the requirements for deactivation, the characterization plan may include the establishment of Data Quality Objectives to

ensure that the information obtained will be of a quality to meet future D&D project requirements. Field Sampling and Quality Assurance Project Plans may be utilized to define the sample locations and the sample collection/analytical procedures. To ensure proper protection of the field characterization team, existing Health and Safety procedures and plans will be reviewed and amended as needed to address any specific hazards associated with implementing the Baseline Characterization Plan.

Facility Characterization

Following approval of the Baseline Characterization Plan, the facility characterization activities will be initiated. The characterization activities include sample collection, laboratory analyses, data validation and data management. The characterization results will be used to select the appropriate decontamination methods, to classify the waste materials into the correct management categories, and to determine the extent of decontamination required to achieve subproject clean-up goals.

Facility characterization may involve two distinct types of documentation: the Facility Characterization Report and the Preliminary Hazards Analysis.

The Preliminary Characterization Report focuses on identifying the nature (nuclides, chemical constituents) and the general locations of the contaminants in the facility. General mapping of dose rates and airborne contamination (rad and non-rad), if present, should be included. Information on quantities of materials (if available) should be included; however, quantitative information is not a primary interest in this preliminary scope.

The Preliminary Hazards Analysis addresses, in general, the hazards present in the facility and the risks presented by those hazards. The principal use of this preliminary analysis is to help frame the S&M program so that risks to persons and the environment are at a low and acceptable level. There should be an evaluation as to whether a formal safety analysis report is required in accordance with DOE Order 5480.23, or whether the concept of a safety analysis as defined in DOE Order 5481.1B would be appropriate.

From a scheduling perspective, it is preferable to initiate the facility characterization as early as possible in the project. Delays in characterization could create detrimental effects on the project critical path planning and scheduling. The evaluation of the analytical results will be factored into the development of the deactivation management and implementation plans.

Safe Shutdown and Deactivation Report

This report addresses the manner in which the facility was taken out of active service and placed in a stable shutdown configuration in compliance with the appropriate DOE Orders. The status of the facility at the time of turnover to EM is to be described, and the measures taken to maintain the safe configuration provided for in an S&M plan. If additional safety-related actions are to be taken in the future, a schedule for such actions should be included. A safety assessment (in accordance with the residual hazards) should consider the presence of an unreviewed safety issues associated with the shutdown configuration. As appropriate to the facility, it may be necessary to modify the Technical Specifications or prepare a Limiting Conditions Document. In some cases it may be appropriate to include in this report the information required by the Preliminary Characterization Report and the Preliminary Hazards Analysis.

DEACTIVATION ACTIVITIES AND PROGRAMS

The most important physical activity of the transition process is the deactivation of the facility subject to transition. Consistent with DOE Order 5820.2A, the deactivation goals for a facility should complement subsequent D&D activities, and should include:

Elimination or reduction to acceptable levels the hazards and risks associated with facility/equipment contamination to ensure worker protection during the dismantling of surplus facilities;

Removal of materials necessary to minimize the potential for spreading contamination and to ensure proper management of wastes; and

Elimination of imminent contaminant hazards to allow the facility and/or equipment to be subject to less stringent controls for S&M or to be reused for other purposes.

The deactivation process should establish the conditions for surveillance and maintenance, and provide the basis for subsequent facility actions.

Deactivation Concepts

The deactivation strategy promulgated by the EM-60 organization has several

underlying concepts that formulate the basis of the proposed program. These include:
1. In many instances, there is little or no difference in the activities conducted at a facility during the deactivation phase and activities that might be conducted as a continuation of typical operations;
2. Facility organization and management typically will require alteration to accommodate the nature of the project-specific deactivation project;
3. The final condition, or end state, of a facility must well be defined in order to determine whether a deactivation project has met the EM-60 objectives for the project; and
4. The process of turnover of a facility to the future custodial organization is important in defining the scope and end states of deactivation activities.
The overall purpose of the deactivation period is to conduct shutdown activities that will assure public, environment, and worker safety. As the deactivation process proceeds, the facility becomes more inoperable, the hazards are reduced, and the requirements for surveillance and maintenance burden are minimized. During this period, work is conducted to put the facility in a stable, low risk condition which is economically and technically practical to maintain for an undefined and/or extended period. Activities that may be conducted during this period include removal of radiological source materials, disposal of hazardous chemicals, isolation of systems and equipment, removal of valuable surplus equipment, and others related services.
Goals for Deactivation
The goals of the deactivation process must be commensurate with the anticipated future of the facility. The options currently considered for most DOE facilities are:
Turnover to the responsible Environmental Restoration field organization for managing final decontamination and dismantlement;
Turnover to another DOE department or government agency for refurbishment and reuse; or
Granting, leasing or selling the facility to a public or private party for future use.
In some cases, it is simple for DOE to determine the future of a facility early in the transition phase. In other cases, additional planning and consideration will be needed to select among options for the future of the facility and therefore the final conditions of deactivation.
Turnover After Deactivation
After making preliminary arrangements with the organization that is to take custody of the facility in transition, it is the responsibility of the EM-60 organization to negotiate the conditions to be achieved prior to turnover. This agreement should be negotiated as early in the process as possible in order for the receiving organization to plan post-transition activities. Topics that should be addressed in this negotiation and agreement should include:
Discussion on the proposed end state of the facility, and whether this end state can be reasonably achieved;
Review of the anticipated condition of the facility at the end of transition, and the requirements to meet the proposed end state; and
Evaluation of the likely near-term and long-term surveillance an maintenance requirements for the facility after transition but prior to ultimate disposition.
This process may lead to the development of a plan for the long-term surveillance and maintenance period, based on the anticipated final transition state. The details of this planning should assist the receiving organization in mitigating potential threat to workers, the public, and the environment.
Turnover is completed when deactivation and end states are achieved, conditions for surveillance and maintenance are set, and the receiving organization takes responsibility.
INNOVATIVE TRANSITION/DEACTIVATION MANAGEMENT TECHNIQUES
The variation in which DOE sites apply the transition and deactivation processes has let to some ingenuity among the managers responsible for these processes. In order to meet schedules, comply with site regulatory requirements and milestones, and to comply with the future mission of the Department of Energy, each responsible manager has been required to identify innovative methods of program implementation. Some of these innovative management techniques include:

1. Avoiding Redundant Oversight -- Minimizing the perceived dual regulation of facilities to be subjected to D&D by remediating waste management facilities as elements of a RCRA or FFCA cleanup process rather than a D&D project;
2. Minimizing Future Work Requirements -- Working with the responsible facilities operations organizations to complete as much mitigative waste management and decontamination actions as possible during the final operating phases, reducing the amount of field activities (and therefore the amount of oversight and paperwork) required for deactivation, safe shutdown, and transition;
3. Using a Systems Engineering Approach -- Utilizing a Systems Engineering/Integration approach to surplus facility management and deactivation programs, which would implement the systems engineering process (as applicable) as promulgated by DOE Order 4700.1. Such an approach to D&D planning could integrate the elements of D&D operations specified in DOE Orders and directives (e.g., EM-40 guidance, DOE/EM-0142P, DOE Order 5820.2A, Sec. V, etc.) and guidance extracted from Nuclear Regulatory Commission guidance (e.g., 10 CFR and various NUREGS) with the system of project management established by DOE Order 4700.1. Since the program requirements for D&D at DOE facilities have not been completely developed and implemented for all field office requirements, the Systems Engineering/Integration approach inherently would involve a graded approach to the development of documentation and the application of directives.
4. Graded Approach to Safety Documentation -- Since the deactivation phase largely consists of ramping down operation of the facility subsystems and equipment, and making it increasingly inoperable, the intent is to stay within the existing bases for operating safety and environmental protection. There will be few, if any, activities during deactivation that fall outside existing analyses or safety requirements. Since most of the hazards that existed during operations will be removed, the need for detailed safety documentation after deactivation should be minimal, and can be handled under the `graded approach' promoted by DOE Order 5480.23. In many cases, it is anticipated that no safety documentation will be required other than an assessment of the remaining hazards in the facility D&D plan.
5. Revised Management Structures -- The requirements for deactivation management are not the same as for production operations; therefore, a revision to a project-based, schedule-intensive organization is more conducive to deactivation and transition efforts. The revised management organization should reflect an effort to condense the decision-making process and to allow the project to be handled with a minimum of administrative participants.
6. Stakeholder Involvement -- In order to promote a smooth transition, it is unquestionably required that the involved stakeholders (both in the transition process and in the post-transition condition) be recognized and involved in the transition as soon as possible. Early involvement of external and internal stakeholders is critical so that any concerns (primarily in the specification of the end states to be achieved) may be addressed. Early coordination and stakeholder involvement is required for efficient and effective termination of operations, transition of ownership, and deactivation of facilities to avoid costly delays and overruns in schedule and budget.
7. Utilization of Experienced Staff -- Many of the activities required to shut down operations, remove materials, isolate systems, and prepare a facility for a post-transition S&M period require the same knowledge and skills as facility/systems operation. These activities may require a special knowledge of the facility, including its design bases, procedures, equipment, and controls. Usually the existing operating staff is the best source of this knowledge; they are a valuable and unique resource that should be fully utilized in the deactivation work.
8. Contribution to the Transition Data Base -- Each transition/deactivation activity presents a unique opportunity to develop information, data, and lessons learned on the processes related to the specific activities. This information is valuable to future efforts, and should be compiled in a concise, retrievable form for future use by other DOE operations.

FUTURE CONSIDERATIONS AND LESSONS LEARNED

The analysis of transition management and deactivation programs supported by Parsons at DOE sites resulted in a number of concerns and considerations that may be applied to all such programs. In developing programs for transition from operational status and deactivation in preparation for D&D, several lessons were learned that may be of value to other sites that are anticipating the transition and deactivation of DOE

facilities. These concerns, considerations, and lessons may be summarized by the following items:

Evaluation of Future Regulatory Considerations

When planning for the transition of a facility, it is prudent to consider the type of regulatory agreements that exist at the site. The future regulatory climate may dictate how subsequent D&D activities are to be managed. It should be evaluated whether the deactivation and shutdown processes can be utilized to mitigate the amount of regulatory concern that will be applied to a facility transitioned to EM-40 for environmental restoration and waste management activities.

Future Use Considerations

There are very few private ventures (with the exception of programs such as the National Conversion Pilot Project) that are awaiting the availability of DOE facilities for commercial/industrial purposes. In order to entice reuse, government will have to [at least partially] subsidize reuse of federal facilities. Also, there is a question as to who would be responsible for maintaining infrastructure systems. Since this is a continuing investment in a terminal program, the wisdom of these investments should be questioned.

Indefinite Facility Disposition

Since future users may not be common, there may be a tendency to start transition processes with the hope of identifying an ultimate user for a facility that would seem to have some utility after use by DOE. However, without a clear mission for the facility, these indecisive plans can be very costly in terms of end state cleanup and S&M costs awaiting a final disposition. Decision up front in the transition process on the final disposition or status of the facility in question is necessary for orderly planning and conduct of activities.

Single Program Management

In some instances the progress of site-specific programs has been hampered by unclear directives and internal `turf battles' over the delineation between operations, transition and deactivation, and D&D activities. While the termination of operations should be manageable, it may be prudent to consider the coordination of all of the activities of transition, deactivation, and D&D under a single program direction. Although funding could be allocated from different DOE-HQ sources, the coordination of deactivation, transition, and D&D under one organization would avoid competing goals and objectives among site technical groups.

Defined Funding Sources

Programs have failed or have been limited in progress due to lack of committed funding for transition and deactivation committees. In order to avoid unnecessary delays and false starts, sources of funding must be identified and committed for all of the activities required for transition and deactivation. If committed funding cannot be defined, initiation of activities (regardless of apparent priority) may not be justified.

CLEANUP OF A DOE NONREACTOR NUCLEAR FACILITY: EXPERIENCE AT THE LOS ALAMOS NATIONAL LABORATORY HIGH PRESSURE TRITIUM LABORATORY

Henry L. Horak
Los Alamos National Laboratory

ABSTRACT
On October 25, 1990, Los Alamos National Laboratory (LANL) ceased programmatic operations at the High Pressure Tritium Laboratory (HPTL). Since that time, LANL has been preparing the facility for transfer into the Department of Energy's (Doe's) Decontamination and Decommissioning Program. LANL staff now has considerable operational experience with the cleanup of a 40-year-old facility used exclusively to conduct experiments in the use of tritium, the radioactive isotope of hydrogen. Tritium and its compounds have permeated the HPTL structure and equipment, have affected operations and procedures, and now dominate efforts at cleanup and disposal. At the time of shutdown, the HPTL still had a tritium inventory of over 100 grams in a variety of forms and containers.

INTRODUCTION
On October 25, 1990, Los Alamos National Laboratory (LANL) ceased programmatic operations at the High Pressure Tritium Laboratory (HPTL), an outdated experimental facility whose design does not meet the requirements of the modern Department of Energy (DOE) complex. The tritium operations formerly conducted at the HPTL will be conducted at the Weapons Engineering Tritium Facility (WETF) at TA-16-205. WETF enables LANL researchers to handle tritium using modern equipment and up-to-date procedures. The Engineering Sciences and Applications Division (ESA) has no further use for the HPTL and plans to remove the accountable tritium and make the facility available for decontamination and decommissioning (D&D), thereby eliminating the risk and cost of operating this now-surplus facility. Early, close communication with DOE led to an approach different from the one originally planned. The revised approach resulted in a reasonable cleanup of the facility and satisfied more stakeholders.

APPROACH
Statement of the Problem
The cleanup process must ensure that the HPTL
  poses a minimal risk to the environment and the safety and health of workers and the public,
  requires a minimum of support and maintenance, and
  is acceptable to DOE Environmental Restoration and Waste Management (EM) for D&D.
Safe shutdown required close attention to a number of critical factors.
  The HPTL is an old, tritium-contaminated facility housing outdated tritium process systems.
  The HPTL contained a large (>100 g) tritium inventory stored in unusual and uncertified containers
  Tritium contaminated equipment was in place for operation or stored in drums.
 A number of other hazardous materials were present at the facility.
  The HPTL had several potentially contaminated outfalls.
  Management consisted of informal oversight and inadequate staffing.
  The HPTL faced serious issues in regulatory and order compliance.
  The HPTL had inadequate documentation and operational procedures.
  The maintenance and surveillance were inadequate
Description
The 7500-square-foot HPTL had potential tritium contamination everywhere. In particular, the tritium-contaminated process systems that had evolved during its 35 years of operation were still in place and in use at shutdown. These systems were a high-pressure fill system, a low-pressure gas transfer system, and an experimental system. The systems consisted of pumps, valves, tubing, cryotraps, cylinders, instrumentation, and so forth.
The HPTL's tritium inventory of over 100 grams resulted in its designation as a Category II Nonreactor Nuclear Facility - the highest possible hazard category for tritium facilities. The inventory was approximately half tritium gas and half tritiated water on molecular sieve. This tritium inventory was in custom-made molecular sieve towers, experimental apparatus (such as a fish float), and uncertified shipping containers consisting of LP-50 and LP-12 gas containers and an AL-M1 tritiated water shipping container. Other tritium-contaminated equipment also remained at the site, including 36 drums of highly contaminated equipment ready for shipment to the waste area pending resolution of a mixed-waste issue. Other hazardous materials at the site included lead, mercury, caustics, flammables, and Class C explosives. The site had four potentially contaminated outfalls: a septic system, a National Pollutant Discharge Elimination System (NPDES) outfall, an acid

sump, and a roof drain. The facility had performed a tremendous amount of work over the years, but as the WETF approached startup, the HPTL was no longer viewed as an important experimental resource and received little attention from management and minimal staffing. At shutdown, the HPTL staff consisted of a full-time staff member operator, a part-time operator technician, a full-time radiation control technician (RCT), and a part-time custodian. This staff was inadequate to operate the facility in accordance with DOE-required formality of operations. The facility design antedated the new DOE for the weapons complex and was used to meet temporary demands until WETF became operational, at which time plans for final D&D of HPTL could be implemented.

Proposed Solution

LANL's prioritized approach for cleanup of the HPTL consisted of removing the tritium inventory, the highly contaminated process systems, the hazardous and mixed wastes, and other contaminated items. We also proposed to clean up the facility using the existing systems and documentation. Our plan included operation of the old process system and reprocessing and recovery of as much of the tritiated water as possible. Stressing technological issues, the original proposal comprised the following major elements.

Consolidation and transfer of tritium gas to the WETF for repackaging and measurement

Recovery of tritiated water and shipment of the tritiated water to Mound for recovery

Removal of contaminated equipment

Disassembly and removal of the contaminated process system

Removal of waste

Compliance with the National Environmental Policy Act (NEPA)

Preparation of updated Technical Safety Requirements (TSRs)

Improvement in facility management

At the time the HPTL was shutdown, EM-60 had not been organized, so HPTL cleanup began with DOE Defense Programs (DP) Research, Development, and Testing (RD&T) funding. Defense Programs through DP652 has been the funding source to date.

RESULTS

To address regulatory issues,

An environmental assessment (EA) was written and then included in the site-wide environmental impact statement (EIS).

Two categorical exclusions from NEPA were obtained.

Stack monitoring was brought into compliance.

National Emission Standards for Hazardous Air Pollutants (NESHAP) were Addressed.

Hazardous materials were stored correctly.

Most of the drains were plugged; only two outfalls remain.

To address operations issues,

A Management Control Plan, embodying a graded approach, was developed and implemented.

A project leader and full-time building manager were assigned to the facility.

Maintenance control increased and maintenance improved.

A general housecleaning was accomplished and maintained, and custodial work was minimized.

A modern liquid scintillation analyzer was installed on site.

Radiological postings and surveys were improved.

A bubble suit system was made available.

To address documentation issues,

A draft graded Safety Analysis Report was written but deferred.

Safe Shutdown Procedures were written.

A Building Emergency Plan was prepared.

Entry procedures were established.

A hazard communication (HAZCOM) program was established.

A Waste Management Plan was written.

Routine Monitoring Instructions were updated.

A draft Maintenance Implementation Plan was written but deferred.

Work was done under Standard Operating Procedures (SOPs), Operational Instructions (OIs), Special Work Permits (SWPs), and Radiation Work Permits (RWPs).

Five process system schematics were developed.

To address technical issues,

More than 70 grams of tritium were removed from the HPTL.
Two thirds of the containers of accountable tritium have been removed.
Thirty-six drums of previously packaged tritium contaminated hardware were removed.
Approximately 50 drums of other contaminated items were removed.

DISCUSSION

Early inspections and other interactions with DOE indicated that LANL would be expected to operate the facility in as close to the new (and evolving) DOE philosophy as possible. Deviations were at the sole discretion of the DOE. To accommodate the DOE needs, we inverted our original approach of addressing technical problems first and procedural problems last. Another critical factor in the HPTL cleanup was the end of the Cold War which changed LANL's operating environment in a number of ways: funding was reduced, the need for tritium was diminished, and tritium-supporting elements of the DOE complex were becoming unavailable. We, therefore, to changed and constantly revise our plan to follow evolving DOE guidance.

Regulatory Issues

NEPA was addressed with two categorical exclusions and an EA. The two categorical exclusions were for interim storage of the molecular sieve towers and for removal and interim storage of the process systems. The draft EA included both transition and D&D and was approved by the Albuquerque Operations Office. DOE Headquarters was reviewing the EA when the decision was reached to prepare a site-wide EIS for Los Alamos. In the course of review and as a result of the categorical exclusions, the EA for the HPTL had been reduced to only the D&D work. Continuing ongoing operations and the two categorical exclusions covered the transition work. The D&D work will be covered in the LANL site-wide EIS.

Stack monitoring was brought into compliance by upgrading the stack tritium monitoring system almost completely. This activity was part of a Laboratorywide compliance agreement with the EPA. The HPTL now has a state-of-the-art stack monitoring system with a bubbler and two real-time monitors. A NESHAP interpretation of stack emissions was obtained. We did not have to perform a preconstruction review because we planned to keep our tritium emissions well below historical levels. In fact, during cleanup such emissions have been about 5% of historical levels. There are no nonradioactive hazardous emissions.

Hazardous materials were dealt with correctly. We identified the hazardous materials at the facility and categorized them as either in-use or waste. The in-use materials were stored according to the type of hazard they posed(such as flammable). The waste was considered mixed because of the potential tritium contamination. It was stored according to its hazard potential in satellite accumulation areas and when possible, shipped to the Laboratory's mixed waste storage area.

As a result of a survey of the HPTL outfalls, we plugged most of the drains and obtained an agreement with the New Mexico Environmental Division to operate those we still needed. We retained a septic system, an NPDES outfall, and a roof drain. The NPDES outfall will soon be plugged because we plan to discontinue its use.

Operations Issues

The Laboratory operates the HPTL under a Management Control Plan that was negotiated with DOE. This plan addresses the various sections of DOE Order 5480.19. In developing this plan, graded approach was used whenever possible. A project leader, a building manager, and an RCT carry out the increased formality of operations. The project leader guided the project, developed much of the documentation, and served as liaison with DOE and other outside organizations. The building manager oversaw the day-to-day operation of the facility. Maintenance and its control improved as a result of ESA-TSE and Labwide initiatives. A general housecleaning was accomplished and has been maintained. Waste minimization procedures were established. The custodial work was minimized by evaluating the effectiveness of mopping on reducing floor contamination. The RCT upgraded the on-site liquid scintillation analyzer to improve posting and surveys. The existing contaminated supplied air (bubble) suit system was replaced with a portable system. Specific operations were staffed on a case-by-case basis using the previous system operators (now retired) and personnel from other Laboratory tritium facilities, such as the WETF.

Documentation

A graded approach was followed to documentation. Operation basis, routine operations, and specific tasks were addressed in that order.

A draft graded Safety Analysis Report (SAR) was written. The DOE Albuquerque Operations Office evaluated the status of the facility and deferred the complete approval of the SAR and associated Technical Safety Requirements. We are operating the facility according to the Operational Safety Requirements written before the shutdown.
Our Safe-Shutdown Procedures were approved by DOE/Defense Programs. These conformed to the procedure format that was uniform across Los Alamos tritium facilities.
The Building Emergency Plan was upgraded to meet modern standards and to reflect improvements and other changes in the facility. Entry procedures were written for normal and non-normal conditions. Site-specific HAZCOM was established. A Waste Management Plan and Routine Monitoring Instructions were written to supplement Los Alamos policies and administrative requirements. The Maintenance Implementation Plan was deferred by DOE based on the cleanup status of the facility.
Non routine tasks were performed under SOPs, OIs, SWPs, and RWPs. SOPs were used for operation of the process system, maintenance of the process system, supplied air (bubble) suit operations, and so forth. OIs were used for decontamination and packaging of nonstandard tritium containers and similar activities. SWPs were used for decontamination and preparation for shipment of containers and equipment. RWPs were used for the remainder of the operations involving tritium. Process system schematics using industrywide notation were drawn to document the system and guide its disassembly.
Technical Problems
The major technical emphasis in the HPTL cleanup was the removal of the tritium inventory. We started with over 100 grams in 50 containers. We have removed over 70 grams of accountable tritium in two thirds of the containers from the HPTL. Approximately half of the tritium was in the form of gas and half in the form of tritiated water adsorbed on molecular sieve.
The gas was contained in uncertified shipping containers (LP-12s and LP-50s) and experimental vessels. The shipping containers were packaged using an SOP as if for normal shipment but were then shipped over a closed road to WETF. The experimental vessels were secondarily contained and also sent over a closed road to WETF. This gas will be consolidated and sent to Savannah River for reuse.
The tritiated water on molecular sieve was in one uncertified shipping container (an AL-M1), in traps and cryopumps, and in several custom containers called towers. The molecular sieve towers were previously used to trap the effluent from the process system. The amounts of tritium in these molecular sieve towers were determined by plotting the pressure rise over time caused by helium-3 generated by tritium decay. The amount was confirmed by a mass spectrometer analysis of the gas in each tower at a given time. The other items will be put in a calorimeter.
Contaminated hardware was sent to the waste disposal facility at Los Alamos. Thirty-six drums of previously packaged tritium-contaminated hardware were removed. These drums were radiographed using Los Alamos Accident Response Group (ARG)/Nuclear Emergency Search Team (NEST) video radiography equipment to determine that no lead was in the drums. Other contaminated hardware was packaged as required by Los Alamos policies and administrative requirements and shipped to the disposal area.
RECOMMENDATION
In the process of transition, proceed with formality first and address technical issues second. In particular, communicate with DOE early, before safe shutdown, to establish the level of formality required under a graded approach. Establish safe shutdown procedures early. Plan ahead and document. Doing so establishes credibility and gives stakeholders confidence in the cleanup effort. Such a process leads to a safe, expeditious transition.

NUCLEAR RESEARCH AND TECHNOLOGY TRANSFER TROUGH SPIN-OFF COMPANIES
Jorma Heinonen
Lappeenranta University of Technology
ABSTRACT
The paper reviews briefly the history of nuclear research centers from technology transfer point of view with particular emphasis to spin-off companies as agents of

transfer. The role and nature of firms spun off from nuclear research centers are examined through a case example from Finland involving three small high -tech companies. In referring to certain traditions and characteristics of nuclear technology and to the referred cases the author concludes that still a remarkable potential for entrepreneurial spin-offs relies in nuclear research. The paper also recognizes that the development of nuclear technology has reached the stage of maturity and therefore the domain of new firms to spin-off would typically be in the field of sophisticated services; such as consultancy, expert-, and educational services.

INTRODUCTION

Society while supporting the research institutions, such as universities and other research establishments, wants to have not only return to the investments but to utilize the accumulated knowledge on a wide basis and more efficiently today than before. The importance of technology as a central factor in creating competitive advantage both at the level of national economy as well as of an individual firm has commonly been recognized. Along the increasing importance of technology its development has become more and more resource intensive. Consequently the firms must rely also in increasing extent on external sources to build up the needed technology competence. This altogether has made transfer of technology a very up to date issue. Spinn- off companies constitute a demonstrative and direct input from research institutions to the economic environment; and typically in a sector considered as particular desirable i.e. small high-tech firms. As a technology transfer agent a spin-off company is potentially efficient, although the main channels in transferring the technology rely elsewhere.

Nuclear research is an interesting example due to several reasons. It is an approach making exercise as a large scale interdisciplinary concerted action to develop science into technology. Further nuclear research has been a forerunner in internationalization of scientific research and later on technology development. Nuclear research and technology have been objects of national investments and inputs of exceptional scale. The countries pioneering in the nuclear research and technology had military applications as primary objectives. In the countries following the early ones, the research objects consisted of peaceful civilian applications. In those countries the large investments were supported much by the argumentation that nuclear research and technology would promote the overall economic and technological development in the country. Besides the potential prosperity brought by the nuclear power the nuclear research establishments were expected to serve as a kind of central source for technology to be transferred to many fields of science, industry and business. Spin-off companies provide a relevant view to the above argumentation.

This paper reviews briefly the history of nuclear research centers from technology transfer point of view with specific emphasis to spin-off companies. In spite of its specific character the case of the Finnish nuclear research and the referred institute it reveals certain aspects of general interest related to the efficiency and practical possibilities of international technology transfer. The referred Finnish spin-off cases are up to date representative examples of small technology based firms spun off from a research institute.

THE IDEA OF TECHNOLOGY TRANSFER

According to Autio a variety of definitions for technology transfer has been presented since 1970"s. He suggests that the majority of them are to narrow in scope. They refer, for example solely to licensing or to transferring technology between developed and developing countries. Autio himself ends to a definition which views technology transfer largely as a social process (Autio, 1993).

Ayres presented already in 1969 a definition for technology transfer, which is very applicable from practical point of view and broad in its scope so that it can well accommodate also the social dimension in the case an explicit emphasis of that nature is needed. Ayres has defined the technology transfer as follows:"Transfer of technology is the application of a technology in a field outside the one for which it was developed or to which it was first applied (as contrasted with diffusion or penetration)'". The technology diffusion according to Ayres is:"'Diffusion of a new technology is the evolutionary process of replacement of an old technology by a newer one for solving similar problems or accomplishing similar objectives"'. These can be handled as consequent phenomena. Technology transfer brings a new technology to the system and diffusion spreads the technology within the system

(Ayres, 1969). Reflecting the terminology transfer refers to an active goal oriented action while diffusion refers rather to a phenomenon which proceeds on its own. According to the above definition technology can be transferred from one system to another both in lateral and vertical direction. The lateral dimension represents the more common and conventional ideas. It covers the transfer of technology e.g. between the countries, between the industries or between the application fields. Lowell Steele in his textbook recognizes the vertical dimension as essential(Steele, 1988) It includes the transform of scientific results first into generic technologies and further to specific applications i.e. processes and products; and still further to different social systems.

Weinberg in his famous book "Refelections on Big Science"" refers mainly to the vertical dimension as well (Weinberg, 1966). He explicitly interpretates the development of science into technology as technology transfer including even steps from generic technology into specific applications. However, Weinberg does not give any definition for the technology transfer. The recognition of the vertical dimension in technology transfer justifies the statement that nuclear research centers represent the first large scale interdisciplinary attempt ever made to achieve a breakthrough from science into technology.

CHANNELS FOR TECHNOLOGY TRANSFER

In this context the idea of transfer channel is viewed broadly covering a wide range of different means and media for transferring of technology.

Depending on the application and actual situation transfer channels can be identified, built up and utilized accordingly. For example, Robinson has identified altogether 16 different means," channels" to transfer "the technology packages" (Robinson, 1988). That model is suitable for examination of technology transfer between firms.

For the purpose of this study referring mainly transfer between research institutions and industry the following more conventional and generic classification of channels is appropriate (Hull, 1990).

1. Contract research and development
2. Consulting and other expert services
3. Training and continuing education (including provision of professionals)
4. Spin-off companies, licensing', "research exploitation"

The experience has proven that people are the most efficient medium for technology transfer. This underlines the importance of category 3. This category includes also the professionals of the research centers recruited by the industry which is traditionally an important and efficient vehicle for technology transfer. Category 4. covers the spin-off companies which inherently includes technology transfer through people as well. Further spin-off companies demonstrate a visible input of a research institution to the economic environment. According to Hull research exploitation is not client oriented. It typically involves advancement of a technology to the point that a licensing deal, or a corresponding arrangement with the industry can be negotiated. European institutions are not involved in research exploitation in the same extent as the American universities.

NUCLEAR RESEARCH AND TECHNOLOGY TRANSFER

The history of nuclear research centers have distinguished different phases. Along this development much experience has been gained which have contributed in various ways to the development of science in to technology. The development of nuclear energy for military and peaceful applications began in the USA, and the history of nuclear laboratories started there during the second world war.

The joint efforts of nuclear physicists, chemists, material scientists and engineers from various fields, supported by large infrastructure of facilities, were expected to achieve a brake through in the nuclear field first for military purposes, and then afterwards for peaceful use. In order to achieve the said breakthrough new types of laboratories were established, which Weinberg called mission oriented laboratories. The term is well justified since the laboratories were set up to carry out a mission defined and given by the government such as reinforcement of national defense and later on production of cheap energy. The mission originated outside science, science was a tool for realizing of nonscientific, politically defined goals. Whilst traditional basic university research is disciplinary oriented and science driven.

The UK, the USSR and France followed the USA in establishing nuclear laboratories. A few years later several other industrialized countries followed, even some

developing countries e.g .; China, Yugoslavia and India.The main motives in investing nuclear research were the military application and keeping abreast of technological development. In those times nuclear technology was seen as definite high technology. Further it was considered to be a generic core for a vast variety of applications in different fields e.g.; energy, medicine, agriculture an industry. From the mission point of view the initial period was successful. The military applications succeeded in all countries, which started early and which had enough political and military power as combined with adequate resources. The large scale peaceful application via. nuclear power as energy source succeeded as well. First demonstration power reactors were constructed already in fifties and in early sixties the large commercial breakthrough took place. After the commercialization of the nuclear power the nuclear industry took the major role from research centers, signifying that part of the mission was successfully completed (Weinberg, 1966). Filling the mission was also a demonstration of transfer of science into technology on a multi disciplinary way and in a scale which was not seen before. further the centers played a key role in introducing nuclear technology into other fields of application e.g. medicine, agriculture etc. as well as in the very successful internationalization of nuclear science and technology.

Filling the main mission was the beginning of the decline of the nuclear centers first in their status and little by little also as regard to the resources allocated for their use. It is true that the decline with reference to the resources was slow and new centers were still established through the sixties even in seventies in developing countries. After the industry assumed the leading role in commercialized nuclear power, the research centers were left in a supportive position. They executed research on the basis of governmental funding and industrial contracts. They never got any new mission to replace the introduction of nuclear power but a variety of different kind of smaller tasks mainly related to nuclear safety and waste management (Heinonen, 1987).

After loosing the mission the second constrain the centers had to cope was the world wide reduction of nuclear power programs. The centers enjoyed in their early times exceptional resource allocations. As result of the changes in the environment the centers tried to compensate the losses in their original role and domain in diversifying into different fields, mostly related to energy and environment. Education was included as an essential part of the original mission. Most of the centers were closely connected to the universities. Power companies and safety authorities recruited their expert staff largely among those trained in research centers. As proven by experience an efficient technology transfer can be realized in transferring qualified people (Steele, 1988).

THE FINNISH CASES

Finland was a late starter in experimental nuclear research and she never established a nuclear research center in an ordinary sense. The Helsinki University of Technology received a zero power reactor in late 50"s and a Triga Mark II Research Reactor became critical in 1962. At this time an independent research laboratory was established, the Reactor Laboratory. It was funded directly by the government but administered by the Helsinki University of Technology. The main purpose of the unit was to educate specialists for the Finnish nuclear power program. Applied research first for educational and scientific reasons was performed which soon extended from nuclear physics to various multidiciplinary activities to support science, technology, medicine and industry in Finland. These activities were supposed to be funded by research contracts, although this was realized to larger extend only in late 70's and early 80"s.

In 1971 the Reactor Laboratory was incorporated into the Technical Research Center of Finland (VTT). a multi disciplinary research center employing nearly 3000 people at its maximum, in 1990. In the early 80's the Reactor laboratory reached its peak in activities employing some 100 people. Government funding was decreasing being as low as 26% in 1986. Active marketing and the needs of nuclear industry gave a secure outside funding. The closer dependence on the industry and business environment showed that a governmental institute is not very efficient organization to sell services. In late 1980's VTT assumed a policy to encourage entrepreneurship and creation of spinn-offs. Consequently some research groups left the Reactor Laboratory to continue their activities as independent private business enterprises. A part of radioactive tracer group established a firm in 1986 and started to compete with the Reactor Laboratory. The new company was successful it overtook the market

and managed to increase the volume of business significantly, while the Reactor Laboratory gave up almost all it's activities in this field. The budgeted turnover of the company, Indmeas Ky, for 1994 is 3,5 mill. FIM and it employs 8 people. Some 80% of the business is export.
The next group to leave was the one doing environmental modeling in lake and sea ecosystems in 1990. Also that business ceased at the Reactor Laboratory, while the new company increased the volume of the business. The turnover for 1994 will be some 3 mill. FIM and the staff consists of 8 professionals. There is a strongly increasing demand in the market also from abroad. The company, SYVA Oy, has intentionally chosen the strategy of slow growth.
The third sector to leave in a form of a spin-off company in 1991, was the production of radioactive pharmaceuticals. It was an activity which over the years since late 60's had required substantial investments. The total return has been less than the inputs. The new company has started off very well and further success would pay back well the investments to the society. The turnover in 1993 was 6,3 mill. FIM and the personnel 16. The company MAP-Medical Technology Ltd., is the market leader in Finland and the share of the growing export is at present some 30% (Ahola, 1994; Heinonen, 1995)

DISCUSSION

In a world wide perspective the nuclear research centers never developed into the kind of centers of excellence as originally anticipated influencing significantly the overall technological and economic development of the respective countries. As a rule the number of spin-off companies originating from nuclear research establishments is relatively small. However, nuclear science and technology as well as the research centers together demonstrated technology transfer in a scale and efficiency, which was not seen before. This refers both the vertical and lateral dimensions: development of science into technology with large scale commercial applications; and dissemination of technology globally and in different application fields.
In spite of its specificity the Finnish case demonstrates certain features which are worldwidely characteristic to nuclear research. The Reactor Laboratory used to be the most central institution for experimental nuclear research in Finland. It produced during 30 years of operation only three spinn-off companies. The small number is somewhat related to the cultural environment. The total number of spin-offs from VTT was 52 by 1992. most of them were created only in late 80's and early 90's. Thus the Reactor Laboratory is even above the average. Their size, technology orientation and internationalization is clearly above the average among the VTT based spinn-offs. Most important is the fact that the business of all the three firms is prospering, in spite of the very severe recession in the country.
The Reactor Laboratory contributed to technology transfer through three distinquished phases as follows.

1. While building up the capacity on nuclear research, education and expertise advantage of the newly established international collaboration was taken i.e. technology transfer from abroad.
2. Besides education and expertise for the Finnish nuclear power program the mission of the Reactor Laboratory included to study and develop nuclear based technologies applicaple in different fields of science and industry, i.e. the vertical technology transfer.
3. This phase represents the transfer of the skills and know-how from the research institution to the environment. It covered primarily education of experts and research services so that the spin-off companies represent only a small share of the whole. All the three companies are based on the the technology developed at the Reactor Laboratory up to the proven commercial phase. MAP is the only firm, which officially bought the rights to the technology and products. Indmeas and MAP have developed further their technologies including new commercial applications. The active international operations include the technology transfer component as well - this time from Finland to abroad.

Reactor Laboratory has been a contributor to international technology transfer already since 1960's via collaboration programs. As already mentioned the most efficient medium for technology transfer consists of people. The staff members of the Reactor Laboratory have worked as visiting scientists and experts in many countries and organizations including developing countries and United Nations"

specialized Agencies. The laboratory has organized training courses and accomodated trainees and visiting foreign scientists. Thus the international nature of nuclear technology has constantly reflected to the activities of the Reactor Laboratory. That is why the international operations have been natural and significant in the business of all the three firms as well.

These three firms are representative examples on the idea of spin-off companies as agents of technology transfer and qualified high-tech contributors to the business environment.

Further the Finnish case as a whole is an example of an efficient utilization of technology transfer. The basic approach was to apply thin organizations and exploit existing resources at universities, research institutions and industry. Advantage was taken of the newly established international nuclear collaboration (Heinonen, 1987).. The assmilation of the transfered technology into the recipient"s technology environment i.e. the degree of completeness of transferered technology is an essential dimension to be examined. A convincing indicator on completness of technology assimilation is when the recipient is able significatly to develope the technology further and act as transfering party itself. In this regard the Finnish case is a representative - but in no means a unique, example.

THE POTENTIAL OF SPIN-OFF COMPANIES

The nuclear technology with all the established major application fields e.g. nuclear power, nuclear medicine, industrial applications, agriculture and different research tools has reached a certain stage of maturity in its development. Therefore new inventions and innovations are not so frequent any more. It further means that the overall potential for spin-off firms is smaller than in the days when the technology was developing rapidly and was spreading to new fields of application. In particular, the manufacturing product related spin-off companies are not typical in the mature stage of technology. The Finnish cases do not have the statistical justification. Nevertheless, two of the three firms represented services. On line with the present stage of development the sophisticated services would be the most natural and suitable domain for the firms to spin-off from nuclear research institutions. There are a vast amount of experience and examples of firms offering different kind of services in the nuclear field including waste management. Management of radioactive wastes is still a very potential area, in particular, in the global market as we have realized in Europe, even in Finland. There is also the possibility to extend the services beyond radioactive wastes to other hazardous wastes.

Power plant maintenance is another area still having potential for development. Two of the writer's students established a firm a couple of years ago which does certain maintenance work in the context of annual revisons of nuclear power plants. They cannot accept all the work they are offered to in this stage.

Education and training, in particular, professional continuing education is a field, where nuclear experts could play a more active entrepreneurial role. Closely related to that is the further development of consultancy business, where certain traditional strengths of nuclear field could be exploited; such as; national and international networking, internationalization, multidisplinary approach, proximity to basic and fundamental scientific research even theoretical developments.

CASE STUDY: COMMERCIALIZATION OF THE INNOVATIVE IN SITU VITRIFICATION TECHNOLOGY

James E. Hansen
Jack L. McElroy
Geosafe Corporation

ABSTRACT

Geosafe Corporation is a development stage company that is commercializing the innovative In Situ Vitrification (ISV) technology. The ISV technology was invented and initially developed by Battelle, Pacific Northwest Laboratory (PNL) for the U.S. Department of Energy (DOE). The technology involves the in situ electric melting of earthen materials for purposes of site remediation and/or waste treatment. The technology holds significant promise for highly effective treatment of sites contaminated with hazardous (organic and inorganic), radioactive, and mixed wastes, including sites with buried waste and debris.

Geosafe holds exclusive license rights to the commercial application of the DOE-patented technology. Geosafe initiated the commercialization process in 1988. The commercialization process has been challenging as various barriers and difficulties associated with bringing the new technology to the commercial marketplace. This case study reviews the chronological development of two concurrent and closely related pathways of events: 1) those associated with the ISV technology development, and 2) commercialization efforts. Positive and negative influences on both pathways are reviewed and a lessons learned conclusion is presented.

INTRODUCTION

The purpose of this paper is to present the major barriers experienced by Geosafe during its ongoing efforts to commercialize the ISV technology. Whereas this paper is one of several in a session on "Business Opportunities and Barriers", it is not the purpose of this paper to identify all the types of barriers that an innovative technology undergoing commercialization may encounter; rather this paper presents Geosafe's experience as a case study that may or may not be typical of other technologies and commercializing companies.

The following summary description of the ISV technology is presented to help the reader relate to the type of technology being commercialized. The ISV technology has been recognized by environmental technologists and regulators as one possessing strong potential for significant contribution to the national problem of hazardous, radioactive, and mixed waste site remediation. The technology involves the in situ electric melting of earthen materials for several possible purposes, including: 1) thermal destruction/ removal of hazardous organic and inorganic compounds, 2) permanent immobilization of hazardous and radioactive heavy metals within a high integrity vitrified product form, 3) conversion of waste materials into recycled products, and 4) production of high integrity vitrified masses for various civil engineering applications.

The ISV technology is a variation of the joule-heated glass melting technology that was adapted to waste management applications by PNL starting in the early 1970s. The technology differs from standard melter technology in that the earthen media itself serves as the containment for the melt. In ISV, an array of electrodes (usually 4) is placed a few inches into the media to be treated, and a graphite and glass frit starter path material is placed between the electrodes. The starter path carries the initial electrical current until the adjacent media is melted. Once melted, the earthen media (e.g., natural soil) becomes electrically conductive and becomes the process heating element. Joule heating occurs within the molten mass. Heat is conducted outward into adjacent unmelted media, causing it to melt, thereby enlarging the size of the melt. This process continues until the desired melt size and shape are attained (to 1,200 tons maximum).

The process is operated with a melt temperature in the range of 1,600 to 2,000 degrees Celsius for most silica-based media (e.g., soil, sludge, sediment, mine tailings). The high temperature of the melt causes the pyrolytic destruction and

vapor-phase removal of organic contaminants present in the treatment volume. Most metal oxides become part of the melt and are incorporated within the glass and crystalline structure that results upon cooling. The process results in a large volume reduction due to the elimination of void volume within the particulate media (e.g., 20 to 50% for most soils). The vitrified product typically possesses outstanding physical, weathering, leaching, and biotoxicity properties. The ISV process and its attendant vitrified product may be the most technically preferred and cost effective technology alternative in cases where: 1) a combination of organic and heavy metal, or hazardous and radioactive, contaminants must be treated, 2) onsite and in situ treatment is highly desired, 3) the site contains non-homogeneous soil conditions and/or debris, 4) maximum treatment effectiveness and permanence are required, and/or 5) high volume reduction is desired.

CASE STUDY CHRONOLOGIES

The chronology of the ISV technology development and commercialization efforts can best be understood in relation to two key timelines: technology development and commercialization. The timelines are presented separately below; however, it should be noted that they are closely related and somewhat interdependent. It should also be noted that two separate technology development efforts, DOE's and Geosafe's, have been pursued since Geosafe's establishment. The DOE program is mentioned in the discussion below since, although separate from Geosafe's efforts, it had major influence of the perception of ISV in the marketplace.

Technology Development Chronology

Figure 1 presents the ISV technology development timeline. This figure identifies key milestones related to the technical development, test and demonstration, and application of the technology. The timeline starts with the invention and proof-of-principle testing in 1980. The following two years focused on initial process exploration and small-scale test and development work, all of which continued to indicate the promise of the technology. There was a strong desire to quickly scale the technology up; thus starting in 1983, the program focus moved away from process and technology development to a pilot-scale (e.g., 10-ton melts) equipment design and demonstration focus. The scope of DOE application interest at that time was limited to TRU-contaminated soil. Pilot-scale equipment was designed and fabricated, and a major milestone was achieved in 1983 by the successful completion of a demonstration test on TRU-contaminated soil.

This success resulted in rapid movement of the program toward design, fabrication, and demonstration of a large-scale ISV equipment system capable of treating 100 ton/day of contaminated soil, and designed to be trailer mounted for over-the-road mobility. Some equipment development work was also performed in the areas of electrode design (for extended life) and electronic depth monitoring equipment (for determining the depth of melt in real-time). The multi-million dollar equipment system was completed in 1984, an amazingly short four years after inception of the technology concept. Four large-scale Operational Acceptance Tests (OATs) were performed in uncontaminated soil during the following 1-1/2 years. The equipment was then applied in 1986 to the Large-Scale Radioactive Test (LSRT) which treated a portion of a TRU-contaminated drain field within Hanford's 200 Area. This test was largely successful; however, some equipment difficulties were encountered, and the depth attained was less than desired. It was learned that the depth had been limited by the presence of a cobble rock layer that served as a thermal barrier to melt growth. This finding was very important to the future development of ISV. The large-scale equipment then sat idle for about four years.

During the meantime, the promise of the technology became infectious and several development and test programs were established within DOE for various types of applications, including: 1) liquid seepage disposal basins at ORNL (started in 1985), 2) buried waste at INEL (started in 1987), and 3) underground tank remediation at Hanford, ORNL, and other DOE sites (started in 1989). In addition, in 1984, PNL started performing small scale tests and demonstrations on many types of hazardous chemical wastes for non-DOE clients. The technology was found to be applicable for the effective treatment of a broad range of earthen media and contaminant types. In 1989 Geosafe procured and initiated testing of a large-scale ISV machine for its commercial use.

In 1991, the technology was applied to another large-scale demonstration at Hanford involving a liquid disposal crib (wooden timber type). While quite successful in most areas, this demonstration too, like the LSRT, came up short in the area of

depth attainment. These two large-scale tests had identified the inability to minimize melt width as needed to allow attainment of desired melt depth. Many ideas for resolving the problem were identified by PNL staff; however, they were unable to obtain the funding needed to resolve this problem. This was the apparent nature of the DOE program at that time (i.e., demonstrations were readily funded, R&D was not).

Fig. 1.

Fig. 1. ISV Technology Development Milestone Timeline.

At this point, within about one year of each other, several ISV tests experienced notable difficulties. First, during pilot-scale testing of ISV on buried wastes at INEL, PNL found that the flow of vapors and gases through the melt was sometimes sufficient to disrupt and splatter the melt, making process control difficult and causing damage to the equipment. Second, during very aggressive testing of its new large-scale equipment, Geosafe explored new limits of application, including buried drums containing water, and experienced a melt splattering event that severely damaged the experimental off-gas hood that was being employed. Third, during a large-scale PNL demonstration test on a 22,000 liter underground tank, a vent tube failed midway through the melt, resulting in a thermal excursion, expulsion of melt, and damage to the off-gas hood. These three events clearly revealed an area of technical difficulty that had not been a concern for simple contaminated soil applications, that being the need for process control and equipment design features capable of handling the volumes of gases that would be generated during such applications.

These testing events resulted in the severe curtailment of the ISV technology development and application program within DOE. DOE's Office of Technology Development took the position that the ISV technology was sufficiently developed for contaminated soil type applications, required little or no further development work, and should be considered as an "available technology" for DOE remediation needs. DOE also terminated its ISV Integrated Program which was established to investigate the underlying technical principles that were needed by the various applications. DOE took the position that further development of "advanced" ISV applications (e.g., buried wastes and underground tanks) would wait until ISV became an established technology for contaminated soil applications. The DOE buried waste and underground tank ISV programs essentially terminated at that point; however, several relatively small test and development projects related to contaminated soil applications at ORNL, SRL, and Hanford were maintained.

Geosafe proceeded to investigate the cause of its testing event and developed a significant advancement in understanding of the generation and disposition of gases and vapors during ISV processing. Geosafe established new application limits and process control standards, and designed a new metal off-gas hood capable of withstanding higher off-gas temperatures. Geosafe resumed testing of its equipment early in 1993 and initiated its first commercial remediation project during the Summer of 1993. Whereas the early stages of the DOE ISV development program focused on proof-of-concept, equipment design and development, and test, development and demonstrations of interest to DOE sites, Geosafe's efforts have focused on process dynamics, process control, equipment refinement, expansion of application types, and developing the know-how required to make the technology operate on a commercial basis. These efforts have resulted in a greatly increased ISV knowledge base being established since 1991.

Geosafe's first commercial project was at the Parsons Chemical Superfund Site in Grand Ledge, MI. That project involved the treatment of 4,800 tons of soil contaminated with pesticides, mercury, and low levels of dioxin and arsenic. The project involved some site and soil conditions that had never been tested at large-scale before; and Geosafe had to respond with several adaptations to the equipment and process. The challenges were successfully met, and a highly successful EPA SITE Demonstration Program demonstration and evaluation was performed. Geosafe then performed a National TSCA Demonstration at a private site in Spokane, WA. That project involved the treatment of 3,100 tons of soil and debris (drums, concrete, asphalt) contaminated with PCBs to a maximum concentration of 17,000 ppm. That project was very successful with no significant process or equipment challenges being encountered. Geosafe's large-scale equipment is now operating at the Wasatch Chemical Superfund Site in Salt Lake City, where it is processing 6,000 tons of soil and debris contaminated with dioxin,

pentachlorophenol, pesticides, and a variety of other organics.
Both DOE and Geosafe continue with ISV technology development and demonstration programs. The current DOE program includes: 1) preparation for a large-scale treatability study on an inactive radioactive liquid waste seepage trench at ORNL, 2) preparation for a "spot melting" field demonstration at PNL, 3) development related to application of ISV to low-alkali soils at SRL, and 4) investigation of possible ISV application to buried wastes at ORNL. Geosafe's program includes performance of tests and development work for pending non-DOE applications within the U.S., and for overseas projects including contaminated soil, LLW, and waste treatment applications in Japan, and a major buried waste application at the Maralinga Test Range in South Australia.

Commercialization Chronology

Figure 2 illustrates the ISV commercialization chronology. PNL scientists and engineers invented the technology in 1980. A patent application was filed in 1981, and a very fundamental patent was granted to DOE in 1983. Similar patents were granted by major industrialized countries throughout the world. DOE granted a license to Battelle Memorial Institute (operator of PNL) in 1986. Battelle initiated marketplace promotion and regulatory awareness efforts on a privately funded basis. These efforts resulted in the selection of ISV for remediation use at three U.S. sites, including: 1) the Pristine Superfund (Remedial) Site in Cincinnati, OH, 2) the Griener Lagoon Superfund (Removal) Site also in Ohio, and 3) a private RCRA closure site in North Carolina. Battelle defined a strategic commercialization plan that involved creation of Geosafe Corporation in 1988 to fulfill the needs of these selections. Geosafe procured its first large-scale equipment system later that year.

The Company suffered a major setback within one year after its initiation as all three of the site selections were withdrawn. The Pristine Site Record of Decision (ROD) was reopened after a surprising turn of events. EPA had issued this ROD and many others in response to Congress' mandate (SARA/1986) to show site selection preference to innovative technologies that involved treatment, reduced toxicity, mobility, and volume, and could be performed onsite and in situ. That mandate essentially specified technologies like ISV for many difficult sites. In response, EPA issued many innovative technology RODs without first having performed treatability tests on the selected technologies on actual wastes from the sites. Congress' Office of Technology Assessment (OTA), in one of its twice yearly critiques of EPA, took EPA seriously to task for having done this. In addition, OTA questioned the wisdom of EPA in making the ISV selection because a competitor of Geosafe's had made claims (unsubstantiated) that "ISV doesn't work". In Geosafe's opinion, OTA's challenge to EPA resulted in significant damage to the advancement of innovative technologies, in direct conflict with Congress' mandate.

The Griener Lagoon site selection disappeared on a similarly unanticipated basis. EPA added lime to the site to make the wet soil easier to handle during staging of soil in preparation for ISV treatment. After the site was ready to treat, EPA performed sampling and analysis to confirm the PCB content of the soil. To their surprise, the PCBs had apparently disappeared. Similar results were noted at other PCB sites. This finding was termed EPA's "lime discovery". The ISV site selection was removed while the discovery was further investigated. Some years later it was determined that the addition of lime to the sites did not really destroy the PCBs, rather it may have removed some by volatilization due to the heat generated from the addition of lime, and the presence of lime was found to mask the PCBs making them difficult to detect and measure by the conventional analytical methods then employed.

The private RCRA site selection was lost when Geosafe determined it was not possible to negotiate an acceptable contract with the site owner.

Geosafe was then faced with reestablishing a queue for its ISV test and remediation services. A significant number of treatability tests were performed in support of Superfund RI/FS work. Within a few months the State of Michigan decided to fund an ISV demonstration at one of its sites. In collaboration with the State, it was determined that EPA would fund the demonstration at the Parsons Chemical Superfund Site under the existing ERCS contract. Geosafe was told to be ready to mobilize to the site within two months. This timing was unfortunate in that EPA administrators shortly thereafter determined that the ERCS contracting provisions should not be used for such projects, wherein a subcontractor (Geosafe) would be doing most of the

work. They proceeded to use a competitive contracting approach that stretched the procurement period from the original two months, by a factor of 11 times, to 22 months. Geosafe finally obtained that contract, and another with a private client, during the Fall of 1990.
During these 22 months, Geosafe's marketing efforts yielded significant fruit, with the addition of 10 site (preferred remedy) selections for the ISV technology. These selections involved Superfund RODs and other comparable decision statements by DOD and private parties. At this point Geosafe was vigorously looking for an investment partner to fund the equipment and working capital that would be required to support this anticipated level of demand.
Fig. 2.
Fig. 2. ISV Commercialization Milestone Timeline.
In 1990, Geosafe hired and trained a full operating crew for its new large-scale system. This crew would perform two large-scale melts as part of its training prior to mobilizing to the first project. The first melt went well. The second employed particularly aggressive operating conditions and resulted in the incident reported in the technology chronology above. Geosafe determined that the incident was significant enough that large-scale commercial operations should be put on hold (suspended) while the cause was investigated. It took about one and one half years for Geosafe to fully evaluate the cause and to determine a recovery plan. An additional half year was consumed designing and fabricating a new metal hood. Geosafe resumed testing early in 1993, and commercial operations were initiated shortly thereafter.
During the suspension of large-scale operations, a number of the site selections understandably went away. Two RODs were reopened and revised due to the uncertainty as to how long the suspension would last. Other "multiple choice" selections which allowed alternatives to ISV resulted in decisions against ISV during this time. Two DOD demonstration selections were withdrawn because of budgetary constraints and Geosafe's inability to meet desired mobilization schedules. At the end of the suspension, three of the original selections remained, and two more had been added. Geosafe then initiated commercial operations in 1993 with five intended selections for site remediation by ISV.
Geosafe is currently working at the third of these sites. The attainment of commercial operations status has been helpful in restoring awareness by the marketplace and regulatory community that ISV has returned after the suspension. At this time ISV is being seriously considered for many possible private and government sites.
BARRIERS ENCOUNTERED
Technology Readiness
At the time of Geosafe's inception, the prior ISV test record had led to the belief that the ISV technology was very capable and fully ready for commercial application to soil remediation projects. The technology had been developed and demonstrated at full-scale in an unusually brief time. It was to be realized later, as the technology was tested under more aggressive conditions and for much more complex applications, that the basic underlying technical principles governing the technology had not yet been fully explored and understood, primarily in two areas: 1) melt width control (which impacted attainable depth), and 2) generation and disposition of gases and vapors during processing. Whereas there had been ample funding for equipment and demonstration projects, funding for underlying principles exploration was not forthcoming from DOE. EPA also declined to fund experimental and test work because "ISV was DOE's technology".
These factors, in addition to the fact that no two sites are exactly the same, caused Geosafe to undertake additional efforts in order to understand and offer a viable technology. It also required Geosafe to establish a relatively tight "applications envelope" wherein the underlying principles were understood for applications within the envelope. Other applications would require further testing and development. In this sense, then, Geosafe considered the initial state of technology readiness as a type of barrier (or limitation) to full attainment of the technology's commercial potential.
Volatility of Site Selections
It may take many years for a site to move through the process from initial discovery and characterization to final remediation. For purposes of predicting firm demand on which to base company decisions, the technology-linked remediation vendor may

look at contracts in hand, which is the firmest indicator, or possibly at official site selections specifying use of the vendor's technology. Since ISV is a sole source technology, Geosafe assumed that site selections specifying the use of ISV were pretty firm. Part of the learned reality was that site selections are not inviolable, and it is common for them to be reopened, overturned, or otherwise made highly uncertain. It was also found that typical remediation contracts allow for the client to terminate the contract without cause, further adding to the difficulty of making credible projections.

Difficulty Establishing Current Awareness

It is a major challenge for an innovative technology company to establish and maintain a current awareness of its technology within the marketplace, including the potential client, regulatory, and environmental engineering segments. Many different organizations (e.g., EPA, DOD, DOE) attempt to assemble and publish standardized data on available technologies on a periodic basis. However, in most cases, the information is seriously out of date (usually at least two years) before it finally gets published and into the hands of users. This problem is particularly important to innovative technology vendors wherein the technology status is usually changing quite rapidly. Significant improvements have been made in this area by EPA's VISITT database and SITE Demonstration Program. However, even now, Geosafe routinely encounters decision makers that are using outdated information on ISV. In an effort to maintain a better current awareness level within the remediation marketplace, Geosafe initiated a periodic publication called the In Situ Vitrification Technology Update. This newsletter has received very good reviews and is obviously much more timely than Government published information. The challenge remains to get the information into the hands of the appropriate decision makers.

Lack of Understanding Regarding Small Commercial Business Needs

Innovative technologies are mostly developed and offered by small business concerns with limited capital resources. Geosafe believes that the needs of such companies are not well understood by the Government organizations attempting to deal with them. For example, EPA's SITE Demonstration Program requires the technology vendor to fund its own demonstration, while the SITE Program will fund data acquisition and evaluation efforts. Such large-scale demonstrations can cost many hundreds of thousands of dollars; small innovative technology companies cannot handle that level of "marketing" cost. The alternatives exist for the developer to find a client to fund the demonstration, or for the Government to provide a demonstration site. In the search for an ISV demonstration site, EPA's SITE Program formally requested DOE to consider providing a site where a demonstration could be performed. For unknown reasons, a suitable site could not be found from the hundreds possessed by DOE. Largely because of this situation, the SITE Program evaluation of Geosafe's ISV technology occurred many years after the technology was accepted into the SITE Program; and even then, the site employed was not the ideal site to satisfy the objectives of the SITE Program.

In similar manner, innovative technology companies are faced with the need to fund large-scale equipment without the existence of firm market demand. The companies are also expected to maintain staff during periods of contracting or regulatory delays of various types. The developer typically is expected to withstand these costs without assistance. The developer may also be expected to provide special low pricing as an incentive to obtain a demonstration opportunity. Such costs can be staggering to a small technology innovative company, and should be recognized by those organizations charged with encouraging the development and implementation of innovative technologies. Such costs also mitigate against profitability, which makes it difficult for companies to raise additional investment capital.

Actions of Detractors

Geosafe considers the loss of the Pristine ROD largely to be the result of the competitor's claims against ISV that contributed to OTA's harsh criticism of EPA for the ISV selection. The competitor's claims have since been shown to be unfounded; however, the damage was done. Other actions by competitors and other uninformed persons resulted in the spread of erroneous information regarding ISV. Geosafe has had to counter many myths, including the following beliefs: 1) that all vapors formed during ISV moved into adjacent soil (the myth of "vapor retreat"), 2) that ISV only worked in sandy soils, 3) that ISV would not work in wet soils, 4) that ISV is extremely energy intensive, and 5) that ISV is extremely costly. Geosafe has had to expend significant resources combatting the damage such myths cause in the

marketplace and regulatory community.

Loss of Momentum

The series of unexpected testing incidents, and Geosafe's temporary suspension of large-scale operations, had a very negative impact on the momentum and enthusiasm that had been established for the technology. The message went out within the EPA community that ISV was no longer available. Nearly the same effect occurred within the DOE community, as ISV went from being hailed as one of Admiral Watkins' "flagship technologies" and a well funded segment of DOE's technology development program, to a technology that was almost put on standby until it was demonstrated as a commercial success on contaminated soil applications. DOE's disappointment even resulted in "bad press" from the technology's previous number one supporter. This loss of momentum has been and continues to be a major challenge to Geosafe, as it tries to reestablish market awareness of the current commercial status of ISV.

It is worth noting that, while DOE's response to the testing incidents was one of significant withdrawal of support, EPA, in approximately the same time frame, recognized the need to accept and expect some reasonable difficulties with innovative technology testing if their efforts to implement innovative technologies were to be successful. EPA issued a policy to this effect that not only recognized the risk of some failures as important lessons learned, but actually encouraging the selection of innovative technologies despite such risks.

Contracting Problems

The difficulty posed to contractors by the Government contracting process was epitomized by Geosafe's experience wherein a two month procurement stretched into 22 months. The location of the procuring office, and the personnel involved, changed several times during that time. Geosafe found there to be a significant disconnect between the operations side of many Government client organizations, and the legal/contracting side. The standard wisdom is for vendors to work both sides of the house at the same time. However, our experience indicated that the legal/contracting side would not usually get functionally involved with a project until it was time to negotiate a contract. This situation not only caused problems for Geosafe, but for the operations side of the client organization itself. It should be noted that at the time of this experience (1990), many of the procurement practices for remediation projects were in the fairly early stages of development, and were subject to many changes. Geosafe has not noticed the extent of such problems when dealing with private clients; however, as a general rule, it does seem to be more difficult in terms of time and effort to negotiate a contract than to perform the technical work associated with project development.

Geosafe also experienced a case wherein the Government client was always right, so to speak, when it came to interpreting contract provisions. The Government held firm to its "promise" that there would be no change orders during the fixed price contract, regardless of whether or not they were justified. Geosafe was obligated to accept the cost of unforseen technical challenges and site discoveries during this project. Even extending the duration of the contract extracted a significant additional financial toll. There exists an obvious dichotomy within the Government wherein, on the one hand they are charged with supporting the introduction of innovative technologies, and on the other hand they are charged with being as hard as possible in the area of contract enforcement. Typical development stage innovative technology companies are seldom positioned to withstand such costly "support" from the Government.

Difficult Capital Market

At the time of Geosafe's incorporation, the enthusiasm of investors for new environmental technology companies had just peaked and was on its way down. It is general knowledge today that raising significant capital (e.g., millions of dollars) for environmental ventures is very difficult until the company has passed through the proverbial "valley of death". An occasional exception may be successful at raising significant capital if it can be packaged and sold before any downside difficulties unfold. This situation poses a significant challenge to small venture companies since the environmental remediation marketplace, with its relatively large dollar volume projects, and the long procurement and payable times, typically requires very costly equipment and large working capital reserves. Geosafe has been fortunate to have a committed and experienced parent company (Battelle) that has enabled the firm to survive such challenges of commercialization.

SUPPORT ENCOUNTERED

Geosafe acknowledges the importance of the DOE technology development program, and the strong initial support directed to the transfer of the ISV technology for commercial application. Geosafe also notes the good support of ISV and other innovative technologies provided by many organizations within EPA and various state regulatory organizations (e.g., Michigan, Washington, Utah). EPA's Technology Innovation Office, SITE Demonstration Program, and Risk Reduction Engineering Laboratory, have been most helpful in supporting the introduction of ISV. EPA was also instrumental in developing independently qualified data on the ISV process that put to rest the unsubstantiated competitor claims mentioned earlier. In addition, the industry media, with the exception of the few who have an agenda beyond providing public information, have been helpful in developing marketplace and regulatory community awareness of the technology. Geosafe is also appreciative of the various "ISV champions" that have emerged within various industry organizations; for without these champions, few innovative technologies would attain commercial success.

LESSONS LEARNED/CONCLUSIONS

Geosafe has encountered and overcome a number of difficult challenges in the process of commercializing the ISV technology. The Company has now operated the technology on a commercial basis for about two years. The future of the technology is very promising. With "perfect 20:20 hindsight", Geosafe suggests the following principles should be considered strongly by parties commercializing innovative technologies:

1) Establish a conservative applications envelope for commercial applications of the technology; and do not take projects that involve opening the envelope further without first ensuring all parties understand the experimental and uncertain nature of the outcome.

2) Do not risk your company's ability to perform profitable commercial operations on experimental, envelope-widening projects that could damage that capability.

3) Make great effort not to let various difficulties destroy the company's marketplace momentum.

4) Do not make major commitments to personnel staffing and large-scale field equipment until firm contracts are in hand.

5) Develop marketplace and regulatory awareness as broadly as possible, taking care not to oversell the capabilities of the technology. This requires some means of periodic information distribution, and means to keep the awareness current as the technology status changes.

6) Recognize that detractors will probably attempt to block your marketplace efforts, and that resources will have to be spent countering their efforts. A strong information distribution program, including publication of performance results, is a good defense against detractors.

7) Take great care, even at extra expense, to negotiate contracts that are appropriate for the degree of uncertainty involved in a project. It may be better not to have a contract than to have one that is one-sided, particularly where there exist uncertainties regarding the technical aspects of the project. Ensure that cost-reimbursible standby provisions are included against the possibility of client- or regulatory-imposed delays.

8) Recognize that the guidance followed by Government contracting officers will be stringently followed regardless of the spirit of compromise or support indicated by non-contracts type personnel. If tolerance of unforseen difficulties is to be accepted, such should be defined in the contract.

9) Be financially prepared for commercialization time and cost estimates to stretch out beyond seemingly reasonable estimates. This requires experienced investors with a long-term outlook and capability.

ABSTRACT
The press, public, government and industry have been hearing, talking about technology transfer and defense conversion for at least the past five years. But where is it?
The national laboratories have tried but, except for an increase in the number of cooperative agreements (CRADAs), little progress has been made moving their behemoth weapons capabilities forward to establish the 'sustainable" economic foundation we will need for tackling the next century. There is almost universal agreement that our national laboratories, with some 40,000 scientists and engineers, could be the basis of a comprehensive strategic planning effort to develop technology that would return the U.S. to future world leadership role while providing a major stimulus for economic development. But where is the vision? It is there largely because their raison d'etre was to provide the nation with a nuclear weapons capability, building a competitive, highly demanding, excellent and imaginative scientific complex.
Now budgets are being directed to competitive programs away from defense. We have to re-emphasize the need for competitive technology development. But to do this, the labs must focus on smaller, multiple projects. In order to keep the levels of employment, the kind of research the labs are doing must be directed to both applied and basic research for market applications. This country needs to have a rapid response for market driven products. This means the labs need to direct efforts to high volume projects with rapid return on investment while devoting a percentage of their time to basic research, proliferation intelligences and scientific curiosity.
This paper intends to examine the need for an approach that implants in the structure of the national labs a capability and expertise to develop technologies at a competitive cost, and within a time frame designed to meet market demands. There is a certain skepticism that has been documented in several journals and press accounts questioning whether the laboratories have the capability to achieve this desired result. The intellectual capital is there, the question that the skeptics raise is "do they have the market understanding, economic discipline and chameleon capability to change? Views will be offered on how DOE, current and future Administrations, and Congress can develop missions and initiate a "seed" program that would include market milestones, along with financial incentives, for those labs undertaking technology development programs to meet future market demands, in competition with low cost third world nations, and maintain U.S. competitiveness.
INTRODUCTION
In 1991 at Los Alamos co-author Leo Duffy, as Assistant Secretary of Energy, gave a lecture series on the need for innovative curiositythe search for innovation through the scientific inherent curiosity. The series of lectures was given to the three weapons labs in anticipation of the end of the weapons era. The message was that significant reductions were anticipated as a result of defense reductions and the new market was world class competitive technology in the environmental market.
The social issue was based on the fact that the world will have the same surface area for our foreseeable future. The amount of potable water will be less than one percent of the total water supply and the population of the world will double every 20 years. An environmental, ecological scientific delight! The first seminar was at the Los Alamos lab and recommended that the Los Alamos scientific resource redirect it's effort and future mission to the total economic scientific system. The suggestion was greeted with the expression on the faces of the august body, "Will somebody get the butterfly net."
A similar presentation was given to the Sandia management team and received an even greater receptive response like, "Is he dangerous when out of the asylum?" Finally, a modified version was given to Lawrence Livermore's management team. Updated and modified to"Innovative Curativity." (That's right curiosity plus creativity equals "curativity.") This series completed the circuit of former Secretary of Energy Admiral Watkins "Jewels in the Crown" with the message that the light at the end of the weapons era was our opportunity to join the commercial world of reality or the world of high anxiety. The series of seminars was not received with the same appreciation as the "Sermon on the Mount", and it did not emphasize or espouse the principle that "the meek will inherit the budget".
What it did espouse was "innovation combined with curiosity would produce creativity" but based on a market driven strategy. The authors believe that cost conscious business partnerships between intelligent engineers and scientists and

their cohorts in the private sector will produce a viable survival in the post weapons era. This considers that all the research centers have been amortized and, with unique business partner incorporations, could accelerate the application of the labs to compete in the new economic opportunities.
The Pavlovian Weapons blanket is still the preferred mother nurture at the weapons laboratories. But as some of the articles in the press indicate progress is slow but it is occurring and it is still progress.
It is interesting that inside the Labs (weapons and research) and in many areas of congress there is a religious fervor that believes that within this great potential hides a "roaring tornado of technological solutions trying to burst the seams of bureaucratic control. This appears to be contrary to a 1992 GAO Study of Federal R&D and the Barriers to Technology transfer. The study indicated that the 10 year expenditure of R&D funds by 21 agencies was .5 trillion dollars and resulted in $37 million in Royalties. Thirty three million dollars to the National Institute of Health for an Aids test kit. The study included 21 agencies, 700 labs and 177.000 scientists hardly an endorsement of a raging technological tornado.
But the good news is that as budgets get tight the survival mode "Innovation Incubator" could form within the Department of Energy and other Federal Labs.
It is continually inferred that the National Labs are the source of technology transfer. It appears that this is a legend in their own minds. This is not to be critical but to be pragmatic. Thirty-seven million dollars of Royalties for a $.5 trillion in research and development is not a whirlwind return on investment.
The ideal concept that is promoted is that within these institutions of complex intra science disciplines are hidden, in the neurones and synapses of the most formidable minds, technical and scientific discoveries that are bursting at the Labs Seams, just waiting to be marketable products.
An excerpt from John Ulman's article in Society Magazine of June 1993 states defense conversion means doing something "new". "Many firms that attempt to get out of government work have been sadly unsuccessful." The cause in short is typical of trying to transform government style research and production systems with their cost plus mentality to compete in a cost competitive market. Without recognition of the need for fundamental changes in the culture of their procedure, they will fail. It appears that government contractor firms and the facilities they operate are unable to function in the competitive market environment. The notion that government research, leads to civilian economic production flies in the face of reality.
Ulman states that conversion of government facilities is necessary to relieve congress from the pressure to continue unnecessary operation in the name of a job preservation program.
Based on the real market metrics, the development of market products must be functional, economically viable and better than the products that currently exist. In order to accomplish this, the Labs must know what the market wants and, more important, what will the market pay.
The culture of a commercial enterprise also flies in the face of conversion of government facilities into technology implementors. Contrary to Federal Facilities, Commercial enterprises do not in most cases receive progress payments. The job is paid for when finished, and performance is key to repetitive business a unique requirement contrary to the current mode of Federal operation.
Where can DOE labs "curativity" fit into a solution? It appears, based on the culture of the government labs, with the past mountain of high cost secrecy mentality and uncertainty in market understanding, market driven schedules and cost control, that the Mohammed of the private sector industry should climb the government lab mountain.
In order to demonstrate success the labs should preferably start with a known quantity, in dire need for improvements, with a clear data base to compare with the commercial performance and demonstrate an immediate short term indication of success. Peter Drucker says that accounting costs models rarely provide the cost of non-productivity. In fact, they usually conceal it. With the temperature of the new climate in Congress, the heat to cut costs and get more bang for the buck will make global warming look like a deep freeze to future budgets.
What area would be the easiest to accomplish? It is the authors opinion from interviews that no lab director, M&O president, or Operations Manager wants to spend time nurturing Administrative support, i.e., Budget Accounting Services, property management, facility preservation, maintenance service and environmental support

services. But that is where the most continuous internal and external criticism exists. Administrative lack of control in the above areas has been a continuous criticism by GAO. Is it a Pavlovian reaction? If you don't like doing something, you don't do it well.

Why not separate out these functions and approach the local community for fixed price proposals with unit price service related capabilities. It would provide all administrative, maintenance, and facility services on fixed price basis based on regional comparative cost, new data reporting systems that compare performance with similar regional industries and premium unit price for unique administrative or technical lab required services to function in the weapons, energy or esoteric research field.

This will provide a local firm to perform a measurable administrative and service support system function based on regional commercial rates and comparable across similar local facilities with commercially performed services and have an initial regional ownership of a straight forward competitive service.

The Federal agency should then define the core government required mission for the lab or facility. Contrary to the Galvin Committee, core missions have not been established. There is a need to isolate the core mission, isolate the lab resource and assure cost budget related requirements rather than facility pro rata costs. The mission should bear its full cost. The core mission, special equipment and special services should be clearly separated and budgeted for their unique needs. Thus with local initiatives, small business curativity and competitive innovators, a privatized example can catalyze the core neurons of the labs to imitate and initiate a local, regional covenant for competitive success with a mutually developed strategic business plan and regionally competitive costs of doing business.

Next identify the cream science and technology innovators who exist in the lab and have the most interest in achieving market product capability. Then make them available to competitive private enterprise recruiting. Most facilities have been written off (amortized) when built and are not amortized on a depreciation basis. These facilities could be turned over to a business development contractor on a 5-10 cents on the dollar basis, similar to the Rouge River Plant , after World War II, to develop a marketable business within a 2-5 year basis. Take a unique approach. As Tom Peters in his new book says, "crazy times require crazy solutions." Invite business in to evaluate the lab facilities, lab personnel and lab costs and ask industry to submit the most productive use of the labs they can dream up. Don't write a detailed government RFP. Let industry state what it will do and select the best proposal guarantee for the government. They must be willing and able to support the core mission on demand, work with academia and meet the intent of DOE orders and procedures-not the letter of the written word. They must be willing to show a profitable operation in a specific number of years while transitioning from the current mode of operation while still providing first priority to the core mission. The bids from local, regional or national entrepreneurs would be based on the most financially attractive proposals that would utilize the laboratory human and physical resource and provide the greatest societal economic development for the locality and the region with respect to business development, not just technology transfer. Examples of complimentary dual research projects that can be developed are: materials development of products that are offshoots of waste stabilization; chemical extraction from soil, sediment or sludge cleanup applied to water treatment or chemical process firms; or analytical laboratory services; data processing and image processing; and software development to provide initial entry of DOE into the data highway. These capabilities represent one-half billion dollars of DOE services per year that are all immediate applications for privatization.

The next segment of the bid would be based on research and production meeting regional needs such as agriculture, mining, lumber, and transportation. This should be developed in conjunction with local, regional governments, business and universities, not just all-knowing government bureaucrats. In fact, minimize national government interaction and show today's current congressionally espoused notion of state and regional direction and support.

Now to make it more interesting provide the first year budget on the basis of historical past, second year budget will require 20 percent of operational cost will come from private sales including royalty payments, third year 40 percent from private sales, fourth year 50 percent and fifth year 60 percent from private sales and the core mission will still be provided by the prime lab. Services will be

provided by private contractors on a fixed price plus unit price options for unique selective services. At the end of five years renegotiate the contracts with expectation of moves to off site locations in 10 years to private facilities in the regional area developing economic growth and stability of newly developed industries. Combining economic stability with local and regional university research can produce a microcosm for a national strategy that would implement a tactical national plan that would make the labs, world competitive and innovative to support commercial economics of the future.

The objective is to establish commercial entities with social responsibility (locally and regionally) within each Lab for the end purpose of providing the core mission, business development, with the main objective of reducing the government financial burden of the facility, growing local businesses business utilizing the existing human resource and maintaining the economic viability of the locality by providing technology and products for the local community growth, resource development and international markets.

The most novel curativity suggestion to help achieve innovation is baseball's "Barry Bond's model". Barry Bond a famous Pittsburgh Pirate was entrepreneurially purloined by the San Francisco Giants for 40 million dollars. For a significantly lower sum, an entrepreneurial firm would offer contracts to the best and the brightest talent at the lab. They would offer employment contracts and profit contracts based on the success of the venture. The company would offer stock on initial value potential redeemable in five years. Stock options could be offered to local communities and shares would be based on marketing and financial or tax incentive contributions obtained for the venture. The offerings to the key individuals would be based on their estimated worth to the new venture. It would entail high personal risk but high potential return. Localities would receive stock percentages and would utilize their portion through a holding company. Profits from their stock would be based on time from initial stock sale to a recommended time to sell based on holding company recommendation.

The lab would maintain its core mission and, contrary to the Galvin Committee, initiate a major mission of business development supported from reduced custodial requirements for support services, because major facility costs would eventually be maintained by the private entities using the facilities.

The profit incentive will be the catalyst to change the perceived cavalier attitude toward costs in government work. This attitude has resulted in a lack of many scientists and engineers in the field of training and capacity for cost efficiency. The government Labs have lost the major portion of their original mission in many cases, but they represent the regional economy of towns like Richland, Aiken, Oak Ridge, Idaho Falls and would result in drastic economic hardship if closed. Yet they try to maintain the continuation of high price minimum return projects like the National Ignition Test facility, and the Advanced Neutron Source Reactor and Fusion. The lack of new missions will result in the loss of the best and the brightest the soonest. The under utilization of the 40,000 DOE scientists and engineers has resulted in frustration in wondering what happened to their skills, as they consider the paper factory morass in which they find themselves mired.

Retraining is not "serendipitous" but it is a fact of life for the high-tech technician, engineer or scientist in the DOE Labs. It's part of his or her historical career development.

The development of a Regional and National competitive boutique of industrial incubators can be the economic developer for the local and national markets. The diversity of the Environmental cleanup technology in water purification is just one potential. Composite materials developments, sensor development and data highway imaging systems, data screening, materials recycling and new fabrication businesses can be the light at the end of the tunnel and avoid the oncoming train.

It is time for a pragmatic introspection. "Multi-splendored" competitive business development as realistic alternatives or "clear cut" local communities who will start a 12,000 person reduction-in-force in the third quarter of FY'95. Without a major change in the labs a new era of Leadvilles, Buttes, Scrantons and the steel and coal towns of Pennsylvania, Ohio and West Virginia will be initiated.

The objective is to establish market-driven businesses and technical boutiques or service companies that would develop a major portion of the facility utilizing those human resources that were interested and capable of surviving in a commercial environment. This should have been the imitative at the beginning of Start II talks

in 1991.
The situation is even more dynamic than just the laboratories not having a mission. There is considerable discussion of combining the Energy Department function with other agencies. One discussion is that the relation in technology principles, combined with economic competitiveness is to combine Energy and Commerce. The basic competitive cost to most industries is the cost of energy.
The major intellectual capital resource of the industrial science community-if properly focused-are the forty thousand scientists in the Department of Energy Labs. President Clinton, Vice President Gore and Secretary of Commerce Brown in their discussions on sustainable technology development did not include DOE labs, but outlined the expansion of the National Institute of Science and Technology from a research budget of $70 million in 1993 to $800-900 million in 1998. This equates to a need of 9,000 scientists and engineers assuming $150,000 cost per engineer, per year. Even the most aggressive business economists would identify this a an unrealistic goal. The objective of the new Congress is privatization, development of government assets, the reduction of government support and the transfer of Washington centralized control of assets to the states for direct control and cost savings. The Western labs of INEL, Lawrence, Berkeley, PNL, LLNL, LANL and Sandia have 12,000 scientists and engineers. The development of local, regional technology could be initiated through the Western Governors Association to utilize this resource rather than NIST. The western DOE labs represent $6 billion a year which, when applied to local regional and national needs through the private sector development, is the substance of competitive economics. The physical and capital resource is directly applicable to the current congressional concept. The Western Governors can be the prototype that illustrates how local direction will provide the guidelines of the new decentralized direction of technology development combines energy science and technology through the application of existing resources. The major western laboratories-INEL, PNL, Sandia, Berkeley, Livermore, Los Alamos, and NREL-could be within two years of implementing a competitive nucleus of a national strategy for commerce and international competitiveness. Private development of national assets and the data management capabilities of the National Laboratory will provide the basic and applied technology for economically developed competitive products.
The key to success is local, regional involvement in the strategic and tactical development of local and regional market needs. The national needs of agriculture, diverse manufacturing and production competitiveness, water purification, regional and national transportation technology will be part of the national strategic plan. The concept is "back to the future" where grass roots provide the direction.
The lack of alternative missions will result in drastically reduced budgets and a forced high cost closure, a loss of valuable physical and human resources in the locality and the traumatic community transition. The lack of a mission analysis for major facilities in DOE and other agencies presents a high anxiety environment for the best and brightest.
Intellectual curiosity, with compelling technical vision of dynamic private business grass roots initiatives and implementing complimentary dual path technology will prevent the traumatic alternative and there will still be a viable option for the skim milk of a defense mission.
The delegations from the western states must be willing to concede that the defense mission will not be sustained by the general public built around the laboratories as the arsenal's of nuclear bombs. When GM lays off 50,000 people, IBM 100,000, Boeing 40,000, and California has a ten percent unemployment burden, a better utilization of the $6 billion is needed. To allow the dismantlement of the focused resource of the 12,000 scientists when world competition is at an increasing demand would be shortsighted at best, criminal at worst.
The mission of weapons must be modified to incorporate a social contract, a more robust technology application to competitive positioning in the world economy.
In Chemical and Engineering News (Oct. 5, 1992), Will Lepowski reported that "the breadth of interest with changing world events has caused a loss of coherence thereby reducing their overall effectiveness in responding to their traditional mission as well as new national initiatives and has led to an overall loss of direction for DOE as a whole." This was the report of the evaluation of Secretary Watkin's advisory board. The Galvin Committee recommends limiting the labs to non-commercial enterprises-a total desert of imagination.

The gauntlet has been thrown down. It's up to the labs to take the challenge or attrit to a single purpose diminishing role in the national and international competitive technology market.

ALTERNATIVE STRATEGIES FOR CONTROLLING COSTS AND AVOIDING DISPUTES ON ENVIRONMENTAL REMEDIATION PROJECTS
Vincent O. Manuele, Esquire
Mesirov Gelman Jaffe Cramer & Jamieson
Philadelphia, Pennsylvania
ABSTRACT
As the focus of this nation's massive environmental initiative shifts from investigation and assessment to remediation, it is critical that all participants in this effort develop comprehensive contracting strategies aimed at controlling remediation costs and eliminating protracted performance disputes. Due to the many unknown factors inherent in remediation projects, contractors and owners alike face tremendous challenges and risks in undertaking such work. In developing appropriate contracting strategies, the parties must recognize the unique challenges which confront them and define their shared project goals.
Initially, greater emphasis should be placed on negotiated, cost-type contracts which are more flexible than competitively-bid, fixed-price contracts. Moreover, the contract instrument must be carefully drafted to eliminate errors and ambiguities, and must fairly address the allocation of risk between contractor and owner. Only a contract which achieves equitable risk sharing, rather than wholesale risk shifting, can form the foundation for a cooperative working relationship where the common goal of successfully completing the project is the primary focus of the contractual relationship.
Additionally, the participants in the remediation process should commit to the use of "partnering" as a framework for contract performance, as well as alternative dispute resolution techniques to swiftly settle disagreements. Through partnering, the owner and contractor seek to erect a contract mechanism to focus resources on resolving job-site contingencies, disagreements, and contract interpretation issues before they escalate into disputes requiring the intervention of third parties. Relying on an extension of the partnering concept to the resolution of performance disputes, alternative dispute resolution ("ADR") techniques are designed to lead to the negotiated resolution of disputes swiftly and equitably without jeopardizing the successful completion of the project and at the lowest cost to the contracting parties.
INTRODUCTION
Site owners often turn to well-established contracting methods in retaining a contractor to perform remediation sitework without giving much consideration to the overall effect of such methods on the cost and efficacy of the remediation. Such an approach to an environmental remediation project, however, is a prescription for disaster because it fails to recognize the unique contracting challenges which these projects present.
These challenges, and their attendant risks, bear on all aspects of the remediation contracting process, including selection of the procurement and contract mechanisms, development of the contract risk allocation scheme, performance of the site work, and resolution of performance disputes. With a commitment to apply innovative contracting strategies to the remediation process, the parties can forge a cooperative relationship which equitably allocates risk and ensures that the common goal of successfully completing the remediation is the primary focus of the contractual relationship.
In addition to placing greater emphasis on negotiated, cost-type contracts and modifying contract terms to achieve an equitable allocation of risk, the participants also must focus on project performance. The use of "partnering" as a framework for contract performance, and reliance on various alternative dispute resolution ("ADR") techniques to facilitate settlement of disputes, will go a long way toward achieving this goal.
PROCUREMENT STRATEGIES
The procurement strategies adopted should recognize that it may be impossible to accurately define the nature and scope of environmental contamination in the assessment and design stages. To accommodate this reality, flexibility is required

in all stages of the remediation process, from contract formation through to completion and closeout of the work. Similarly, the contract should establish a reasonable allocation of risk. To achieve these goals, greater emphasis must be placed on negotiated, cost-type contracts which are inherently more flexible and allocate risk more equitably than do competitively-bid, fixed-price contracts. Negotiated procurement methods provide the owner the greatest flexibility in discussing appropriate alternatives for the remediation and in selecting the remediation contractor best-suited for the project. Similarly, the contract mechanism employed must be flexible enough to equitably account for changes in the scope of work arising during performance. A cost-reimbursable contract can readily accommodate a changing scope of work as well as a changing design. With proper cost and project management oversight, contracting on a cost basis can lead to the elimination of unnecessary work and to overall cost savings to the owner.

RISK ALLOCATION

Considerable attention also must be given to the terms of the contract instrument and the allocation of risk between contractor and owner which it achieves. Only a contract through which the parties share risk can form the foundation for a cooperative working relationship. The inequitable allocation of risk which characterizes most construction contracts has plagued both owners and contractors alike for some time. It is undeniable that the extensive use of risk-shifting provisions in construction contracts has contributed to the proliferation of claims and disputes in the industry. In recent years, there have been a number of studies examining this phenomenon and proposing realistic solutions, including studies by the Business Roundtable's Construction Industry Cost Effectiveness (CICE) Project (1) and the Construction Industry Institute's (CII) Contracts Task Force (2). These reports conclude that the owners' practice of shifting performance risk to the contractor undermines the relationship of the parties, and undermines the ability to control costs and timely achieve the contract's performance objectives. Relying on the contract to insulate it from risk which it should otherwise bear, the owner assures that an adversarial relationship will exist on the project.

To remedy this problem, the contracting parties should adopt a realistic and equitable allocation of risk. Therefore, rather than seeking to transfer liability to the contractor for all contingencies, the owner and contractor should agree on contract language which places performance risks on the party best able to avoid or mitigate the problem and requires the parties to share the risk associated with uncontrollable events.

PARTNERING PROJECT PERFORMANCE

Once the remediation begins, considerable effort must be made to resist the temptation to view the other contracting party as the enemy and the project as a series of conflicts. Although nothing constructive is accomplished by adopting this approach, it continues to be the norm for construction contracting projects in this country. Rather than perpetuate this self-destructive means of conducting business, the contracting parties should seek to achieve a non-adversarial relationship. This relationship is made possible in the first instance by a flexible contracting scheme which relies on an equitable allocation of risk. Through the "partnering" of projects, the owner and contractor seek to control costs and avoid disputes by maintaining a cooperative working relationship throughout performance. Critical to the success of this approach is a commitment to avoid protracted disputes.

The Construction Industry Institute conducted a study of the partnering process in which it acknowledged the many benefits inherent in its application (3). The project participants maintain constant communication throughout performance, jointly evaluate the progress and quality of the work, share resources to devise solutions to performance problems, avoid adversarial posturing, and develop strategies for attaining their shared goals.

Where there is a strong commitment by both parties to work together, they can strive to prevent disagreements from becoming disputes; when that is not possible, the parties will be in a position to resolve disputes in the course of performance through the involvement of management and the application of alternative dispute resolution techniques.

The mechanics of the partnering process are described in various industry publications, including ones issued by the Associated General Contractors of America (4) and the U.S. Army Corps of Engineers (5). However, the nature and complexity of each project will dictate the precise partnering strategy employed by the

contracting parties.
Recognizing the potential of partnering in the remediation industry, the Hazardous Waste Action Coalition ("HWAC") and the U.S. Army Corps of Engineers entered into a partnering agreement "to enhance the delivery of timely, cost-effective, and quality services on Superfund and defense cleanups" (6). This agreement falls under the umbrella partnering agreement between the American Consulting Engineers Council and the Corps, and addresses issues such as risk sharing, dispute resolution, safety, use of innovative technologies, and small business opportunities.

RESOLVING PERFORMANCE DISPUTES

In the event the parties cannot resolve performance disputes, mechanisms must exist which promote and encourage their negotiated settlement. The parties should commit at the outset of project performance to pursue alternative strategies for dispatching with lingering, unresolved performance problems. Relying on an extension of the partnering concept to the resolution of performance disputes, such alternative dispute resolution ("ADR") techniques seek to remove disputes from traditional forums and place them in settings conducive to prompt and equitable settlements.
The most effective ADR systems rely on continuing and open communication during performance, and the involvement of field personnel. Of particular benefit is the use of a "dispute escalation network" which defines the parties' internal mechanisms for approaching the resolution of disputes. The precise makeup of a particular dispute resolution system depends on the nature of the project; the goal of all such processes, however, is the low-cost, negotiated resolution of disputes during performance before adversarial positions harden and litigation becomes unavoidable.
Given the potential that the parties may be unable to resolve performance disputes among themselves, a mechanism to involve third-party mediators to assist in the resolution of such disputes should be in place at the outset of the project. One of the most promising alternatives in this regard is the use of a "standing neutral," such as a single project advisor or a more formal Dispute Review Board, which is available throughout performance to evaluate and resolve disputes. The standing neutral concept is flexible, and is designed to effect a swift resolution of disputes which survive the partnering process.
Where initial efforts at dispute resolution are unsuccessful, moving to the next level implicates various alternatives which have enjoyed considerable success in all types of contractual relationships (7). Among the most common ADR techniques used following contract performance are mediation, mini-trials and arbitration.
Recognizing the benefits inherent in the widespread use of various alternative dispute resolution techniques, the U.S. Congress passed the Administrative Dispute Resolution Act (8) in November 1990, authorizing and encouraging the use of ADR by federal agencies. Contractors performing remediation work for the government therefore are encouraged to pursue the use of appropriate ADR techniques to resolve contract disputes, regardless of whether the dispute is in the early stages of agency review or is the subject of protracted litigation.

BARRIERS TO INNOVATION IN THE MARKET FOR ENVIRONMENTAL REMEDIATION TECHNOLOGY: A MODEL, A CASE STUDY, AND PRELIMINARY IMPLICATIONS FOR POLICY

Susan E. Fuhs
John R. Anderson
RAND

ABSTRACT

The U.S. faces extensive and varied waste management problems, both remediating existing contamination and preventing further pollution. The perception exists that there are many unnecessary barriers to the development and deployment of innovative environmental technologies which might help address these waste management problems. However, many of these barriers are intricately tied to otherwise beneficial policies, and thus can not simply be excised. Furthermore, several innovative technologies have been developed and deployed, thus providing indications that these barriers are not always insurmountable.

This paper describes two complementary efforts: development of a model for examining barriers to environmental technology development in the context of rational policy decisions, and a case study of a successful innovative environmental technology firm. The case study has provided examples to test the model. The initial sections of this paper describe the development of the barriers model, and present the case data gathered for the successful innovative technology company. The case data include descriptions of the company, Terra Vac, Inc., and its soil vapor extraction system, but the primary focus of the case data is how the company has overcome or avoided barriers to development of soil vapor extraction systems. The paper then describes the use of the model and case data to develop general policy options for eliminating or reducing barriers. One detailed example and an overall summary of the analyses are provided. Finally, conclusions regarding the applicability of the model are drawn, and areas needing further research are highlighted.

INTRODUCTION

Most studies of barriers to development of innovative environmental technologies have focused on the deleterious effects of these barriers on various technologies and on developers and purveyors of technologies. These same studies have tended to ignore the existence of some successful innovative technologies whose success argues that the barriers are not universally insurmountable. The study described in this paper seeks to develop a model which explains the presence of barriers in the environmental technology market and which can be used to develop and evaluate various policy options for removing or otherwise mitigating these barriers. The study also includes a case study of a successful environmental technology company. The case study provides examples for testing and using the model.

The first section of this paper describes the development of the barriers model. Subsequent sections discuss the methodology used for the case study, present brief descriptions of the selected environmental technology and environmental technology company, and present the case data which show how the company has dealt with the barriers it has faced. A subsequent section then describes the use of the model, combined with the case data, to develop general policy options for eliminating or reducing barriers. One detailed example and an overall summary of the analysis are provided in this section. Finally, conclusions regarding the applicability of the model are drawn, and areas needing further research are highlighted.

BARRIERS MODEL DEVELOPMENT

This study is not intended to simply provide another list of barriers to the development and deployment of innovative environmental technologies. Numerous such lists, developed by a variety of working groups, government agencies, industry associations, and individuals, already exist.(1-7) However, compilation, paired with subsequent analysis, of barriers was required for this effort, both to provide a framework for the subsequent case study and to provide a basis for the resulting policy suggestions.

A simple aggregation of the various lists of barriers contained in the references cited above would have been unwieldy. The source documents present and discuss barriers at various levels of sophistication. Some, such as the DOIT report,1 are intended to be detailed discussions of barriers with extensive back-up material,

which could be used to help define appropriate actions for the future. Others (2) are intended to provide general overviews for the purposes of familiarizing those outside actual environmental practice with the obstacles present in this market. Still other reports address causes and/or effects of barriers.

Since merely enumerating a diverse list of barriers was insufficient for this study, a model has been proposed to facilitate analysis of barriers in the environmental technology arena. In general, a model is a simplified representation of some aspect of the real world, and is intended to be a useful and intentional reduction of a mass of information to a manageable size and shape. (8) This model provides a structure which serves two main purposes:

The model provides guidance for grouping and understanding disparate barriers, and for eliminating from consideration those factors and circumstances which may not be true barriers, and

The model facilitates understanding of the interplay between barriers and desired policy goals and thus can serve as an aid to developing policy options to address barriers.

The model, which is presented graphically in Fig. 1, assumes that barriers in the environmental technology market are unintended results or secondary effects of rational policy decisions which have been implemented to meet distinct environmental policy goals. This assumption leads to a corollary: that few, if any, barriers have arisen spontaneously, or have been put in place with deliberate obstructionist intent. If these assumptions hold, they have a major implication: it usually will not be viable to remove or streamline barriers simply by removing the policies which have given rise to the barriers. Rather, it will be necessary to carefully design ways to provide continued attainment of the original policy goals, while reducing or removing the barriers desired to be addressed.

Figure 2 shows the structure which results when the model is applied to the lists of barriers assimilated from the many documents referenced above. The left-most column of boxes contains a set of generally accepted environmental policy goals. The middle group of boxes represents policy choices which have been made to enable one or more of the policy goals to be achieved. The lines connecting the two sets of boxes identify which choice(s) support which goal(s). Finally, the right-most set of boxes depicts the barriers which are unintentional results of the policy choices listed in the middle column of boxes. Again, lines show the ties, this time between the choices and the barriers they engender. Comparing Figs. 1 and 2, it can be seen that the sequence from policy goals to policy choices to barriers which is depicted across the top of Fig. 2 is the same sequence depicted across the top of Fig. 1. Since this effort is primarily focused on barriers, however, the "feedback" loop which appears in Fig. 1, and which connects the desired results of the policy choices to the policy goals, has been omitted from Fig. 2.

METHODOLOGY FOR INITIAL CASE STUDY

As discussed in previous sections, substantial effort has been devoted to examining barriers within the environmental remediation technology market. However, previous efforts generally have focused on the barriers themselves, and have emphasized the negative impacts these barriers have had on specific technologies, or even specific projects. Such analysis can be flawed: the assumption has been made that the technologies studied are in fact "good" technologies and should have been able to surmount all barriers.

As a result, the initial case study carried out for this project was chosen to be a case study of a successful innovative environmental remediation technology, and in particular, a case study of the individual(s) and/or company which introduced this technology in the marketplace. A two step process was used to select the technology and company to be studied. First, a successful technology was selected from a number of possible alternatives, and second, the pioneering entity marketing this technology was examined to determine whether it would be suitable for this study. No ranking or endorsement is intended in the selection of technology and company to study; rather the first pair of technology and pioneering company which met the criteria was selected.

Table I details the criteria used to determine whether a technology was appropriate for study. Several technologies were considered at this stage, including vitrification technologies, bioremediation technologies, and extraction technologies. A tentative selection of soil vapor extraction as the technology for the case study was made. The company which pioneered the technology in the

marketplace, Terra Vac, Inc., then was examined to determine whether it met the criteria for suitability of study enumerated in Table II. Terra Vac did meet these criteria, and thus soil vapor extraction and Terra Vac were selected for this study. A two part process also was used to carry out the case study. In the first part of the process, publicly available information concerning both the technology (soil vapor extraction) and the company (Terra Vac, Inc.) was gathered. This information, together with the barriers framework developed in the preceding section, was used to develop a list of areas which required additional information. This list of areas was used to provide topics for discussion during the second part of the process: interviews with employees of the company, including the company founder, Mr. James Malot, and with USEPA personnel who were familiar with the company. Interviews focused primarily on how Terra Vac had addressed barriers, but also included discussion of other subjects, including history of the technology, history of the company, and barriers which might arise in the future.

DESCRIPTION OF SELECTED TECHNOLOGY

The concept behind soil vapor extraction is fairly simple. A vacuum is applied to soil that contains volatile contaminants. The flow induced by the vacuum is drawn from wells drilled into the soil with screened intervals placed at depths corresponding to areas of high contaminant levels. The vacuum induces air flow through the soil and the volatile contaminants evaporate into the passing air stream. Depending on the types and concentrations of contaminants, the air stream, which now contains some concentrations of contaminants, then may either be released to the air or subjected to appropriate post-treatment. Possible types of post-treatment include collection of contaminants by a filter (e.g., activated carbon), conversion of contaminants to non-harmful compounds via catalytic oxidation, or extraction of contaminants from the air via some sort of air stripping technology. Soil vapor extraction systems lead innovative remediation technologies in frequency of use, and have been selected in more than 30% of Superfund records of decision. (9) A schematic view of a typical soil vapor extraction system is presented in Fig. 3. (10) The specific soil vapor extraction technology chosen for this study is the in-situ vacuum extraction system originally developed and patented by Mr. James Malot of Dorado, Puerto Rico and Mr. Melvin Visser of Portage, Michigan.

DESCRIPTION OF SELECTED COMPANY: TERRA VAC, INC.

Technology Development

Vacuum extraction technology was developed by Mr. Malot and Mr. Visser in the early 1980's. Much of the work was done while Mr. Malot was employed as an engineer with Upjohn Corporation at the facility located in Barceloneta, Puerto Rico. In response to a release of carbon tetrachloride at this facility, Mr. Malot proposed the use of a vacuum extraction system to remediate contaminated soils. Most of the equipment and techniques (such as vertically and horizontally drilled wells, vacuum pumps, and carbon filters) needed for a vacuum extraction remediation system already had been developed for other applications, such as oil and gas extraction. However the process of in-situ vacuum extraction of volatile contaminants in soil was new, and was deemed patentable in 1986. Although the initial patent was assigned to Upjohn,11 Mr. Malot now owns exclusive rights to this technology, and to an extension of this technology which allows simultaneous soil and groundwater cleanup. Mr. Malot established Terra Vac, Inc. in 1984 as a licensee of these technologies.(12)

Initial Deployment

Vacuum extraction was first deployed as a remediation technology at an Upjohn Corporation site in Barceloneta, Puerto Rico. The Upjohn facility located in Barceloneta (hereafter referred to as Site 1) was an active pharmaceutical manufacturing plant on the north coast of the island of Puerto Rico. Site 1 was located in a sparsely populated portion of the island near the towns of Tiburones and Garrochales. The total population of the area was approximately 3,000. During August 1982, approximately 15,300 gallons of liquid waste were spilled from an underground storage tank at Site 1. The waste was estimated to be comprised of 65% carbon tetrachloride (CCl_4) and 35% acetonitrile. CCl_4 is a volatile organic compound (VOC) and is a suspected human carcinogen.13 CCl_4 is regulated as a hazardous substance under CERCLA, RCRA, the Occupational Safety and Health Act (OSHA), and Puerto Rico's Regulation for the Control of Hazardous and Non-Hazardous Solid Wastes. Table III presents the chronology for Site 1, including relevant

regulatory events.
In January, 1983, Upjohn began an investigation of soils on and around Site 1. The investigation revealed levels of CCl4 in soils of up to 2,200 parts per million (ppm). Also during January, 1983, a pilot vacuum extraction system was installed at Site 1. The system consisted of three vacuum extraction wells, four vacuum monitoring wells, one vacuum pump, a cold water condenser, and a collection tank.(14) By late 1984, Terra Vac and Upjohn had expanded the system to full scale operation with a total of 19 vacuum extraction wells using six vacuum pumps. Although the system initially used the cold water condenser to remove contaminants from the extracted gas, it was found that significantly more CCl4 was recovered in the exhaust stack, so the condenser was removed for further operation.
The Terra Vac system operated at Site 1 from January, 1983, until March, 1988, when the criterion established by USEPA Region II for closure, that the exhaust stack of the system show "non-detect" levels of CCl4 in its emissions for three consecutive months, was met. At that point the Terra Vac system had removed a total of 17,781 gallons of CCl4 from soils at Site 1. This is almost double the amount of CCl4 that reportedly spilled during August, 1982.
Participation in the USEPA SITE Program
Soil vapor extraction was one of two technologies that were incorporated into the USEPA Superfund Innovative Technology Evaluation (SITE) program at its inception in 1986.(15) As part of the SITE program, Terra Vac deployed a vacuum extraction system at the Groveland Wells Superfund site in Groveland, Massachusetts during December 1987. The specific location for the demonstration of the vacuum extraction system was the Valley Manufacturing Company (VMC) site. VMC was a manufacturer of various metal and plastic parts.
The former waste disposal system associated with the VMC facility had dispensed liquid wastes to buried leachfields. Between 1964 and 1970, up to 20 gallons per month of hazardous materials, such as cutting oils, VOC's, and acid bath wastes, were disposed of in this manner. In 1979, two of Groveland's municipal wells were shut down due to high levels of trichloroethylene (TCE). The entire watershed and aquifer (including the Valley Manufacturing site) was placed on the NPL on September 8,1983. Remedies selected for the site included groundwater treatment and soil vapor extraction.(16)
The demonstration phase of the project ran for 56 days from December 1987 through April 1988. Approximately 1,300 pounds of VOC's (mainly TCE) were removed from soils at the site. Conclusions from the demonstration report stated that "the process achieved non-detectable levels of VOC's at some locations and reduced the VOC concentration in soil gas by 95%... the technology successfully remediated soils contaminated with TCE." (17)
Commercialization
Approximately concurrent with the incorporation of vacuum extraction technology into the SITE program and initiation of the SITE demonstration, Terra Vac became involved with remedial actions at two other Superfund sites: the Tyson's site in Montgomery, Pennsylvania, and the Verona Well Field site in Battle Creek, Michigan. Terra Vac had also installed systems at several non-Superfund contaminated sites dating back to 1984. By June 1989, more than 60 Terra Vac systems had been installed, and by May, 1993, Terra Vac had more than 400 successful application sites worldwide.12 Included in these numbers are 23 Superfund sites at which Terra Vac has deployed a vacuum extraction system. These 23 sites account for more than 25% of Superfund sites at which a soil vapor extraction type technology has been deployed.
CASE STUDY RESULTS
Interviews were conducted with Mr. James Malot, president of Terra Vac, Inc., and with Mr. Joe Pezzullo and Mr. Steve Johnson, also of Terra Vac. Interviews were also conducted with USEPA personnel familiar with Terra Vac, including Ms. Mary Stinson, and Mr. Jim Cummings. Additional information was gathered from newspaper articles and trade publications. The primary focus of this case study was to examine how Terra Vac met and addressed barriers to design, development, and implementation of soil vapor extraction systems. The interviews and other information indicated that the company had generally developed creative ways of addressing the barriers it faced. For example, Terra Vac obtained large amounts of operating data to support permit applications by initially using its technology, not for regulated remediation activities, but for monitoring applications, which were subject to less regulation. There were also some barriers which Terra Vac did not

have to face, usually as a result of the company's early entry into the market, or because Terra Vac's headquarters are located in Puerto Rico. The following sections provide a barrier-by-barrier discussion.

Splintered Markets

Terra Vac has found the splintered markets resulting from multiple levels of regulation to be a barrier both dealing with regulators and dealing with individual clients. Both groups have been reluctant to accept demonstrations conducted elsewhere as applicable to their particular jurisdiction or site. However, Terra Vac has been able to address this barrier by making use of its extensive collection of data on soil vapor extraction system performance with different types of contaminants and in different soil types. Terra Vac also has had some success overcoming this barrier by using an incremental approach with some clients and regulators, that is, by setting up a pilot system, and then, as favorable results are obtained, gradually expanding the scope of the pilot system until full scale implementation is achieved. Finally, Mr. Malot indicated that approximately 50% of the U.S. remediation market is found in only five states. Recognizing this concentration has helped Terra Vac address its efforts towards less splintered markets.(18)

Because Terra Vac has mostly been financed internally and with standard banking procedures,(12) rather than using venture capital funding, the company has not experienced one of the more commonly described results of splintered and difficult to verify markets, difficulty in obtaining venture capital funding. Mr. Malot did not believe that splintered markets would have been a major issue if he had chosen to vigorously pursue venture capital funding. However this belief remains untested.(18)

Technology Lock-In

Technology lock-in has not been a barrier for Terra Vac. In fact, since soil vapor extraction was one of the earliest innovative technologies to reach full-scale implementation, soil vapor extraction has sometimes benefited by being the technology which is locked-in.(18)

Loss of Intellectual Property Rights

Intellectual property concerns have been a major barrier for Terra Vac.(12,18) A particular source of difficulty has been problems with patenting a process, rather than a physical object, such as a piece of equipment. Terra Vac now addresses this barrier primarily by maintaining a position as a technology leader rather than by relying on patent infringement concerns to protect Terra Vac's soil vapor extraction technologies. In other words, Terra Vac continually pursues improved performance and added capability from their soil vapor extraction systems. Another major intellectual property problem for Terra Vac was its participation in the initial SITE program. Mr. Malot feels that the extensive data Terra Vac had to release in SITE program reports were very beneficial to competitors, yet provided little benefit to Terra Vac in terms of increased business.(19) Malot does not feel that Terra Vac would participate again in a similar program without significant changes in the requirements for public disclosure of intellectual property.(18)

Lengthy and Expensive Development Process

Although Terra Vac's initial implementation was relatively rapid, many subsequent implementations have been slow. Although Mr. Malot attributes this barrier to regulatory hurdles,(12) he believes the hurdles are due less to the regulations themselves and more to the inadvertent incentives built into the current system. For example, potential clients frequently wish to postpone expenditures, and are often able to do so by taking time for additional studies and planning. Although this approach may raise the total cost of the remedial action, it can postpone immediate outlays of funds, and without strong regulatory incentives for completing cleanups, postponement of expenditures be very attractive. Terra Vac was able to overcome this barrier at its initial implementation site of Barceloneta because it had a pro-active client (Upjohn) and a single local regulatory agency (the JCA) who were willing to try the then relatively new technique of soil vapor extraction so long as they were kept well informed of progress. Terra Vac has continued to use this approach to address this barrier by searching for pro-active clients and by involving applicable regulatory agencies early in the implementation process.

In other cases Terra Vac has found the self-interest of consultants and attorneys to be a barrier to implementation, since consultants' and attorneys' roles are much reduced once studies are completed and treatment is underway. Again, Terra Vac

tries to overcome this barrier by finding and encouraging pro-active clients.
Terra Vac has found that the need to collect extensive amounts of data to substantiate permit applications is a barrier which contributes to the expense of the development process. Although Terra Vac needed the same large amounts of data as any other innovative technology developer, Terra Vac was able to overcome this barrier by indirectly benefiting from a 1984 Puerto Rican law which required companies with underground storage tanks to be able to detect leaks from those tanks at the moment they occurred. By initially marketing soil vapor extraction as a monitoring technology, Terra Vac was able to partially defray the costs of gathering needed data.
Terra Vac has also found that the expense of obtaining funding, especially in a market that is not conducive to venture capital funding, can be a barrier. Terra Vac has addressed this barrier in two ways. First, since Terra Vac is incorporated in the Commonwealth of Puerto Rico, Terra Vac has been able to take advantage of Section 936 funding, a pool of funds "trapped" in Puerto Rico due to restrictions on transferring these funds to the 50 states. Second, again due to its incorporation in Puerto Rico, Terra Vac has been able to reinvest high proportions of its profits due to extremely advantageous federal and commonwealth tax codes.(18)

Public Opposition

Terra Vac did not face public opposition to its initial implementation. There were no active stakeholder groups other than the client and the applicable government agencies. The Barceloneta site is remote and there was little interest on the part of local residents or workers.(18)

PRELIMINARY IMPLICATIONS FOR POLICY

General Methodology

This section describes how the model can be used to examine the strategies used by successful environmental technology companies to overcome barriers, and to derive, from these strategies, more generally applicable policy options to address barriers in the environmental technology industry. As depicted in Fig. 4, each strategy is examined to derive one or more generally applicable policy options if possible. It should be noted that, in some few cases when a strategy is very specific to a technology or company, it may not be possible to derive any general policy options. The model is then used to identify, for each option, those policy choices and policy goals which may be affected if the option is implemented. The probable effect of the option on the goal is then evaluated to determine whether the effect is likely to abrogate the original intent of the policy goal. These further steps are also shown in Fig. 4.
This procedure can, and should, be carried out at more than one level. For example, at an early, conceptual stage of policy option development, the model can be used to identify policy goals which might be impacted, and which should thus be areas of concern during more detailed development of policy options. At a later, more detailed level of development, the model can be used to provide a yes/no type answer to the question, "Is this policy option likely to unacceptably weaken the implementation any policy goals?"

Application to Case Study: Terra Vac

The following sections of this paper use the model at the initial, more conceptual, level to examine possible policy options which might be derived from approaches used by the case study company, Terra Vac, to overcome barriers to development and implementation of soil vapor extraction technology. An example, which examines policy options to address splintered markets, has been traced in detail in the next section, and is depicted pictorially in Fig. 5. Since such detailed descriptions quickly become lengthy and cumbersome, however, the results for other barriers have been summarized following the detailed example.

Detailed Example: Preliminary Recommendations to Address Splintered Markets

Initially Terra Vac was able to use an extensive collection of data, much of which was gathered in a non-remedial application (monitoring of underground storage tanks), to overcome the concerns of regulators and clients about the applicability of the soil vapor extraction process at different sites in different regulatory environments. Since there will rarely be corresponding non-remedial applications available to facilitate gathering such large amounts of data, it will be necessary to develop a more general approach if other technology developers are to be able to use this strategy. One policy option which might facilitate gathering performance data is modifying regulations and/or the regulatory process to make it easier to get

permits for development and demonstration testing. Another policy option which might also facilitate gathering performance data is to make government remediation sites more available for development and demonstration testing. Both of these policy options would be intended to reduce the impediments caused by splintered markets, and in a detailed treatment both should be more completely examined. However, the rest of this section will only examine one policy option, that of modification of regulations and/or the regulatory process to make it easier to obtain permits for development and demonstration testing.

By using the model to track "backwards" from the barrier of splintered markets, it can be seen that the policy choices most likely to be affected by implementation of this option are the multiple levels of regulation, the complex and exacting nature of regulations, and the opportunity for public input to cleanup plans. Modifying the regulations and/or the regulatory process to make it easier to get permits for development and demonstration testing would definitely affect the complex and exacting nature of regulations. Depending on how these modifications are enacted, they might also affect the multiple levels of regulation and the opportunities for public input. As a result, it is not possible to eliminate any of the policy choices from consideration at this level of definition. However, this discussion will examine only the policy choice of complex and exacting regulations.

The model then is used again to trace backwards from this policy choice to the policy goals which might be affected. The goals which might be affected by changes to the complex and exacting nature of regulations are the need to reflect priorities of local, regional, and national stakeholders, the need to choose appropriate methods, the need to ensure appropriate implementation, and the need to reduce risks associated with cleanup. These further steps are also shown in Fig. 5. It appears, at this rather low level of definition, that the policy option of modifying the regulations and/or the regulatory process to make it easier to get permits for development and demonstration testing could adversely affect any or all of these policy goals. Thus all need to be retained for consideration during more detailed definition of this option.

Although it is not within the scope or capability of this paper to provide high-level definition of policy options to address barriers, two contrasting examples should illustrate how this further definition can occur and how the model can assist in this part of the process as well. In the first example, one can envision that one way to ease the process of getting development and demonstration testing permits would be simply to eliminate any regulatory requirements for such permits. But the model indicates that one of the policy goals met by requiring development and demonstration permits is reducing the risk of cleanup , and simply eliminating the need for permits might raise, rather than reduce the risk of cleanup by allowing poorly conceived demonstrations to proceed without adequate forethought, preparation, or review. Possible ill-effects of a poorly conceived demonstration could include further spread of contamination, perhaps by release from a poorly designed reactor, or increased difficulty of cleanup, perhaps by a poorly understood chemical transformation of contaminants into compounds that are less volatile or that are bound more tightly to soil. Thus, without some safeguards in place, risks might increase rather than decrease, and simply eliminating the need for development and demonstration permits is unlikely to provide satisfactory results.

A second policy option, however, intended to accomplish the same purpose, might be more promising. Most regulations already contain some provisions for less stringent requirements for obtaining development and demonstration testing permits. These provisions often go unexercised, however, either due to ignorance about or unwillingness to use these provisions.20 Thus an educational program intended to familiarize and better train regulators in the writing of development and demonstration testing permits would most likely facilitate gathering of needed performance data for innovative environmental technologies. Careful examination of this policy option shows that it seems unlikely to adversely affect any of the original goals (the need to reflect priorities of local, regional, and national stakeholders, the need to choose appropriate methods, the need to ensure appropriate implementation, and the need to reduce risks associated with cleanup), and thus this policy option shows more promise than the previous approach.

It should be noted that this model does not provide a methodology for evaluating and comparing the likely performance of the options. Rather the model provides a

context for making sure that any options considered do not themselves have unintended deleterious side effects.

Summary for Other Barriers

The model has been used to examine the strategies which Terra Vac has used to overcome barriers to development of soil vapor extraction technologies. The results of these analyses are presented, barrier-by-barrier, in Table IVA, B, C, D. The specific barrier being considered is identified in column 1, and columns 2 and 3 respectively identify all policy choices and policy goals which the model indicates may be affected by policy options chosen to address the barrier described in column 1. Column 4 identifies specific strategies which Terra Vac has successfully used to address the barrier in column 1, and general policy options derived from the specific strategies are described in column 5. Finally, a brief discussion of the likely effects of the policy option on the goals is presented in column 6. As indicated in the previous detailed example, it is not within the scope or capability of this paper to provide high-level definition of policy options to address barriers, so the discussion of likely effects indicates potential areas of concern, rather than specific recommendations.

Close examination of Table IV shows that there are two barriers, technology lock-in and public opposition, for which no policy options are presented. This is because the company studied, Terra Vac, has not had major problems with these barriers, and thus has not developed strategies to address these barriers. As a result, the methodology can not be applied to these two barriers. This does not indicate that these barriers are not real, nor does it indicate that there are no policy options to mitigate these barriers. Rather it simply indicates that, with the limited data set of one company, there is no basis for developing options or making recommendations. Close examination also shows two Terra Vac strategies for which there are no corresponding policy options. These two strategies are specific to Terra Vac, and although other companies might choose to adopt similar strategies, no policy actions would be required to enable other companies to pursue these approaches.

CONCLUSIONS

A model has been presented which treats barriers to development of environmental remediation technologies as unintended results of rational policy choices made to meet specific policy goals. The model has been successfully used to examine a lengthy list of barriers drawn from trade publications, industry reports, and anecdotal evidence. Because the model emphasizes that barriers are closely tied to policy choices and policy goals, the model shows that it will normally not be possible to simply remove the causes of barriers, because those policy choices which result in barriers normally also have intended, beneficial, effects which support desired policy goals. However, because the model clarifies the ties between barriers and policy goals and choices, it can be used to evaluate the broader impacts of policy options which might be used to address barriers. More specifically, at an initial stage, when approaches to eliminate or lower barriers are being conceptualized, the model can be used to highlight desired policy goals which might be affected by the various options. And, at later stages, when detailed development of options to address barriers is ongoing, the model can be used to determine whether an approach will unsatisfactorily impact desired policy goals.

Use of the model to develop top-level policy options to address barriers to development of environmental remediation technologies has been demonstrated for one case, the successful environmental technology company, Terra Vac, Inc. Terra Vac was the first company in the market with soil vapor extraction technologies, and has successfully overcome many barriers to continue developing and growing since its inception in 1984. As part of this study, strategies used by Terra Vac have been generalized into policy options whose viability has been evaluated using the model. Since resources have limited this effort to one case study of a single company, the effort has resulted in an incomplete, preliminary, list of policy options to address barriers. However, this effort has successfully demonstrated the use of the model for examining policy options to deal with barriers in the larger context.

The model does have some limits. First, an implicit assumption is made that the policy goals which drive the policy choices are valid. Any attempt to evaluate desirability or validity of top-level policy goals is well beyond the scope of this paper. Second, the model does not address deliberately obstructionist actions by those who may wish to maintain existing barriers to serve as barriers to entry by

newcomers. Although barriers may inhibit the process of development and implementation of new environmental technologies, those already in the environmental technology market, especially those who have invested significant resources to develop approaches to overcome barriers, may actually have interest in seeing these barriers maintained due to their inhibitory effect on newcomers. Finally, the model does not provide any basis for prioritizing or ranking policy options, but is limited to evaluating whether policy options will have unacceptable impacts on desired policy goals.

Additional research is needed. The scope of the study has been limited to one study of a successful company, and thus use of the model has been limited to addressing those barriers which were met and overcome by that company. This means that the model has seen only limited testing. Additional case studies of successful companies would broaden the scope over which the model has been tested. Interesting results might also be expected from case studies of unsuccessful, or marginally successful companies, marketing what appear to be promising technologies, but having significant problems with one or more of the barriers described in the model. Finally, there are some technologies which have been developed and then abandoned within the private sector, only to be picked up for further development and possible use by the federal government. Applying the model to this type of situation might assist in determining whether the initial developers abandoned promising technologies due to barriers which they were unable to surmount, but which the federal government was better able to address, or whether the federal government is considering flawed technologies whose development was halted for valid reasons.

ACKNOWLEDGMENTS

We would like to thank Mr. James Malot, Mr. Steve Johnson, Mr. Joe Pezzullo, and Ms. Esther Soto, all employees of Terra Vac, for their willingness to spend time with us and participate in this case study. A special thanks goes to Mr. Malot, who took an entire morning out of his busy schedule meet with us. We would also like to thank Ms. Mary Stinson and Mr. Jim Cummings of the USEPA for their willingness to spend time with us as well. Finally, we would like to thank Mr. David Rubenson and RAND for providing intellectual and financial support for this study.

RECYCLING OF RADIOACTIVE SCRAP METAL IN DOE AND A CONCEPT FOR OVERCOMING THE CRITICAL IMPEDIMENT

George R. Bierman, P.E.
Booz, Allen & Hamilton, Inc.
Germantown, Maryland

ABSTRACT

This paper addresses the need for recycling radioactive scrap metal in U.S. Department of Energy's (DOE) Environmental Restoration (ER) Program and potential actions to enhance recycling. The quantities of these metals currently on hand within the DOE complex and large quantities expected to be generated by the ER Program are described and discussed in terms of their asset value rather than merely as waste to be disposed of. The DOE has an opportunity for realizing substantial cost recovery utilizing secondary metals markets, with emphasis on long term savings, through decontamination and recycling of radioactive scrap metals. Also discussed is the critical impediment to achieving worthwhile recycling of these metals arising from the lack of release and decontamination standards established by regulatory agencies that would allow metal to be processed and released for unrestricted use. To aid in overcoming the critical impediment, a new concept utilizing a multi-tiered approach for returning these metals to the general metals markets is suggested. The tiered approach has a potential for not only realizing a direct monetary return, but that also could minimize the need for extensive decontamination of some radioactive scrap metals prior to recycling.

INTRODUCTION

The Environmental Restoration Program in the Department of Energy (DOE) was formalized and begun in earnest only a few years ago, and is still in its infancy. However, the pace is quickening as the program advances from the assessment phase into the remediation phase, and will accelerate as the Department continues the phase-out of its old plant facilities that are no longer needed. Dismantling and removing those facilities will result in massive quantities of materials requiring disposal, especially radioactive scrap metals. Historically, DOE production sites generated substantial quantities of radioactive scrap metal that were simply held in inventory rather than being disposed of, and many of those inventories are still on hand, awaiting a disposal decision.

All too often, considerations for disposal of radioactive scrap metals are limited to long-term storage or burial, especially the latter. Seldom is disposal of these

unwanted metals considered in terms of returning them to the stream of raw materials flowing into production processes, that is, recycling. However, recycling can solve several problems at once. In addition to returning the metals to the raw materials stream, recycling also will conserve natural resources by reducing the mining of virgin materials, and recycling can reduce demand for energy needed for processing virgin materials that would be used if recycled metals were not available.

There are many compelling reasons for disposing of radioactive scrap metal by recycling. Foremost are the volumes of metallic wastes on hand and the significant amounts expected from future remediation work. Any large quantities should be viewed as an incentive and a great opportunity for recycling. This is not to say that recycling the metals would be easy, particularly where volumetric contamination is concerned. Radioactive scrap metals present an excellent opportunity for technology development and application, from two viewpoints. One is the need for faster, more efficient techniques for surveying scrap metal in a wide variety of shapes to determine the levels of radioactive contamination. The other is the need for faster, more efficient technology for decontaminating the metal so it can be returned to productive use.

MAGNITUDE OF THE DOE SCRAP METAL PROBLEM

Precise quantity data are not available for the current DOE inventory of contaminated materials, and a survey is currently underway that it is hoped will put some boundaries around the problem of establishing reliable inventory estimates. However, existing estimates range from about 400,000 tons to over 1.5 million tons of radioactive scrap metal in storage at various DOE sites. The high end of this range resulted from an informal (and disputed) survey a few years ago. The resulting estimate broke down the inventory as follows: aluminum, 195,000 tons; copper, 38,000 tons; lead, 3,000 tons; nickel, 245,000 tons; and steel, 1,300,000 tons. If the same ratios were to hold for the low end of the range, the breakdown would be: aluminum, 43,797 tons; copper, 8,535 tons; lead, 674 tons; nickel, 55,027 tons; and steel, 291,980 tons.

Similarly, there is no current estimate of the annual generation rate of scrap metals within the DOE complex, but as the pace of major DOE facility decontamination, decommissioning and dismantling increases in the Environmental Restoration Program, the levels of scrap metal inventories are expected to increase substantially. Preliminary estimates indicate that the program will add at least 1.0 million tons of radioactive scrap metal to the DOE inventory. This is expected to be a low estimate. The conceptual planning for decommissioning the Oak Ridge Gaseous Diffusion Plant (ORGDP) indicate that this plant alone may generate 775,000 tons of radioactive scrap metal over a 10-year period. Similar quantities could occur at other major DOE sites.

The great majority of DOE radioactive scrap metal bears low levels of radioactive contamination. Thus, much of it is or will be available for decontamination and release for unrestricted reuse. The remainder could be at least partially decontaminated and put into a variety of industrial or nuclear uses where the material would not come in contact with workers or the public, or would do so in restricted ways.

COST TRADE-OFFS

The potential value of DOE scrap metal can be understood by reviewing a few metals, their typical secondary market prices, and the extrapolation of scrap-metal market values from the identified quantities as previously discussed.

METAL	MARKET PRICE	QUANTITY	MARKET VALUES (LOW-END EST.)	
Nickel	$6,000 per ton	55,027 tons		$ 330,162,000
Steel	107 per ton	291,980 tons	31,242,000	
Aluminum	600 per ton	43,797 tons	26,278,000	
Copper	1,500 per ton	8,535 tons	12,802,000	

These prices are displayed as nominal amounts because scrap metal prices change on a daily basis due to market factors. These prices are typical of levels in the American Metal Market 1991 series (1). Nonetheless, these data provide insight into the potential direct dollar value of the DOE scrap metal inventory. Also, these values may support development of appropriate expenditures on research and development for processing and decontamination methodology that could result in

alternative waste management approaches.
Market prices, however, are not the only important aspect of scrap metal recycling. Anyone considering the relative merits of recycling versus burial must also account for the costs of not recycling the scrap metal. The additional aspects include:

The value of natural resources conserved from not mining and processing materials represented in the scrap metal;

Environmental preservation and cost avoidance from not building or expanding scrap metal disposal facilities;

Avoidance of the costs of long-term storage of scrap metal wastes and maintenance of disposal facilities;

Avoidance of the costs of environmental restoration of subsequently contaminated storage areas.

Aluminum provides an example of the cost benefits available from recycling and the conservation of natural resources. Approximately four tons of raw bauxite ore are needed to produce one ton of aluminum and the nominal value for the raw ore is $20 per ton. On that basis, the DOE scrap aluminum inventory (low-end estimate) represents a potential resource conservation of 175,000 tons of bauxite ore at a cost avoidance savings of about $3.5 million. Additionally, there is a significant energy savings because processing scrap aluminum requires only 5% of the energy required for smelting and handling raw bauxite ore. Aluminum industry specialists have calculated that 15,000 kilowatt hours are used in producing one ton of aluminum from raw ore. Thus, use of scrap aluminum would save 14,250 kilowatt hours per ton or $6.24 million for the 43,797 tons of aluminum scrap metal, with power conservatively priced at $0.01 per kilowatt hour. Viewed from this perspective, the cost of not recycling DOE scrap aluminum is comprised of the scrap market value loss of $26.3 million plus the costs of raw bauxite ore ($3.5 million) and energy in production ($6.24 million), bringing the total to some $36 million. These costs do not consider the environmental impact of mining 175,000 tons of ore, nor the aluminum's replacement value if purchased new at new-metal market prices.

While such costs are substantial, they must also be considered relative to the alternative option of disposing of the metals as low level radioactive waste. There are two aspects to consider. Burial disposal costs for low level radioactive wastes are within a range from $60 up to $160 per cubic foot. Therefore, disposal costs for a scrap metal inventory of approximately 400,000 tons, assuming roughly 400 pounds per cubic foot after some volume consolidation, can be calculated in to be in a range from $120 million up to $320 million. Less efficient volume reduction will increase the costs. In the case of burial disposal of the 43,797 tons of aluminum scrap metal, assuming a density of roughly 200 pounds per cubic foot, disposal costs can be calculated in to be in a range from $26 million up to $70 million.

Note however, that this does not consider the potential cost impact if any of the radioactive scrap metal must be considered mixed waste due to contamination by any hazardous substances defined by the Resource Conservation and Recovery Act (RCRA). If this were the case, the cost for disposal would be likely to increase significantly, because the Federal Facilities Compliance Act requires that mixed waste be treated before land disposal. Alternatively, it is possible that the nature of the decontamination process and in particular, a melting process, would result in the waste no longer being required to be considered hazardous under RCRA and permissible to be disposed of as low-level radioactive waste. This would be the result of the melting process removing or oxidizing many possible RCRA constituents and the resultant waste may no longer meet the requirements of a RCRA characteristic waste. Consequently, this is a RCRA compliance benefit completely incidental to the scrap-metal melting process.

There are still further costs to be considered. These are the costs for long-term surveillance and maintenance at radioactive waste material disposal sites. Over the period of radioactive decay for even short half-life elements, these costs can be significant. The important point here is that these long-term costs can be completely avoided by recycling the metals.

The final key point that must be recognized on the subject of costs is that involving technology development for decontamination and recycling. When the types of costs described and discussed above are accounted-for (e.g., the aluminum example above), their total provides an indication of the amount that could be spent on technology development.

THE CRITICAL IMPEDIMENT: LACK OF STANDARDS

Given that recycling may be economically and ecologically attractive, the question naturally arises as to why recycling is not being implemented on a large scale. The most critical impediment confronting recycling of radioactive scrap metal is lack of definitive release standards. Radioactivity level standards are essential for both surface and volumetric contamination, to qualify the metal for release into the marketplace or to some restricted use. This problem requires action by the appropriate regulatory agencies (the Nuclear Regulatory Commission and the Environmental Protection Agency) before recycling of the scrap metals can implemented on a large scale in a publicly acceptable way. The cut-off often has been defined by concerns of institutional liability or adverse public reaction rather than direct risk reduction.

The U.S. Nuclear Regulatory Commission (NRC) has established release limits for surface contamination and has published them in its Regulatory Guide 1.86. These guidelines incorporate the "As Low As Reasonably Achievable" (ALARA) concept, which states that decontamination efforts should not stop when the stated release limits have been reached, but should proceed to decontaminate as far below those limits as is technically and economically feasible. Decontamination efforts that achieve such ALARA levels (below release limits) constitute successful decontamination. The result is that the material is considered to be safe for any use.

The DOE has adopted the NRC guidelines and incorporated them into DOE Order 5400.5, "Radiation Protection of the Public and the Environment." The NRC guidelines are not technically enforceable standards, although many entities (especially NRC licensees) treat them as enforceable standards. Faced with the uncertainties, especially the potential liability, associated with the lack of standards, even those who might be in favor of decontamination and recycling are opting for immediate and ultimate disposal, that is, burial.

Surface contamination is relatively easy to remove from metals, because it is limited to a few microns in depth. The shapes of individual pieces, however, can make surface decontamination a time-consuming task, and the more complex the shapes, the more tedious and time-consuming the task. Therefore, there is a need for more efficient technology. This is also true for the measurement of extremely low level contamination, both the capability and speed for practical application.

Unlike the case of NUREG 1.86 Guidelines for surface contamination, there are no guidelines or standards for volumetric contamination. Neither the NRC nor the Environmental Protection Agency (EPA) have resolved this issue and this lack effectively has precluded volumetric decontamination for recycling in this country. A few other countries have developed at least limited volumetric contamination standards (2)(3), but the lack of consistency, together with the lack of U.S. standards, has precluded the decontamination and recycle of radioactive scrap metals for trade on international markets. The fear is that metals imported into a country would not be sufficiently decontaminated before being converted into products that would then be exported from that country for unrestricted use. Worse would be the importation of presumably clean metal subsequently discovered to be contaminated.

It must be noted that both the NRC and the EPA are continuing their studies of the standards problem. However, no definitive answers are anticipated in the near future.

WASTE MINIMIZATION OPPORTUNITY

It is inescapable that some quantities of radioactive scrap metal will not be reusable and will have to be permanently disposed of, most likely by burial in engineered facilities. Our continuing objective should be to reduce to the absolute minimum the metal quantities that require permanent disposal. Active pursuit of this objective will aid in minimizing both the cost and number of disposal facilities that will be required. If we - all of us - do the job correctly, there will be only two types of scrap metal waste requiring permanent disposal. One type will be characterized by slag, dross, small shavings and grinding dust from scrap metal recycling processes. The other will be quantities of contaminated metal that are too small for cost-effective processing/recycling, even for re-entry into nuclear use.

The challenge of achieving this minimum scrap metal waste for disposal will require a significant departure from conventional wisdom for managing radioactive scrap metals. It will require that we implement a concept that will provide flexibility in reusing the metals and which recognizes two key factors: 1) there are great

quantities of metals that can be safely decontaminated and returned to productive use without undue restrictions; and 2) there are many industrial applications for metals that would require only partial decontamination and which would pose no threat to the public. One such concept is presented below.

THE TIERED CONCEPT FOR RECYCLING RADIOACTIVE SCRAP METALS

Radioactive scrap metals, because they are metals, could be recycled and utilized in many applications and products. Not all of these would require that the metals be decontaminated to levels that would permit release for unrestricted use. Therefore, it appears that a "tiered concept" for decontaminating for recycling would be very useful. Three basic tiers are suggested:

TIER 1: This would be a "below regulatory concern" level of contamination, i.e., a level below which the metals can be released for reuse without radiological restrictions. This means that the material is considered to be safe for any use. There would be no need for tracking or record keeping after the verification survey or sample measurements are completed and unrestricted release is authorized. Manufacturers would be free to utilize the metals in any products, including consumer products - household appliances, toys, tools, furniture, automobiles, etc., with no concern for liability for radioactivity.

TIER 2: This would be a non-regulated, "limited use" level of contamination which would allow the metals to be used in industrial or other pre-established specific applications. The standard could be set by the critical exposure group, most likely the workers, to assure their safety. However, certain worst-case scenarios assumed in Tier 1 would be eliminated by the nature of the limited use restrictions and the pre-established applications, and thus allow a higher level of contaminant concentration without risk of increased public exposure. In particular, consideration would be given to the remelting of the scrap after release as Tier 2 material to the specified user, such as a maker of construction rebar. Other examples of potential applications are 1) use of radioactive nickel as a catalyst in petroleum or other chemical refining; 2) use of the nickel in alloys for induced draft fans for hazardous material incinerators or power plants; 3) use of steel to make railroad rails or rolls for steel rolling mills ; 4) use of copper in selected electric power substation equipment, for example, transformers; 5) use of steel in pipe designated for cross-country petroleum pipelines; and, 6) use of various metals in heavy-duty industrial or other structural applications which go unattended for long periods e.g., bridges. The point is that they are all uses where people (workers or the public) would have little or no opportunity for exposure to the radioactivity. The list of such uses is limited only by the imagination of the potential user. It should be noted that the NRC has, through its licensing process, already exempted from regulatory disposal controls the use of uranium in fire detection units and thorium in finished aircraft engine parts, on the basis that the impact of the contamination is minimal and the cost of maintaining regulatory controls would be disproportionate. In general, however, this level would require that records be maintained as to the specific first use and application of the contaminated metals. The key to this tier is the recognition that certain conservative assumptions in Tier 1 can be easily overcome with limited restriction, that is, the first use of the material would be such that the otherwise unusable material can be reused in specific practical, but non-regulated ways. Tracking and record keeping would be required for the contaminated metal until it goes into the decontamination process, but no records would need to be kept after the residual contamination level has been verified and the end-use specified.

TIER 3: This would be a regulated, but non-controlled "nuclear industry use only" level, and would allow the direct reuse of the metals by either government or industry in nuclear applications, without restriction within the nuclear site boundary. Within this tier, metals would be restricted from off-site release as any suspect material is from a nuclear site, but available for use within the site without restriction, that is, outside the controlled areas. One example would be the manufacture of new waste containers which could be stored anywhere on site until loaded with radioactive waste. Other uses might be structures, piping, etc., i.e., direct re-use without further processing. Records would have to be maintained to document the on-site existence of the material, especially if sent off-site to a licensed melting, re-forming, or decontamination facility for re-working prior to the re-use, but would not be required within the site boundary.

One issue that needs to be resolved is the potential use of dilution processes, that

is, allowing the mixing of radioactive scrap metal with uncontaminated metal (new or scrap) in melting processes to reduce the final contamination level of the melt to either the unrestricted-use level or the limited-use level, i.e., Tier 1 or Tier 2. However, there appears to be no reason for not allowing - in fact, even promoting - the use of dilution to reduce contaminant concentrations in recyclable metals to acceptable levels.

SUMMARY AND CONCLUSIONS

The institutionalization of the proposed Tiered Concept rather quickly could lead to a strong, ongoing program of decontaminating and recycling DOE's existing and anticipated inventories of radioactive scrap metal. Its extension into the international arena, accompanied by agreement on equivalent regulations among all concerned nations, also could resolve the dilemma of international trade in contaminated metals. This approach is also consistent with the European approach of obtaining licenses for project or site specific applications, as opposed to the establishment of general national standards. In this regard, generators and scrap metal processing facilities could obtain licenses for specific recycle operations that would permit metal recycling at one or more of the approved Tiers. Licensing the operations should result in the ability to remove unwarranted conservatism in the development of generic standards.

There are a number of points to be remembered when considering the potential for recycling radioactive scrap metal. It has been shown that there is an opportunity for substantial cost savings when all costs, both near-term and long-term, are taken into account. There is a significant opportunity to introduce new technology for decontaminating the metals, especially to address volumetric contamination, whereby the metallic waste that would require permanent disposal could be decreased to an irreducible minimum. Achievement of this minimum is a desirable national objective that could be enhanced materially through implementation of tiered standards governing residual contamination.

Before making a decision to send radioactive scrap metal to a burial ground burial rather than recycling, there is a fundamental question that must be addressed: "Is the permanent disposal of large volumes of low-level contaminated metal in the nation's best interest?"

THE DEPARTMENT OF ENERGY APPROVAL PROCESS FOR FREE RELEASE of VOLUMETRICALLY CONTAMINATED RADIOACTIVE SCRAP METAL

Dr. Anthony Kluk
US Department of Energy

J. Wynn Phillips
Analytical Services, Inc.

Belfort Engineering, Inc.
Michael Elo
Burns and Roe Environmental Services
ABSTRACT
Volumetrically contaminated metals are those metals which, through either neutron activation, accelerator activation, or the melting of surface contaminated metals, have radioactive contamination distributed throughout their volume. Unlike materials with only surface contamination, no Federal standards apply to the disposition of these materials by any means other than disposal as a radioactive waste. Department of Energy Order 5400.5, Radiation Protection of the Public and the Environment, provides for the disposition of such materials by other means in specific cases approved by the Assistant Secretary for Environment, Safety and Health.
This paper reviews three requests from DOE field organizations for approval to dispose of materials containing small quantities of radioactive volumetric contamination. One request utilized the format of an Environmental Assessment with the addition of an ALARA analysis. This request has been reviewed and approved by the Assistant Secretary, permitting the future sale of the material for unrestricted use.
This paper discusses the type of information included in the approved request and is not to be considered as formal guidance.
CURRENT REGULATORY POLICY FOR RECYCLING, REUSE, AND DISPOSAL OF NON-RADIOACTIVE WASTES
On July 3, 1990 the Nuclear Regulatory Commission (NRC) issued a policy statement on the disposition of materials with levels of contamination identified as "Below Regulatory Concern," or BRC. This BRC policy met with substantial opposition from both environmental groups and industry and was eventually withdrawn. In the Energy Policy Act of 1992 (1), Congress directed NRC to refocus its efforts and stated that "The policy statements of July 3, 1990 and August 29, 1986 relating to radioactive waste below regulatory concern, shall have no effect after the date of enactment of this act." NRC has undertaken an enhanced participatory rulemaking to develop cleanup standards for NRC-licensed sites. This standard will not address the release of materials in the same manner as the original BRC standard was intended. On January 26, 1994, the NRC issued their "Draft Radiological Criteria for Decommissioning.(2)" While these criteria do not apply to the release of contaminated materials, the Commission recognized that for decommissioned sites the possibility exists that materials left on site could subsequently be recycled. In its response to comments on the draft criteria during the public hearings the Commission states that:
"The Commission plans to consider separately the issues of how to deal with cases where the licensee proposes to release material containing residual radioactivity intentionally for reuse or recycle either as a part of decommissioning or ongoing operations. In the interim the Commission will continue to be (sic) review such actions on a case-by-case basis."
Although EPA stated publicly in 1987 that "We intend to establish criteria for identifying wastes with sufficiently low levels of radioactivity to qualify as `Below Regulatory Concern' (3)," to date no such standard has been developed. Current activities of EPA are focused on assessing the scope of the recycle metals market, the economics of recycling, identifying recycling options, and the risks and impacts from those options. Once these questions are answered then other issues regarding the acceptability and implementability of a standard will be answered.
In the absence of Federal standards governing the disposition of materials containing low levels of volumetric radioactive contamination, DOE must make decisions regarding recycling, reuse, and disposal of these materials in facilities not licensed to accept radioactive materials.
INTERNATIONAL POLICY
Several European countries have either adopted standards established by the International Atomic Energy Agency (IAEA) or have developed their own for recycling contaminated scrap metal in their countries. These various regulations are presented in Table I. The IAEA proposed to call such standards "clearance levels"

for releasing materials from regulatory control.

DOE POLICY

Unlike scrap materials with only radioactive surface contamination, for which Federal free release limits exist, no corresponding release limits exist when the contamination is an integral part of the material. Volumetric contamination may result by either activation of atoms in the material by irradiation in a neutron flux or by other particles in an accelerator, or when metals with radioactively contaminated surfaces are melted.

DOE policy on the release of materials containing "volume contamination", contained in DOE Order 5400.5 (4), permits such materials to be released if criteria and survey techniques are approved by the Assistant Secretary for Environment, Safety and Health. However, formal guidance on the approval process has not been issued. Figures 1 and 2 show what happens when metals of various thickness, having surface contamination at the maximum levels allowable under DOE Order 5400.5 (in disintegrations per second per 100 square centimeters), are melted, and how the resulting volumetric contamination (in picocuries per gram) compare to the proposed IAEA standards.

Since DOE Order 5400.5 was last revised in 1990 a limited number of requests for EH review and approval of activities that would lead to the release of radioactively contaminated materials have been submitted. These materials resulted from DOE research and development, and D&D activities.

Recently, the DOE Oakland Operations Office requested and received permission from the State of California Department of Health to dispose of limited quantities of copper, concrete and rebar, and oil that contained low levels of radioactive contamination. Although the concrete and rebar was disposed in a local landfill, OAK was informed that disposition of the copper and oil would have to wait pending review and approval by DOE Headquarters. These and other requests are described below.

Fig. 1.

Fig. 2.

Oakland Operations Office

On August 2, 1994, the Assistant Secretary for Environment, Safety and Health, approved a request to disposition 140 metric tons of high-purity (99.99%) copper by selling the material to a scrap metal dealer. The copper was used as coil windings in the 184-inch Cyclotron at Lawrence Berkeley Laboratory which was dismantled several years ago (5). It is currently stored in an outdoor storage area in wooden crates in seven foot long strips, four inches wide and a quarter inch thick. The copper contains 60Co (a gamma emitter) at concentrations ranging from 0.1 pCi/g to approximately 20 pCi/g, with an average concentration of 3 pCi/g. The copper also contains a small quantity of 63Ni at a concentration of 1.5 pCi/g. 63Ni is a beta-emitter and in the metallic form does not contribute to external dose. An additional 150 tons of auxiliary coil copper was found to have concentrations of 60Co greater than 20 pCi/g along with traces of 106mAg, and was disposed of as a radioactive waste at Hanford.

A second request, involving the proposed recycle of waste oil contaminated with tritium at a concentration less than the 20,000 pCi/g limit for drinking water, has been withdrawn.

Chicago Operations Office

In February, 1993, a document entitled "Radioactivity Release Criteria for Materials and Equipment" developed by Fermi National Accelerator Laboratory (Fermilab) was submitted to DOE for approval. This document does not address any specific material, but generically identifies the release limits that could be applied for volumetrically contaminated materials and the instrumentation necessary to assure compliance. Specifically, the document states that:

"Studies conducted with radioactive materials and calibrated g-emitting radioactive sources with energies between 0.5 and 1.3 MeV have indicated that 2000 counts (per minute) above background on such an instrument corresponds to exposure rates between 0.006 and 0.012 mR/h with an average of about 0.01 mR/h. Reasonably long-lived radioactive isotopes produced at high-energy accelerators (such as those at Fermilab) that constitute the nuclides in the equipment and material released are mostly 3H, 7Be, 22Na, 54Mn and 60Co. Except for 3H these isotopes are gamma emitters with energies between 0.478 keV and 1.33 MeV. The Bicron survey meter mentioned above is particularly sensitive to such energies of emission."

"The detection criterion stated here results in a minimum detectable specific activity of between 20 and 50 pCi/g (depending on the gamma ray energy) in bulk materials such as aluminum, concrete, or iron if irradiated uniformly."
This document is currently under review by DOE.

Paducah Gaseous Diffusion Plant

Another request is for the approval to sell of 9,300 tons of contaminated high-purity nickel from the Paducah Gaseous Diffusion Plant. One of the options being evaluated is to decontaminate this material in the United States at a NRC-licensed smelting facility for sale overseas for the production of stainless steel.
This request is presently under review by DOE.

OBTAINING DOE APPROVAL FOR RELEASE OF RADIOACTIVELY CONTAMINATED SCRAP

This section provides information on the documentation prepared to support the request for recycling of high purity copper. The intent is to review the type of information which was provided and a sample format for the request document.
It should be noted that while the basic documentation package was an environmental assessment (EA) (5), there is no formal requirement that an EA be prepared. However, because the NEPA process is well defined, it allows for a consistent methodology for both preparer and reviewer of these requests.
This EA was later supplemented with an ALARA Assessment (ALARA stands for As Low As Reasonably Achievable.) The content of these documents follows the format of a standard NEPA environmental assessment and the actual ALARA Assessment submitted. Additional information in italics is based on guidance provided by the DOE Office of NEPA Oversight (9).

Environmental Assessment Format

Introduction:

The introduction provides a short overview of what is included in the document. It identifies why it is being written; for compliance with the National Environmental Compliance Act of 1969 (42 U.S.C. 4321-43470 and DOE Order 5400.5, Radiation Protection of the Public and the Environment. It provides a short general description of the proposed action, the types of impacts, a general discussion of the alternatives, and other DOE policies considered in the evaluation, such as waste minimization.

Background:

This section contains a discussion of the origin of the material, how it became radioactive, what the concentration of the radionuclides are. The information provided in the text is general in nature with details provided in an appendix.

Purpose and Need:

The purpose of the proposed action and any additional benefits of that action are described. (NOTE: Under guidance provided by the Office of NEPA Oversight this section should not address the purpose of the proposed action. The section on Purpose and Need should discuss why there is a need to take any action and what the purpose of that action is. For example, the purpose and need of an action would be to disposition scrap metal that contains low concentrations of radioactive contamination by the most cost effective means. The purpose was not to recycle scrap metal.)

Description of the Proposed Action and Alternatives:

A subsection is devoted to the detailed description of each alternatives, starting with the proposed action. The description of the proposed action is slightly more detailed than the others. In this case the proposed action was to sell the copper to a local scrap metal dealer who would probably resell the material to a processor. Because of the sensitive nature of the material the EA identified the possible options available to the reprocessor; reuse as is, melt and refine with or without being added to other material, or possibly ship overseas for reprocessing. As with all EAs and EISs a discussion of the No Action Alternative was also included.

Description of the Affected Environment

This section contains a discussion of the existing environmental conditions relative to the general area in which the copper was stored, generally restricted to human health issues, and a discussion of the environment that could be affected by the proposed action and each of the alternatives. With respect to the environment, topics include:

Air Emissions - an estimate was made of the particulate emissions that would be associated with reprocessing the copper by melting.

Water Quality - Water use in cooling towers is the only water use identified associated with copper reprocessing but no specific releases were identified in the blowdown.

Energy Use - Energy use savings greater than 90 percent were identified as being realized by reprocessing as compared to mining and processing new ore into products.

Traffic - The number of shipments, seven, needed to transport the material to any one of three scrap dealers within ten miles of the site was identified. The risks associated with this number of shipments was reported to "have been analyzed and found to present an acceptable low level of risk."

Geology, Soils, Hydrology, Aesthetics, Waste - The discussion in this section was directed towards activities associated with the mining of new copper ore. These topics are not relevant with respect to the proposed action or any of the alternatives.

Natural Resources - A comparison was made between the quantity of copper to be recycled (140 metric tons) and the total quantity of copper produced in the United States annually and mined world wide annually.

Land Use - Land use as it relates to landfill space, should the material be disposed of in a local landfill, was identified as part of the affected environment.

Existing conditions relating to human health were the potential exposures from the 60Co in the copper and from background radiation and other sources of radiation. Dose rates were estimated based on the quantity of 60Co if taken as a point source. Dose equivalents are calculated at 1, 30 and 50 years depending on the alternative (actual doses were in the impacts section). Self shielding considerations were evaluated.

The discussion on Background Radiation and Doses is very complete and provides valuable information which was used for comparative purposes.

Environmental Consequences of the Proposed Action and Alternatives

As stated in the opening paragraph of this section in the EA, "This section addresses the potential environmental and human health effects of the proposed action and the five alternatives. Direct impacts, as well as indirect impacts (such as averting air emissions from mining and smelting an equivalent quantity of copper) are assessed." Normally, only the impacts associated with the proposed action are assessed in an EA, and a comparison of impacts of the alternatives is performed in an EIS.

(NOTE: The Office of NEPA Oversight has stated in their "Recommendations for the Preparation of Environmental Assessments and Environmental Impact Statements", May 1993, that:

"Unlike EISs, where generally the depth of quantitative analysis is approximately the same for each alternative analyzed in the range of reasonable alternatives, EAs often can focus the quantitative analysis on the proposed action; that is, discussions of alternatives in EAs generally can be qualitative. However, certain EAs may need to identify and analyze more alternatives in the range of reasonable alternatives and provide more in-depth analysis than usual (e.g., greater quantitative analysis). These EAs generally deal with proposals where there is heightened technical controversy surrounding potential impacts from the proposed action or where there is otherwise greater potential for significant environmental impacts from the proposed action.")

Until applicable standards are promulgated which are specific to volumetrically contaminated materials, EAs prepared for the purpose of obtaining DOE approval for the recycling of such materials will probably be considered as falling into this category of "heightened technical controversy." (See above quoted section.)

In addition to the seven categories of affected environment (Air Emissions, Water, etc.) for which the impacts of each alternative are assessed, assessments are made of the impacts for each alternative for the following topics:

Maximum Lifetime Individual Worker Excess Fatal Cancer Risk
Maximum Collective Transport Worker Excess Fatal Cancer Risk
Maximum Lifetime Individual Public Excess Fatal Cancer Risk
Maximum Collective Public Excess Fatal Cancer Risk
Maximum Collective Public Excess Fatal Cancer Risk from Transportation

Both the exposure, in person-rem, and the risk, expressed as excess fatal cancers, are identified. Exposures were calculated using the NRC IMPACTS Code. Doses to the public were calculated assuming that the copper would be used in home electrical wiring and plumbing.

ALARA Considerations

The EA contains a section on ALARA in which an estimate of the "Total ALARA Cost" is made. This "cost" is defined as follows:

"The ALARA Cost is the estimated value of the sum of the collective dose equivalents using the DOE recommended value of $10,000/person-rem. This value allows comparison between the `cost' of the radiation exposure and other costs and benefits."

In the case of the copper the maximum dose associated with the proposed action is 0.072 person-rem to the public, for an ALARA Cost of $720. (NOTE: In the licensing of commercial power plants, NRC used an unofficial ALARA cost of $1,000 per man-rem. This means that if the cost of reducing the population dose equivalent by 1 manrem/yr was less that $1,000 it was considered cost effective and should be incorporated in the design. If, on the other hand, that 1 manrem/yr dose reduction cost more than $1,000 it was not cost effective.)

In response to the EA, DOE prepared an ALARA analysis in which they discussed the costs, or cost savings, associated with each alternative. While the proposed action has the highest exposures to both the public and to workers, both exposures are so small as to have no consequence in terms of health effects. Their analysis stated: "The relative insignificance of the collective dose for all options in this example eliminates the health effects as a significant factor in deciding on a course of action." The proposed action results in significant cost savings compared to the alternatives. The DOE analysis states that cost should not be a consideration in selecting the preferred alternative or proposed action unless the impacts are assessed as essentially being equal amongst the alternatives.

ESTABLISHING REUSE POLICIES FOR RADIOACTIVE SCRAP METAL

Tad McGalliard
Bruce Clemens
Energy, Environment, and Resources Center
Michael Gresalfi
Oak Ridge National Laboratory

ABSTRACT

Radioactive scrap metal (RSM) is a waste management issue with implications for several industrial and governmental organizations. Establishing effective and acceptable reuse policies for RSM may require a stakeholder focused involvement process. Two examples of stakeholder involvement include the Nuclear Regulatory Commission's (NRC) enhanced participatory rulemaking, and the Department of Energy's (DOE) Recycle 2000 Initiative. Both incorporated important stakeholders early in the

developmental stages of policy making.

INTRODUCTION

The end of the Cold War has fueled tremendous forces of change within DOE. "With the shift in the defense mission, a large number of new sites and facilities will be added to the inventory of surplus facilities and inactive sites during the next 20 to 30 years" (1).

In 1989, the Environmental Management (EM) division of DOE was created with a goal of fostering more environmental responsibility (1). A growing cultural change is brewing within DOE. After over 40 years of primarily a military mission, the nations nuclear weapons complex needs to be cleaned up. How to effectively do so is a task of enormous complexity.

An important element of DOE's environmental restoration and waste management program is the recycle and reuse of RSM. RSM presents many technical uncertainties. For example, although the question, "how clean is clean" in regards to radioactive contamination generates many answers, there is little consensus among experts. Moreover, there is a lack of adequate health risk standards to guide the development of acceptable RSM policies.

Even more important than the technical unknowns may be the political uncertainties. In the 1980s, the NRC issued a policy statement known as "below regulatory concern" or simply BRC.

Section 10 of the Low-level Radioactive Waste Policy Amendments Act of 1985 requires the NRC to develop standards and procedures for expeditious handling of petitions for rulemaking to exempt disposal of radioactive waste determined to be below regulatory concern (2).

The BRC policy met with vocal opposition from a coalition of interest groups, and concerned members of Congress. Both the Environmental Protection Agency (EPA) and DOE expressed concern about the BRC policy in comments submitted to the NRC. The BRC initiative eventually was revoked by Congress in the Energy Policy Act of 1992.

This paper first describes the politically charged atmosphere that surrounds complex and controversial issues such as radioactive waste. Like other areas of radioactive waste management, the establishment of effective and acceptable RSM reuse policies likely will be the focus of intense political debate. The second part of this paper describes stakeholder involvement in policy decisions. In the search for effective RSM policies, decision makers should consider more proactive methods of incorporating stakeholder input into the policy making process.

METHODS

In 1992, the Energy, Environment, and Resources Center (EERC) commenced a research project on RSM, with a particular focus on stakeholders. Several reports and articles have been written during this period, providing a foundation for our current effort. Our methods for acquiring information include a review of the relevant literature, interviews with important policy actors, a survey of executives in the steel and scrap metal industries, and attendance at numerous conferences, forums, and symposiums.

SCRAP METAL AND RADIATION

In this paper, RSM is defined as those metals that either emit measurable levels of radioactivity or that potentially could be radioactively contaminated. We feel it is prudent to classify potentially contaminated metal as RSM until the extent of contamination is proven otherwise

RSM is generated from a number of sources. In accordance with the DOE Weapons Complex Scrap Metal Inventory Report, DOE controls roughly 400,000 tons of RSM. An additional 600,000 tons of RSM is anticipated from the dismantlement of the Department's three gaseous diffusion plants (3). Figures presented at various conferences and in a number reports suggest that there is some disagreement over the amount of RSM that actually exists at DOE sites. However, even the most conservative figures indicate that an enormous amount of RSM already is stockpiled with much more likely to accumulate through ongoing and future decommissioning and decontamination (D & D) operations at federal facilities.

The nuclear power industry also produces a certain amount of RSM during routine maintenance and retrofit operations. Roughly 5,000 tons of RSM from nuclear power plants is recycled annually (4). Many nuclear power plants are scheduled for decommissioning in the coming years. Should widespread D & D of nuclear power facilities commence, a significant amount of RSM could become available.

A third source of RSM results from naturally occurring radioactive materials (NORM).

The petroleum industry is a major generator of NORM contaminated materials, primarily piping and oil extraction equipment. A study conducted for the Petroleum Environmental Research Forum (PERF) focused on the potential advantages and disadvantages of recycling NORM-contaminated equipment (5). During the 1980s, the oil and gas industry recognized with growing alarm that elevated levels of radiation could be detected on piping and oil processing equipment. "In response to such concerns, facilities in the United States have been characterizing the nature and extent of NORM in oil and gas production equipment, evaluating potential exposures to workers, and developing methods for properly managing such low specific activity wastes" (5). No clear numbers are available on the total volume of NORM contaminated metals.

The scrap metal recycling and metal manufacturing industries have a different perspective on RSM. Representatives from these industries have expressed concern over radiation in the scrap metal stream. Radiation potentially presents serious health risks to a facility's workers. Moreover, several facilities have smelted a source of radiation, resulting in multi-million dollar decontamination operations. The Institute of Scrap Recycling Industries (ISRI) and the Steel Manufacturers Association (SMA) have lobbied for tougher controls on radiation sources.

Several waste management companies view RSM as an opportunity. Scientific Ecology Group (SEG), American Ecology, Manufacturing Sciences Corporation (MSC), and Alaron Corporation have contracted with DOE in projects involving RSM. A trade association representing these and other industries is currently in the early stages of formation.

THE POLITICAL ENVIRONMENT

The development of public policy in the United States was never meant to be quick and easy. The Constitution outlined a republican democracy through which the tumult of public opinion, public participation, and politics would be canalized. The output hopefully would be good public policy.

The process of public policy development has intrigued many observers of the American political system. Walter A. Rosenbaum offers one model of the public policy process in his excellent work, Energy, Politics, and Public Policy. In his view public policy develops through a series of stages: agenda setting, legitimation, implementation, evaluation, and termination.

Policy implementation is "the manner in which a policy is translated from the language of law into action" (6). The implementation stage of the public policy process is arguably the most difficult. The number of policy actors involved (including nongovernmental groups), confusing or vague legislation, fiscal constraints, political demands, and overlapping authority between regulatory institutions are just a few of the hurdles that must be overcome before implementation of a policy can proceed.

The next few sections describe in more detail, developments that are affecting the public policy process. In the latter part of the twentieth century the establishment of effective radioactive waste management policies has become an increasingly difficult endeavor.

GROWTH OF GOVERNMENT

On the opening page of his book, American Public Policy: Promise and Performance, B. Guy Peters discusses the growth of government.

> Government in the United States has grown from a small, simple "night watchman state" providing defense, police protection, tax collection, and some education into an immense network of organizations and institutions affecting the daily lives of all citizens (7).

The explosive growth of government is primarily a post World War II phenomena. New demands for social programs, health and safety standards, as well as energy and environmental concerns resulted in legislative and regulatory initiatives. Further, new governmental institutions at the local, state, and federal levels evolved from these demands. Moreover, the growth of government has strained the nation's fiscal resources and has often limited programmatic success.

The growth in government and certain governmental reform efforts have led to a "diffusion of political authority." Several federal agencies including NRC, EPA, DOE, the Department of Defense (DoD), and the Department of Transportation (DOT) maintain certain responsibilities in the radioactive waste policy arena. Moreover, state agencies are responsible for overseeing radioactive wastes. The number of regulatory institutions has led to concurrent and sometimes overlapping

jurisdiction.

EXPANSION OF POLITICAL ACTORS

Another development of the past three decades is an expansion of political actors. The constitution produced a "benign political climate" in which citizens were free to form organized groups and petition the government (6). Over the course of the last thirty years citizens have done just that in incredible numbers.

The explosion of environmental advocacy organizations, and antinuclear groups has added a new dimension to policies related to nuclear technology. Public Citizen, Inc., and a coalition of groups led the charge against BRC. The coalition levelled a lawsuit against NRC in 1990 claiming failure to conform with several national laws. The case was eventually deemed not ripe for review; however within two years BRC implementation was suspended.

CRISIS OF LEGITIMACY

Possibly the most troublesome changes in the American political environment are the low levels of trust citizens express towards their government. Polls have indicated that distrust of the federal government is widely diffused among cross-sections of American citizens (8). More specifically public confidence in science and technology has gradually declined.

During the last 15 years the relationship between the general public and those who create, manage, and profit from science and technology has gradually soured. A litany of ecological disasters and technical failures - from Love Canal to the space shuttle Challenger explosion to the Chernobyl nuclear meltdown- has turned many Americans away from their technological optimism. More important, Americans have lost their faith that those who control technology will do so competently and in the public interest (9).

STAKEHOLDER INVOLVEMENT AND THE NEW POLITICAL ENVIRONMENT

The new dynamics of the public policy process, almost certainly ensure that the development of public policy in complex and controversial areas such as radioactive waste will be exceedingly difficult. Thus, successful development and implementation of RSM policies may require a more proactive means of involving interested parties. A stakeholder is defined as "any group or individual who can affect or is affected by the achievement of an organization's objectives"(10). In this paper we adopt this definition with clarification. Two statements elevate "stakeholder" to a more practical level for the RSM issue.

First, a stakeholder must have a legitimate interest in the development of RSM reuse policies. For example, scrap metal brokers have an important economic interest. Radiation in the scrap recycling stream can result in enormous financial difficulties for scrap dealers. Also, citizens living near a decontamination facility are another set of stakeholders with a legitimate interest.

A second criteria suggests that a potential stakeholder must have knowledge and experience with an issue. For example, the International Atomic Energy Agency has recommended safety standards for the recycle and reuse of radioactive materials. Some environmental groups were adamant opponents of the Nuclear Regulatory Commission's "below regulatory commission" policy. Moreover many of these groups have been active participants in the enhanced participatory rulemaking process for site decommissioning standards.

In this paper as with previous reports we loosely identify three general categories of stakeholders for RSM reuse. Table I outlines the stakeholders.

As Table I illustrates, stakeholders for RSM reuse policies incorporate a diverse array of organizations, institutions, and industries. Moreover, the listing above incorporates those stakeholders with a legitimate interest and relevant experience. Several of the stakeholder categories identified above are general descriptions of a wide array of individuals and organizations. For instance, "state and local radiation protection bureaus" could be represented by not only individuals from particular states but also delegations from the Conference of Radiation Control Protection Directors (CRCPD) or the Organization of Agreement States. Scrap metal companies are represented by the Institute of Scrap Recycling Industries (ISRI). Trade associations also represent the different manufacturers of metals. A decision maker should carefully identify all relevant stakeholders before proceeding with an involvement process.

Stakeholder involvement procedures have been utilized in a number of ways for the development of different policies. Two examples are particularly relevant to the establishment of RSM reuse policies: the NRC's enhanced participatory rulemaking

and, the Recycle 2000 Initiative.

ENHANCED PARTICIPATORY RULEMAKING

In 1992, following the demise of BRC and a short lived consensus building effort, the NRC initiated an enhanced participatory rulemaking (EPR) process. The EPR was designed to facilitate the development of site decommissioning criteria for NRC licensed facilities.

The objective of the rulemaking is to enhance the participation of affected interests in the rulemaking by soliciting commentary from these interests on the rulemaking issues before the NRC staff develops the draft proposed rule ... the Commission believes that this will be an effective method for illuminating the decision making process on complex and controversial public health and safety issues (11).

NRC sponsored seven workshops around the United States and the meetings were facilitated by the Keystone Center. Participants included representatives from environmental groups, public interest organizations, local community groups, industrial and trade association representatives, state and local governments, the medical community, Native American tribal representatives, officials from federal agencies, and labor unions.

RECYCLE 2000 INITIATIVE

At the July 1994 Workshop on Radioactively Contaminated Scrap Metal hosted by the Energy, Environment, and Resources Center and Oak Ridge National Laboratory, the Recycle 2000 Initiative was unveiled.

The Department of Energy is considering a policy which would encourage the reuse of Office of Environmental Management (EM) generated radioactively contaminated materials within the EM program (12).

A stakeholder workshop was held in Denver, Colorado during December, 1994. DOE invited participants from a number of different stakeholder organizations. The final participants list includes representatives from environmental and public interest organizations, the metals industry, management and operation (M & O) contractors, academia, the medical community, decontamination industries, labor unions, and federal and state governmental agencies. With the Recycle 2000 Initiative, DOE has radically shifted its decision making process. Instead of interested parties reviewing a virtually completed policy, stakeholders were given opportunity to comment and help develop the Recycle 2000 Initiative from conception.

CONCLUSIONS

Cyril L. Comar eloquently expresses the gulf that often exists between risk analysis and risk acceptance:

Society is becoming increasingly well informed and anxiety-prone about technology-associated risks which leads to desire for their elimination. The logical and traditional approach is first to estimate the risk, a scientific task. Then comes the issue of risk acceptance, a most difficult step -moving from the world of facts to the world of values (13).

Establishing effective RSM reuse policies is as much a scientific and a technical process as it is a political undertaking. History has shown the difficulty that regulatory agencies can face when trying to establish effective policies for managing radioactive waste.

Proactive involvement of affected interests is one means of combating the difficulties of policy implementation especially those involving highly complex and exceptionally technical issues. However this statement must be viewed in light of certain caveats. A proactive participatory environment likely will entail greater resource expenditures in time and money. Moreover, the debates over reuse policies for RSM could run into communication problems. Nuclear technologists and scientists work in a complex field and converse in a highly specialized language. The possibility of communication problems is very real. Finally, BRC is still on the radar screen of many nongovernmental environmental organizations. RSM reuse policies will inevitably stimulate comparisons with the failed BRC policy.

Stakeholder involvement processes offer no guarantees of success. However, given the past record of regulatory attempts to establish radioactive waste management programs, stakeholder involvement methods may offer the best means of establishing effective and acceptable RSM reuse policies.

DEVELOPMENT OF NATIONAL STANDARDS FOR COMMERCIAL REUSE OF BUILDING CONSTRUCTION PRODUCTS AND RECYCLED METALS FROM DECOMMISSIONED DOE FACILITIES

A. Gwen Eklund
Radian Corporation
Donald E. Sandberg
Westinghouse Hanford Co.

ABSTRACT

The American Society for Testing and Materials (ASTM), with it's membership open to all organizations and individuals, is a leader in the development of voluntary, consensus standards on characteristics and performance of materials, products, systems, and services. ASTM administers the U.S. Technical Advisory Group (TAG) to the International Organization for Standardization (ISO) Technical Committee 207 on Environmental Management. ASTM is currently developing a number of national standards on environmental management likely to affect DOE facilities: assessment, waste management, biological effects, environmental fate, and pollution prevention, reuse, recycling, reclamation and environmental efficiency measurements, and lifecycle analysis.

In accordance with the 1993 Executive Order, recycling by Federal facilities is encouraged in response to the Pollution Prevention Act of 1990. This paper focuses on development of ASTM standards for recycling and reuse of radioactive contaminated materials and facilities. ASTM Committees interested in DOE facilities decontamination and decommissioning have targeted low-level contaminated and potentially nonhazardous commercial reuse of building construction products and recycled metals for the first standards to be developed with open participation of government, public, and academia via the ASTM process. Among the participating committees developing these standards include:

ASTM E 50 on Environmental Assessment. Subcommittee E 50.03 on Pollution Prevention, Reuse, Recycling and Environmental Efficiency;

ASTM E 10 on Nuclear Technology and Applications. Subcommittee on Radiological Protection for Decontamination & Decommissioning of Nuclear Facilities and Components;

ASTM D 34 on Waste Management. Subcommittee D 34.07 on Mixed Waste; and

ASTM C 26 on Nuclear Fuel Cycle. Subcommittees C 26.05 and C 26.07 Methods of Test and Waste Materials.

INTRODUCTION

Cooperation among nongovernment technical standards setting organizations, both national and international, offers the American Society for Testing and Materials

(ASTM) opportunity to show leadership in world standards with DOE. Technical and management standards packages to support federal facilities represent an immediate opportunity. Members of an ASTM Inter-Committee Task Force (ITF) met on October 7, 1994 with the Department of Energy's (DOE) Technical Standards Program. A possible new leadership role for ASTM in this regard was favorably received and the task force has held subsequent meetings to initiate these activities.

APPROACH TO DEVELOPMENT OF ASTM/DOE TECHNICAL STANDARDS

The overall goal of the newly formed ASTM Inter-Committee Task Force (ITF) is to provide DOE with nongovernment standards packages that integrate related technical and management standards targeted to high priority DOE issues/problems.

This goal is just beginning to be accomplished by various ASTM committees working together to meet identified DOE standards needs. The first proposed project for the newly formed ASTM ITF is "commercial reuse of building construction products and recycled metals from decommissioned DOE facilities"; this group of ASTM standards for DOE may serve as a model for ASTM "Teams" to meet needs of other federal organizations. This first project is being developed using the following phases:

Phase IStandards Project and Product Definition;
Phase II"Test Case" DOE Standards Packages;
Phase IIIBuilding ASTM-DOE Partnerships; and
Phase IVParticipation by Other Federal Agencies.

Phase I - Standards Project and Product Definition

In Phase I, the ITF has begun to define the approach, interfaces, specific work within and the format for the product standards packages. Phase I includes planning and further development of the model approach to implementing this activity. The ITF has begun the following activities:

Working with DOE-TSP to identify DOE program needs.
Working with DOE-TSP to define an interdependent process for developing the standards packages.

Development of a recommended methodology to evaluate the applicability of non-government standards (e.g. ASTM, ANSI, ISO) and DOE standards using consistent decision criteria. Discriminators such as technical, economic, legal, and availability will be structured into a decision-focused spreadsheet.

Interface with ASTM regarding efforts to identify possible inclusion of non-ASTM standards in the packages.

Coordinating with the ASTM Publications, Marketing and Information Technology Division the "design" of a format for the product standards packages.

Phase II - Providing "Test Case" DOE Standards Packages

In Phase II, ASTM standards packages for additional "test case" activities identified by DOE may be developed. Inter-committee teams will combine existing ASTM technical standards with existing or new management standards into standards packages specifically designed to meet identified "priority" DOE needs. Each team will include at least one ITF member. The "drafting" teams will likely be DOE/contractor employees who are members of the involved ASTM committees. DOE may be requested to identify a programmatic point of contact for the team leader and, if necessary, additional non-ASTM members to participate. To accomplish this, the teams will:

Select "test cases" to be pursued.
Develop process descriptions, including diagrams if applicable, which identifies specific steps within the target activities where standards may be an asset.
Review standards for application and develop abstract information.
Recommend accelerated standards development where there are gaps.
Facilitate DOE decision-making about standards applicability and the need for standards development.
Manage and participate in ASTM standards development including accelerated standards.
Identify additional standards development with external standards organizations.
Assemble standards packages for the target activities.

Phase III - Building ASTM-DOE Partnerships

In partnership with DOE TSP, ASTM task forces may in the future expand this approach to general application throughout DOE. The ITF and DOE-TSP may work together to update the model as a result of the Phase II activities. With a proven, functioning model in place, ASTM and DOE may in the future develop funded mandates and/or working arrangements for continued application throughout DOE. Additional

activities that may be required to finalize the model might include:
Developing detailed descriptions of the process including roles and responsibilities and protocols for interface among ASTM, involved committees, and DOE.
Defining the means for matching DOE "project" needs with appropriate committees.
Determining the best options for project coordination and communication.
Institutionalizing of any contractual and financial protocols by DOE and ASTM.
Identifying training needs and developing training programs for DOE/contractor staff. Development would be coordinated with ASTM Standards Technology Training.
At this point, general application of the model would be expected to be implemented throughout DOE. The extent of this implementation will be in direct response to DOE program needs, interest, and (where required) funding. The ITF will be supported by ASTM committee members and identified DOE/contractor staff.

Participation by Other Federal Agencies

If the ASTM/DOE standards packages are successful, ASTM intercommittee task forces may extend the development of standards packages to other federal agencies. This may require adapting or customizing the model for other identified agencies.

Project Management

Don Sandberg, Committee Chairman of C-26 (and a DOE contractor) is currently coordinating our ITF. In this role, Mr. Sandberg has met with DOE's Technical Standards Program staff to identify and prioritize DOE needs. The ITF will be supported by Pat Barr, ASTM Headquarters staff, in identifying ASTM Committees and resources to review standards packaging and accelerate standards where important gaps are identified. Members of the Inter-Committee Task Force are:

Gwen Eklund, ASTM E-50 Vice Chair (a DOE contractor), provides liaison on any environmental management standards that may be appropriate and provide input into pollution prevention/recycle reuse planning for DOE sites and facilities.

Bill Gulledge, ASTM E-50 and E-51 Executive Committee member and Board member ISR (former DOE employee), who participates in ISO and other national standards organizations provides technical and strategic advice on coordination of Task Force activities internal and external to ASTM and the involved committees.

Dick Meservy, ASTM E-10.03 Subcommittee Chairman (a DOE contractor) represents specialized knowledge of a DOE Site Contractor and specialized knowledge of nuclear applications that can be expected to be targeted by DOE as high priorities.

Jim Satterfield, ASTM E-51 Chairman who provides liaison on environmental risk management issues, and, as needed, serve as an "on-site" liaison to ASTM headquarters including attendance at meetings to represent the Task Force in Philadelphia.

Nancy Trahey, Past Chairman of ASTM Board of Directors provides senior technical review of process and liaison with existing ASTM governing bodies.

Srini Venkatesh, ASTM D-34.07 Subcommittee Chairman (a DOE contractor) represents specialized knowledge of a DOE Site Contractor and specialized knowledge of mixed nu clear/toxic waste management issues that have already been acknowledged by DOE as high priorities.

This ITF is combines ASTM leadership with DOE/contractor staff to achieve the proper liaison between non-government standards organizations and those with the internal knowledge of DOE's needs. This task force approach also combines quality and cost effectiveness with strategic focus on priority DOE activities.

STATUS OF STANDARDS DEVELOPMENT FOR COMMERCIAL REUSE OF BUILDING CONSTRUCTION PRODUCTS AND RECYCLED METALS FROM DECOMMISSIONED DOE FACILITIES

Thus far, five ASTM Committees have agreed to participate in the development of standards development for commercial reuse of building construction products and recycled metals from decommissioned DOE facilities. Figure 1 illustrates some of the likely technical standards areas for defining necessary technical standards. In some cases, these initiatives will require only the grouping of existing standards into the new DOE format. Table I, B shows examples of some of the environmental, nuclear, and decommissioning ASTM standards that already exist that may be applicable to this package. Table II, B shows examples of ASTM standards under development that may be applicable to the recycled metals and reuse of building construction products. ASTM E 50.03 on Pollution Prevention, Reuse, Recycling and Environmental Efficiency has begun to develop industry end use requirements for reused and recycled materials; these standards also will have to be reviewed by the committees on building construction materials.

EFFORTS TO STANDARDIZE LOW LEVEL RADIOACTIVE WASTE CONTAINERS TO BE MADE FROM RECYCLED RADIOACTIVE SCRAP METAL

Philip L. Winston
Thermo Technology Ventures
P.O. Box 1625
Idaho Falls, ID 83415-1631

ABSTRACT

Containers used by the U.S. Department of Energy (DOE) for transportation, storage and disposal of low level radioactive waste are widely varied in design and cost. Optimization and standardization of these products will yield a broad range of cost savings, including bulk procurement costs, reduction of redundant design costs, improved handling procedures and equipment, and minimization of disposal void volume. The current move away from plywood strong-tight packages into metal Type A packages, coupled with efforts to recycle radioactively contaminated scrap into metal packages for use within DOE provides an opportunity to introduce refinements. Use of a metric volume container is preferred for bookkeeping purposes and also to comply with DOE Order 5900.2, which requires system-wide adoption of metric units. Historically, low level waste containers have been 4' x 4' x 8' dimensions (with variations). Existing DOE facility capacity for recycling metal includes rolling mills that have 42" wide capacity. If plate were produced on such a mill, a typical container based on a four foot wide dimension would require an additional section to be welded onto plate stock to meet requirements. While greater than 90 percent of most radioactive material can be removed during the recycling process, the potential for residual contamination to exist in material produced from recycled radioactive scrap will dictate the degree of personnel protection required during welding and fabrication to assure that exposure is "As Low As Reasonably Achievable" (ALARA). Designing packages to a metric standard (39.37"=1 meter) would minimize the need to weld plate sections together for fabrication, thus reducing ALARA concerns. Design of products that have less void volume associated with access points for handling will minimize the final disposed volume of the waste package. These concerns are being considered by a working group with representatives from several DOE sites. Implementation options currently underway include development of one or more standardized containers and revision of waste acceptance criteria to ensure the widest use of such containers. This paper discusses the issues raised concerning implementation of recycling radioactive scrap metal into standardized containers and the proposed solutions posed by the working group.

DISCUSSION

If a nation were to prosecute a war by arming its warriors with perhaps a dozen different kinds of rifles, supply, and repair of these weapons would become an unmanageable quagmire. If each branch of the armed services and each unit procured their weapons according to their own specification of "rifle, anti-personnel," such a quagmire might come to pass.

Waste generation, shipment, and disposal bears no fundamental similarity to fighting a war other than the fact that the government pays for it. Within the Department of Energy, a variety of wastes are generated at its 49 sites. The diversity of material being disposed is phenomenal. Similarly, the diversity of packages being used to store, transport, and dispose of these materials is phenomenal. The single largest disposal site in the DOE system has documentation for receipt of 27 different packages. The fundamental question arises as to whether the number of packages is clearly consistent with the number of waste types.

If one were to survey the packages, it becomes obvious that essentially, there are drums and there are boxes. Drums are generally 22-1/4" diameter by 33-1/2" height, presumably an artifact of some oil company collusion in the early days of near monopoly.

Boxes, on the other hand, are 48" x 54" x 96" or 84" or 72" or 28" x 48" x 96." Some are plywood while some are steel. Some are intended to meet DOT Type A, and some are "strong, tight."

Designs are often vendor-dependent, and, of course vendors are bid-dependent, so the same specification may be filled by one vendor in one procurement and by another in the next procurement with different designs.

A variety of people within the DOE system have observed that there is little

justification for this degree of diversity. If drums can be standard, why not boxes? In an ideal world, all sites could use one product to ship, store and dispose their wastes. Most low level waste is low density material whose longest dimension does not exceed six feet.

The Westinghouse GOCO Waste Minimization committee led by Dave Zigelman of Savannah River began work on trying to unify the procurement of boxes under one specification in 1993. This committee was composed of waste minimization personnel from Savannah River, Hanford, West Valley and Westinghouse Idaho Nuclear Company (WINCO).

The GOCO group produced a specification for a nominal B-25 type DOT 7A metal box with 48" x 54" x 72" dimensions. This container will be procured for Savannah River and other Westinghouse GOCO operations as desired. Efforts to approve a specification for a cargo container (also known as a Sea-Land) 8' x 8' x 20' were also pursued. At the time of this writing, the Sea-Land specification was not completed.

In parallel with the GOCO work, the Westinghouse Hanford Waste Management group designed a family of metal DOT 7A containers. This "family" procurement would allow waste generators to buy boxes of several different dimensions without going through the approval process for each design. This family included nominal B-25 dimensions, as well as long narrow boxes to accommodate 20 to 40 foot long tank lances. The family specification is not a product specification, and the vendor may offer the closure design of his choice, for example.

The decontamination and decommissioning (D&D) group of EG&G Idaho funded the efforts of Don Kenoyer and Dale Wells to develop a new generation of containers. The Idaho design is intended to replace the current plywood 4' x 4' x 8' boxes. Idaho has several types of waste that are stored rather than disposed, so this metal box will be coated with a thermoplastic layer to protect it from the elements.

The Idaho work became broader when the idea of complex-wide standardization was suggested in early 1994. The WINCO Metal Recycle group expressed the idea that metal recycle could be benefitted by standardizing a product that could be made using recycled contaminated scrap. Bruce Becker of Nevada Test Site and Ron Pope of Oak Ridge confirmed that there was a broad-based interest in such a concept. An April 1994 meeting was held in Salt Lake City to test the waters of fleshing out this support. Ultimately, 4 meetings were held in 1994, attended by people from Fernald, Hanford, Idaho, Los Alamos, Rocky Flats, Sandia, Savannah River.

The outcome of these discussions was that although each site has its own interest in the box that they use, at least 85% of the waste generated throughout the complex could be stored, transported and disposed in a single design. Existing designs should be revised to minimize or eliminate the amount of void space that the container represents to maximize effective use of the disposal site.

With respect to structural strength, there are some discrepancies. Some sites stack boxes 4 high. Some sites stack 5 high. If the Savannah River design is loaded to its 5,000 lb capacity, the bottom box in a 5 high stack must support 25,000 lbs, although it is tested to 20,000 lbs. Idaho National Engineering Laboratory Radioactive Waste Management Complex (RWMC) uses the standard of 4,000 lbs per square foot as a strength limit. A plywood RWMC box should meet a 12,800 lb load. This means RWMC would need to revise their operations if they were to adopt the Savannah River design. The 12,000 lb limit used at the RWMC would crush the SRS B-25 if used in a 5 high stack.

The plywood box used at INEL and some other sites suffers from another of the flaws that were identified. It has significant amounts of unusable void space. The internal bracing of 2 x 4 studs consumes 10 cubic feet, but more on the order of 26 cubic feet of the volume is unusable because the space between bracing cannot usually be filled with waste because the liner does not allow it to reach that space. Coupled with the 3/4 inch plywood walls, the double floor, and the 4 inch risers that it sits on, a nominal 128 cubic foot package can only serviceably hold approximately 80 cubic feet of waste. If Nevada Test Site received 1,000 such boxes, 48,000 cubic feet of void space at seven dollars per cubic foot would equal $336,000 of disposal cost that could largely be avoided by adoption of a more space efficient container. Add the low fire rating, and it is easy to conclude that the plywood box is an undesirable package.

Other void-generating culprits are closures and risers. The closure on a metal box is often a bolt lip that extends out 3 inches in most cases. The riser is usually a 4" high block that allows forklift access to the bottom of the box. On a 4' x 4' x

6' box, the bolt lip represents a 20 cubic foot void while the riser is 8 cubic feet per box. This is not to say that all voids can be eliminated, but there are improvements that can be made. Nevada Test Site can handle packages without risers, and RWMC is working on designs that can be handled by a lifting fixture, eliminating the riser.

All of the voids that consume valuable disposal sites also enter into the volume that can be transported. More efficient designs would reduce the number of trips to disposal sites, ultimately improving safety for the public as well as saving in transportation costs.

The suggestion that a new paradigm be developed led to the thinking that a metric package would serve the D&D groups by having a lower lift height while having nearly the same useful waste volume. It could also accommodate production of plate using the existing rolling mills that are in use in the DOE system. A 39.37" box could be made with a single piece of plate from a 42" mill more easily than a 48" dimension box.

The ultimate outcome of the discussions from the several sites and groups is that a standard should be set. There is clear disagreement as to what that standard should finally be. The standard could be mandated from DOE headquarters, but adoption could be complicated in the field. The most clear cut solution that has been advanced to date is that the disposal sites determine the best solution in a dialogue with the waste generators and transporters, and be empowered to buy the containers and supply them to the generators. This could be enforced by provisions in each site's waste acceptance criteria documents that would exclude non-approved, non-standard containers.

The emphasis must be maintained that this development be supported by the several affected components of DOE Headquarters; Environmental Restoration (EM-40), Waste Management (EM-30), and Transportation Management Division. The dialogue must involve the field personnel who are most familiar with system problems, and it must involve the full range of those who use and handle the containers. In this way, integration can save money and waste disposal volume.

RADIOLOGICAL RELEASE CRITERIA AT THE FERNALD ENVIRONMENTAL MANAGEMENT PROJECT THEORY AND PRACTICE

Robert W. Lehrter
FERMCO*
P.O. Box 538704
Cincinnati, OH 45252-8704

ABSTRACT

As environmental restoration activities progress at the DOE's Fernald site, and across the country, large volumes of radioactive scrap metal (RSM) are being generated. Despite the existence of "free-release" guidelines from DOE, the strategy of onsite decontamination and release of RSM for unrestricted use has been generally overlooked in recent years. A pilot project was completed at Fernald in which 120 tons of RSM were decontaminated onsite and released for unrestricted use. This paper compares that strategy to more traditional DOE RSM management practices.

BACKGROUND

In managing the Fernald Environmental Management Project (FEMP) for DOE, FERMCO has established an organization founded on the EPA concept of Operable Units (OUs). For the Fernald site, five distinct OUs have been defined, each with a corresponding management organization, known as a CERCLA/RCRA Unit (CRU). CRU3 is responsible for managing the cleanup of OU3, which covers 136 acres and consists mainly of the former uranium processing area, including buildings, equipment, stored wastes, and associated materials. A map of the site showing the boundaries of the various OUs is shown in Fig. 1.

Fig. 1.

The FERMCO Recycling Department was established to support the CRUs, particularly CRU3, in their remediation efforts. Specifically, Recycling provides CRU3 with information to evaluate the viability of recycling or beneficial reuse as compared to other management options for various materials and waste streams. When recycling is selected as the preferred approach, the Recycling Department then generates the plans, procedures, contracts, etc. to implement the strategy.

DOE Order 5400.5 "Radiological Protection of the Public and the Environment," was

issued in February, 1990. Based on the requirements of this order, personnel and equipment have routinely been "free-released" from the OU3 radiologically controlled areas. However, the release of equipment has been strictly limited to relatively small-scale items, such as tools, trailers, and vehicles. The free-release of large amounts of RSM was considered too ambitious (almost "taboo"). FERMCO Recycling sought to demonstrate the viability of free-releasing RSM, after onsite decontamination, by performing the Material Release Facility (MRF) Pilot Project.

DOE GUIDELINES AND REQUIREMENTS

DOE Order 5820.2A "Radioactive Waste Management," issued in 1988, stresses waste minimization. It states "...LLW shall be managed on a systematic basis using the most appropriate combination of waste generation reduction, segregation, treatment, and disposal practices...." This requires DOE contractors to utilize a portfolio of strategies in managing their LLW. For RSM, one element in the portfolio is decontamination and free-release.

In 1990, DOE Order 5400.5 "Radiological Protection of the Public and the Environment," established the radiological contamination guidelines for the free-release of materials and equipment. These guidelines include numerical limits for residual surface contamination (see Table I) and a qualitative evaluation of the effectiveness of segregation and treatment efforts (ALARA evaluation).

At Fernald, the predominant nuclides of concern are U-natural, U-235, and U-238. The corresponding surface contamination limits from DOE Order 5400.5 are well within the capabilities of swiping and hand-held surveying techniques routinely utilized at Fernald and other DOE sites. Theoretically, material with measurable surface contamination, but which was below the 5400.5 limits, could be released without restriction on end use.

MATERIAL RELEASE FACILITY (MRF) PILOT PROJECT: INTRODUCTION

A multi-disciplinary team of FERMCO personnel was assembled to plan the free-release project. Team members were selected based on experience, area of responsibility, and organizational affiliation, so that all FERMCO divisions with a stake in project outcome were represented. Management empowered each team member with the authority to make decisions which impacted project outcome.

The team's first task was to develop a strategy for conducting the project. Presented in Fig. 2 is the basic approach devised by the team. Based on this flowchart, a work plan was developed to decontaminate and free-release 120 tons of RSM.

Fig. 2.

The team capitalized on several factors which combined to give a strong indication that the Pilot Project would be successful. First, a building with adequate decontamination and material handling capabilities was readily available. The FEMP's Building 78 was originally designed to decontaminate vehicles and process vessels used in the production of uranium. By the time construction was completed, production operations had ceased and Fernald's mission had become one of environmental restoration. This brand new facility basically sat idle, until the Pilot Project was conducted. Building 78 became known as the Material Release Facility, or "MRF."

Another factor which bode well for the project was the abundance of seemingly ideal RSM available in OU3. Several lots of material were targeted for decontamination and free-release, including stacks of unused structural steel (50 tons), sheets of steel deck plate cut from a decommissioned U.S. battleship (45 tons), and unused furnace pots (120 tons). Although none of these items were ever used in the production of uranium, they had all accumulated significant surface contamination through years of storage in radiologically controlled areas of OU3. The 120 tons of furnace pots were ultimately chosen as the target for the Pilot Project.

The third factor which pointed to a successful project was the existence of a fairly thorough infrastructure of SOPs at Fernald. Although there was no "How to Free-release RSM" procedure, nearly every step of the MRF Process Flow Diagram (see Fig. 2) was covered by an existing SOP. The MRF Work Plan was generated to coordinate the existing SOPs and to fill in any gaps. The MRF Work Plan served as the overall SOP for the Pilot Project.

Quality Assurance (QA) is an integral part of all activities at Fernald. Since this was a somewhat unprecedented undertaking, QA was especially rigorous for the MRF Pilot Project. FERMCO QA was involved throughout the project, from the earliest planning sessions through project completion. Through this QA involvement, the need

for extensive documentation was identified as a means to control the system.

MRF PILOT PROJECT: IMPLEMENTATION

With QA input, a new form called the "MRF-100" (see Fig. 3) was implemented. This form became the foundation for the documentation package required to free-release material. The MRF-100 served as a reservoir for all information and documentation generated during each step of the MRF process. It was designed to provide QA with a comprehensive, straightforward summary of all the steps taken to justify the free-release of the furnace pots. The MRF-100 greatly simplified QA's job of certifying that the material and documentation met all requirements for free-release.

Fig. 3.

To move 120 tons of furnace pots (600 individual items weighing 400 lbs. each) completely through the MRF process took about two-and-a-half months. The main decontamination technique was steam/detergent spraying, although some grinding, scraping, and torch cutting were required for small areas of particularly stubborn surface contamination. All material handling and decontamination tasks were performed by FERMCO hourly (union) employees.

For the final, comprehensive radiological characterization, a conservative approach was adopted. As discussed above, DOE Order 5400.5 theoretically permits the free-release of items with measurable surface contamination, assuming ALARA requirements are satisfied. The approach adopted for the MRF Pilot Project required that no detectable activity be found on any item to be free-released. Again, the radiological surveying techniques used were capable of measuring contamination levels well below the 5400.5 limits. By adopting the "less than minimum detectable activity (<MDA)" limit, a safety net was built into the system and the ALARA process was greatly simplified.

The total cost of release activities for the project was about $72,500. This figure includes ALL costs associated with the onsite processing of the furnace pots: transportation to and from the MRF, material handling at the MRF, flame cutting of stubborn contamination spots from some pots, decontamination activities, radiological surveying, technical, clerical, supervisory, and management support, and supplies. See Table II for a task-by-task breakdown of the total cost on a percentage basis.

As illustrated in Table II, only 31% of the total cost actually went to release activities (material handling, transportation, and decontamination), while radiological surveying ate up 42% of the budget. This figure was probably driven up by the difficult shape of the pots and by the adoption of the "<MDA" limit. Nevertheless, a seemingly inordinate chunk of the budget was consumed by this activity. Although MRF processing is a very cost-competitive option for processing some material types (as illustrated below), a great opportunity to improve the system exists in the area of radiological surveying.

MRF COST VS. BURIAL AT NTS

Traditionally, disposition of items like these furnace pots is accomplished by burial at NTS. Fernald has a great deal of experience shipping LLW to NTS, and so an accurate estimate of the cost to disposition 120 tons of furnace pots at NTS was readily available through the FERMCO Estimating Services Dept. This estimate includes the material and labor for packaging, transporting, and burying the material. As depicted in Table III, MRF processing is a very economical option, costing slightly more than half the price for NTS disposal.

PLANNED ENHANCEMENTS

Because of the success of the Pilot Project, and the abundance of material remaining in OU3 which is ideal for MRF processing, the work plan under which the trial was conducted has been upgraded to an SOP. Funding has been secured for FY-95 to decontaminate and free-release RSM at a rate of 50 tons per month, using a production line approach.

Additional decontamination technologies are also envisioned for FY-95. Start-up of the MRF's high pressure (2,500 psi) and ultra-high pressure (35,000 psi) water spraying systems is anticipated by April. Also this spring, a vacuum grit blaster will be purchased and installed at the MRF (thanks to funding received through EM-334). Procurement of automated radiological surveying equipment is also being considered, as is leasing a mobile, self-contained decontamination facility for specific material lots. With these enhancements, an ambitious goal of 800 tons per year may be achievable.

SUMMARY
Many options exist for managing RSM. DOE orders dictate that contractors demonstrate flexibility in utilizing a combination of techniques to optimize the benefits of waste management activiites. The FERMCO Recycling Department led an effort to provide their customer with an economical alternative to the traditional approach of burying contaminated metal as LLW, based on established DOE free-release guidelines.
Fernald's MRF Pilot Project demonstrated that onsite decontamination and free-release is a viable option for managing RSM in the DOE complex. In developing an overall environmental restoration plan, this approach should be included in the portfolio of strategies to be considered. At Fernald, decontamination and free-release of RSM is becoming a routine operation, part of everyday life.

32-7
POTENTIAL IMPACTS OF PENDING RESIDUAL RADIOACTIVITY RULES

Daniel D. Burns
Fernald Environmental Restoration Management Corporation*
P.O. Box 538704
Cincinnati, OH 45252-8704

ABSTRACT
The purpose of this paper is to present an overview of pending rules governing residual radioactive release criteria and radioactive waste management, and the potential impact of these rules on the Fernald Scrap Metal program. More than 300,000 cubic meters of radioactively contaminated waste will be generated during the dismantlement of three complexes at the Fernald Site over the next year and a half. Under current regulations, as much as 70% (5,000 tons) of steel will be either recycled or re-used in controlled applications. Depending on regulatory developments, the ratios of recycling to burial will range from 100% burial to recycling more than 90% of the waste.
The absence of federal rules and regulations for classification of permissible levels of residual radioactivity is one of the most troublesome issues in the nuclear industry. The issue is growing in importance with the approaching end of useful life for many nuclear power generating stations and the planned remediation of the DOE nuclear weapons complex. Federal regulators have been involved in the "Enhanced rulemaking" process for over two years. The DOE Fernald site offers a good opportunity for understanding the potential impacts of the pending residual radioactivity regulations due to the maturity of the planned D&D activities, aggressive recycling program, and simple nature of contamination. The Fernald experience may offer a point of departure for many facilities engaged in D&D and waste management.

BACKGROUND
The Fernald Site is a former uranium metal production facility which was utilized for the conversion of UF6 to uranium metal and other applications within the Department of Energy. The production mission commenced in 1952, and proceeded through 1989. In 1989, the Department of Energy made a decision to end the production mission at the Fernald facility and began the remedial action dedicated to the cleanup of the former production facility.
As a result of production activities, uranium contamination was dispersed throughout the 80 acre production area. Two major areas being addressed within the complex include the former production facility and the waste pit area west of the production facility used for land placement of various process generated from the beginning of operations until 1985.
In 1985, land burial at the facility was ended and process waste were either stockpiled or packaged for transport and burial at the Nevada Test Site (NTS).
The mission was very straight forward with respect to the operations at the Fernald facility. The primary contaminants associated with all areas at Fernald are uranium, and thorium. No reprocessed fuel was used at the facility, therefore, fission products and activation products are not suspected at Fernald.
Various forms of Uranium were produced during the life of the project, which included a depleted uranium metal, normal distribution metal, and also low enriched uranium up to approximately 2% Uranium 235. The goal of the remedial action at the Fernald site is to excavate and stabilize the waste that was previously placed in the ground, remove contamination from an aquifer which underlies the entire

facility, and to take to grade or demolish all of the production facilities formerly used for uranium production.
As a result of the remedial actions, a large quantity of radioactive waste will be generated. Table I depicts the volumes of the major categories of waste. As can be seen, the total is nearly 3,000,000 cubic meters of waste, two-thirds of which will be soil and clay. The next major contributor to the volume of waste requiring remediation is 600,000 cubic meters of waste pit contents, and the remaining portion, nearly 300,000 cubic meters, will involve the management of the construction debris from the dismantlement.

SCRAP METAL MANAGEMENT

Historical Practice

The historical practice for the management of radioactive scrap metal generated during the production mission was to stockpile the metal in the northeast section of the production area. By 1989, more than 6,000 short tons of radioactive scrap metal had been placed in the scrap metal storage area. An aggressive project was initiated in 1991 to clean up this area and plans were developed for the management of the radioactive scrap metal.
Nearly 4,000 tons of the radioactive scrap metal were packaged into large 8 foot x 8 foot x 20 foot containers and transhipped to the Nevada Test Site for burial. A project was initiated in 1991 to recycle or beneficially reuse the remaining metal stockpiled at the scrap metal storage facility.
The radioactive scrap metal destined for recycling or beneficial reuse consisted of both ferrous and non-ferrous metals (primarily ferrous metals) with a nominal contamination level of 50,000 dpm per 100 centimeters squared or 8.3 becquerel per centimeter squared with natural uranium.
A turnkey project was initiated to hire a subcontractor to provide characterization, size reduction, packaging, transportation, surface decontamination, metal melt, and secondary waste disposition. The end product for the action was the fabrication of shield blocks which would be transhipped to the Department of Energy for use as shielding in accelerator projects within the medium energy physics program. At the completion of the project, 90% of the material by weight had been beneficially reused or recycled.
A cost assessment was performed for the activity in which the recycle and reuse contracts was compared to the historical practice of disposal at the NTS. Disposal of the 2,210 tons of scrap metal would have cost approximately $4 million as compared to the expenditure of nearly $4.8 million to contract the services for beneficial reuse.
A net cost advantage was realized, given that the DOE avoided the expenditure of more than $1.7 million for the purchase of virgin metal shield block for the medium energy physics program. The benefit equated to nearly $1 million savings within the DOE.

Future RSM Management

At the completion of the initial scrap metal recycling project the management at Fernald reviewed the performance of the contract and the methodologies employed. A primary consideration was made to further segregate any future generated radioactive scrap metal. The segregation would occur primarily based on physical form, with the distinction being made on not only the radiological characteristics, but the presentation of the substrate.

METAL CLASSIFICATIONS

Metal waste at the FEMP is divided into two categories: refuse and recoverable. Recoverable metal (scrap metal) is further divided into two subcategories; recyclable and reusable. The distinctions are based on the physical and radiological characteristics of the metal form. Disposition of these materials can only be identified once the materials are appropriately categorized. Appropriate segregation into these categories will facilitate the most cost effective and timely final disposition of metal waste. The following are descriptions of the categories:

1. REFUSE - Refuse metal waste is metal which is radiologically contaminated or suspected of being radiologically contaminated. The physical form of the metal is such that is excessively oxidized or a bimaterial form where separation of the metal from the other materials is not cost effective. Evaluation of cost effectiveness requires a comparison of the cost of managing the material as refuse considering the regulatory status of the material as a waste (a specific material may be

cost effective to recover if it would be regulated as mixed waste, whereas it may not be cost effective to recover if it would be regulated as low level radioactive waste).

2. RECOVERABLE - Recoverable metal is metal which is radiologically contaminated and can be processed for unrestricted release or controlled reuse. Generally, this category includes all metal which does not have the refuse characteristics.
   A. Unrestricted Release metal is metal which can be decontaminated and all potentially contaminated areas are accessible for direct contamination survey. Generally, unrestricted release scrap metal has a low surface area to mass ratio. Examples of reusable scrap metal are structural steel, tanks and decking. Metal forms may be considered for unrestricted release even if there are minor portions which cannot be cleaned or monitored if that portion can be effectively removed from the form.
   B. Restricted Release scrap metal is metal which cannot be decontaminated or surveyed to verify that the release limits have been met. Generally, restricted release metal is light gauge or has inaccessible areas where contamination may be present, such as ductwork, cabinets, machinery, and odd sized forms. Restricted release scrap metal may include unrestricted release metal when it is determined that the restricted end-use is more cost effective.

Fernald will be generating large quantities of radioactive scrap metal. It is anticipated that during the demolition of the former production area, more than 50,000 tons of radioactive scrap metal will be generated. Nearly one-third of this will fit into the category of Unrestricted Release Recoverable metal, while the remainder will be considered Restricted Release Material not conducive to free-release in accordance with existing surface radioactivity guidance.

Plant 7

As a result of the demolition of the building of Plant 7, 710 tons of structural steel and deck plate has been generated. All of this material has been containerized into reusable containers, and is awaiting shipment to an offsite facility for surface decontamination and free-release. The contamination level of the structural steel is a nominal 30,000 dpm per 100 centimeters squared or 4.51 becquerel per centimeter squared.

Only depleted uranium was processed at this facility, and measurements were taken to determine the thickness of lead base paint on the members. 8 mils of lead base paint were discovered to be on the surfaces. A contract has been let for the transportation, surface decontamination, survey, release, and secondary waste disposal of the 710 tons of scrap metal. The end product will be recycled scrap metal with no restrictions, and will be sold to a commercial vendor. It is believed that 95% by weight will be recycled.

The cost of the activity is approximately $1.4 million, as compared to a disposal cost of $2.6 million for this material. An important consideration in conducting cost comparisons between recycle and reuse options versus disposal is an understanding of the packaging efficiency for this type of material. Previous experience at Fernald has indicated that a density of 16 lbs/cubic foot can be obtained without exhaustive size reduction actions. Given that no automated or methodized size reduction capabilities exist at Fernald, it is appropriate to use this density in the disposal analysis.

Material Release Facility

Another project initiated at the Fernald site is the utilization of a previously unused facility as a Material Release Facility. The purpose of this facility is to provide the necessary quality assurance, survey and decontamination operations to release metal from the radiologically controlled area. The candidate material identified for processing through this facility is in general heavy gauge, lightly contaminated material that is suspected of not requiring exhorbant decontamination technologies. In fact, the only decontamination techniques which are employed are dry vacuuming, scrubbing, scraping and low pressure steam with detergent additives. It is anticipated in the future that additional decontamination technologies (i.e. grit blast, close circuit grit blast) will be employed but will not be complex from the perspective of either capital investment or technology.

Through the first five months of the project nearly 180 tons of metals have been

released and sold to local scrap dealers for nominal scrap value. This facility operation will continue through the life of the remedial project. As long as activities are ongoing in the radiologically controlled area, there will exist a need for the controlled survey and release of items that may become potentially contaminated.

Fernald believes that it will process approximately 600 tons of material through this facility annually.

Waste Management Approach

The approach at Fernald is to develop a portfolio of disposition options for the waste generated as a result of the remedial action. At different times within the life of the project, various needs will become priority. Most notably, the needs will consist of economic evaluations and scheduler concerns. It is felt that with a portfolio of options for the management of the various types of radioactive waste the most responsible disposition will be able to be utilized.

Regulations

All of these management techniques have been developed to conform to the currently existing regulations. Changes are anticipated in the regulation of radioactive waste treatment storage and disposal. Most notably in the definition of radioactive material itself and also recycling radioactive scrap metal criteria.

At this point, the existing regulations only allow for the release of material which can be demonstrated to conform to surface radioactivity guidance. No regulatory foundation exists for the release of volumetric contamination or material that has inaccessible contamination for surveying.

As a summary to the pending regulations within the United States, Table II is offered to depict the activity. When cleaning a facility, it is easily visualized that there are four modes of releasing contaminants into the environment which could result in potential exposures. Of the four exposure pathways two are extremely well regulated. Air emissions resulting from the operation and decommission of a facility are well regulated under the Clean Air Act. Additionally, any water effluent associated with a facility are well regulated under the Clean Water Act and the Safe Drinking Water Act. The direct exposure associated with the facility, and the exposure associated with the solid waste generated at the facility are less well regulated.

There are two pending regulations for the control of direct exposures as a result of a facility being remediated. One regulation, "Radiological Criteria for Decommissioning" issued by the United States Nuclear Regulatory Commission (NRC), is designed to regulate facilities which operate under an NRC license. A parallel regulation issued by United States Environmental Protection Agency entitled "Radiation Site Cleanup Standards" is being developed for implementation at facilities other than NRC license facilities, such as federal facilities.

By definition, if the air, water, and direct exposure routes are regulated to certain levels, this will dictate a certain amount of solid waste be generated to conform to these standards. The industry is in great need of regulations which will adequately address the issue of solid waste, of which recycling regulations would be a subset. The U.S. EPA is developing regulations for solid waste. The overall program originally titled "Radiation Waste Management" has been developed and will continue to be worked on for the next several years. As a subset of this, a specific regulation will be developed for the management of materials which may be recycled out of this solid waste.

DESCRIPTION OF PENDING REGULATIONS

The U.S. EPA Decommissioning Staff Draft

The scope includes setting standards for the remediation of soil, groundwater, surface water, and structures at Federal facilities. A staff draft is in review and comment resolution. Pathway analysis and modeling are in progress, the most mature of which are the soil regulations. The major element of this regulation is the establishment of a 15 millirem per year effective dose equivalent exposure to the reasonably maximumly exposed individual. If this level is met, the facility may be abandoned with no restrictions based on its future use.

The 15 millirem per year value includes a four millirem per year component dedicated to the groundwater associated with the facility. The basis for this regulation has been developed from the International Atomic Energy Agency, the International Council on Radiation Protection, and the National Council on Radiation Protection recommendations. The risk based levels are consistent with the CERCLA requirements

for an excess cancer rate of 10-4 to 10-6. In actuality, the 15 millirem per year dose equates to a 3 x 10-4, which is considered to be within the range described by the U.S. EPA.

United States Nuclear Regulatory Commission Radiation Site Draft Cleanup Staff Draft

The scope includes specific radiological criteria for decommissioning of soils and structures at NRC license facilities. A final rule is anticipated in May 1995. The major element of this regulation is the establishment of a 15 millirem/year total effective dose equivalent, distinguishable from background and with ALARA considerations. The basis is the International Council on Radiation Protection and the National Council on Radiation Protection recommendations for individual dose.

Solid Radioactive Waste Regulations

The scope of regulations under being developed are, however, not fully determined. They may include source material, special nuclear material, byproducts, high-level waste, mixed waste, transuranic waste, and low-level waste. An issue paper and a preproposal draft have been developed. The proposed draft, Environmental Radiation Protection Standards for the Management, Storage and Disposal of Low Level Radioactive Waste (40 CFR 193), was issued in December 1994. The major elements will include requirements for treatment, storage and disposal of radioactive waste.

The most significant issue being discussed in the preliminary development of this regulation is the inadequacy of current waste classification systems. In essence, it may be appropriate for regulators to come up with a new classification system based on hazard rather than the generating process. In some cases, low-level waste are more hazardous than some forms of high-level waste, as well as some forms of NORM waste being more hazardous than mixed waste.

U.S. EPA Radioactive Material Recycling

The scope for recycling radioactive material rules has not been determined, but may include both restricted and unrestricted scenarios for regulation and implementation. The current status is that an issue paper is being developed to initiate the discussions and identify the need for any future regulations. Presumably, the regulation will rely on recommendations issued by the IAEA, OECD, ICRP and NCRP. The IAEA has issued a document on exemption criteria for radioactivity and the NCRP has authorized the formation of a committee to make recommendations on clearance levels.

Impact of Potential Pending Regulations

It is premature to address the impact of the pending regulations on the current waste management practices at the Fernald site. The desire is to have consistent and accepted rules governing the activities associated with radioactive waste management. At the Fernald site the question is extremely significant because the issuance of any of these rules will occur during the implementation of the Fernald cleanup. Therefore, adjustments will have to be made as the work is conducted. At the Fernald site it is not possible to wait for resolution of these issues and issuance of these regulations.

Recycling radioactive scrap metal will continue to play an important role in the remediation of the Fernald site.

Risk Based Regulations are welcome, and it is felt that they can be implemented at the site with little concern. The impact of any regulation will primarily be associated with the cost of dispositioning the material. In the absence of adequate regulation, or with regulations that result in clearance levels which are indistinguishable from the background radiation, Fernald may elect to provide timely land burial versus recycling or reuse.

SUMMARY

The Fernald site is an ongoing project. We are on the verge of implementing large scale activities which will result in a generation of large quantities of radioactive waste, including radioactive scrap metal. Under the current regulations, Fernald is able to recycle a portion of the radioactive scrap metal being generated at a cost which is comparable to other viable options such as land burial.

The pending regulations will be issued during the life of the Fernald project, and may have a severe impact to the ability of Fernald to continue beneficial reuse or recycling of its radioactive scrap metal, and may result in the burial of this material along with the contaminated soils and other radioactive waste residues. At this time, however, it is premature to speculate on these impacts given the lack of scope definition and lack of confidence in the ability to develop a widely accepted regulation concerning release of radioactive scrap metal.

NAVY TECHNICAL RISK MANAGEMENT:
A TEN YEAR STRUGGLE

Douglas O. Patterson
Product Integrity Directorate
Office of the Assistant Secretary of the Navy
(Research, Development & Acquisition)

ABSTRACT

Poor Naval weapon system reliability in the late 1970s led to a DoD manual, DoD 4245.7-M, which identified areas of risk in selected design, test and manufacturing topics, called templates, and provided outlines of ways to reduce these technical risks. Subject to differences in Government and industry interpretation, most assessments of these risks remained qualitative and dependent on the experience of the assessor, in spite of Navy awareness/education efforts. The absence of metrics and the inability to quantify and communicate technical risk led the Navy in 1993 to begin an effort to collect, organize and publish specific metrics for the Design, Test and Production templates. The result, Methods & Metrics for Product Success, is currently under review by selected industry and government representatives. Today, the Navy and DoD are beginning to focus on technical risk at defense acquisition program milestones. The lengthy evolution of this methodology and the cultural changes that were necessary for success are the subjects of this paper.

BACKGROUND

"In the beginning was Apollo." The manned lunar landings and lunar surface operations culminated the most massive technological buildup since the Manhattan Project. Beginning in the 1950s with sometimes futile attempts to place small satellites in orbit, and spurred on by such early Russian feats as Sputnik (October 1957) and Yuri Gagarin's orbital flight (April 1962), the technology to minimize technical risk gradually evolved through the Mercury and Gemini missions, reaching its apogee on Apollo's first lunar landing mission in 1969.

Early in Apollo's history, efforts were still being made to meet reliability requirements using math models based on piece part failure rates and mission functional and environmental timelines. The Apollo spacecraft fire in 1967 probably did as much as anything to prove the futility of statistics-based reliability math models and the need for technical excellence (not to mention common sense) in design and manufacturing. Probability and statistics were finally discarded and the focus turned to leaving no design or manufacturing stone unturned.

Little new technology was developed-rather, the importance of the old was rediscovered. For example, the extreme influence of stress derating on failure potential was underscored. Everything was made redundant that could be, and alternative modes or workarounds were developed for nearly everything else. Design of redundant elements tried to ensure that a single failure mode could not wipe out the whole function. For example, redundant relays might be oriented at different angles or located in different spaces. The designs of the few items that could not be made redundant were more heavily derated and tested. In the factory, rigorous manufacturing process specifications and controls such as those defining acceptable techniques for soldering were put in place, and everything at all levels from piece parts to end items was subjected to test environments designed to stimulate and detect latent defects for immediate corrective action. Rigorous environmental qualification and certification tests were keystones of the manned space program. Everything was "flown" to the maximum extent possible on the ground, and many special facilities such as huge thermal vacuum chambers were constructed to simulate mission environmental conditions as nearly as possible.

NASA put in place a very large reliability and quality organization at Headquarters and the three cognizant Centers (Houston, Huntsville, and Cape Kennedy). These engineers were largely technical specialists who came to disdain statistical approaches to R&QA. Each an expert on a particular subsystem, they consulted daily with their contractor counterparts during design and manufacturing of an end item, and visited the contractor frequently to review documentation and to get answers to

any technical issues requiring resolution. Everything was questioned. Every "untoward event," however seemingly small, was documented for review and satisfactory closeout, resulting in an exhaustive audit trail. Only unresolved technical issues were discussed at milestone decision points, and decisions were based on satisfactory plans to resolve these issues before the next milestone.

DEPARTMENT OF DEFENSE

In the 1970s, the Navy was experiencing problems with Fleet readiness. Sophisticated weapon systems were seriously compromised by low reliability and quality. The high rate of equipment failure required too many spare parts. The maintenance overload was worsened by the continuing difficulty in recruiting, training and retaining specialists for increasingly complex systems. The cost of parts and man-hours, aggravated by inflation, was taking its toll on the budget.

Encouraged by the dramatic success of the manned space program, the Navy turned to NASA experience in 1973 for new ideas to make weapon systems reliable. At the conclusion of the last manned lunar landing mission, the Naval Material Command invited Mr. Willoughby, then director of Apollo reliability and quality, to come aboard to aid in improving the readiness of Navy weapon systems based on Apollo experience. The Navy didn't need space technology per se-only the approach to lower technical risk.

This new Navy office initiated space-program-oriented technical reviews of individual programs, reorienting them where necessary to correct the most flagrant problems. Changes were directed at shifting emphasis from statistics to engineering; from measuring reliability to designing it in. At the risk of oversimplification, this approach could be said to focus on (1) designing to reduce stress, (2) testing under simulated field conditions to find design shortfalls, (3) using manufacturing processes that minimize defects, and (4) stress screening to stimulate and find remaining manufacturing defects.

These get-well efforts were faced with difficult obstacles, including a hostile working-level organization which was fearful of change, a competitive defense acquisition environment, an oppressive burden of unnecessary and cost-driving specifications and standards, budget constraints, political influence, program manager turnover, military bureaucracy, and even tradition. Without an infrastructure of appropriate directives and instructions to replace the existing faulty ones, this seat-of-the-pants approach worked only because the Navy delegated program approval authority to the new office, short-circuiting the bureaucracy. In effect, top Navy management decided to put reliability and quality first, ahead of cost and schedule. It may have been a risky decision for the Navy but it worked.

DEVELOPMENT OF THE TEMPLATES

By the early 1980s, the need for expanding the attack on unreliable weapon systems was beginning to be recognized by the Department of Defense. The many specific design and manufacturing fundamentals and disciplines were seen as components of a transition process from development to production. And reliability from a global perspective was more appropriately thought of in terms of risk. The transition from development to production had proven to be a major source of defense system acquisition risk-risk of cost escalation, schedule slippage, failure in service, and reduced readiness. Consequently, in 1982, the Under Secretary of Defense (Research and Engineering) commissioned the Defense Science Board (DSB) to organize a task force to examine the transition from development to production from a technical risk viewpoint, and Mr. Willoughby was asked to be the task force Chairman. Membership included corporate officers from the technical operations of Bell Labs, Boeing, General Dynamics, Gould, Honeywell, Hughes, Litton, Lockheed, McDonnell Douglas, Northrop, Raytheon, Texas Instruments, and Westinghouse, as well as DoD officials concerned with material acquisition.

The task force stated that "This industrial process of weapon system acquisition demands a better understanding and implementation of basic engineering and manufacturing disciplines. Once rigorous, disciplined engineering practices are employed and institutionalized, both the risk of deploying unsuitable weapon systems and the time in the acquisition cycle associated with design, test and production will be reduced." Drawing on the experience of their respective companies, this task force documented a subset of specific technical issues in the classic product design and manufacturing cycle which have the greatest influence on risk. It called this carefully identified subset the "minimum technical baseline." The task force document was published in 1985 by the Secretary of Defense as DoD Manual 4245.7-M,

Transition From Development to Production.
This "Transition Document" addresses specific technical issues which, based on industry experience with many programs, are revealed as having the greatest influence on acquisition risk, accounting for virtually all cost, schedule, and performance shortfalls in current systems. These technical issues are described in "templates" because each outlines a pattern for minimizing risk, reflecting best practices that defense systems contractors should follow in both new and ongoing programs.
To satisfy a need for more detailed guidance, the Navy enlisted technical consultants from several of the companies represented on the DSB task force to identify proven best practices for the minimum technical baseline defined in the Transition Document. Their knowledge of industrial technology, combined with Navy experience involving several hundred material acquisition programs, resulted in a second document, Best Practices: How to Avoid Surprises in the World's Most Complicated Technical Process, NAVSO P-6071, which describes the best practices for reducing technical risk that are used in industry today. Each template in the Transition Document is amplified in this "Best Practices Manual," published in 1986.
To be useful predictively, technical risks must be identified well before they become actual problems. An assessment of risk areas early in the development process can provide a systematic foundation for further analysis and revision as a system moves through acquisition. But an assessment based, for example, on tests conducted just prior to production does not assess the risk that the problems will occur. It uncovers the fact that problems have already occurred. The General Accounting Office, in its April 1986 report on the status of DoD technical risk assessment efforts, defined five requirements for technical risk assessment:

- Prospective assessment
- Planned procedures
- Explicit attention to technical risk
- Documentation
- Reassessment in each acquisition phase

If an assessment is to be called a "technical risk" assessment, all five of these criteria must be present.

THE NEED FOR EDUCATION

Efforts to implement widespread use of these best practices were hampered by inconsistent understanding or total lack of understanding in many subject areas. References for the risk areas defined by the templates were scattered, often existing as technical reports, standard practices in corporate manuals, and informal documentation. Specific references for some were nonexistent. Table I lists technical documents that the Navy's Product Integrity Directorate sponsored or supported to fill some of the most critical voids. Some risk areas concern basic engineering fundamentals, emphasizing design approaches which have seldom been included in academic curricula. Others involve the practical applications of those fundamentals, approaches which have been proven to reduce or eliminate risk through their use in successful programs. Still others are based simply on time-tested industry experience. As templates were tailored to specific programs, and as more experience was gained in their application and use, they were frequently modified and refined, which further complicated the references and resources picture. As a result, the risk areas were subject to differences in specific interpretation. Government and industry implementation of templates for reducing risk was not consistent and often did little to reduce risk.
Most government people lacked enough hands-on industry experience to utilize the templates effectively. The practical engineering and manufacturing know-how evolved by industry on-the-job and embodied in the templates was not taught in formal engineering curricula. Industry generally retains a greater range and depth of corporate knowledge and technical experience than the government because design and manufacturing are its stock in trade, while government programs are affected by an oversight mentality, limited hiring flexibility, engineers without industry experience, and program managers with little appreciation for design and manufacturing fundamentals. The irony in all of this is that industry still looks to the government for guidance because the government is the customer, and their lack of technical experience is too often considered irrelevant. There were other factors involved, of course, such as affordability, politics, competition and procurement legislation. Results, therefore, were largely dependent on individual knowledge and

experience.
It was obvious that an awareness/education effort would be required. Unfortunately, there were no courses available which teach the technical processes of defense acquisition. To solve this problem, the Navy's Product Integrity Directorate called on industry to assist in the implementation of educational programs to indoctrinate the material acquisition community-industry and government alike-in the fundamentals of best practices for technical risk management. This effort began in early 1988 with a contract to AT&T to prepare comprehensive technical reference guides for the templates and to develop the classroom education program. The objectives of the program were explicitly to

Increase awareness and understanding of design, test, production and logistics fundamentals

Provide a technique for assessing technical risk in accordance with DoDD 5000.1, DoDI 5000.2, and DoD-5000.2-M [DoD's top-level defense acquisition policies and procedures]

Over the period of a year beginning in mid-1990, pilot courses using technical reference guides as they were completed by AT&T were presented to some 200 government and contractor personnel. Later, completed course modules were presented to a similar number of personnel in the Navy acquisition community. At the same time, McGraw-Hill edited and published the AT&T technical reference guides as a set of four textbooks on design, test, production, and logistics. The Defense Systems Management College eventually incorporated the series into its education program for program manager designates. But at the working level, implementation of a DoD-wide or even Navy-wide education program for the defense acquisition community proved elusive-top management commitment was missing and adequate resources for staffing and funding could never be identified, especially in light of the end of the Cold War.

METHODS & METRICS FOR PRODUCT SUCCESS

Since DoD Directive 5000.1 requires technical risk assessment and management in major acquisition programs, DoD program managers are required to perform technical risk assessments prior to major program decision milestones and to develop aggressive risk management plans in order to obtain approval to proceed into the next program phase. However, technical risk assessment has continued to be primarily qualitative and subject to the experience of the assessor. In virtually all approaches, experts are asked for subjective judgments of what the risk elements were, as well as the likelihood of their occurrence. Ratings are based on various sources of information, such as expert judgment, test or simulation results, and published technical reports on similar systems.

We realized that managing technical risk requires the ability to identify, measure and communicate it, and that the Navy lacked the metrics to measure it; consequently, poor communication was impeding implementation efforts. Starting in 1993, we began to collect and organize specific metrics for the design, test and production templates. Technical risk occurs where there are differences between the technical practices of design, test and production, as implemented, and corresponding proven best practices. Metrics provide a means to quantify the deviation of implemented practices from best practices in order to minimize subjectivity and provide a sound and consistent basis for program management decisions.

The results are documented in our Methods & Metrics for Product Success handbook. They include both risk management methods (process identification, process baselining, risk mitigation and reporting) and risk assessment metrics. A typical risk assessment summary chart for a defense acquisition program is illustrated in Fig. 1. The colors (green, yellow, red) signify the degree of compliance between actual and best practices as determined using the metrics for each template appropriate to the program phase. This approach is especially good at assessing changes in technical risk over time, as a result of mitigating actions. The Navy's Product Integrity Directorate has used this methodology successfully in diagnosing technical risk and recommending appropriate mitigating actions in several major defense acquisition programs to date. A small printing of the handbook has been distributed to various government and contractor people to get feedback before we commit to full publication. We are encouraged by early reports of its use.

FIG. 1.

IN RETROSPECT

This approach to defense acquisition has required a cultural change in the acquisition community-from reliance on specifications and standards; legal, financial and contractual regulations; reorganizations; latest fads, whims and slogans; and armies of auditors-to best design and manufacturing practices and technical risk management. Over the ten year struggle since Transition from Development to Production was published, progress is seen in the top-level DoD defense acquisition policies and procedures which now focus on design and manufacturing, and require technical risk assessment. Instances of successful risk assessment and management, not only by Navy program offices but also other services as well, are increasing. With DoD acquisition reform phasing out military specifications and standards, we are convinced that focus on best design and manufacturing practices and processes, using technical risk management techniques such as those in Methods & Metrics for Product Success, offers the best opportunity for continued product success.

33-2
STRIPPING AWAY THE BUREAUCRACY:
A RETURN TO BASIC ENGINEERING PRINCIPLES
Brian D. Willoughby
Computer Sciences Corporation
ABSTRACT
Many of the problems in Government programs today are the result of a lack of engineering and scientific product and process engineering. We have moved away from running programs based on sound engineering and scientific decisions. Instead, we are making decisions based on bureaucratic considerations.
To help overcome these problems, CSC developed a series of expert systems and associated tools to provide acquisition personnel with Knowledge, Insight, and Experience into the world's most complicated technical process. This system, the Program Managers' WorkStation (PMWS), was created for the Best Manufacturing Practices (BMP) Program and is available to anyone in the U.S. industrial base.
A key PMWS tool is the Technical Risk Identification & Mitigation System (TRIMS). TRIMS establishes a technical risk management system utilizing a knowledge-based approach. The PMWS and TRIMS are fully compliant with the DoD 5000 series directives; yet, they are not cumbersome. These tools are regularly used by commercial industry throughout the U.S., Canada, and the United Kingdom.
A number of large programs are successfully using the PMWS tools. Some of these programs are CAS (Aircraft Automated Test Set), U.S./U.K. Surface Ship Torpedo Defense (SSTD), Photonic Mast, and P3 Upgrade.
There are many companies which have adopted PMWS as a standard. One such company is McDonnell Douglas. Still others, such as Texas Instruments, credit BMP/PMWS as a major contributor to their winning the Malcolm Baldridge award. A DOE facility, Martin Marietta Energy Systems (Oak Ridge Centers for Manufacturing Technology), operates as a BMP Regional Support Center. They are using PMWS tools to evaluate and improve their internal operations, as well as support regional businesses and educational institutions.
EXPEDIENCY OR ENGINEERING?
For the past few years, acquisition programs, and engineering in general, have been under attack by the troops from "buzz word land," e.g., TQM, QFD, Re-Engineering, CALS, CE, IPD, and many more. While these "buzz words" all represent potentially useful processes, in many cases we have become enamored with their infrastructure and philosophy and have lost sight of the goal -- improved profits, quality, and market share.
The engineering process needs to return full circle, back to the basic engineering principles of the past. However, the process will need to add a modern day slant through the use of COMPUTERS. Even though this will be a return to basic engineering principles, employing current computer technology, specifically expert systems, can improve the efficiency of the systems engineering process by orders of magnitude.
If the problems of today's Government acquisition community are to be solved, we must first understand how they got there or we will end up right back here at some future date. A key problem that has been identified is a lack of engineering knowledge on the part of senior decision makers. Today, MBAs and accountants rule the world of engineering; directives are written mandating the solution of technical problems (erroneously thinking this will magically solve the problem). Key front end

engineering practices are ignored because the benefits cannot be shown using limited or inappropriate accounting systems. Another factor is the past DoD budgets. These budgets were robust and made it possible to not worry about how well a system worked. The system could always be "fixed in the field," regardless of how inefficient or expensive that might have been.

As program failures increased, the oversight organizations (made up mostly of non-engineers) started adding "wickets" to the Defense Acquisition Process. These 'wickets" were added to insure program success, or so it was thought. In DoD, they are embodied in the current DoD 5000 series directives. At this point, it must be made clear that the writer is not against the DoD 5000 series, rather, against their use as an acquisition or engineering model. An effective acquisition program cannot follow a DoD 5000 model. Engineering should be based on a good Concurrent Engineering (CE) model and the results of this activity used as input to oversight reports, completed in a DoD 5000 format. This problem is further complicated by the fact that the DoD 5000 is a highly political document. Hence, it is subject to change at any time, routinely changing several times throughout the life of a program. Good engineering, on the other hand, remains essentially constant, unchanged by political events.

Problem

Engineering processes are evolutionary and technology breakthroughs cannot be directed. Good engineering cannot be based on bureaucratic considerations.

Solution

Decouple engineering from reporting and oversight models.

Results

Better, less expensive, products and more timely oversight data.

A SOLUTION: AN ELECTRONIC ENGINEERING CONSULTANT

What program managers' need is a super smart, experienced, fast thinking "Consultant" -- with a perfect memory. This "Consultant" would not only provide them with rapid access to sound engineering practices, but would lead them right to what they should be doing each day. The Program Managers' WorkStation (PMWS) shown in Fig.1 is the program manager's electronic "Consultant."

Fig. 1.

The PMWS was developed and is maintained by CSC for the Navy's Best Manufacturing Practices (BMP) Program, under the direction of Ernie Renner. The PMWS tools have been used successfully on many programs and are now available for use by anyone in the U.S. industrial base!

The PMWS consists of a series of expert systems and decision assistance tools. It provides knowledge, insight, and experience, in addition to an extensive network of information and software resources all easily accessible via PC. PMWS tools are centered on the systems engineering and acquisition process itself. If all engineering processes are understood, appropriate, and under control, the results will be as good as the state-of-the-art equipment will allow.

Workload reduction is a top priority of the PMWS. Typical project management tools, based on cost and schedule, use the graphical power of the computer to show numerous items on the screen at once. While these tools have their place and "master schedules" are critical for long lead planning and coordinating between organizations, there are many acquisition programs "failing" despite the use of these tools. Their power to display and "scroll" through data is enormous. The graphical interface makes it very easy for the user to maneuver through the data. However, they do little to reduce the heavy manager/engineer task loads; in fact, studies have shown that displaying large amounts of data tends to confuse the user and distract from focusing on the critical items that need attention. Rather then displaying potentially thousands of things involved in a particular program, or even the entire critical path, the PMWS typically shows the user the one to five most critical items that he or she should be concerned with NOW!

The goal of the PMWS is to do for acquisition personnel what the CAD terminal did for designers. CAD terminals allow designers to concentrate on designing instead of paperwork; likewise, the PMWS will allow program management personnel to concentrate on running their program(s).

THE POWER OF PMWS

Workload reduction is provided by the PMWS combination of knowledge, insight, experience, and communications features.

KNOWLEDGE through KnowHow, an automated and intelligent information access system

that speeds a search for required information by up to 95%. Typically, the information needed is on the screen in less than three minutes. This tool has several unique features. One is a high speed fuzzy-logic text search, capable of searching several inches of documention in only a few seconds. The system can be automatically tailored to users' needs. Both DOS programs and cut-and-paste in Windows features are supported.

INSIGHT through the Technical Risk Identification & Mitigation Systems (TRIMS), a technical risk management system illustrated in Figure 2 that identifies when corrective actions are required and who is responsible. This system can be tailored to a program's unique requirements. TRIMS currently has two knowledge bases for Systems Engineering and Software Development. TRIMS is compliant with the DoD 5000 series, NAVSO P-6071, DoD 4245.7-M, and the Software Engineering Institute's Software Risk Evaluation Methodology model.

Fig. 2.

Cost and schedule are downstream (sometimes way downstream) indicators of technical problems. This is why TRIMS monitors technical processes. It identifies engineering problems at the earliest possible point. In this way, problems can be addressed and mitigated before cost and schedule problems are indicated.

For example, if TRIMS indicates that a program has/is incurring a risk due to a Design Reference Mission Profile (DRMP) not being conducted; the user can go directly to the corporate knowledge base, KnowHow, and get full details on why a DRMP is needed and how to develop one, including metrics and examples. This type of problem would typically be identified by the PMWS early in the design process. However, cost and schedule indicators of this problem usually will not surface until the operational test and evaluation process; when the system did not perform properly because the design environments did not reflect current life cycle operational environments. This is just one simple example of how the PMWS can support the program manager.

EXPERIENCE through the Best Practices Database; proven and verified solutions from industry, government, and the academic community can be applied to a program. Table I presents a sample database output.

TABLE I

COMMUNICATIONS through BMPnet. Currently, BMPnet is used to facilitate communication between DoD components - DOE, DOC, FAA - and commercial companies. As shown in Fig. 3, program managers can now simply and easily communicate with each other when solving problems, gaining insight from each other's experiences.

Fig. 3.

BMPnet provides several productivity-enhancing tools. As an example, E-mail is available with several unique functions. The system not only records each user's name, but, also cross-references each user to any Special Interest Group (SIG) in which he or she has expertise/interest. In this way, a user can send a message, for example, to the welding SIG (via BMPnet or Internet) and every user who signed up as an expert in welding will get the message - even though the sender does not know them personally. The ability to "CHAT" with other users online is also provided by BMPnet. Nine "conference rooms" are available to hold online conferences, of up to six people, for problem solving that requires a quick turnaround. The system will even take notes automatically.

All PMWS programs can be downloaded from BMPnet for use on local computers/Networks.

CONCLUSION

Many programs are presently reaping the benefits that the PMWS has to offer. Currently, more than 10,000 copies of the PMWS software have been distributed, with the BMPnet answering more than 50,000 calls per year. PMWS success stories include: the Navy CASS program ($1.2 billion and failing - now exceeding requirements); McDonald Douglas (adopting PMWS company-wide); U.S./U.K. Surface Ship Torpedo Defense Program ["best IPS Risk Management Annex D ever seen" by ASN(RDA)]; Texas Instruments (significantly helped in winning the Malcolm Baldridge award); P3 Upgrade program (mandated use); and the Photonic Mast and Universal Modular Mast programs (required TRIMS assessment with proposals).

Through the use of current PMWS tools and the expansion of this methodology in both breadth and depth, acquisition managers and systems engineers will have an ever-increasing knowledge base to draw from. Future enhancements to the PMWS are currently underway. These enhancements include: fuzzy logic text searches for the BMP database; a performance specification generator based on the proven KnowHow

technology (with editing and formatting capabilities); expanded Internet capabilities (WWW, TCP/IP remote control of BMPnet sessions); Windows versions; distribution on CD-ROM; lexical analysis links between PMWS programs; and much more. While pleased with the current PMWS product, both CSC and the BMP Program Office are firmly committed to continuous process improvement. People are asked, with an open mind, to put the PMWS tools to use; they are then encouraged to call or E-mail comments to the PMWS Help Desk personnel (703-538-7253). The PMWS is the user's tool. It would not be what it is today without the quality feedback that has been received from its users.

You are invited to experience the expanding benefits of the PMWS. Exercise sound engineering-based decisions while you advance the competitiveness of the U.S. industrial base and the Nation.

ACQUISITION AND CONSOLIDATION FOR SUCCESS AND SURVIVAL

Len M. Stuessel
John J. Sennikoff
Hughes Missile Systems Company

ABSTRACT

The steadily declining and changing nature of the defense business in the 1990's requires dramatic action on the part of defense contractors. The ability to effectively and efficiently face this competitive challenge is a matter of survival. In August 1992, the Hughes Aircraft Company acquired the Air Defense Systems Division and the Convair Divisions of General Dynamics and on January 1, 1993 merged the acquired activities with its Hughes Missile Systems Group to form the Hughes Missile Systems Company (HMSC). The physical consolidation of the HMSC activities in the Hughes Tucson, Arizona plant resulted in one of the largest and most ambitious industrial defense consolidations in US history. The Manufacturing consolidation was planned and completed within eighteen months and the Engineering consolidation within twenty-four months of the acquisition.

Consolidation planning methods were developed based on critical element definition, risk assessment and risk management. Transition and consolidation planning techniques were established based on an adaptation of the "Willoughby Templates" and a planning review process established which involved customer representatives. Six major in-production programs, seven key associated manufacturing processes and nine technology-based engineering transition teams were formed. A real time system of lessons learned feedback was employed to refine and modify the planning and implementation process as new transition teams were established. The major lesson learned during the merger and consolidation was that personnel issues were the most complex, demanding and important issue addressed. Transition planning and implementation examples will be presented along with a discussion of what worked particularly well, and what did not.

DISCUSSION

Fiscal Year Defense Planning (FYDP) in the 80's was typically overly optimistic in terms of availability of defense spending dollars. During the late 80's and on into the early 90's, it was becoming more apparent that defense spending was to be drastically curtailed (See Fig. 1). To survive in this financial environment, it became obvious that contractors would have to obtain 'critical mass' through liquidation, restructuring and/or consolidation, buying, selling or merging, or some combination of these activities. Companies were forced to respond to unpredictable, accelerating change and many contractors were experiencing an excess of facilities, equipment, real estate and personnel. In the face of reduced business volume,

overhead rates were soaring while compliance with procurement procedures remained unchanged.
Fig. 1.
Hughes responded to this crisis by initially committing to remain in the tactical missile business. Then, in an effort to obtain 'critical mass', Hughes acquired the General Dynamics missile businesses. It established the Hughes Missile Systems Company as a subsidiary of GMH Electronics by merging the Hughes Missile Systems Group and the General Dynamics missile businesses into a single unit. Further, it was decided to consolidate all manufacturing and engineering assets in Tucson, Arizona. In the end, real estate was trimmed from 9.0 M to 3.5 M square feet, employment reduced from 14,000 employees to 8,000 of which approximately 3,000 employees were relocated to Tucson.
In order to accomplish the consolidation and relocation efforts, a significant planning exercise was undertaken to determine the methodology for doing it. No data was available relating to an effort of this magnitude. During this review process, it was decided to utilize the "Willoughby Template" approach because of the risk assessment/risk management philosophy embraced by these guidelines and the rigorous discipline imbedded in the implementation process. This uniquely developed planning process was utilized for each transition team. This process is shown pictorially in Fig. 2.
Fig. 2.
Each transition team was required to receive the same training in terms of format followed with particular emphasis placed on risk identification, risk assessment and risk mitigation techniques. As each team progressed through its planning cycle (typically on the order of 6-8 weeks), lessons learned from earlier teams were transferred to the next team in the process. Each transition team was comprised of cross-functional organization representatives who were responsible for determining the planning parameters for their particular area of responsibility. Figure 3 illustrates a typical example of this representation.
Fig. 3.
The first transition team to conclude its planning activities and physically complete its relocation and consolidation was the Tomahawk program in January of 1993. Within a year of its transition, Tomahawk all-up round assembly time had not only duplicated prior performance levels in San Diego, but total assembly time had been reduced from an average of approximately 100 hours to 55 hours. This was primarily attributed to a new workforce looking at assembly procedures with "new eyes" and not constrained by traditional approaches. A comment made by one of the manufacturing managers was that "...a brand new workforce isn't necessarily bad", and in this case was a positive influence on the program. In September of 1994, it was announced that HMSC had won the Tomahawk single-up bidding against Mcdonnell Douglas, a contract worth approximately $1 billion over the next five years. The successful transition of this program, and of course, many other factors contributed to this success.
Results on other programs have been equally dramatic. Although the AMRAAM program was resident in Tucson during the consolidation process, improvements implemented during this period in the Seeker assembly area resulted in a:

- 41% productivity increase
- 36% WIP decrease
- 68% area layout decrease
- 28% lead time decrease

Stinger guidance section and seeker test yields were 5% higher than average results at General Dynamics/California operations. TOW test yields exceeded the 99% 1994 goal.
By mid-year 1994, all production programs had transitioned to Tucson on schedule, the last being the Stinger program. All engineering transition activities were completed by year-end. Four engineering organizations were combined into one; engineering managers were reduced from 240 to 70 and layers of management were reduced from four and five to three. Total relocated personnel to Tucson from the various off-site locations was approximately 3,000. In general, reduced operating costs resulted from efficient use of facilities, assets and a very skilled workforce.
A number of factors were responsible for the successful transition of the overall effort. HMSC constantly appraised its customers of transition status and involved

them in the teaming activities. Dedicated transition team leaders were selected for close-out activities and were not tied to new organizational structures. All production systems and processes were moved "as-is" so as not to introduce any new variables during the transition process. Key to the entire effort was the detailed and disciplined up-front program transition planning that was imposed on every team. Most important, we sustained financial performance and achieved all major transition milestone dates during the consolidation process.

To be expected with a consolidation of this magnitude, some things did not go as expected. The impact of the consolidated procurement and dock-to-stock transition overwhelmed the system in Tucson. For example, requirements increased from about 4,000 to 50,000 parts per month. The engineering transition decision, which occurred after the operations transition started, resulted in a change of receiving inspection location and delayed its timely installation. There were difficulties encountered in combining five different MRP systems into one. The sale of the Camden, Arkansas CCA facility fell through near the end of transition resulting in loss of job security for its personnel and the lost of a number of key personnel. Transferred kits were inaccurate with parts shortages, and combined with the planned reduced area capacity, resulted in a 9 month - 1 year delay in getting back up to rate production.

There were situations that arose that could not be avoided as a result of the relocation/consolidation decision. Our customers felt at risk until success could be demonstrated; the best people in the organization had the greatest ability to leave the company. Systems, procedures and terminology differences between sites caused confusion and delay and the housing/rental market differences between California and Tucson caused considerable consternation.

As a result, there were a number of considerations that were noted to be used as suggestions for improvement for the 'next time'. On September 12, 1994, Hughes announced the details of the new Hughes Aerospace and Electronics (HAEC) company. HAEC headquarters would be based in Washington D.C.; activities would be consolidated into four business units (Radar, Communications, Electro-Optical, and Weapon Systems); 3M square feet of office and manufacturing space will be vacated over the next 18 months, primarily affecting the Hughes Fullerton operation in California. The Fullerton plant (about 286 acres of real estate), would be basically closed down, transferring operations to El Segundo and Long Beach, California and several Southeast sites with an announcement that approximately 4,000 employees would be laid off by year-end 1995.

Things that needed improvement were deemed to be the following:

- Sell the consolidation/transition strategy to the employees
- Define the new organization and leaders early
- Identify process owners up-front
- Accelerate the decision making process
- Execute the program transition per the developed plan
- Communicate better and more frequently to all affected employees
- Reduce the time span for consolidation
- Make the tough staff reduction decisions and do it
- Facilitate empowerment
- More realistically consider the volume and capacity of affected systems

SUMMARY AND CONCLUSION

One of the most important elements in the success of the Tucson consolidation was the early involvement and participation of all Hughes customers. It was critical to sell them on the benefits of the plan and get 'buy-in'. Essential to the plan was the early selection of organizational and process leaders who could assist in the staff reduction decisions and selling of the business strategy on a one-to-one employee basis. It was recognized that once the implementation phase of the plan began, that it was important to move rapidly to sustain the momentum of the previous intense planning efforts. Tough decisions had to be made in not changing any more than was really necessary to consolidate and that after the consolidation was completed to then implement improved processes and procedures, and of course, to continually address staff size and performance.

Although the consolidation effort wasn't perfect, HMSC successfully completed a very challenging consolidation involving differing cultures, people and products. It was found that management attention was equally important at both the sending and receiving facilities; it was easy to neglect or give only passing attention to the

facilities to be shut down. Problems with differing processes and systems cannot be over-emphasized. If there was only one major lesson learned throughout this entire process, it was that successful handling of people and people related issues was dominant in ensuring consolidation success. This knowledge was utilized again in the formation and consolidation of the HAEC organization which predominantly affected the Hughes Fullerton operation. This facility will be, with minor exceptions, closed down and selected employees will be given the opportunity to continue employment with other Hughes sectors.
The process of becoming (and remaining) competitive . . . is never ending, and as the Hughes organization continues to change over time, all the lessons learned to help assure success will be recorded and utilized.

33-5
TECHNOLOGY TRANSFER:
A PERFORMANCE-BASED SYSTEM
James E. Ferguson
Planning and Evaluations
Office of Technology Transfer
William R. Martin
Vice President
MMES
Office of Technology Transfer*
ABSTRACT
The paper briefly describes the performance-based system used to assess technology transfer activities at the Department of Energy facilities in Oak Ridge, Tennessee, managed by Martin Marietta Energy Systems, Inc. The progress of program activities is measured and evaluated by selected indicators. Results are discussed and benchmarked against other leaders in the field. Efforts are under way to achieve a step-function additional improvement in performance, with several new emphasis areas discussed.
INTRODUCTION
Technology transfer projects need to be performance based to 1) effectively analyze risk and benefits before initiation, 2) effectively negotiate the terms and conditions of the project with the collaborating partners, 3) maintain cost and performance tracking during the project, 4) measure the "outcome" of the project after its completion, and 5) determine if the achievements of the project can be applied elsewhere to important needs, thereby leveraging the taxpayer's and the private sector's investments.
The primary focus of this discussion will be on number (4), methodologies used to measure and evaluate the success of our technology transfer programs.
PERFORMANCE MODEL
The foundation for a performance-based system is a performance plan (including strategic and operational elements) to give direction and to establish goals that must be accomplished. Achievement needs to be measurable by key performance indicators appropriate to the activity involved. The performance model we are using is shaped after the Deming Cycle (some know it as the Plan, Do, Check, Actor PDCACycle) set forth by Dr. Edwards Deming (Fig. 1). A strategic plan was developed in which 11 key strategic goals were established. The planning horizon was the year 2000 and beyond. Our vision for technology transfer is that the commercialization of Oak Ridge technologies will have national impact on the economy, thus creating high-value private sector jobs.
Fig. 1.
This discussion will concentrate primarily on the "evaluation" portion of this model, with brief comments on the "execution" and "improvement" elements to illustrate specific points.
Performance evaluation is key to understanding and improving our technology transfer processes. Internal evaluations of federal technology transfer have traditionally focused on easy-to-count items such as the numbers of licenses and numbers of Cooperative Research and Development Agreements (CRADAs) signed. Much government- and academic-sponsored researchby recognized experts such as Barry Bozemen and David Roessner of Georgia Institute of Technologyis being conducted to explore methodology useful in the systematic assessments of the technology transfer processes. However, measuring the effectiveness is complicated, and no consensus exists to date

regarding a best method.
Technology transfer includes many different technologies and is accomplished through many different transfer mechanisms:
- licensing,
- cooperative research and development,
- industrial assistance and consulting,
- guest workers and personnel exchanges,
- use of facilities,
- contract research, and
- alliances and partnerships.

Usually, one thinks of licenses or CRADAs with the ultimate metric being jobs, invested capital, or new products and services. However, no universal measure of success is available. Technology transfer depends on the particular partner's need, technology area, and the mechanism that is employed.
The objective of our technology transfer program is commercialization of technology, with the ultimate impact being to strengthen and grow the economy. Within this context, time is an important element in the overall process. In particular, the time requirements for commercialization vary significantly (Fig. 2).
Commercialization of some technologies occurs faster than others; for example, software can take a 6- to 12-month cycle compared with advanced materials, which may
Fig. 2.
have a 10-year cycle. This time factor is important to consider when measuring and evaluating private sector benefits from a particular technology transfer program. This time element can also mean one may have to rely on process measures to evaluate performance in the early stages, followed by such indicators as capital investment, research and development spending, and jobs created as the technology moves along the commercialization cycle. In addition, one must recognize that these ultimate measures are long-term in nature, with statistical viability not being realized for 5 to 10 years.

EVALUATION

Using widely recognized process metrics, FY 1994 data indicate a strong technology transfer performance from Oak Ridge (Table I). These performance levels showed a significant increase over FY 1993 levels. However, one cannot escape the fact that performance can be affected by external factors, for example, financial stability, market dynamics, luck, and the home run hit! If you look just at the numbers from our licensing program, we are achieving good success for a 10-year-old program (Fig. 3): 23 licenses in FY 1994, with a cumulative total of 113 at the end of FY 1994. These licenses, which generated royalty revenues of $520K in FY 1994 alone, have generated a cumulative total of $2.8M over the life of the program. When comparing our performance with other Department of Energy (DOE) federal laboratory systems, Energy Systems is one of the leaders. When comparing our performance with top universitiessuch as the multiple campuses of the University of California, Massachusetts Institute of Technology, and Stanfordwe are lower; however, ages of our programs differ, as do the types of technologies being transferred.
Fig. 3.
Our Energy Systems technology transfer organization is participating in one of six DOE Reinventing Government pilot projects. The focus of this technology transfer pilot is emphasizing planning, measurement, and evaluation efforts. Program elements at DOE Headquarters and at the Operations Office as well as selected contractors are involved. Four of our strategic goals were selected to measure, evaluate, and report on performance during the life of the pilot (Table II). Each of these goals has three to six performance indicators that are tracked and evaluated. Results after the first year demonstrated performance above expected levels for three of our four goals. Expectations are that at the end of the pilot phase (1995-1996), the lessons learned will be shared throughout the DOE technology transfer community, thus resulting in adoption of more consistent measurement methods.
The technology transfer program at Oak Ridge is in transition, striving to attain a step-function improvement in performance. We are moving from the "numbers game" to a more focused attention on private sector impact aimed at improving regional and national industrial competitiveness as a result of our programmatic technology transfer efforts (Fig. 4). Our activities will place more emphasis on 1) technology commercialization via licensing; 2) proactive industrial regional assistance such as Technopolis, the 21st Century Jobs Initiative, to assist the region in utilizing

DOE-developed technologies; and 3) technical assistance to small- and medium-sized businesses.
Self-assessment and benchmarking efforts are leading to changes to improve and strengthen our licensing program. Changes are targeted to improve 1) interfacing with corporate Business Development leaders, who can be sources of future deals; 2) nurturing after completion of a deal; 3) increasing the experience base of internal staff through lessons learned workshops, intermediaries, and collaborative efforts; 4) developing improved licensing strategy methods; and 5) encouraging the entrepreneurial development of new ventures by way of new company starts.
Fig. 4.
Customer feedback is an important source of information to measure the success of any business effort. In actuality, it is the ultimate test because without satisfied and repeat customers, one will not be successful. We are making an active, consistent, and sustained effort to survey our customer base to measure and evaluate their satisfaction with our technology transfer interactions. At the same time, our organization is attempting to avoid typical traps of 1) "pestering" our industrial partners for data or 2) requiring the disclosure of competitive information considered to be proprietary in nature. This feedback is improving our understanding of the impact these interactions are having on their customers' businesses; in addition, we can use this information to drive change. Conducting customer feedback surveys also serves to market our services as being truly customer oriented.
INCENTIVES
Incentives are an integral part of any performance-based system. Three incentive systems particularly important to the technology transfer program are 1) award fee; 2) royalty sharing, including both inventors and technology maturation; and 3) recognition and reward. These incentives impact all levels of our business from the corporate level to the scientist or principal investigator. Technology transfer has high visibility with our DOE sponsor and with Congress. For this reason, technology transfer performance is designated a "special emphasis area" in the Martin Marietta Energy Systems award fee contract with DOE. Our inventors and support personnel receive 25% of the royalty funds from licensed inventions annually. This amount has reached approximately $700K over the life of the program. In addition, 25% of royalty revenues go back to the technical organizations to support further maturation of selected research and development projects. This money helps ensure the continued support of the technical community and helps provide future sources of technology for licensing and commercialization. An additional incentive is the recognition and rewards received for accomplishments from technology transfer activities. These accomplishments are integrated into our performance reviews and our reward systems and are used to promote and encourage involvement in the program. One of our strongest incentives and motivations is to improve the benefits of the program so that the value of technology transfer programs is recognized from a cost-benefit perspective. We are attempting to shift our paradigm. The goal is to move from a 100% government-funded effort to a program that is fully supported by royalty revenues. This change will make us be driven by a bottom line and will move us closer to the business environment of our private sector partners.
CONCLUSION
These are challenging and exciting times for the federal laboratory technology transfer community. Given the changing political climate and tight federal budgets, increased pressures will exist to demonstrate the contribution programs make to the national economy. Significant progress has been made over the life of the program (the past 10 years). The future challenge is to double orin some casestriple these performance levels in half the time: a difficult job . . . yes, but we believe we know the path to success.

ABSTRACT
Los Alamos National Laboratory (LANL or the Laboratory) is developing and implementing a comprehensive, Integrated Standards-Based Management System (ISBMS) to enhance environmental, safety, and health (ESH) compliance efforts and streamline management of ESH throughout the Laboratory. The Laboratory recognizes that to be competitive in today's business environment and attractive to potential partnerships, Laboratory operations must be efficient and cost-effective. The Laboratory also realizes potential growth opportunities for developing ESH as a strength in providing new or improved services to its customers. Overall, the Laboratory desires to establish and build upon an ESH management system which ensures continuous improvement in protecting public health and safety and the environment and which fosters a working relationship with stakeholders. A team of process experts from the LANL Environmental Management (EM) Program Office, worked with management system consultants, and the Department of Energy (DOE) to develop an ESH management systems process to compare current LANL ESH management systems and programs against leading industry standards. The process enabled the Laboratory to gauge its performance in each of the following areas: Planning and Policy Setting; Systems and Procedures; Implementation and Education; and Monitoring and Reporting. The information gathered on ESH management systems enabled LANL to pinpoint and prioritize opportunities for improvement in the provision of ESH services throughout the Laboratory and ultimately overall ESH compliance.
Preliminary results of the ESH management systems self-assessment were analyzed to determine trends, and compliance management system gaps and redundant activities. Based on the study results, LANL identified short-term and long-term goals for improving the ESH compliance process throughout the Laboratory, and options for achieving the goals. The Laboratory is using this baseline of ESH management systems performance to establish a framework for identifying, developing, evaluating and implementing ESH compliance requirements. By assessing its baseline performance and utilizing benchmarking data to reeingineer the ESH compliance management process, LANL is laying the foundation in its effort to establish a Laboratory-wide ISBMS.
BACKGROUND - ESH MANAGEMENT SYSTEM SELF-ASSESSMENT
The LANL EM Program Office initiated the effort to improve its formalized ESH management system. To be successful, an ISBMS must: establish management commitment to ESH compliance; assure compliance with external and internal requirements; focus on prevention and continuous ESH improvement instead of "fire fighting;" reduce costs of compliance and increase competitive advantage; and identify related operational and ESH costs including short and long-term liabilities, thereby revealing hidden costs and potential benefits.
To accomplish this task, LANL's EM Program Office contracted Environmental Resources Management (ERM) to jointly conduct an ESH management systems self-assessment and to provide a process and framework for enhancing existing management systems. ERM's approach addresses three fundamental questions:
Where is the Laboratory Now? To determine the current performance of the Laboratory's ESH management systems.
Where Does the Laboratory Want To Be? To identify a set of goals and measurable objectives for improving ESH management systems throughout the Laboratory.
How Does the Laboratory Get There? To design and implement an Integrated ESH Standards-Base Management System to facilitate the achievement of Laboratory goals and objectives.
The scope of the self-assessment covered Laboratory-wide management systems for compliance, monitoring and prevention programs for air quality, water quality, solid, hazardous, radioactive and mixed wastes, environmental restoration, occupational safety and health, training, emergency preparedness and response, recordkeeping and reporting, measurement and improvement, hazardous and nuclear materials management, and process safety. The self-assessment addressed ESH programs at the Division, Group, and facility levels, focusing on both Laboratory research and operations.
Assessment Methodology

A proven private sector methodology, the GEMI ESAP (Global Environmental Management Initiative's Environmental Self-Assessment Program) coupled with established "best-in-class" management system elements was used to benchmark Laboratory's ESH management systems. The ESAP is a management tool designed to assess an organization's progress in meeting the intentions of the International Chamber of Commerce (ICC) Business Charter for Sustainable Development. The ESAP tool was customized to address the unique characteristics of the Laboratory and was also supplemented to include elements of the International Standard Organization's draft Environmental Management Standard (ISO 14000), as well as the Malcolm Baldrige National Quality Award criteria. Together, these standards define the "best-in-class" ESH management system characteristics and provide the Laboratory with a pathway to achieve improved performance in ESH management.

The modified ESAP is comprised of sixteen principles for effective and sound ESH management. Each principle contains a series of elements which describe the management systems and activities necessary to implement the principle. Each element contains four successively comprehensive performance levels, which allows respondents to rate the Laboratory's performance from one to four. A score of "one" indicates a baseline level of compliance where management systems are reactive and informal and regulatory compliance is not always achieved. Level "two" indicates that formal management systems are in place to maintain compliance. A score of "three" indicates the presence of an integrated ESH management system that ensures the facility always meets or exceeds compliance. Level "four" indicates that a fully implemented, integrated ESH management system with total quality management is in place that allows the facility to always exceed compliance. The protocol also requires the respondents to weight the importance of each element to arrive at a weighted average score for each principle. Figure 1 presents LANL's self-assessment results for one of the management principles - Process of Improvement. The Laboratory achieved a level of 1.5 based on the status of ESH management systems processes of improvement. System elements necessary to improve performance to successive performance levels are described at each increasing level of compliance.

Fig. 1

To conduct the assessment, representatives from 39 Laboratory organizations, plus Johnson Controls (LANL's facility support contractor), and DOE were interviewed using the modified ESAP protocol. Interviewees comprised "top-to-bottom" LANL personnel including senior and mid-level Laboratory management, facility managers, line staff, and ESH coordinators. These interviewees provided substantive insights regarding the performance of ESH management systems throughout the Laboratory. ERM also reviewed documentation of numerous Laboratory and DOE policies, strategic plans, procedures, requirements, and reports to supplement the understanding of Laboratory organizations and activities.

COMMON THEMES FROM THE SELF-ASSESSMENT

The self-assessment results were presented to the interviewees and other Laboratory personnel with ESH-related responsibilities. LANL's results are illustrated in Fig. 2. LANL's self-assessment results can be grouped into the following topics: Laboratory ESH Management Systems; Accountability, Priority, and Goals; Integration; and ESH Issues Management. The following discussion summarizes self-assessment observations on these topics.

Fig. 2.

Laboratory ESH Management System

Basic components of an ESH management system include: Strategic Planning; Organizational Roles and Responsibilities; Policies and Standards of Performance; Programs and Implementation;

Training and Communication; and Measurement of Performance. Overall, the assessment revealed that basic ESH management systems are in place for the majority of issues identified in the assessment protocol. However, many of these management systems are ad hoc, fragmented or not Laboratory-wide.

Due to fragmentation and inconsistent application, some ESH management systems are perceived as ineffective and are, therefore, not utilized by many of the respondent organizations. Once systems are established, however, they become entrenched and are not systematically evaluated for improvement opportunities.

Although an overwhelming array of ESH policies and procedures, administrative requirements and internal Laboratory standards define "what is required," a lack of

"how to" guidance for operations and facilities impedes implementation. The requirements do not assign responsibility, or define criteria for measuring performance. Consequently, without supporting management systems and limited tools to interpret, customize and implement requirements, compliance cannot be sustained.

Accountability, Priority, and Goals

Accountability is critical at each level of the organization to ensure that individual responsibilities for ESH management are defined, communicated, understood, and fulfilled. Accountability starts with top management commitment through identifying ESH priorities and goals and establishing policies and standards of performance. It also occurs through such measures as effective oversight and monitoring, routine reinforcement of positive performance, written job descriptions, written performance standards, and when performance lags, disciplinary action.

The self-assessment results indicate a lack of accountability for ESH performance throughout Laboratory organizations. Although staff and management interviewees voiced a personal commitment to ESH performance, most respondents indicated that ESH priorities, goals, and expectations are undefined, and it appears that effective systems are not in place to hold management accountable. Respondents were quick to point out that in an environment of competing priorities and resources, responsibility for ESH compliance is often shifted to individual ad hoc initiatives versus an organized, systematic, integrated effort.

Integration

As discussed in the Assessment Methodology section, Laboratory ESH management systems were benchmarked against performance criteria contained in the ICC Business Charter, ISO 14000, and Baldrige National Quality Award. A fundamental principle of these standards is the integration of ESH systems with mainstream operating and business activities of an organization. The most effective and efficient ESH management occurs by identifying and addressing ESH issues routinely within the context of day-to-day management, operating, and research functions.

The self-assessment results indicate that ESH roles and responsibilities are not consistently integrated with position descriptions, ESH procedures are not integrated with standard operating practices, and communication of ESH priorities is not generally integrated with existing forums and mechanisms for communicating Laboratory-wide initiatives and priorities.

The Laboratory has undertaken efforts to integrate ESH management as evidenced by recent ESH re-engineering activities, and development and implementation of a Facility Management Model, which will streamline and coordinate building management functions, including ESH. These are important steps in moving the Laboratory from a reactive, crisis management-mode of operation to preventive, cost-effective consideration and attention to ESH issues.

ESH Issues Management

ESH issues management is a critical function in an effective ESH management system. An issues management system facilitates the identification, tracking, evaluation, and response to new information, such as upcoming regulations or advances in technology, allowing an organization to proactively manage ESH issues.

At the Laboratory, ESH issues typically are recognized when they pose a potential problem. Extensive efforts are then made to characterize and assess the issue, often with no attempt to match dedicated resources to the seriousness of the problem, and without assigning "ownership" to ensure the issue is resolved. Extensive resources are also directed at collecting ESH data; however, little attempt is made to determine which data is important for operations, and should be funneled to the operating groups, and which data is for DOE consumption or external public relations. While these efforts to collect and disseminate information and data are necessary, it is equally important to synthesize and prioritize information for the end user. As a result, critical ESH issues may not get the attention they deserve, while other less significant problems may reap ample resources which may not be warranted. This is especially evident with regard to DOE Orders. Interviewees noted that continually shifting priorities from DOE leads the Laboratory to inefficient issues management.

Similarly, tremendous resources are expended in preparing for and responding to continuous and simultaneous ESH-related audits (by DOE, New Mexico Environment Department, US Environmental Protection Agency, and internal auditors). Audit prioritization and rationale are often not communicated, and corrective actions responding to audit findings do not focus on improving the management systems which

are, in many cases, the root cause of the deficiencies.

INTEGRATED STANDARDS-BASED MANAGEMENT SYSTEM

Results of the ESAP self-assessment, and preliminary improvement goals and objectives were presented to senior Laboratory management (the Operations Working Group) in early August 1994. Coincidentally, DOE Headquarters had begun a number of new initiatives designed to move the Department and its subcontractors from a compliance-based approach to regulatory requirements to a performance-based approach. Inherent in these initiatives are efforts to reduce DOE Orders and establish standards for documenting expectations of how work will be performed. To address this initiative, the Operations Working Group established a Standards Committee in early Summer 1994 to review current Laboratory standards and identify a process to develop and implement one consistent set of Laboratory standards. Additionally, the Operations Working Group established the Compliance Process Team (CPT) to work with the Standards Committee to evaluate specific ESH compliance-related requirements and ongoing activities throughout the Laboratory to address the requirements.

Subsequently, the Operations Working Group directed that the ESH management system project and the Standards Committee be merged with the initiative to move the Laboratory toward an ISBMS in accordance with Criteria for DOE's Standards Program. This entire effort is currently under the direction of the CPT. Key elements of the Integrated Standards-Based Management System as it has been defined by the CPT are depicted in Fig. 3.

Fig. 3.

The ESAP self-assessment established a performance baseline, including system gaps and overlaps, for broad, Laboratory-wide ESH issues. To supplement the assessment results, additional information was gathered by the CPT from throughout the Laboratory to identify and better understand specific program initiatives, efforts, and institutional functions and organizations addressing ESH compliance. This effort confirmed the preliminary ESAP self-assessment results, that redundant efforts to develop compliance standards, collect performance data and conduct audits are routinely occurring without coordination, integration, or communication. Additionally, systems are not in place to ensure implementation of standards, measure and improve compliance performance, or to hold employees accountable.

The findings were presented to an expanded group of representatives from numerous Laboratory Divisions, Groups, facilities, and levels of management at workshops conducted by the CPT in December 1994 and January 1995. The goals of the workshops were to: verify and enhance the identified list of redundant ESH compliance activities and system gaps; evaluate options for eliminating redundant activities and closing system gaps; and determine preliminary goals and actions to move the Laboratory towards an ISBMS.

To identify redundant ESH compliance activities and system gaps, workshop participants defined the "As Is" process flow of each management system element in Fig. 3. Workshop participants then defined how each system element process flow "Should Be," following the ISBMS approach advocated by DOE. This effort to define the "Should Be" process flow included establishing detailed procedures and organizational roles and responsibilities for identifying applicable ESH requirements, developing standards, implementing standards, and measuring and improving performance for each management system element in Fig. 3.

The Laboratory's ISBMS will address customer (DOE) requirements, prioritize compliance activities, define areas to be measured, and establish a continuous improvement process. The preliminary ISBMS is under review by DOE Headquarters and senior Laboratory management. The Laboratory CPT is proposing to "jump start" the system by developing preliminary Laboratory-wide standards by mid-June 1995 and finalizing the standards by November 1995. Additionally, the CPT is proposing to test the ISBMS by modifying and implementing a Laboratory standard to address radiation worker protection requirements of 10 CFR 865 as a pilot ESH compliance project.

SUMMARY

The implementation of an ISBMS will allow the Laboratory to align current efforts for assuring ESH compliance while eliminating system gaps and overlaps. By identifying goals, objectives, responsibilities, accountability, and measurable endpoints, the Laboratory can achieve its goal of cost-effective compliance assurance.

SYSTEMS MANAGEMENT - A CLASSIC WAY TO APPLY SYSTEMS CONCEPTS AND SYSTEMS ENGINEERING PROCESSES FOR LARGE, COMPLEX PROGRAMS

K. M. Tominey
S. C. Marschman
Pacific Northwest Laboratory

ABSTRACT

Classic systems management represents an alternate way to use conventional systems engineering (SE) techniques, particularly when dealing with large complex programs. SE has tended to emphasize specific techniques for analyses and drifted away from thoughtful consideration of the implications of work in complex systems. This technique-over-art focus is powerful because of its narrow focus. The narrow focus is clear in terms of what it depicts, but what is depicted is not necessarily complete; this condition leads to less successful systems.

Classic systems management, as articulated by practitioners in the mid-60s and early 70s (1), provides relief from this overly narrow focus. These practitioners directed attention to the broad, holistic nature of the real environment that makes up our systems. They recognized that complex undertakings involve many more influences, both external and internal. This complexity and fuzzy definition means that the systems developed to respond to complex undertakings must be able to evolve. Both external and internal influences are integral parts of the system. External influences, or externalitites, are such considerations as societal values, public policy, or markets. Internal influences, or internalities, are such factors as organizational values or the design system. In classic systems management any major human activity exists in and produces systems that are holistic, open, and dynamic. The term holistic includes factors that influence a system and creates more complex, less well-defined systems than envisioned by conventional SE. This type of system means that the use of SE methodologies is even more important. However, SE has difficulty with such systems because they are fuzzy both in terms of defining boundaries and in dealing with change. Systems problems are pared and defined to fit technique capabilities rather than the reality of the environment. We can free ourselves from the pitfall of rigid adherence to technique by using the classic systems management vision of open, dynamic systems. Such systems can integrate influences that may not be obvious interfaces in conventional systems.

The Hanford Site Systems Engineering effort is an example of the holistic approach

of classical system management. The set of system functions from this effort includes Program Management, Stakeholder Acceptance, and Acquiring Capability. These nonconventional functions are provided equal weight by the decision makers with the more conventional function of "Remedy Unsafe or Unacceptable Conditions." The overall system being created to meet these functions can be more realistic because it responds to critical influences of the real environment. This kind of system is unconventional but realistic given the scale and context of the mega-sized mission at Hanford.

Conventional systems engineering methodologies are essential tools to use in this process, but need a modified paradigm in terms of defining the environment for large complex undertakings. Classic system management provides that modified paradigm and bridges the gap left by using conventional SE on the unconventional environment for such undertakings.

ACKNOWLEDGMENT

Pacific Northwest Laboratory is operated by Battelle Memorial Institute for the U.S. Department of Energy under Contract DE-AC06-76RLO 1830.

THE ISSUES OF EMOTIONAL FEARS AND TECHNICAL REALITY--INCINERATION WORKS

Edward J. Martin, Ph.D.,P.E.,DEE
Executive Director
Hazardous Materials Control Resources Institute

ABSTRACT

In the public outcry over the risks of hazardous waste incineration, it's important to fight fire with facts. Misperceptions and bad information can be overcome, but how much is the federal governments reaction adding to public reluctance to accept this effective form of waste disposal and reduction?

NO SECOND CHANCE FOR A FIRST IMPRESSION

In the arena of public reputation, how issues arc perceived is usually more important than what those issues actually are. Politics is a great example of this. But so, unfortunately, is the business of waste management--especially when it comes to hazardous waste incineration.

By way of an example, one can imagine oneself in the role of an ordinary citizen, and picture whatever comes immediately to mind when the word: "Furnace" is used. The image most people come up with is the friendly little machine in the basement that keeps them from being cold during the winter months. It's usually a pleasant association.

But something happens when the word "Incinerator" is used. All of a sudden, the mental image of the little heating machine turns into that of a bigger, more menacing, apparatus--usually either belching smoke or barely containing the fire within it. The word incinerator is widely taken to imply destruction. And this is not wrong; whatever is in the incinerator is going to be destroyed. But the implied threat to humans in that destructive force is hard to get past.

The situation is even worse if the image is a amplified to: "Hazardous Waste Incinerator." The mind's eye has now added a dimension to this picture that no amount of P.R. yet has overcome. The mental association with danger has shifted from implied to explicit--there may be radioactivity, toxic gases, noxious smoke, or invisible fumes. Psychologically we have crossed from the territory of fear into the realm of potential death.

Is this just a word game? A battle of competing images that the hazardous wastes industry has lost? I believe it is more than that. We need to use facts to overcome fear, and to learn that rhetoric can be turned into an effective tool rather than the media cudgel it has become.

FACTS FIGHT FICTION

There is a way to combat the negative images, but it takes a united and concerted effort.(1) The facts relating to hazardous waste and mixed waste incineration must be made widely and thoroughly known. For example:

Fact: incineration is the best method currently available for destroying--that's right, destroying hazardous organic compounds.
Fact: incineration reduces the volume of refractory contaminants so they can be recovered if useful or stored if not.
Fact: incineration is not perfect, but it works; there is no comparable alternative.
Dempsey and Oppelt point out: "Of all the 'permanent' treatment technologies, properly designed incineration systems are capable of the highest overall degree of destruction and control for the broadest range of hazardous waste streams. Substantial design and operating experience exists in these areas and a wide variety of commercial systems are available.''(2)
Now this is not to say that there are no problems associated with incineration of hazardous wastes. There are, of course, both technical problems and real risks. By taking a technical approach to the problems and a comparative risk-analysis to the dangers, however, it can be shown that incineration not only makes sense as the best way to deal with much of our hazardous waste materials, but in some cases incineration should be considered the primary or even sole method of disposing of them.
According to one Environmental Protection Agency estimate, some 150 million tons of what is classified as hazardous waste are generated each year. And that figure is increasing over time.
More than 75 percent of hazardous waste is treated. 20 percent is placed in landfills, injection wells, or other similar methods that may well be neither permanent nor dependable. Poor containment, flooding, leaching, or other disturbances can allow substances once labeled "disposed" to become new or different disposal problems.
Less than one percent of our hazardous waste is recovered and used again.
And less than two percent of what remains of our annual output of hazardous waste--some two-and-a-half-million tons--is burned. Approximately half that amount is burned as waste in incinerators, the rest is used a fuel in boilers, cement kilns, or industrial furnaces.
The figures are just for hazardous waste. The amount of mixed waste being burned is even smaller, with more than 80 percent of commercial mixed waste being treated in boilers, cement kilns, and industrial furnaces. For some types of mixed wastes--like those generated by medical facilities using low-level radioactive materials in their diagnostic procedures--incineration is the only method available for treatment. The labs that generate this kind of mixed waste have no other means available to them for disposal.
This potpourri of percentages adds up to one simple sum: at this time, very little hazardous waste is being incinerated, and very little of that is mixed hazardous waste. Is this because incineration is a poor way to treat hazardous waste? Is this because of some flaw in the incineration process? If we look to the facts, the answer is no.
Fact: incinerators are theoretically capable of complete and permanent destruction or removal of organic constituents. In practice, the performance is almost that good--good enough that well-operated incinerators routinely exceed the 99.99 percent efficiency required by regulations.
Fact: while the remaining solid waste may still contain a fraction that is hazardous--and mixed waste will still contain a fraction that is radioactive--the volume of waste that comes out of an incinerator is usually smaller by orders of magnitude than the volume of waste that goes in. What's more, the residue is much easier to contain, transport, and store.
Fact: even when incinerators are not operating at maximum design efficiency, the combustion process is so efficient in and of itself that even an incinerator burning at far less than its 99.99 percent ideal will not cause significant health risks. No matter how a fire gets started, once it's underway it's pretty hard to put out until whatever it's burning is destroyed. Thus also with incinerators.
One real problem with incineration is emissions, and there is no getting around the fact that once an emission makes it out of the stack, the ability to control it ends. This is probably the main issue that incinerator critics can point to, because these emissions can pose a health risk to people who live nearby.
But we can also fight fears of hazardous waste incineration and emissions by emphasizing the facts behind the comparative risks of its alternatives.
The following discussion skews the available data to the disadvantage of the

incinerators--to assume that the data show incineration to be safer than it actually is--to assume that scrubbers don't work as well as we know they do, and that destruction efficiencies have been dramatically overstated.
The federal government's basic unit of measurement in calculating the health hazard posed by hazardous wastes is called the incremental lifetime cancer risk--the chance that an exposed individual will develop cancer over a 70-year life span due to exposure to emissions. The threshold value for most hazardous air pollutants is one chance in one hundred thousand for exposure to air containing one microgram of contaminant per cubic meter of air. This method of risk measurement would result in a threshold value of an additional 2500 cancers per lifetime--or 36 per year--for the population of the United States.
According to the EPA, the risks from emissions from hazardous waste incinerators is 21 lifetime cancers--or 0.3 annual cancers--as a result of emissions from the incineration of hazardous waste, less than one percent of the threshold value given above (1)
What are the risks for some common hazards? According to the EPA, air pollution from motor vehicles results in 1,115 additional cancers per year in the U.S. population as the result of exposure to organic emissions--more than 78,000 lifetime cancers. Even if this estimated figure is three times as high as the real risk, it still makes auto exhaust two orders of magnitude more dangerous than incinerator emissions.
Here is another case: the incremental risk of disposing of hazardous waste in a Treatment, Storage, or Disposal Facility--or TSDF--rather than burning it in an incinerator.
According to the EPA, emissions of dioxins from TSDFs are responsible for more than 6,600 lifetime cancers, or 94.5 incremental cancers per year in the U.S. population. As our understanding of the long-term effects of dioxin improves, this risk may be revised upward. To make the worst possible case for incineration, I'll assume that incinerator emissions are three times as hazardous as EPA's figures, and that the risk from TSDFs is only one-third of EPA's estimate. Even with that adjustment, Treatment, Storage, and Disposal Facilities represent 35 times the risk of incinerators.
How about a comparison with other processes involving combustion? Is an incinerator more dangerous than burning municipal waste? No--statistics show dioxin emissions from burning municipal waste represent 20 times the cancer risk.
Smelters? Incinerators beat the formaldehyde emitted by smelters five-to-one.
That cozy wood fire in the fireplace? The products of incomplete combustion (PICs) coming out of the chimney are responsible for 100 times the annual cancers than would result from a hazardous waste incinerator running at one-third efficiency.
These are the facts. And even though incineration poses a relatively small risk when compared to more common hazards, public opposition is intense and seems to be growing. But those people who are unwilling to accept the very small risks associated with incineration often tolerate other, greater dangers willingly.
Because another fact is that, as individuals and as a society, we voluntarily accept risks on a daily basis--sometimes knowing the odds, frequently disregarding them.
For example; automobiles kill more than 40,000 of us each year and maim an additional quarter of a million of us. Yet most of us--even those of us who live, work, and play in major cities with excellent mass transit systems--would not think of giving up the family car.
Sometimes the risks we accept are tradeoffs for other risks. The clinical trials of the drag Tamoxifen are an example of this. The drag appears to be a breakthrough for treatment of breast cancer. But at the same time it may triple the chance that a woman taking it will develop endometrial cancer. Why accept such a risk? Because the statistical likelihood is that the drag will save more lives than it threatens. In this case, the increased risk of endometrial cancer is offset by the benefit of preventing a greater number of cases of another form of the disease.
But frequently our own risk acceptance is based more on personal preference than on a careful risk analysis. Actor and bodybuilder Arnold Schwartzenegger--former President Bush's advisor on physical fitness--is seldom seen off-camera without a cigar in his mouth. Baseball players who need to be in passable physical shape--when we have a baseball season--frequently chew wads of carcinogenic tobacco. Women who talk over a glass of wine or a cup of coffee about starting their families may be drinking the very substances which decrease their fertility.

Our current methods of storing hazardous wastes must include the possibility that fences will not keep out vandals, that liners will not prevent leaching, and that containers or treatment systems will fail or perform badly. So in a nation where our cars and our fireplaces pose a greater and more immediate threat to our health than the incinerators which would reduce or eliminate vast amounts of stockpiled hazardous wastes, why are we as a society reluctant to move toward the technology that could assist us?
Some negative public reaction is to images and not reality.
THE PACE OF PROGRESS SLOWED
When the government agency set up to regulate and oversee how we as a nation deal with the toxins that we as a nation produce takes a public stand that waste combustion policies need to be re-examined, the logical result is that people are going to wonder if the old rules were somehow lax or "wrong." And when that agency says it's decided to decrease reliance on incineration and instead pursue the course of reducing waste generation, it makes incineration look either unnecessary or undesirable, or both.
This is just what the EPA has done over the past couple of years.
But waste reduction and incineration are not an either/or proposition. We are generating those 150 million tons of hazardous waste every year. Those 150 million tons generated every year and not disposed of before the next years wastes are generated. And we're only incinerating less than two percent of that waste. So that means the leftover wastes, the wastes that were not buried or encased are with us. Waiting.
Yet in a Combustion Strategy memorandum this past May, the EPA called for increased inspection of existing incinerators, and a tightening of permitting rules for proposed incinerators.(3) In addition, EPA says it's giving "low priority" to issuing those permits for new
incinerators. Some of the agency's most recent statistics show this policy to be well-documented. The total number of incinerators in the U.S.--commercial and non-commercial, demilitarized and remedial--is 164. Those are the ones either with permits or on interim status, awaiting final permits. By the end of fiscal year 1995, EPA estimates there may be an additional 14 incinerators permitted. By the end of FY 1996, 15 more. This is not the sign of a booming incinerator industry.
The statistics for boilers and industrial furnaces are also less than encouraging. In a universe of 142 permitted and interim status facilities, them may be another 10 BIFs by the end of fiscal year 1995, and by the end of FY 1996, 31 more permitted boilers and industrial furnaces. These are the facilities that use hazardous waste and mixed waste as fuels.
Waste reduction is an important goal. The creation of less waste materials will mean lowered risks from whatever the source. But what is not openly taken into account is that unless we treat more waste, we are not decreasing our risks in any meaningful way. The stockpile stays put. The risk remains about the same.
And the EPA recognizes that. In that same May 1994 memo, EPA Administrator Carol Browner is quoted as observing that "remediation wastes present a different circumstance than newly generated wastes and, given the finite set of options for dealing with historic cleanup sites, combustion may be the most appropriate remedy. In addition, waste minimization opportunities at cleanup sites are usually severely limited." (2)
The EPA memo goes on to delineate agency guidelines which slow that "most appropriate remedy" by requiring site-specific risk assessment for incinerators, site-specific emission levels for furans and dioxin, unspecified assessment methods which the EPA says should "ensure that an incinerator can be operated in a manner protective of human health and the environment," and a vague call for "effective public participation" in the process of developing proposed incinerator sites.
While the EPA is saying that for existing hazardous wastes--especially at sites on the Superfund National Priorities List--incineration may be the most appropriate means of reducing the stockpile, the agency is at the same time promoting an internal policy of painstaking assessment that is resulting in delay of permitting for some incinerators, and complete abandonment of other proposed incinerator plans.
And how is the public concern about the safety of incinerators addressed by this policy? In essence, it isn't. A provision for reciprocal exchange of real information that might allay anxiety about the incineration process. The voice that's left out of the EPA's policy is the voice that can cite the facts about the

risks, explain the technology behind the process--the industry that builds and operates incineration facilities across the country and around the world.

CONFRONTING THE 'NIMBY' MENTALITY

Apprehension cannot be overcome by repetition. Encouraging individuals or groups to express and repeat their fears does not change those fears. So the EPA's public comment approach is lacking a key element--dialogue.

Hearts and minds can be changed. One good example of this is the growing number of American communities that embrace and endorse recycling. Ten years ago--or 20-- it would have seemed ludicrous that would all be picking through and separating our trash on a weekly basis. American industry has adopted a plastics numbering system to help distinguish containers.

Recycling has come to pass because we as individuals and communities have come to understand that the efforts we make are an accommodation for the greater good. Plenty of consumer education went into our "greening" and plenty of industry adaptation accompanied it. Both sides learned to see the benefit of cooperation.

The same can be with incineration. But we need to see the carrot--not the same old stick. Communities have grown used to fighting facilities which are seen as society's necessary evils--like prisons, landfills, and even highways. The rallying cry often is "Not In My Back Yard"--the zoning acronym NIMBY.

The NIMBY mentality needs to be seen as a luxury no community can afford. For any one group of people--through affluence, obstinacy, or whatever force--to deny its role in the common scheme of society is wrong. If we need the prisons, they must go somewhere. Likewise the landfills, the highways, and incinerators.

The federal government may have a role to play here, as will local governments and community groups and industry representatives. But the role should not be one of asking whether a particular place "wants" a hazardous waste incinerator; who would answer such a question in the affirmative? The approach should instead be one of consensus-building. If a particular area is producing a concentration of hazardous materials, the questions need to be: where should an incinerator be located to pose the lowest possible threat to health and public safety? what kind of incinerator will best perform the needed task? and what will be done with any products of incomplete combustion?

If the infamous WTI incinerator in East Liverpool, Ohio, had not been built within sight of an elementary school, the community reaction to it would have been appreciably different.4 East Liverpool is a worst-case example of how site selection cannot be performed in a vacuum, and how dialogue before the fact could have averted a huge community outcry and much hostility.

The fact is that incinerators are not risk-free, but they bear up well by comparison to other methods of hazardous waste disposal and other socially-accepted risks. The current level of suspicion and anxiety regarding incinerators can be reduced through the sharing of expert information about the need for and process of hazardous waste combustion, and early involvement of community and industry representatives even before a particular incinerator site is chosen.

CONCLUSIONS

The facts about hazardous waste incineration are supportive of using this important technology for hazardous and mixed waste disposal.

The facts are that incineration works. It destroys organic contaminants, reduces the amount of remaining waste that needs to be stored, and can be shown to pose a much smaller risk than any alternative treatment developed thus far.

While the EPA's recent focus on risk assessment may be beneficial in theory, the agency needs to reexamine what it is saying to a fearful public about incineration and slowing the permitting process with layers of site-specific requirements. If the government will begin to promote dialogue among all concerned parties, perhaps we will all start to agree on how we can move forward together to address the hazardous waste problem through the judicious use of incinerators.

And finally, we need--as neighborhoods and individuals--to get over our insular approach to our communities. The problems of hazardous waste belong to us all, and must be confronted as a communal challenge. The days of the NIMBY mind set are past. For our common good, we must work together to resolve the conflict over where, not whether, hazardous waste incineration is in our future.

RADIOACTIVE AND MIXED WASTE INCINERATION: AN UNCERTAIN SOLUTION

David W. Kershner
Institute for Energy and Environmental Research
Brian Costner
Director
Energy Research Foundation

ABSTRACT

There is a sound basis for many criticisms of waste incineration. Incinerators emit a wide range of toxic substances, many with poorly understood toxic properties. While well-maintained, state-of-the-art incinerators can keep emissions to low levels, U.S. regulations have tended to provide inadequate assurances of health and environmental protection for two principal reasons: 1) they do not ensure that low emissions are maintained during routine operations through frequent monitoring of key pollutants, especially toxic metals; and 2) emission limits are based on risk assessments that involve a high degree of uncertainty and often fail to consider important factors. In making decisions about the appropriateness of incineration, many key issues are often poorly considered, such as the variability of waste feeds, the viability of alternatives on a waste-specific basis, and equity issues. Incineration has too often been used as a catch-all treatment method, while other technologies that may be more appropriate for specific waste streams have not been thoroughly investigated.

INTRODUCTION

Incineration has come under increasing criticism from environmentalists and citizens impacted by these facilities. There is a factual, analytical, scientifically sound basis for much of this criticism, especially with respect to incineration of radioactive and mixed waste streams. In this paper, we provide examples of policy decisions and technical issues which underlie much of our criticism. In preparing this paper, we have drawn upon our experience reviewing an incinerator under construction at the Department of Energy's (DOE) Savannah River Site, known as the Consolidated Incineration Facility, as well as information gleaned from a review of incineration technology completed by the Institute for Energy and Environmental Research in 1993.

We do not, however, attempt to provide a complete catalogue of the criticisms that have been raised about incinerators. Many issues are specific to individual facilities or to the relationship between facility operators and local communities. An effective effort to address concerns about a specific incinerator should include a review of site-specific information and involve local communities and facility managers.

Incineration may be an effective treatment for many waste types, but the tendency to adopt incineration as a catch-all treatment technology for widely varied waste streams is not supported by the current state of the technology and existing regulatory controls. Successful incineration of waste material depends on relatively uniform and consistent waste feed...In practical applications considerable variation in feed materials may be present," as the U.S. Environmental Protection Agency (EPA) noted in a 1991 document on incineration of radioactive and mixed wastes (1).

While high temperature can destroy toxic organic compounds with high efficiency, it can lead to volatilization and potential release of metals and radionuclides. Yet real-time (continuous) monitoring of some individual toxic emissions of concern such as heavy metals and dioxins has not been demonstrated. Indeed, given limitations inherent in the combustion process, incineration may not be at all suitable for wastes containing significant quantities of volatile metals or long-lived radionuclides.

In the sections below, we touch briefly on each of the following issues: potential emissions and uncertainties associated with those emissions; the need for more frequent, more comprehensive monitoring; pitfalls of risk-based regulation; and the importance of public participation in waste management decision making.

WHAT DO INCINERATORS RELEASE INTO THE ENVIRONMENT?

Incinerators release a wide variety of substances; the toxicity of many are poorly understood. Some of these emissions are highly carcinogenic or cause other health effects at low concentrations, are long-lived, and can accumulate in the tissue of animals and humans.

Incinerators can reduce the volume and total toxicity of the waste burned. By reducing the volume of solid and liquid materials, incineration can reduce releases following disposal for some wastes. Incinerators cannot, however, break down all of the complex chemicals fed into them. Some portion of these chemicals, generally a very small percentage, escapes the combustion process unaltered or partly burned. By-products of combustion also are formed from the recombination of compounds following combustion, as with all combustion processes. Some of these "products of incomplete combustion" (PICs) are more toxic per unit of weight than the original waste; the toxic properties of many PICs are not well-understood, while others have not even been well-identified. The EPA has described the problem as follows (2):

> ... small quantities of "new" organic compounds may form from the breakdown and recombination of the original compounds. These products are called "products of incomplete combustion" (PICs)...Among the types of compounds found in various analyses of PICs are some that are considered toxic, including dioxins and dibenzofurans.

The total quantity and toxicity of PICs created in full-scale incinerators is uncertain (3). Data are limited in part because monitoring is done only on an infrequent basis during trial burns when incinerator maintenance and operator performance are at their peak (4). Further, the EPA has found that at most 60 percent of PICs emitted during past test burns have been chemically identified (5). While the most toxic PICs known, dioxins and dioxin-like compounds, apparently can form during any combustion process, there is a clear relationship between chlorine content of the waste and dioxin formation. For instance, in one study commissioned by Germany's Environmental Protection Administration, Umweltbundesamt, researchers found that incineration of chlorinated products contributed disproportionately to dioxin formation (6). Other characteristics of the waste can confound this relationship however (e.g., the presence of sulfur in the waste).

Even though many air pollutants are emitted in very small quantities compared to the volume and weight of the original waste, their high chemical toxicity makes pollution control particularly crucial. The health effects of many of these compounds (e.g., dioxins), even when present in small quantities, are the focus of much of the controversy surrounding incineration. Some data suggest that the background environmental concentration of dioxin is near levels that could cause adverse effects on the human immune and reproductive systems (7). Yet, the focus of regulation is not on such effects, but on cancer risk.

Incineration does not destroy metals or reduce radioactivity of wastes. Radionuclides and metals either leave the incinerator in the stack gas, or are left behind in ash, filters, or waste water. Radioactive waste incinerators, when equipped with well-maintained, state-of-the-art pollution control systems, can capture all but a very small fraction of the radionuclides and metals in the waste. Radioactive particles that do escape, however, are small in diameter and can be carried by winds over long distances. Due to their small size, fine particles (radioactive or otherwise) can be inhaled more easily than larger particles, and become lodged in the lungs.

At Lawrence Livermore National Laboratory (LLNL), an internal review panel raised some of these issues when recommending against a proposed mixed waste incinerator in the increasingly urban Livermore, California community (8):

> We have never been comfortable with the EPA's position that incineration of mixed waste to eliminate its chemical toxicity should be the first procedural step and burial of its radioactive residuals the second step. This approach commits to the volatilization of important radionuclides, including tritium, carbon-14 and several isotopes of iodine. Furthermore, the incineration of non-volatile nuclides, including those of uranium and plutonium, leads to a finite, although exceedingly small, probability of radioactivity being emitted from the incinerator's stack.

We view incineration as a violation of the cardinal principal of radioactive waste management; namely, containing radioactivity rather than spreading it. The LLNL panel, nevertheless, went on to recommend incinerating the waste in a more remote location, pointing out that an incinerator at the Idaho National Engineering Laboratory, "is allowed to, and currently willing to, process [Livermore] Laboratory's mixed- and low-chlorine-containing waste into a form suitable for burial (9)." While the remoteness of the Idaho incinerator may reduce the number of exposed people, it creates additional transportation risks and does not resolve the inconsistency between incineration and the principle of containing radioactive waste. It also does not resolve equity issues associated with urban centers transferring risks of disposal to rural communities.

Air Pollution Control Devices

Incinerators require careful operation and maintenance to ensure optimal performance. They rely on complex, often fragile, pollution control systems to capture volatile metals, radionuclides, unburned toxic organic compounds, and by-products discharged from the combustion chamber. Emissions can be expected to increase as a result of poor maintenance, carelessness or error on the part of the operator, and facility aging (10). If pollution control systems are improperly maintained, emissions can increase substantially. For example, in a compliance test at one new municipal waste incinerator, lead emissions increased by roughly two orders of magnitude due to a bag filter coming loose in a baghouse system composed of several hundred individual bags (11)(see Table I). Radionuclide filtration systems are especially vulnerable to failure and leakage. The High Efficiency Particulate Air (HEPA) filters most commonly used for fine particle capture "can sustain structural damage relatively easily under conditions of higher-than-designed-for rates of airflow, shock waves (for example, as a result of incinerator explosions), higher-than-designed-for temperatures, excess humidity, and excess particulate deposits (12)."

Secondary Wastes

Incineration produces secondary wastes in the form of wastewater from wet scrubbers and ash. The more efficient the pollution control system, the more PICs and metals that are concentrated in secondary wastes--primarily ash. Although typically at very low concentrations, some pollutants in treated wastewater may accumulate to potentially harmful levels if the receiving waterway is already polluted. For example, polychlorinated biphenyls (PCBs) show significant patterns of accumulation in fish (13). Some epidemiological evidence suggests that PCB levels in some people could already be at body burdens that are producing developmental and behavioral effects in offspring (14).

The majority of toxic substances leaving the combustion chamber end up in the ash. These residues can leach into groundwater and contribute to off-site exposures. On one hand, the greater surface-to-volume ratio of ash relative to the original waste form tends to increase leaching for a given chemical solubility. On the other hand, incineration or post-incineration treatment may reduce leachability of the ash (e.g., by converting some constituents of the ash to less soluble oxide forms). The net effect will depend on specific circumstances and must be evaluated on a case-by-case basis.

REGULATORY INADEQUACIES

Federal regulations on emissions from hazardous and mixed waste incineration in the U.S. are inadequate for three principal reasons. First, they fail to require continuous, or even frequent, monitoring of key emissions. Second, they are based on risk assessments that involve a high degree of uncertainty and fail to consider important factors. Third, they are focused primarily on cancer risk, though other risks, such as reproductive risks, may in specific instances be far more important.

Emissions Monitoring

Frequent emissions monitoring of individual toxins is critical to evaluate the health and environmental impacts of incinerators for two key reasons:

- combustion products can vary markedly depending on waste inputs and operating conditions, and
- pollution control systems can deteriorate or fail during normal operations.

While incinerator performance tests are designed to stress a facility by requiring operation under non-optimal conditions, the EPA has stated that "many incinerators run very efficiently during a trial burn...it may not be possible to achieve this

high efficiency [referring to carbon monoxide levels--one indicator of PIC formation] on a consistent basis (15)." The EPA has further stated that, "In addition to differences in waste feed compositions, incinerators may have uneven temperature distributions, poor mixing conditions, or low temperature areas, which might lead to poor combustion conditions that result in an increased likelihood for the formation of PICs (16)."

These fluctuations have occurred frequently at some facilities. In a survey of records from 29 incinerators burning hazardous waste (two of which were DOE mixed waste incinerators), the EPA and the U.S. Occupational Health and Safety Administration found that over 40 percent of the facilities required emergency feed cutoffs more than a hundred times in during a 30-day study period (17). Waste feed cutoffs indicate that permitted limits on carbon monoxide or other indicators of combustion efficiency were exceeded. Describing the formation of PICs during these and other "upset" (or non-optimal) conditions, the EPA's Science Advisory Board noted that "the amount and composition of PICs will depend in a complex and unpredictable way on the nature of the perturbation."[emphasis added](18). In tests at one full-scale hazardous waste incinerator, researchers found that formation of some toxic organic compounds increased 10-fold or more during observed upset conditions (19). In compliance tests at a state-of-the-art municipal incinerator, measured total dioxins and furans at the stack were 70 times higher during "unstable operation" than under "normal conditions (20)."

Federal regulations in the U.S. rely on carbon monoxide (CO) and total hydrocarbon (THC) limits to determine incinerator performance during day-to-day operations. However, low levels of these compounds do not necessarily indicate low levels of products of incomplete combustion. According to the EPA's Science Advisory Board, "The correlation of CO, THC, or other parameters with combustion efficiency and PIC emission is weak for some conditions and some combustion devices (21)."

Analysis of known toxic PICs such as individual dioxins and furans is only conducted on a limited basis, at most annually, due to the time-intensiveness and high cost of the process. A system has yet to be developed that can continuously, or near-continuously, monitor even the most well-studied PICs emitted from incinerators, let alone the poorly understood components of the combustion gas. Analysis of toxic metals is also costly, but more feasible on a near continuous basis. Germany requires some incinerators to sample for a range of individual metals once a week. For example, the Karlsruhe Nuclear Research Center's incinerator in Germany is required to sample weekly for 13 individual metals (22)(see Table II). At the 3M corporate incinerator in St. Paul, the company has been using an innovative metals sampling technique on a weekly basis for several years (though the procedure has some limitations)(23). At one hazardous waste incinerator in Biebesheim, Germany, toxic metals are sampled daily (24).

Continuous or near continuous monitoring of key pollutants could contribute to improved compliance and enforcement at incinerators and build public confidence in the efficacy of air pollution control. Improved public access to this data could also build public confidence and contribute to better enforcement of emissions limits. Data could be transmitted directly to a public venue, in the same way that some states now require "telemetering", or direct transmission of basic emissions data such as CO, to the regulatory agency (25).

Risk Assessment

The EPA has adopted a strategy of setting facility specific limits on individual pollutants based on risk analysis focused on cancer risk.* Assessing the health and environmental risks of incineration, however, involves a high degree of scientific uncertainty. Assumptions must be made where data are absent or highly variable. While risk assessments generally include many highly conservative assumptions, the overall conclusions may not be conservative if key variables are omitted or underestimated. For example, risk assessments of exposure to dioxin emissions from incinerators that have assumed only the inhalation pathway have been found to dramatically under represent the exposures of some individuals. Researchers have estimated that food chain exposure can exceed doses from inhalation by one to three orders of magnitude (26)

Although food chain risks of dioxins and furans are now being incorporated into permitting and compliance decisions, many potentially toxic compounds released from incinerators have not been adequately characterized. As noted previously, a large portion of PICs emitted during test burns have not been identified. These unknown

compounds could be more toxic than identified compounds or could have synergistic effects when combined with other substances. Similarly, releases from other facilities could produce synergistic effects when combined with incinerator emissions. These factors introduce large uncertainties into risk assessments.
Risk assessment procedures typically focus exclusively on cancer-risk potential when evaluating carcinogenic substances, although other effects may be of greater significance at low exposure levels or for some pollutants. The EPA has concluded, for example, that the effects of dioxin on reproduction and development are of greater concern than dioxin's ability to cause cancer (27). Summarizing key findings of the EPA's dioxin reassessment panel, EPA's Assistant Administrator for Research and Development, Erich W. Bretthauer, stated in a late 1992 memorandum to the EPA's Administrator, "Some data suggest that [non-cancer] effects may be occurring in people at body burden levels that can result from exposure at, or near, current background (28)."
Further, risk assessments often fail to quantify background levels of pollutants that can amplify risks; the cumulative effects of releases from various sources over time; the existing body burdens of toxic and carcinogenic pollutants in the local population; or significant past exposures to toxins. For example, children already exposed to toxic levels of lead from paint or other sources may be harmed by quantities released from incinerators that on their own would not be likely to cause health effects. According to the American Academy of Pediatrics, 2 to 4 million children already have blood lead levels sufficient to slow growth and delay development (29).
Finally, risk-based regulation does not reflect many values important in decision making. For example, equity is a legitimate consideration when reviewing who benefits from waste generation and who is affected by waste treatment and disposal. If a community has already been disproportionately impacted by activities designed to benefit the society as whole, society has an obligation to redistribute additional costs or at least recognize that equity concerns justify the financial and regulatory commitment necessary to minimize risks to the lowest level technically feasible. Risk-based regulation also fails to address economic and cultural impacts on communities near incinerators. These and other values, such as urban-rural equity, are vital to democratic decision making and underline the limitations of using risk assessment alone for decisions potentially affecting entire communities. In addition, regulatory officials and facility managers must recognize that small risks, if involuntarily imposed, are much less tolerable than higher risks one voluntarily chooses to face.
PUBLIC PARTICIPATION: THE CIF EXAMPLE
The decision-making process leading to the construction of the Consolidated Incineration Facility (CIF) at the Savannah River Site illustrates the need for more thorough analysis of specific waste streams, treatment options, and greater stakeholder participation. The CIF started in the mid-1980's as a plan for combining three incinerator projects into a single, consolidated facility. That was certainly a reasonable idea which should, at least theoretically, have reduced construction and operating costs. In subsequent years, however, the capacity needs changed due to changes in activities generating waste. Rather than reevaluating the CIF in light of these circumstances, the DOE chose to proceed with construction.
It was only after extensive public pressure that the DOE agreed to review the CIF. The agency initially identified compaction as a viable alternative for perhaps 50 percent of the projected waste feed. Also as part of the CIF review, the DOE was encouraged to reconsider supercritical water oxidation as an alternative for specific wastes (30). This closed-system is being used on a commercial scale for some hazardous wastes and a demonstration plant for mixed wastes is expected to operate in 1995 (31). The DOE has recently proposed vitrification as a potential alternative to incineration for much of the waste, noting that this option may put secondary wastes in a more stable form for disposal. Public participation encouraged the DOE to reevaluate the CIF incinerator. By expanding public input in decision making, the DOE may have identified a more effective slate of treatment options for the Savannah River Site.
CONCLUSIONS
Though incineration has crucial limitations, incinerators should not necessarily be rejected as waste treatment facilities. Rather, the appropriate role of incineration should be better defined, and the regulatory system should be changed

to reflect valid concerns about the technology. Specifically, we conclude:

There is a need for proper segmentation and control of the waste feeds to incinerators, in order to reduce health and environmental risks from their operation.

Given variability in incinerator performance, continuous, or near continuous monitoring of emissions is necessary to ensure compliance with regulatory limits on specific compounds. Frequent monitoring would enable and encourage better operating performance and build public confidence in the efficacy of pollution control at incinerators.

All reasonable efforts must be made to minimize involuntary risks to local citizens from waste incineration.

The highly uncertain nature of risks from incineration dictates special efforts to include democratic participation in decision making and to thoroughly investigate alternative waste management solutions on a waste-specific basis.

INCINERATION AND NON-INCINERATION OPTIONS FOR TREATING A BROAD SPECTRUM OF HAZARDOUS AND RADIOACTIVE WASTES

ABSTRACT

The mixed low-level hazardous waste in the U.S. Department of Energy (DOE) complex consists of organic and inorganic solids and liquids comprising a wide variety of materials contaminated with radioactive substances. Treatment systems are needed to destroy the hazardous organic materials and to immobilize any hazardous inorganic materials, along with the treatment residues and radionuclides, in order to comply with the regulations promulgated by the Environmental Protection Agency (EPA), state agencies, and the DOE. This paper briefly describes 19 fully integrated systems for the treatment of mixed low-level waste that are being evaluated by DOE in a comprehensive Integrated Thermal Treatment Systems Study.

INTRODUCTION

DOE's Environmental Management Office of Technology Development has commissioned an Integrated Thermal Treatment Systems (ITTS) Study to assess alternative systems for treating contact-handled, alpha and non-alpha mixed low-level radioactive waste (MLLW). The ITTS study is a systematic engineering evaluation of a variety of integrated MLLW treatment systems. The emphasis is of the total system -- from the receiving dock through disposal of the treated wastes. A total system approach is critical since the selection of one treatment technology over another can impact other parts of the system, such as waste sorting and sizing or immobilization of the residues.

Some innovative technologies under development within DOE and industry are being proposed as alternatives to incineration. However, they may not be a direct substitute for an incinerator as they may require substantially more or fewer support facilities because of different waste input requirements (e.g., for composition, physical size, or both). They may also have different requirements for air pollution control (APC), residue stabilization, etc. Therefore, before any technology is selected as an alternative to something else, an evaluation must be performed to determine the system changes associated with the use of the new technology. Is one set of problems replaced with another? Can the same wastes be treated or will some waste types be excluded? Will the technology produce the same or a different quantity of residuals? What auxiliary systems will be necessary to

treat the portion of the waste stream not treated by the alternative technology? Will the residuals have better or poorer long term stability in the environment? This study has attempted to address these and other related questions for nineteen systems using different combinations of technologies.

The technologies included in this study consist of both conventional and innovative treatment concepts combined in ways to examine the effect of the primary treatment system, air pollution control, type of oxidant, type of residue stabilization, type of energy (methane vs electricity), and other subsystems. The systems selected not necessarily represent concepts that would be advocated by the investigators, but the selections all have one or more attributes that appeared at the outset of the study to merit evaluation in the system context.

A major constraint in this study was the requirement for each system to treat the same waste profile and at the same mass throughput. If a particular primary unit operation could not accept a certain waste type, an additional treatment subsystem was added to accommodate the excluded waste type. The study developed a set of consistent functional requirements and then proceeded to develop preconceptual designs and relatively rigorous mass and energy balances. The preconceptual designs consisted of functional diagrams, facility layouts, equipment lists, and construction and operational cost estimates. Each system had the same waste processing throughput, treated the same waste profile, and was required to produce a waste form from the residuals that was believed to be able to pass EPA Land Disposal Restrictions (LDR) under the Resource Conservation and Recovery Act (RCRA) and DOE Performance Assessment Objectives identified in DOE Order 5820.2A. Since this was a conceptual study, only engineering judgment could be used to determine acceptability for the final waste forms. Similarly, air pollution control systems were configured such that the systems would represent state-of-the-art concepts producing air emissions at least an order of magnitude lower than current requirements.

STATUS OF THE STUDY

Two publications from the first phase of the study are currently available: 1) a description of the waste profile used for the analysis of the mass and material balance, and 2) the documentation describing the design of the first ten systems analyzed (1,2). The study is nearing completion and the final results will be soon be published (3).

WASTE PROFILE

The waste profile used in this study (1) was derived from a DOE report (4) that was compiled from inputs from 49 DOE sites. The data were known to be imprecise but represented the best possible inventory that could be developed at the time. The waste in storage at the DOE sites comes from operations that span almost 40 years -- long before requirements for good record keeping, waste treatment, and disposal existed. Consequently, the source data on physical matrices generally do not have a significant level of detail. Nevertheless, an effort had to be made to define the DOE MLLW in terms of physical matrices in order to get some estimate of the chemical composition of the wastes for use in performing mass and energy balances for each of the treatment system concepts. After assigning a chemical composition to the physical matrices and combining the data, the final waste profile was developed for the mass balance calculations as shown in Table I.

TREATMENT REQUIREMENTS

The waste consists of many physical matrices contaminated with RCRA-listed or RCRA-characteristic hazardous wastes. The wastes include significant quantities of mercury and lead, neither of which should be subjected to thermal treatment since, because of their volatility, they will pass through a thermal treatment system and pose a challenge to the air pollution control system. Thus, a requirement for segregation of the bulk lead and mercury was imposed on the system design. These metals are treated in separate subsystems. Also, two separate ferrous metal treatment subsystems were included in the baseline concept -- one for removal of surface contamination and one for bulk metal melting. A basic premise of the system concept was that real-time radiography could be used to examine all the containers, that containers having lead, mercury, or ferrous metal in bulk quantities could be identified, and that those materials could be removed for processing in the appropriate subsystem. Finally, a "special waste" subsystem was included in the preconceptual design, with building space and equipment allowances provided to accommodate the unknowns.

With some exceptions, the quantity of the RCRA contaminants and radionuclides in the

DOE MLLW can generally be considered at the trace concentration level. Toxic metals and organically contaminated sludges and some organic liquids are some of the notable exceptions. Since the waste inventory was limited to that specified as contact-handled (i.e., <200 mR/h at the surface of the container), radioactive constituents will be present only in the parts per million level. Thus, with few exceptions, the treatment processes must be selected to treat the physical matrices and the process must ensure that the RCRA contaminants are either destroyed or immobilized along with the radionuclides, to a satisfactory level, in the final waste form.

RESIDUE IMMOBILIZATION

As indicated above, the residues from the treatment process are expected to require immobilization to meet EPA LDR requirements for hazardous materials because of their hazardous characteristics or because they are covered under the "derived from" rules. Immobilization is also assumed to be required to meet DOE disposal and performance assessment requirements. Consequently, this study included immobilization as an integral part of the integrated treatment system.

For purposes of this study, it has been assumed that the baseline process for immobilization of the radionuclides would be vitrification (vitrification will be used throughout this paper to describe any process that melts the residues regardless of whether the final product is a glass or a ceramic material). Vitrification was selected as the baseline process because it achieves the maximum volume reduction and provides the most stable long term waste form for radionuclides. Much of the MLLW has alpha emitting radionuclides that remain radioactive for very long times and, thus, should be stabilized for long periods. The study also includes various combinations of cement and polymer stabilization to identify the comparative costs of these processes. Some of the systems evaluated produce only a vitreous waste form from the thermally-treated solids. Systems that produce acid gases have a scrubber in the air pollution control system that produces an aqueous waste stream laden with soluble salts. This stream is processed and dry salt is produced, which is subsequently stabilized with a polymer for disposal because it is presumed that the salt will be contaminated with some radioactive elements that pass through the filter systems. If this were not the case, stabilization of the salt would probably be unnecessary.

TREATMENT SYSTEM DESCRIPTION

The systems being evaluated in this study are summarized in Table II along with some of their major features. Detailed process flowsheets have been developed for all systems (2,4). The APC subsystem for most of the systems consists of an equipment lineup that allows the fly ash to be separated from the scrubber salts [partial wet quench, baghouse, pre-filter, carbon bed filter, HEPA filter, packed bed scrubber, demister, NOx abatement (if required), fan, and stack]. Thus, the scrubber salts are separated from the fly ash and can be immobilized independently in a polymer matrix. The fly ash is returned to the vitrifier for vitrification along with the bottom ash and soil. (Soil is added to the vitrification systems to help produce a leach-resistant final product). Additional benefits to DOE are expected to be derived if the soil used as the additive is contaminated soil from DOE sources. The balance of the paper briefly describes the systems selected for the study and some of their major features.

System A-1, Rotary Kiln with Vitrification of the Ash Residues (Baseline System)

This system uses conventional rotary kiln technology for the treatment of both the combustible and non-combustible waste streams. For this study, it is assumed that the poorly characterized DOE waste has some RCRA contaminants and that it is less costly to treat everything than to attempt to sample the heterogeneous waste to determine if RCRA-listed or -characteristic hazardous materials are present. All wastes will be shredded prior to feeding to the kiln to enhance the uniformity of the feed and to reduce the chance for classical "puffs" caused by excesses of combustibles that cause an oxygen demand beyond that to which the incinerator control system can quickly respond.

In addition to the wastes, the soils for vitrification are also sent through the rotary kiln. It has been observed in tests at the Idaho National Engineering Laboratory that if soils are pretreated at high temperatures prior to vitrification, the subsequent process is easier to control and less material carryover occurs. The pretreatment of soil drives off moisture and decomposes any carbonates that may be present. A side benefit of the soil in rotary kiln operation is the reduced

requirement for excess cooling air in the kiln. The vitrification system receives both the bottom ash and the fly ash recovered from the baghouse operation. As noted earlier, the baseline APC system uses a scrubber for chlorine removal down stream of all filter equipment. Unlike some commercial systems that use similar equipment lineups, the scrubber water is sent to a waste water treatment system rather than being recirculated to the quench where the fly ash becomes commingled with the scrubber salts.

System A-2, Rotary Kiln with Vitrification of the Ash Residues and Enriched Oxygen for Combustion

Except for the use of oxygen instead of air for oxidation, this system is nearly identical to system A-1. The reduced use of air (air in-leakage is still assumed) substantially reduces the total gaseous mass flow through the system, thus allowing a smaller air pollution control system to be used. To maintain the proper operating temperature, cooling water is injected directly to the kiln. Much less quench water is necessary to drop the temperature before the baghouse. All other parts of the system are identical to System A-1.

System A-3, Rotary Kiln with Vitrification of the Ash Residues and Wet APC System

This system is identical to System A-1 except that a wet APC system replaces the wet/dry system described above. In this system, the gas leaving the secondary combustor is quenched to below saturation. The gas then is filtered by a hydrosonic scrubber, sent to a packed tower for neutralization, passed through a mist eliminator, reheated, HEPA-filtered, treated to reduce NOx (if required), and released to the stack.

System A-4, Rotary Kiln with Vitrification of the Ash Residues and Retention of CO2 Emissions

This system is similar to System A-2; a subsystem to capture CO2 has been added and 90% of the inert gases are recirculated through the kiln. A small gas bleed system is used to prevent inert gas accumulation. Air in-leakage is assumed, as for the other systems. CO2 retention is employed to delay the release of the off gas until such time that it can be sampled to verify that there are no unacceptable contaminants present. A fluidized bed of CaO is used to adsorb the CO2, forming CaCO3. After the CaCO3 is determined to be clean, it is sent to a calciner to drive off the CO2 and the CaO is reused. It is assumed that the CaO can be used 10 times, after which the discarded CaCO3 is polymer stabilized. The packed bed scrubber is eliminated from this system since any acid gases in the system will react with the CaO to form salts in the fluidized bed.

System A-5, Rotary Kiln with Polymer Stabilization of the Ash Residues

This system is similar to System A-1, except that instead of using vitrification for the primary stabilization system, a polymer such as polyethylene is used for stabilization of the bottom and fly ash and the scrubber salts. This equipment lineup greatly simplifies the system by eliminating the vitrification system and the associated air pollution system, but at the expense of producing a much larger disposal volume. The rotary kiln and its APC are identical to System A-1.

System A-6, Rotary Kiln with Vitrification of the Ash Residues and Maximum Recycling of Salt Residues

This system is identical to System A-1 except that the scrubber salts are processed to recover HCl and NaOH. This eliminates a waste stream that requires polymer stabilization.

System A-7, Rotary Kiln with Integral Vitrification of the Ash Residues

This system, similar to System A-1, was evaluated in Phase 2 to assess the overall effect of combining combustion and vitrification in one unit. The kiln operates at a higher temperature to accomplish the vitrification. Depending on the waste makeup, fluxing agents may be required to reduce the kiln ash melting temperature to a range where kiln operation and refractory lifetime are acceptable. This system eliminates the need for ash cooling, handling, and storage, and for the separate vitrification system included in the baseline rotary kiln system and all of its variations (Systems A-1 - A-6).

System B-1, Indirectly Heated Pyrolyzer With Vitrification of Ash

This system uses an externally-heated pyrolyzer to destroy the organics in a reducing atmosphere. Offgas from the pyrolyzer is fed to an electrically-heated secondary combustor. The ash is fed to a closely-coupled vitrification unit so that ash handling, cooling, and storage is not required. Oxygen is used instead of air to minimize the total gases in the system. Only combustibles are fed to the

pyrolyzer. The noncombustibles and soil are fed to a blender/dryer and then to the vitrifier. Oxygen is provided to the vitrifier via an oxygen lance to ensure combustion of any hard carbon coming from the pyrolyzer. The APC for this system is the same as used on the baseline system, but it is smaller since the total gas flow through the system is less than 10% of that in the baseline system. A single APC system is provided for the pyrolyzer and vitrifier rather than separate units as were provided for the rotary kiln systems. This system has the second lowest offgas of any system in the study.

System C-1, Plasma Hearth Furnace

This system uses a plasma hearth furnace to destroy the wastes and to vitrify the residues in a single unit. It requires less waste preparation and sizing because entire drums can be fed to the plasma unit (if safety and regulatory practices allow). Soil is fed to the plasma unit in the same quantities as for all other vitrification systems in this study. The APC subsystem is similar to that of the baseline system, but sized for the reduced gas flow. This APC system uses an electrically-heated secondary combustion chamber (SCC) to minimize total system gases. The use of electricity for the plasma and SCC heat source greatly reduces the volume of offgas compared to systems using methane, such as a rotary kiln.

System C-2, Plasma Hearth Furnace with Oxygen for Combustion and CO2 Retention

This system is similar to System C-1, but oxygen replaces air for combustion. The CO2 produced is retained in a holding system identical to that described for System A-4, except it is smaller because no methane is used in the plasma process.

System C-3, Plasma Hearth Furnace with Steam Gasification

This system uses a plasma concept similar to that of System C-1, but the wastes are reacted with high temperature steam rather than air. The endothermic steam gasification reaction produces CO and H2 from the combustibles. If a use for this synthesis gas were readily available within the treatment facility, the energy could be tapped. For this study, however, the gases are passed through a thermal oxidizer to combust with air. The total gaseous effluent is the same in either case. Because the thermal oxidizer is downstream from the APC, the gas mass flow through the APC system is very small, comparable to that of System C-2.

System D-1, Fixed Hearth Pyrolyzer with Oxygen and CO2 Retention

This system uses a fixed hearth incinerator fired with methane for the combustible fraction of the waste. Additional sorting is assumed to separate the combustible wastes. Oxygen is supplied to the incinerator and the secondary combustor. The CO2 in the offgas is treated as in Systems A-4 and C-2. The ash from the incinerator is blended with the dried noncombustibles and the additive soil and sent to a vitrification unit. Polymer is used to stabilize the spent salts from the CaO regeneration unit.

System E-1, Thermal Desorption and Incineration with Grout Stabilization

This system limits the amount of material that is incinerated. RCRA regulations allow debris to be grouted without other treatment. This system provides some additional treatment beyond that required by RCRA, but less than other systems in the study. Combustible solids and liquids are treated in a small rotary kiln, while noncombustibles are treated in a thermal desorption system. The solid effluent from the thermal desorption system is grouted along with the ash from the rotary kiln. The rotary kiln has an APC system identical to the baseline system. Vapor effluent from the thermal desorption system is condensed and destroyed in the SCC unit of the APC.

System F-1, Molten Salt Oxidation with Vitrification of Ash Residues

This system employs a molten salt oxidation (MSO) unit for the combustible fraction of the waste. Molten NaCO3 is used in the bed. Finely shredded organic wastes are injected into the bed along with combustion air. The bed provides the thermal environment for oxidation and neutralizes any acid gases in situ. Due to viscosity limitations, the bed ash content must remain below 20%, and thus a salt overflow system is used for viscosity control. The discharged salt must be recycled or the volume of waste for disposal would be enormous. Therefore, a salt recycle system is used to separate the ash, NaCl, and NaSO4 from the unused NaCO3, which is returned to the MSO reactor. Ash from the salt recycle system is combined with the noncombustibles and soil, dried and blended, and fed to a vitrifier for melting into a vitreous waste form. Waste salts from the salt recycle unit are stabilized with polymer for disposal.

System G-1, Molten Metal Melter

This system uses a molten metal melter for decomposition of organic wastes in a molten steel bath. The bath is operated in a reducing mode such that CO and H2 are the primary gaseous effluents. These gases are eventually reacted in a thermal oxidizer prior to release (similar to System C-3). This system is assumed to accommodate large quantities of metal directly, and thus separate metal melting subsystems are not required. (Methods of feeding this system with bulk metals are under development but not yet demonstrated.) All waste must be finely shredded for injection into the molten metal bath. It is assumed that a method will be developed to provide the fine shredding capability for pretreatment of the DOE waste stream (both combustible and noncombustible). If these key development requirements are met, this system may be as omnivorous as the plasma torch and slagging rotary kiln systems. The system uses an APC fairly similar to that used in the baseline system, but the aqueous quench is replaced by a fluidized bed sand cooler that rapidly drops the offgas temperature to below 200F. Dry gas is filtered in equipment similar to that used for the baseline system. A unique aspect of the molten metal reactor is that CaO is fed into the reactor along with the waste and reacts with the chlorine released from the waste to form CaCl2 in situ. This salt is expected to combine with the slag. Some HCl (10%) is expected to escape unreacted, so a scrubber is provided downstream of the filters to capture the remaining acid gases. Similar to the plasma systems, this reactor makes two separate forms of solid effluent waste in the same reaction vessel: metal and slag.

System H-1, Steam Gasification System with Vitrification of Ash

This system uses an indirectly-heated fluidized bed to gasify the finely shredded combustible waste fraction. Ash from the bed blowdown stream, bed material, and fly ash entrained in the gas flow are separated from the offgas stream by a series of coarse and fine filters and sent to the vitrification unit. Noncombustible wastes are blended with the waste from the gasifier, combined with the soil, and vitrified. Acid gases are separated from the gas stream in a wet scrubber and the salts are polymer stabilized. H2 and CO are sent to a thermal oxidizer, similar to Systems C-3 and G-1. Since heat for gasification is indirect, offgas passing through the system is small and the gas cleanup equipment is small compared to the rotary kiln systems.

System J-1, Joule-Heated Vitrification

This system uses a high-temperature, Joule-heated vitrification system to combust the organic wastes and melt the residues, along with the noncombustible wastes and soils, in a single unit operation similar to the slagging rotary kiln, the three plasma systems, and the molten metal reactor. The waste is shredded and fed to the melter along with the soil; a slag waste form is produced. For Joule-heated melters, it is important to minimize the amount of metal in the melt to prevent short-circuiting of the electrodes, so additional sorting is required for this system. Except for waste preparation steps, this system is similar to the plasma system (C-1). An APC subsystem similar to that of the baseline system is used, but sized for the smaller offgas load (electricity has replaced methane). Air is used for combustion in this system.

It is also appropriate to point out that this system could have been configured with an AC or DC graphite electrode melter instead of the Joule-heated unit. These types of melters are not sensitive to metal content in the feed and require less waste sorting and shredding. The use of one of these melter types would allow elimination of the separate metal melter subsystem that is required for the Joule-heated melter system. Their waste preparation requirements are similar to the pretreatment requirements defined for the rotary kiln in this paper, i.e. shredding.

System K-1, Thermal Desorption and Mediated Electrochemical Oxidation (MEO)

This system is designed to treat shredded waste using only low-to-moderate temperature processes. Thermal desorption using an indirectly-heated desorber is used to heat the combustible and noncombustible solids to vaporize and remove volatile organic compounds (VOCs). The VOCs are condensed and oxidized in a MEO cell. The desorbed solids and residues from the MEO reactor are stabilized in grout.

System L-1, Thermal Desorption and Super Critical Water Oxidation (SCWO)

This system is similar to System K-1. All solids are shredded and fed to a thermal desorption system to remove low-boiling-point VOCs, which are then condensed and oxidized in a SCWO unit operation. The solids from the thermal desorber and residues from the SCWO reactor are solidified in grout.

SUMMARY
The ITTS study has identified a variety of MLLW thermal treatment systems and explored the differences among several core thermal treatment technologies, combustion gases, air pollution control systems, CO2 management methods, and techniques for stabilization of residues. When complete, this study will establish the variations in gaseous effluents, solid residues, and preliminary life cycle cost estimates for these 19 systems. Cost sensitivity analysis will be performed to show the effect of uncertainty on system cost.

U.S. Department of Energy

ABSTRACT
Through its Mixed Waste Integrated Program (MWIP), the U.S. Department of Energy (DOE) is identifying and evaluating technologies capable of treating DOE hazardous organic mixed wastes without the problems associated with permitting and siting incinerators. Various innovative thermal processes have been evaluated, including supercritical water oxidation, molten salt oxidation, molten metal bath, steam reforming, chem-char oxidation, packed-bed reactor, and electric arc. Some of these technologies will treat only aqueous or gaseous waste, but several show promise for treating the DOE's range of wastes. The MWIP has prepared a Technical Area Status Report for waste destruction technologies that tabulates and discusses available options. This paper discusses various thermal processes as alternatives to incineration, evaluating their advantages, disadvantages, and state of development.

INTRODUCTION
The U.S. Environmental Protection Agency's land disposal restrictions (as set forth in Title 40, Code of Federal Regulations, Part 268 [40 CFR 268]) require that mixed waste be treated prior to land disposal. Mixed waste streams containing hazardous organic compounds, which are typically treated by thermal systems, are a particular problem. The DOE has 247,000 cubic meters of mixed waste to be treated (1), the largest portion of which is aqueous. The aqueous waste is largely wastewaters and can be treated to meet regulatory requirements with available technology. The second largest portion of the DOE's mixed waste is inorganic sludges and particulates. These wastes can be treated by stabilization or thermal technologies. It is the remaining waste, which is a debris consisting of a wide variety of process solids and rubble, that represents the greatest challenge in terms of treatment.
There are conventional and innovative treatment options that can potentially be used to treat the DOE's mixed waste. The MWIP was formed to provide a vehicle for the DOE to identify and support new technologies that could improve cost-effectiveness, environmental safety, process performance, and waste form performance. The MWIP was charged with identifying technologies that could be applied to mixed waste across the entire DOE complex. In pursuit of this goal, the MWIP has supported numerous waste destruction, off-gas treatment, waste characterization, and final-form technology evaluations. The MWIP has focused primarily on two technologiesplasma hearth processing of a wide variety of waste streams and vitrification of mixed

waste sludges and soils.
The MWIP has prepared a Technical Area Status Report for waste destruction technologies that tabulates and discusses available options (2). This report evaluates technologies based on the following criteria: regulatory acceptance and stakeholder concerns, treatment efficiency and effectiveness, volume reduction, and improved environmental safety.
This paper is based on the Technical Area Status Report and discusses various thermal treatment alternatives to incineration. Technologies that will be described in this paper include:
- Supercritical water oxidation
- Molten salt oxidation
- Molten metal bath
- Steam reforming
- Chem-char oxidation
- "Flameless" secondary combustion system
- Electric arc.

Nonthermal alternatives are discussed in a companion paper presented in this conference by Schwinkendorf et al. (3).

TECHNOLOGIES

Incineration is a mature, well-developed hazardous waste treatment technology. Traditional incineration processes, including controlled air, rotary kiln, liquid injection, fluidized bed, and infrared, commonly heat waste to temperatures between 900C and 1,200C, volatilizing and oxidizing organic constituents. Some recent incinerator designs in remediation applications are using enriched or pure oxygen for the oxidation. Incinerator off-gases generally contain entrained particulates, NOx, products of combustion, and excess air. Other off-gas constituents may include SOx, volatile metals, HCl, and volatile metal chlorides. Trace quantities of light organics (residual organic stack emissions) are commonly present, and recombination products such as dioxins and furans can be produced during the off-gas cool-down period.
The thermal processes discussed in this paper use processes other than flame combustion in excess air. These include thermally oxidizing organics in an oxygen-starved or inert environment, or causing an organic material to react with something other than oxygen. In pyrolysis processes, the off-gas will contain combustible gases that are typically treated in an afterburner (4). Systems are also being developed to oxidize wastes in baths of molten salt or to break down organic molecules into elements in baths of molten metal.

Supercritical Water Oxidation

Supercritical water oxidation (SCWO) involves the oxidation of organic wastes in the presence of a high concentration of water at temperatures and pressures above the critical point of water, i.e., 374C and 22 Mpa (705F and 218 atm). Above the critical point, the properties of water change significantly, such that oxygen and most organic compounds become completely miscible with the supercritical fluid (eliminating the usual transport and mixing problems associated with reaction of two or more phases), and above 450C inorganic salts become almost completely insoluble. The organic waste feed may be in the form of an aqueous waste stream containing organics or a pumpable organic sludge. The oxidant may be air, oxygen, or hydrogen peroxide; in some cases, nitrates have been used successfully. Under these conditions, the waste is treated at high-destruction efficiencies of over 99.99%, and the resulting effluents, which consist primarily of H_2O and CO_2, are relatively benign (5).
Advantages:
- SCWO processes achieve high organic destruction efficiencies at lower temperatures without producing NOx (5).
- SCWO can process aqueous wastes with low concentrations of organics.
- Residence times are short, due to extremely good heat and mass transfer.
- The liquid phase medium facilitates recovery of combustion heat to heat the incoming waste stream and minimize auxiliary heating requirements.

Disadvantages:
- No metals should be present. The waste must be sorted.
- As currently developed, solid wastes require pulverizing prior to injection into the reactor.
- Corrosion-resistant alloy construction is required to contain the radioactivity at

the temperature and pressure requirements. Testing has not identified good long-term construction materials for the reaction chambers.

Safety provisions are expected to be extensive to protect against high-pressure releases.

Process thermodynamics and kinetics are not well understood.

Inorganics in the waste are not soluble in superheated water, resulting in plugging the oxidation chambers with inorganic salts.

Required Development:

Scale-up and demonstration of reliability and continuous, long-term operation on a variety of DOE wastes.

Monitoring, control, and determination of the fate of radionuclides in the SCWO process.

Definition of pretreatment requirements and demonstration of pretreatment systems.

Identification of suitable construction material.

Molten Salt Oxidation

Molten salt oxidation (MSO) has been identified as a potential alternative treatment process for low-level radioactive and organic mixed waste streams. The MSO process entails destroying the organic component of the waste at elevated temperature in the presence of the catalytic molten salt. The basic concept is a combined chemical and thermal waste treatment technology that does the following:

1. Feeds wastes and air into a ceramic-lined vessel containing a bed of molten salt at 900C to 1,000C
2. Oxidizes organic wastes using air sparged into the catalytic salt bath
3. Neutralizes acid gases in the bath
4. Discharges the salt for disposal or processing and recycling.

The molten salt acts as a dispersing medium for both the waste being processed and the air or oxygen used in the processing. It enhances the completeness of chemical reactions by providing improved physical contact and a stable heat-transfer medium that resists thermal surges. It also acts as a catalyst for the oxidation reactions to accelerate the destruction of organic material. The melt retains soot and char for more complete reaction and retains most of the radionuclides and other noncombustible materials associated with the waste. Sodium carbonate, or sodium carbonate mixed with other salts, is typical of the salts used in the melt. Tests performed by Rockwell demonstrated >99.9999% destruction of polychlorinated biphenyls, chlordane, trichlorobenzene, and other organics (6). The two-stage MSO unit at Lawrence Livermore National Laboratory has achieved organics destruction efficiencies of 99.99% for organic liquids when the temperature is maintained above 900C in the second stage (7).

Advantages:

MSO can accomplish destruction up to 99.9999% of various organics, acid gas absorption/neutralization, and some particulate and volatile metal removal from a waste stream in a single-unit operation.

This technology may be able to process difficult-to-treat wastes successfully, such as nuclear-grade graphite and tributyl phosphate, and may be suitable for other difficult waste streams containing low-melting metals, such as sodium.

Gas/liquid contact in the melt is intimate, providing high mass and heat-transfer rates and resulting in high destruction efficiency.

Disadvantages:

Fine shredding is required to achieve good solid/liquid contact.

Selection of construction materials for long-term operation is a challenge, as molten halide carbonate salts in an oxidizing atmosphere constitute an extremely corrosive chemical environment for the refractory lining.

No metals are to be present. The waste must be sorted.

Real-time monitoring of molten salt composition and viscosity is necessary to ensure high combustion efficiency. These controls have not been demonstrated.

The salt itself generates particulates in the off-gas, in addition to particulates generated from the waste. This carry-over could cause buildup in the system or pluggage of off-gas ducting.

There is a potential for adverse reactions of certain wastes with the molten salt.

Required Development:

Scale-up and demonstration of reliability and continuous, long-term operation on a variety of DOE wastes.

Monitoring, control, and determination of the fate of radionuclides in the MSO

process.
A simple, cost-effective method for the disposal or recovery of salt.
Molten Metal Bath
Metal-melting and refining technology is a decontamination method in which contaminated steel, copper, or other contaminated waste can be melted to form a molten metal phase and a molten oxide slag. This technology may be used to treat metal-bearing waste to destroy the organic contaminants, achieve waste volume reduction, recycle the contained metal, and produce a compact, leach-resistant waste form. The waste is introduced into a molten metal bath within a refractory-lined vessel, and the process parameters are controlled so that the constituents separate into a metallic layer and a slag layer (oxidized material). Uranium, transuranic elements, and many radionuclides of concern are preferentially oxidized and concentrated in the oxide, or slag, phase. Cooled slag is chemically stable and resistant to leaching. The organics are decomposed by the intense heat of the metal melting operation, producing either gasification products or oxidation products, depending on the mode of operation of the bath.
Advantages:
Destruction and removal efficiencies (DRE) of >99.9999% for injected organic compounds are regularly achieved (8).
Efficient in-bath heat transfer and the benefits of a homogenous catalytic solution can result in lower operating costs.
Metal recovery for recycling is possible.
Disadvantages:
The waste needs to be shredded.
The dissolution of the refractory material by the slag in a hazardous and radioactive environment can result in frequent maintenance in a difficult environment.
The off-gas system solids will contain fine particulates, metals, and radionuclides that are volatilized or otherwise carried from the melt at temperatures around 1,600C.
There may be a potential need for additives to control metal and slag properties, which will decrease the potential for volume reduction.
Keeping the metal in a molten state at all times is necessary to avoid substantial delays incurred in a shutdown.
Required Development:
Scale-up and demonstration of reliability and continuous, long-term operation on a variety of DOE wastes.
Monitoring, control, and determination of the fate of radionuclides in the molten metal bath process.
Effects of organic content of the waste on radionuclide partitioning and generation of particulates.
Steam Reforming
With steam reforming, hazardous organic chemicals can be destroyed by reacting with steam to produce a synthesis gas consisting of CO, CO2, H2, and H2O, in addition to light organics. Several variations of the basic steam-reforming system have been commercialized and are under development or demonstration. A system that has been used to demonstrate treatment of DOE wastes is the Synthetica Technologies system (4). The Synthetica Detoxifier consists of a two-stage destruction process. In the first stage, organics are volatilized by heat and high-temperature steam in a waste-feed evaporator. The hydrocarbons are vaporized within the evaporator upon exposure to superheated steam at 300C to 600C, which begins the steam reforming chemistry to thermally decompose and fragment the organic molecules. These gases generated in the evaporator pass to a noncatalytic, high-temperature steam reforming reactor (or detoxifier) operated at 1,200C, where they are mixed with superheated steam, and the reaction proceeds to completion. For many organic solvents commonly found in mixed wastes, greater than 99.99% destruction efficiencies have been achieved at 1,200C. An alternate process by MTCI uses a fluidized bed of sodium carbonate for reforming and acid gas control.
Advantages:
Greater than 99.99% destruction efficiencies have been achieved for various organic components of the mixed wastes.
The system is suitable for a wide variety of DOE waste streams at various concentrations.

SOx and NOx formation is minimized.
The system, sized for drum quantities of waste, is easily transportable.
A useful energy source (combustible gas) is generated.
Disadvantages:
One of the major limitations of the Synthetica system as it is currently configured is the limits on chlorine content of the waste (9).
The combustible gas stream must be burned for energy recovery, or energy input is required.
Required Development:
Scale-up and demonstration of reliability and continuous, long-term operation on a variety of DOE wastes.
Monitoring, control, and determination of the fate of radionuclides in the steam reforming process.
Identification of a method of treating chlorinated wastes.
Chem-Char Oxidation
Chem-char oxidation takes place in a reaction chamber that consists of a cylinder packed with a triple-reverse burn (TRB) char, which is a low-grade activated carbon product. The process can treat wastes in the form of solids, liquids, sludges, and soils. Liquid wastes are adsorbed on the char, contaminated soils and sludges are mixed with the char, and solid organic wastes are pulverized and mixed with the char. Oxygen is passed through the reactor from the top and flows countercurrent to a flame-front traveling upward. The primary destruction process is reduction of the waste to a combustible synthesis gas consisting of CO2, CO, H2O, H2, CH4, and trace volatile organics, and a dry, inert, carbonaceous solid. Radioactive and heavy metal constituents are retained in the char residue or ash. Organic DREs >99.9999% have routinely been achieved with second-stage combustion, with no detectable dioxins and furans. Tests have shown that the char can retain over 98% lead and over 99% of copper and zinc (10). Additional tests have demonstrated over 98% retention of radionuclides on the char (11).
Advantages:
Organic DREs of greater than 99.9999% have been achieved.
The process can treat a wide variety of wastes, including high ash, high water content, and viscous sludges.
The process requires no energy inputs.
A high percentage of heavy metals and radionuclides are retained in the regenerated char and slag.
Disadvantages:
Wastes must be shredded.
The technology involves a high processing temperature (1,200C), where some ash constituents may melt.
A secondary combustion chamber is required, typically a flame-type device, and potential permitting issues are involved.
The need to purchase or generate TRB char from coal.
Required Development:
Scale-up and demonstration of reliability and continuous, long-term operation on a variety of DOE wastes.
Monitoring, control, and determination of the fate of radionuclides in the chem-char process.
"Flameless" Combustion Systems
The Thermatrix technology is a flameless thermal destruction process for vapor-phase organics, which takes place in a packed-bed reactor (12). In the packed-bed, high-temperature thermal oxidation occurs within a reaction zone in a bed of chemically inert ceramic material, typically operated at 870C to 1,000C. The packed-bed consists of an insulated cylinder, lined with an alumina and silica refractory and containing a ceramic matrix composed of oxides of aluminum and silicon, with low levels of oxides of titanium, calcium, manganese, and magnesium (13). The matrix is immune to moisture and acid, is noncatalytic, and has a temperature rating up to 1,400C. Various test results by Thermatrix have indicated destruction efficiencies greater than 99.99% over a range of volatile organic compounds. The ceramic matrix does not deteriorate during operation.
Advantages:
DREs are >99.99% over a range of volatile organic compounds.
Low NOx formation, typically below 2 ppm.

Low CO formation, typically not detectable.

Low-pressure drop across the system, typically 3 inches water gauge.

Ability for internal heat recovery.

Ability to treat low flows with low concentrations, as well as high flows with high concentrations.

Disadvantages:

The system can process only gaseous feeds with no particulate.

Low organic content gases require supplemental fuel.

The inability of the system to handle certain compounds that may precipitate on the packing and potentially cause sticking and agglomeration of the packing material.

Required Development:

Demonstration on DOE wastes or as second-stage destruction device.

Electric Arc Heating

Arc melters maintain an arc between carbon (graphite) electrode(s) and the processed material. In the vicinity of the arc, a plasma is produced. The electric arc provides the primary energy for heating and melting the target material. This occurs in a sealed chamber, thus reducing the amount of gas produced during pyrolysis and allowing the gas to be removed from the system in a nonoxidizing atmosphere. During operation as a melter, an unopened drum may be fed into a molten bath. The drum melts, and the waste material is subjected to intense radiation from the arc and heat of the molten bath. As a result, organic material vaporizes and decomposes, and inorganic material is melted, producing a slag. The decomposition products are further decomposed by the electric arc. The products are sent to an off-gas system, where volatile or particulate organics are captured and the remaining organics are destroyed.

Advantages:

The system can accept a variety of inputs and waste matrices, including combustible and noncombustible wastes.

The wastes can be treated in their original container in an "as-received" condition with minimum characterization or pretreatment.

The use of electrical energy significantly reduces the volume of off-gas and particulates, along with associated pollution control requirements.

Disadvantages:

Off-gases containing trace organics and volatile metal compounds will require secondary oxidation.

High temperatures may produce high NOx levels.

High temperatures tend to volatilize heavy metals, which require capture in the off-gas system.

Required Development:

Scale-up and demonstration of reliability and continuous long-term operation on a variety of DOE wastes.

Routine electrode replacement.

CONCLUSIONS

The discussed thermal technologies individually have advantages over incineration in specific applications, but they also have several disadvantages and uncertainties. Some are not capable of handling all kinds of waste streams, i.e., solids, liquids, and vapors. A few of the technologies are not capable of handling the large volumes that incineration can handle; other processes may be suited for treating the low volumes of wastes existing at some facilities. Most of the technologies have not been tested in the field, and hence their performance standards and efficiencies are uncertain.

Supercritical water oxidation, in its current state of development, is capable of treating hydrocarbon contaminated aqueous wastes. The flameless secondary combustion system could process gases from a primary thermal treatment system or waste hydrocarbon gases from other processes. Molten salt oxidation, molten metal bath, steam reforming, electric arc treatment, and chem-char are being developed for solid (and liquid) waste processing. Overall process throughput requirements, waste composition, and project timing are factors that could justify application of one of these technologies to a waste destruction. In general, however, none of these processes are developed to the point that they can be accepted as a universal replacement for current incinerators.

ABSTRACT

Recently the Department of Energy's Mixed Waste Integrated Program initiated an evaluation of technologies capable of treating DOE mixed wastes without the problems associated with permitting and siting incinerators. Various categories of non-thermal technologies were evaluated including direct chemical oxidation, radiation induced oxidation, biological treatment, dehalogenation, and gas phase destruction. Although most of these technologies cannot directly replace incineration, many can destroy organics prior to separation and/or concentration and subsequent incineration. Three technologies appear to be relatively versatile, able to treat a variety of waste streams and contaminants including some solids, and are near field demonstration. These include the DETOXSM, the electrochemical oxidation, and the acid digestion processes. However, integrated systems must be demonstrated for secondary waste recovery and/or treatment before field implementation.

INTRODUCTION

The United States Department of Energy (DOE) is identifying, evaluating, and developing appropriate waste destruction and stabilization technologies for a variety of mixed waste streams. The DOE has approximately 250,000 m3 of mixed low-level waste (MLLW) to be treated. Aqueous liquids (containing <1% organics) comprise the bulk of these wastes (approximately 39%), inorganic sludges and particulates comprise approximately 33% of these wastes, and the remainder is

organic liquids, soils, debris, and other wastes. Although the concentrated organic material requiring destruction is not large, hazardous organic compounds and radionuclides are spread throughout these matrices in various concentrations presenting a challenge in terms of treatment.

Mixed waste containing hazardous organic compounds, which is typically treated by incineration, is a particular problem. Although incineration is the EPA BDAT for many organically contaminated wastes and is an omnivorous treatment process (i.e., it can treat a variety of wastes and can tolerate changes in the waste stream in terms of content, concentration, and feed rate), DOE is concerned about the current difficulty of permitting and siting incinerators. Public acceptance and perceptions associated with air emissions of toxic metals and organics are major issues (1).

Recently the Department of Energy's Mixed Waste Integrated Program (MWIP) initiated an evaluation of alternatives to incineration to identify technologies capable of treating DOE mixed wastes and which may be more easily permitted. It was expected that several non-thermal technologies would alleviate stakeholder concerns by decreasing off-gas volumes and eliminating the emission of particulates, volatilized metals and radionuclides, PICs, NOx, SOx, and recombination products (dioxins and furans).

Technologies are being evaluated based on the following criteria: regulatory acceptance and stakeholder concerns; treatment efficiency and effectiveness; volume reduction; and improved environmental health and safety. Ideally the technology would be versatile, relatively omnivorous, capable of treating a variety of wastes with varying constituents with minimal pretreatment or characterization, easy to implement, and would produce secondary waste stream volumes significantly smaller than the original waste stream.

The low-temperature alternatives to incineration were grouped into the categories shown in Table I. This paper will discuss these technologies with respect to the above stated criteria.

TABLE I

TECHNOLOGIES

Although the effectiveness of most non-thermal technologies increases at elevated temperatures, for the purposes of these evaluations a low-temperature technology is defined as one that is capable of destroying or decomposing organic molecules at temperatures 350C.

These processes may provide a direct or indirect substitution for incineration. That is, certain incinerable wastes may be directly treated to destroy the organic contaminant in lieu of incineration. For example, most direct chemical oxidation systems can treat some organic solids and organic liquids that are legacy wastes, or condensed from a thermal desorber carrier gas or from an air stripping or soil vapor extraction operation. Application of gas phase destruction techniques can eliminate the condensation process and treat the organic vapors directly. Waste streams that cannot be incinerated, such as dilute aqueous wastes, may be treated to destroy the organic contaminants thereby eliminating the need for separation processes (e.g., oil/water separators, activated carbon beds, etc.) and indirectly eliminate the need for subsequent incineration of the concentrated organic waste stream.

Most of these technologies have minimal off-gas (typically CO2, water vapor, CO, HCl, and in some casesVOCs and NOx), metals are not vaporized and dioxins are not produced, and it may be easier to gain public acceptance and permitting. However, because these technologies will not accept bulk wastes, except possibly acid digestion, care is required in the pre-treatment (size reduction) and metering of waste into the process, and most of the technologies are limited in waste type and matrix for which they are effective.

Except for wet air oxidation, the direct chemical oxidation processes are the most versatile of the low temperature technologies, and are effective in treating organic liquids, sludges, and some solids if adequately reduced in size. Other technologies are limited to specific waste streams such as halogenated organic liquids, organic vapors, or dilute organics in an aqueous matrix. Many of these technologies involve relatively weak oxidation processes so that long residence times may be required for adequate destruction, or rate limiting reaction byproducts may be produced requiring post-processing. In almost all cases destruction and removal efficiencies (DREs) and reaction byproducts depend on the contaminants in the waste stream and residence time in the reactor. These technologies are discussed in somewhat more detail in the following sections. Greater detail and additional references are provided in Ref. 2.

Direct Chemical Oxidation Processes

Direct chemical oxidation processes use a chemical oxidizer (oxygen, nitric acid, or oxidizing cation) to decompose and oxidize organic contaminants that are either in solution or suspension in the reacting medium. These reactions are most effective on soluble organic compounds, although some solids and immiscible liquids may also be treated. However, because the reaction rates depend on surface area, solids require size reduction and liquids require mixing for the reaction to take place in a reasonable period of time.Wet air oxidation (WAO) is a commercialized process that involves the aqueous-phase oxidation of dissolved or suspended organic substances with oxygen. Typical reactor temperatures range from 150C to 325C, and pressures of 2,069 kPa to 20,690 kPa are maintained to control evaporation and maintain the liquid state. However, high pressures in a radioactive environment introduce complexity and additional hazards to the operation.

WAO is not a highly predictable process, and the design is usually based on bench-scale tests for specific compounds so that a thorough knowledge of the waste to be treated is necessary. The degree of oxidation of organics and inorganics is limited by the solubility of oxygen in water. Up to 95% to 99% destruction in 15 to 60 minutes can be achieved; however, only 60% to 70% destruction is achievable with more resistant compounds (3). Although WAO has a high DRE for many organic compounds, they are rarely completely mineralized and some hazardous compounds can be produced as products of oxidation. This oxidized effluent, which contains residual organics, suspended solids, and soluble metal salts, generally requires further treatment to meet EPA treatment standards. Oxidized sulfur and nitrogen species are retained in the liquid phase; thus, SOx and NOx do not pose air pollution problems.

Catalyzed chemical oxidation refers to the class of reactions that use oxidizing agents with a catalyst to oxidize hazardous organic material to CO2, H2O, mineral acids, and less toxic organic materials. An example is the use of Fe(III) as an oxidizing agent in an HCl solution in the DETOXSM process being developed by Delphi Research, Inc. Such oxidizing agents are stronger oxidants than O2 and overcome wet-air oxidation process limitations caused by the limited solubility of oxygen in water. Cocatalysts increase the oxidation rate for organics, and Fe(II), formed in the organic oxidation process, is oxidized back to Fe(III) by a second catalyzed reaction with oxygen (4). The process typically takes place at 100C to 300C, depending on the waste form and composition, and at pressures of 240 kPa to 1480 kPa. The low temperature process produces no NOx, SOx, dioxins, or furans; however, elevated pressures in a radioactive environment introduce complexity and operational hazards.

This process is capable of treating dilute organic solutions, concentrated organic liquids, and certain organic solids up to 1 cm in size, and is highly tolerant of waste composition, form, water content, and particle size. However, care must be taken to meter in concentrated organics to prevent excessive temperature buildup and a runaway reaction, and to meter in aqueous wastes to prevent dilution of the acid bath and allow excess water to evaporate. In addition to oxidizing waste organics, most heavy metals and radionuclides are solvated and concentrated in the acidic catalyst solution. Thus, organic and inorganic contaminants may be removed from various matrices such as soils and debris.

The process is currently at the bench-scale level of development, although a pilot-scale demonstration is scheduled for FY95. Tests have been performed on various organic compounds, heavy metals, and radionuclide surrogates. Organic DREs >99.5% have been achieved in several hours, although faster destruction rates are expected in a well-mixed reactor with higher organic loadings. Small quantities (mg/liter to g/liter) of residual volatile and semivolatile organic compounds, including chlorinated hydrocarbons, have been found in the condensate and process solution (5). The secondary wastes produced by the process are primarily residual solids, heavy metal salts precipitated from the reaction solution, condensate, and exhausted reaction solution. The condensate containing HCl is typically returned to the DETOXSM solution or used to rinse filtered residual solids before being returned to the reaction chamber. The offgases, principally CO2 and O2, are recirculated to aid in agitation of the solution and to oxidize remaining volatile organics.

Acid digestion uses nitric acid as the oxidizing agent. Two acid digestion processes were investigated: the sulfuric acid process developed by Westinghouse Hanford Company (WHC) in the 1970s and 1980s, and the nitric-phosphoric acid oxidation

process being developed by Westinghouse Savannah River Company (WSRC). Both systems operate at temperatures of 200C to 250C and at atmospheric pressure.
Acid digestion systems are able to treat a wide variety of waste streams containing hazardous organics. The process works especially well for cellulosic materials and is suitable for polymers and non-volatile chlorinated hydrocarbons such as PCBs. Low volatility liquid organics may be treated by injection beneath the liquid surface to prevent flash-off and to increase residence time. Waste streams with high ash or metal content may produce large secondary wastes, and the offgas from both systems consists of HCl from chlorine-containing waste, and NOx released from solution as the nitric acid is depleted. The off-gas from the WHC system also contains SOx. Sulfuric acid and phosphoric acid act as dehydrating agents, but phosphoric acid raises the temperature at which nitric acid remains liquid from 150C to 190C. Preliminary results indicate that a 30C increase in temperature increases reaction rates by an order of magnitude. Tests at WHC on ion exchange resins, decontamination rags, HEPA filter frames, wooden structural materials, high plutonium bearing sludge, and plastic bottles were successful and demonstrated the removal of Pu from the treatment residue, and overall organic destruction efficiencies of 99.99%. However, the system was shut down in the mid-1980s due to lack of funding. The SRS system has been tested on combustibles such as plastics, neoprene, cellulose, and tributylphosphate with good results; however, destruction efficiencies are not yet available.
Electrochemical oxidation processes are similar to the two preceding processes in that an oxidizing cation (usually Ag(II)) in a nitric acid solution is used to produce highly reactive OH and NO3 radicals. The cation and free radicals attack organic compounds converting most of them to CO2, water, and inorganic ions. The resulting Ag(I) is recycled to Ag(II) at the anode of an electrochemical cell to maintain a supply of oxidant and minimize consumption of Ag. The Ag(II) migrates back into the bulk electrolyte to continue the oxidation process. A microporous membrane is usually placed between the electrodes to prevent the oxidizer produced at the anode from being reduced at the cathode. The oxidizers and acid also dissolve inorganic compounds that may contain radionuclides, including PuO2 which is not soluble in nitric acid alone.
Experiments at Lawrence Livermore National Laboratory (LLNL) achieved nearly 100% destruction of Trimsol and reagent-grade cellulose. Tests at Pacific Northwest Laboratory (PNL) have achieved destruction efficiencies for oil of >99% of the organic carbon at temperatures in the range of 60C to 90C. An ultrasonic generator was used to produce a micro-emulsion of the immiscible organics in water to increase the surface area, and the oxidation rate, of the organic material (6). PNL has also tested cerium as an oxidizing agent in HNO3 and, at higher temperatures (~100C), found it to provide the same or better oxidation rates for Trimsol as did silver without precipitation as a halide (7). Work in the United Kingdom (8), using the same Ag/HNO3 based electrolyte, has shown that a variety of organic materials can be destroyed including aliphatic and aromatic hydrocarbons, phenols, organophosphorous compounds, organosulfur compounds, and chlorinated aliphatic and aromatic compounds, including PCBs. Several ion exchange resins were also destroyed with the oxidation of the organic component nearly complete; however, comparative trials with flaked polyethylene showed almost no reaction.
Problems with the Ag(II)/HNO3 process include precipitation of Ag as a halide salt when treating halogenated organics; leakage of cations and anions through the electrode separator; degradation of polymeric membranes; excessive corrosion of the anode in the presence of acids; and generation of HNO2 and NOx at the cathode. The process also typically operates with low concentrations (<5 wt %) of oxidizable materials (9).
All direct chemical oxidation processes operate with highly reactive media making corrosion and compatibility with materials of construction major engineering and safety issues. Secondary wastes include organic reaction by-products or products of incomplete reaction, inorganic sludges, and depleted acids. Thus, these systems tend to be complex due to the need for an integrated system to recover and/or treat acids, and recover dissolved metals either for reuse or for disposal. An off-gas system will be required to insure no acid fumes are vented with the CO2 and CO produced in the destruction process, and to regenerate nitric or sulfuric acid from the off-gases.
Radiation Enhanced Oxidation

It is generally inappropriate to treat large-volume, dilute streams with incineration or direct oxidation processes designed for higher concentration organics. Radiation induced oxidation technologies destroy dilute organics in water eliminating the need for separation processes and subsequent treatment of concentrated wastes. Radiation is used to generate OH radicals in an aqueous medium which in turn attack the oxidizable materials. Various radiation sources have been used (such as ultraviolet radiation, ultrasound, electron beams, and x-rays), along with oxidation agents such as H2O2 and catalysts (such as metal ions), as a means to generate hydroxyl radicals.

These systems generally operate with low organic concentrations (typically <5%), and are applicable to existing waste and groundwater, and effluent from soil washing and decontamination operations. Destruction efficiencies are affected by the presence of OH scavengers in the water (such as carbonates and bicarbonates) so that characterization and pre-processing to remove these scavengers may be required. Room temperature and ambient pressure operation, and the lack of corrosive media, minimize safety hazards associated with these systems.

UV light induced oxidation of organic contaminants in aqueous waste streams has been commercialized for several years and is under investigation at several DOE facilities to determine its applicability to specific wastes. The principle of UV/oxidation technologies is the generation of hydroxyl radicals through UV photolysis of various oxidants such as H2O2, O3, or Fenton's reagent. Because the reaction rate is directly proportional to light intensity, the waste stream must be low in turbidity and solids, and the glass window of the reactor must remain clear to allow penetration by the UV light.

Although some organic species are easily destroyed by UV oxidation processes, including water soluble cellulosic material, they are rarely converted completely to carbon dioxide and water, and hazardous compounds can result. In addition, the applicability of these technologies to complex mixtures is unknown. Systems developed for specific waste streams that have unvarying species and concentrations lack operational flexibility to accommodate the changing stream characteristics in many waste treatment facilities. Thus, waste streams must be characterized and the process tailored for the contaminants to achieve optimum destruction and minimize generation of toxic end-products.

Ultrasound affects organic oxidation primarily through cavitation, which is the growth and catastrophic collapse of a gas- or vapor-filled bubble in a liquid. The high localized transient temperatures (thousands of degrees Kelvin) and pressures (hundreds of atmospheres) in the center of the bubble cause direct pyrolysis of organic vapors within the collapsing bubbles, and decomposition of water molecules into free radicals that propagate outward into the surrounding fluid to react with organic material. As with the common ultrasonic cleaning technology, ultrasound can be used in conjunction with soil washing to remove organic contaminants from soil and destroy the organics that migrate into the aqueous matrix.

The technical feasibility of this process has been demonstrated in small batch units at Argonne National Laboratory. This process can be used to treat a wide variety of organics, due to the non-specific nature of the process, and should be able to handle aqueous streams with moderate amounts of suspended solids and low light transmissivity. However, this is a new and emerging technology and will require extensive development and testing before it can be applied with confidence in the field. Work has not been done to determine the nature of the end-products of this process, and application to the destruction of a variety of solid organic materials needs to be determined.

Electron-beam processing involves exposing material to high-speed electrons produced by electron accelerators. The process of irradiation in aqueous solutions produces sizable quantities of the free radicals eaq-, H., OH., and the more stable oxidant H2O2 that react with organic contaminants to break the chemical bonds and produce CO2, H2O, and salts. Various studies have been performed, and e-beam systems tested within and outside the DOE complex on dilute (in the hundreds of ppm range) organic/aqueous waste streams. These include high-voltage (1.5 Mev to 2.0 Mev) systems tested at Los Alamos National Laboratory (LANL) and at Florida International University (FIU).

Typical DREs >99% for most common solvents have been achieved. Although some removal efficiencies are less than desirable (e.g., 60% for 1,2-dichloroethane and 77% for methylene chloride), these are based on a single pass through the system. Since this

is a flow-through system, there is essentially no retention timeonce the electrons enter the water, treatment occurs in a fraction of a second. Therefore, the waste stream can be recycled two or three times to achieve the required removal efficiency or to destroy stable intermediate reaction products. This technology can handle variations in the waste stream and is not sensitive to the treatability of the contaminants, the particular target species, or the water quality. However, the system is currently in the development stage and is applicable only to dilute organics in aqueous waste streams.

X-ray and gamma ray treatment of organically contaminated soil and water products is based on the in-depth deposition of ionizing radiation. Collisions of energetic photons with moisture in most waste streams generates a shower of energetic secondary electrons within the contaminated waste material. These secondary electrons produce both highly oxidizing radicals and highly reducing aqueous electrons similar to the electron beam process. While hazardous by-products may form during treatment, the complete conversion of contaminants and by-products is claimed to be achieved at sufficiently high dose levels and residence times without undesirable waste residuals or air pollution (10). Because of the range of x-rays, large volumes can be treated and standard container walls will not absorb a significant fraction of the ionizing radiation so that waste contained in vented disposal barrels can be treated. As with the electron beam process, the major hazard associated with this technology is high voltage and radiation, which can be mitigated by adequate shielding.

Biological Treatment

Biological treatment (or biodegradation) refers to the degradation and detoxification of wastes using microorganisms like bacteria and fungi. Biodegradation is directly related to environmental conditions and, when implemented successfully, is simpler, less expensive, and less disruptive compared to conventional physical/chemical or thermal treatment methods, and not as much of a regulatory hurdle. Although destruction rates are slower compared to thermal treatment methods and maintenance of the microbial culture is required, biological treatment is perceived as more acceptable by the public and other stakeholders. Biotreatment processes operate at near-ambient temperature and pressure and neutral pH, reducing the risk and severity of accidental releases due to process failure. In general, the contaminant is most available to the microorganisms if it is in an aqueous environment. Aqueous or organic liquid waste streams and soils have the most promise for biological treatment, although biodegradation of neat organics (pure non-aqueous phase) is generally not practical. Microorganisms can also initiate oxidation-reduction reactions that can cause metals to precipitate from solution and facilitate their separation. The end result of biological treatment of organic waste is the conversion of the contaminant into biomass (more microorganisms) and by-products (water and carbon dioxide in the case of complete aerobic mineralization). Typically 40% to 50% of aerobically degraded waste is converted to biomass, which becomes a secondary waste sludge that must be disposed or treated. Biomass sludge in anaerobic environments may be only 5% to 10% of the mass of the organics degraded (the remainder of mass going to carbon dioxide, methane, and water). Metals, radionuclides, and other refractory compounds that are not degraded will either remain in aqueous solution/suspension and exit the process with the treated effluent, or may sorb to the biomass and exit with the biosludge.

The DRE from biological treatment will require evaluation on a case-by-case basis, but when implemented successfully can be very high and comparable to other physical/chemical treatment technologies. However, even under optimal conditions, microorganisms may not be able to reduce contaminant concentrations to the required health-based limits due to inadequate sustenance of the microbial populations at very low concentrations. In these cases, post-treatment may be needed to polish the final treatment products to meet governing regulatory limits. The challenges to more widespread use of biological systems for the treatment of hazardous and mixed wastes include the lack of successful full-scale examples, and the ability to translate results from controlled laboratory conditions to field conditions. Large-scale demonstrations of anaerobic systems have been rare, in part due to the sensitivity of the anaerobic cultures to upsets or variations in the process, and the lengthy recovery periods required once the balance of the system is upset.

Dehalogenation

Dehalogenation processes remove halogens from the molecular structure, rendering the

compound less- or non-hazardous. Reaction by-products, some of which may be toxic, may require post-treatment to meet discharge requirements. The technology is most effective for wastes contaminated with semivolatile halogenated organic compounds and pesticides. These technologies include chemical- and radiation-induced dehalogenation, and DREs >99% have been achieved. However, some contaminants may require extensive residence time in the reactor vessel to complete dehalogenation. The two most common types of chemical dehalogenation processes are KPEG (potassium hydroxide with polyethylene glycol), and APEG (alkaline polyethylene glycol). In these processes, wastes are mixed with the dehalogenation reagent and heated to replace halogens with polyethylene glycol, rendering the compound nonhazardous and generating a chlorinated liquid secondary waste stream. The Base-Catalyzed Decomposition Process (BCDP) destroys PCBs and produces aliphatic hydrocarbons, biphenyls, and sodium chloride. In the Birch process, soil contaminated with PCBs is slurried with liquid NH3 and Ca/NH3 at ambient temperatures to produce NH3 (which is flashed-off upon completion), calcium chloride, calcium hydroxide, and biphenyls. Photo-dehalogenation processes use UV light combined with a reducing environment to dehalogenate organics. The Light Activated Reduction of Chemicals (LARC) dehalogenation reactions are normally conducted in a basic water, alcohol, or hydrocarbon solvent. The Reductive Photo-Dechlorination (RPD) technology uses ultraviolet light in a reducing atmosphere and elevated temperature to remove chlorine atoms from vaporized organochlorine compounds. Typical reaction products from the LARC process include biphenyl and sodium chloride; by-products from the RPD process include HCl and hydrocarbons such as ethane, acetylene, ethylene, and methane. No oxygenated derivatives, such as dioxins or furans, have been observed.

Gas Phase Destruction

There are a variety of gas or vapor phase organic destruction technologies that require a pre-treatment process to vaporize the organic material such as thermal desorption, vapor phase extraction of VOCs from soils, etc. The low-temperature technologies in this category include electron beams, cold plasmas, and photolysis, and involve direct destruction of the molecular bonds or generation of radicals that attack the contaminants. Application of these technologies eliminates the need for condensation or carbon adsorption of the organic vapors and subsequent incineration. Electron-beam and cold plasma discharges, although different in concept, use similar chemical processes to achieve organic destruction. Electron-beam technologies use accelerators to produce medium energy electron beams (in the 200 kev range) to directly break the chemical bonds of the organic compounds or produce free radicals from oxygen in the carrier gas. Cold electric discharge plasmas, generated by an alternating electric field established between two electrodes, produce lower energy electrons (in the 10 ev range) that react with the organic contaminants and carrier gas much the same way as the higher energy electrons.

In the silent discharge plasma (SDP) device developed at LANL, small electrical discharges occur in the space between two opposing insulated planar electrodes connected to a source of alternating high voltage. A large number of micro-discharges of short lifetime but high instantaneous current are uniformly distributed over the discharge space. In the case where the annular space between a pair of cylindrical electrodes is filled with dielectric pellets, the high-strength electric fields developed in the interstitial spaces between the pellets form multiple corona sites which generate high-energy electrons. This configuration is termed a high-energy corona (HEC) process and is being developed at PNL. Destruction and removal efficiencies greater that 99% have been achieved. However, a variety of reaction by-products have been detected in the effluent from these processes including phosgene and small quantities of dioxins and furans from the SDP process. Tests with gas phase photolysis have demonstrated destruction and removal efficiencies of >99% in seconds to hours, depending on the contaminant. Low-temperature and high-temperature photolysis have produced a large number of toxic reaction by-products, depending on the temperature and parent compound.

CONCLUSIONS

Although non-thermal technologies do not have the large volume off-gas problems associated with incineration, they do have several general disadvantages: 1) in some instances, depending on the waste constituents and the technology, the organic material is not completely oxidized and intermediate toxic compounds may be produced that require post-process destruction; 2) many processes cannot treat organic solids, and those that do either require size reduction (sometimes to powder form)

or can treat only a limited class of solids such as ion exchange resins or soluble cellulose; and 3) the inorganic solids in the waste stream results in a sludge that requires additional treatment. For most technologies, thorough characterization of the waste stream is required to choose a particular treatment system, determine optimum processing conditions, and determine the required pre-treatment to remove OH. scavenging species.

Most of these technologies are limited in effectiveness to specific waste streams such as dilute aqueous wastes, concentrated chlorinated liquids, or vapor phase organics. However, these processes can achieve destruction of the target organic species without separation, concentration, and subsequent incineration. Three technologies appear to be relatively versatile, able to treat a variety of waste streams and contaminants including some solids, and are near field demonstration. These include the DETOXSM, the electrochemical oxidation, and the acid digestion processes. However, integrated systems are required for secondary waste and acid recovery and/or treatment. These technologies and their supporting systems require further development before field implementation can be accomplished.

ACKNOWLEDGEMENTS

These technology evaluations are being performed as part of the DOE Headquarters EM-50 support contract.

ABSTRACT

The U.S. Department of Energy's Office of Environmental Management (EM) has developed Waste Acceptance Product Specifications (WAPS) for Vitrified High Level

Waste Forms. These WAPS define the technical requirements and documentation requirements that must be satisfied before the producer's vitrified high level waste form can be accepted into the Civilian Radioactive Waste Management System. The waste form producers are required to document their compliance with the WAPS in the Waste Form Compliance Plan (WCP), the Waste Form Qualification Report (WQR), the Production Records, and the Storage and Shipping Records.

This paper describes the compliance methods and strategies being used at the Defense Waste Processing Facility (DWPF) and at the West Valley Demonstration Project (WVDP) to demonstrate compliance with each of the WAPS technical specifications. Several different methods are employed including: laboratory experiments, vitrification pilot plant studies, waste qualification testing, engineering calculations, and radioactive startup. This paper also assesses the compliance methods and strategies and assigns each a technology maturity level. The technology maturity level is an indicator of the degree of complexity in complying with the WAPS specifications. Technology maturity is defined as either High, Moderate, or Low. High Technology maturity means that the methods used to comply with the WAPS is based on long-term testing, well-defined procurement documents, and/or field proven implementing procedures. Moderate technology maturity is assigned to a compliance methodology that is somewhat complex but not entirely a new approach. A low technology maturity is used for a methodology that is being implemented for the first time for this application or is significantly complex.

The conclusion describes the effort being made by the facility operators to get the low and moderate approaches to work successfully. The programs and procedures necessary to implement these strategies/methodologies are approved and in place. Personnel staffing is adequate and the systems needed for waste qualification have been verified as operational.

BACKGROUND

In the late 1970's, DOE was investigating different approaches for immobilizing HLW resulting from its nuclear materials processing operations. A number of options were investigated, and in early 1980 the Savannah River Site (SRS) requested funds for a project to design, construct, and operate a facility to immobilize HLW via a vitrification process (formation of glass in a high-temperature melter). An Environmental Impact Statement (EIS) (1) and Record of Decision for the design, construction and operation of a vitrification facility was issued in 1982. Later that same year, the Department prepared an Environmental Assessment (2) which identified borosilicate glass as the preferred waste form for immobilizing SRS HLW. Shortly thereafter, vitrification was identified as the technology for immobilizing HLW into borosilicate glass at the West Valley Demonstration Project (WVDP). In 1990, the Environmental Protection Agency issued a determination that vitrification was the Best Demonstrated Available Technology for the treatment of high-level mixed waste, which exists at DOE facilities.

Two facilities are being completed by the Department of Energy (DOE) to immobilize HLW using the vitrification process for ultimate disposal in a federal repository. One of the facilities, the WVDP, located in western New York, is being constructed on the site of a former commercial nuclear fuel reprocessing facility. The other facility, the Defense Waste Processing Facility (DWPF), is being completed at the Savannah River Site (SRS) near Aiken, S.C.

INTRODUCTION

As part of the high-level waste acceptance process, the U.S. Department of Energy's Office of Environmental Management has developed Waste Acceptance Product Specifications (WAPS) for vitrified high level waste forms. These WAPS (3) define the technical requirements and documentation requirements that must be satisfied before the producers' vitrified high-level waste form can be accepted into the Civilian Radioactive Waste Management System.

The WAPS, which are based on the system-level requirements defined in the Waste Acceptance System Requirements Document or WASRD (4), are divided into five sections dealing with the borosilicate glass waste form, the canister, the canistered waste form, quality assurance issues, and documentation and other requirements. The DWPF and the WVDP are required to document their compliance with the WAPS in the WCP, the WQR, the Production Records, and the Storage and Shipping Records. The WCP is the waste form producer's plan for demonstrating compliance with waste acceptance product specifications which will assure that the waste forms will be accepted into the Civilian Radioactive Waste Management System (CRWMS) for eventual disposal in a

geologic repository. The WQR is a compilation of the results of the testing and analysis programs identified in the WCP.
This paper describes the methods and strategies by which DWPF and WVDP plan to demonstrate compliance with each technical specification in the WAPS. Several different methods are employed including: laboratory experiments, vitrification pilot plant studies, waste qualification testing, engineering calculations, and radioactive startup. (The quality assurance and documentation specifications, while very important to the waste acceptance process, are not covered in this paper because their compliance strategies are not technical per se).

WASTE FORM COMPLIANCE PLAN

The overall strategy for complying with the WAPS is to assure the quality of the product (i.e., canistered waste form) by a combination of component specifications and process controls. Many of the WAPS specifications require that the canister and waste form be well-characterized before DWPF and WVDP begin production of their actual waste forms. Some specifications are satisfied through a series of research and development activities. Others are satisfied through production scale operations using non-radioactive simulated waste. The remaining WAPS specifications address canistered waste forms produced during radioactive operations. This strategy is intended to demonstrate that the product will be acceptable over the range of anticipated chemical compositions and operating conditions.
At DWPF, a comprehensive test program has been developed covering all aspects of facility startup. Those portions of the DWPF startup test program which demonstrate integrated operation of the facility to produce an acceptable product are called Waste Qualification Runs. During the Waste Qualification Runs, the compliance strategies for many of the WAPS specifications will be demonstrated. At WVDP, the five year series of Functional and Checkout Testing of Systems (FACTS)* runs has provided considerable qualification data. FACTS included fully integrated melter runs. The melter runs had durations ranging up to 45 days. Simulated waste, based on the most recent analyses of waste tank samples with appropriate elements substituting for the radioactive elements, were used during these tests.

DESCRIPTIVE OVERVIEW OF THE METHODS AND STRATEGIES BEING EMPLOYED TO DEMONSTRATE COMPLIANCE WITH THE WAPS SPECIFICATIONS

The methods and strategies being used by the producers to demonstrate compliance with each of the WAPS Specifications are described in Table I. Each of the compliance strategies in Table I is assigned a technology maturity level. The technology maturity level is an indicator of the degree of complexity in complying with the WAPS specifications. Technology maturity is defined as either High, Moderate, or Low. High technology maturity means that the method(s) used to comply with the WAPS is based on long-term testing, well-defined procurement documents, and/or field-proven implementing procedures. Moderate technology maturity is assigned to a compliance methodology that is somewhat complex but not entirely a new approach. A low technology maturity is used for a methodology that is being implemented for the first time for this application or is significantly complex.

EVALUATING THE METHODOLOGIES AND STRATEGIES FOR THEIR TECHNOLOGY MATURITY

The methodologies/compliance strategies being employed are evaluated below for their technology maturity. Each of them is associated with a previtrification development activity or a vitrification process activity. This is depicted in Table I. Except where specifically noted, the compliance methodologies/ strategies discussed are used at both WVDP and DWPF.

Qualification Activities

Feed Batch Preparation: This activity is associated with WAPS specifications 1.1 and 1.3, which verify feed batch composition and project the Product Consistency Test (PCT)[5] results. A blending algorithm that utilizes chemical analyses information is embedded in the control scheme that verifies the composition of the melter batch. The batch (waste plus glass formers) acceptability strategy uses a statistically based process control model. The statistical process control model is complex and requires a cognizant engineer to interpret the model's output which correlates to the durability of the final product. Also, there is uncertainty associated with any model because it is developed from a finite amount of measured data. This approach is rated as low technology maturity.
Canister Fabrication. The canister fabrication activity covers six of the WAPS specifications:

Verify Canister and Filler Metal Composition (WAPS 2.1)

Test canister Integrity (WAPS 2.2)
Verify Unique Canister Label (WAPS 2.3)
Document Canister Dimensions and Welds on As-Build Drawings (WAPS 2.4)
Inspect Canisters for Foreign Materials and Package for Shipment to Facility (WAPS 3.3 and 3.4)

All of the methodologies/strategies for this activity are rated as high technology maturity. This is because they are straightforward compliance measures that have proven to be successful in the past.

Canister Receipt Inspection. This activity involves four WAPS specifications:
Remove Packaging and Inspect for Shipping Damage (WAPS 2.4)
Reinspect Canisters for Foreign Materials (WAPS 3.1, 3.3, 3.4)
Transfer to Shielded Facility and Install Temporary Cover (WAPS 3.3, 3.4)

Each of the methodologies are rated high technology maturity because they are proven, state-of-the-art approaches.

Canister Closure. This activity involves eight WAPS specifications:
Control Glass Fill Height Equivalent to 80% of Canister Volume (WAPS 3.6)
Remove Glass Samples and Analyze Representative Fraction of Samples (WAPS 1.1, 1.2, 1.3, 3.8, 3.9)
Install Lid and Perform Canister Closure (WAPS 2.2, 3.2)

The methodologies/compliance strategies for demonstrating compliance with the Canister Fill Height (3.6) and Sampling of the Glass Product (1.1, 1.3) are rated as low technology maturity. The canister fill height specification is demonstrated (at both DWPF and WVDP) with the Infrared (IR) camera Level Detection System. The IR system is a new application. The IR level detection system is not completely automated. It requires an operator to perform final control actions to ensure the specified fill height is reached. The methodology/compliance strategy for removing glass samples from the melter (at DWPF) and from the canister (at WVDP) use special-design sampling hardware. The technology maturity is low.

The methodology/compliance strategy for demonstrating Canister Weld Closure (2.2) is rated as moderate maturity because it makes use of new equipment and highly qualified operators, but the approach is based on standard welding techniques.

Decontaminate Canister. The methodology/compliance strategy that demonstrates that the filled canister's external surface is decontaminated and free of adhering glass particles (WAPS 3.7) is given a moderate technology rating. The decontamination process is not complex. At DWPF, glass frit slurry blasting is the method used. At WVDP, the method involves immersing the canister in a nitric acid/cerium solution. After the decontamination process, smear tests will be done to show that the alpha and beta/gamma contamination is less than specified levels. The smear test is demonstrated at the time of shipment. Adding some complexity is a remotely-operated needle gun. The needle gun is used to remove any glass particles adhering to the canister's external surface.

Canister Storage. This activity involves monitoring the interim storage cell/building temperature to ensure that it remains below the glass transition temperature of approximately 450o C (WAPS 1.4). The methodology/compliance strategy utilizes a combination of thermal analyses calculations and resistance-temperature-detectors (RTDs). The technology maturity level is High.

Transfer Canisters to CRWMS. This activity involves seven WAPS specifications:
Report the Radionuclide Inventory During Production (WAPS 1.2)
Certify Canister Storage Temperature (WAPS 1.4)
Verify Label Integrity (WAPS 2.2)
Swipe Canister and Repeat Decontamination (WAPS 3.7)
Estimate Heat Generation and Surface Dose Rates (WAPS 3.8, 3.9)
Weigh Canisters and Verify Dimensions and Ability to Stand Upright (WAPS 3.11)

Only one of these compliance strategies is rated low technology maturity. It is the one that demonstrates smearing of a decontaminated canister and counting of the smear's radioactivity with standard instrumentation (WAPS 3.7). The smear survey is carried out remotely. This compliance strategy can only be implemented after radioactive operation begins. The other compliance strategies are rated as High Technology Maturity.

Previtrification Qualification Activity. This activity involves eleven WAPS specifications:
Estimate Crystalline Phases Present in Waste Form Based on Conservative Canister Cooling Rates (WAPS 1.1)

Formulate and Verify Glass Composition Based on PCT Response Model (WAPS 1.3)
Prepare Time-Temperature-Transformation (TTT) Diagram (WAPS 1.4)
Verify Waste Form does not exhibit RCRA Hazardous Characteristics via the Toxicity Characteristic Leaching Procedure (TCLP) (WAPS 1.5)
Show Glass does not Generate Gas and Calculate Radiogenic Gas Generation Rate (WAPS 3.2)
Demonstrate that melting process destroys organics and pyrophoric materials (WAPS 3.3, 3.4)
Show waste form does not lead to canister corrosion (WAPS 3.5)
Demonstrate canistered waste form shall not result in nuclear criticality accident (WAPS 3.10)
Perform canister impact tests (WAPS 3.12)
Design and test canister grapple for use at the repository (WAPS 3.13)

One of the compliance strategies (WAPS 1.3) has a low technology maturity. It deals with verifying the product glass composition and product durability. The compliance strategy makes use of a predictive mathematical model. The model development is based on extensive pilot plant and laboratory testing. The other compliance strategies are High Technology Maturity and are discussed in Table IA, B, C, D.

CONCLUSION

Some of the methods that DWPF and WVDP employ to demonstrate compliance are complex and are being implemented for the first time. A concerted effort is being made on the part of the facility operators to get these to work successfully. Extensive testing and characterization of the waste have occurred. The programs and procedures necessary to implement these strategies/methodologies are approved and in place. Personnel staffing is adequate and the systems needed for waste qualification have been verified as operational.

We believe that sufficient measures are being taken in development, design, testing, procedure formulation, personnel training and Quality Assurance to ensure that DWPF and WVDP will comply with the WAPS and produce satisfactory and acceptable waste forms.

HYDROGEN EVOLUTION AND SLUDGE SUSPENSION DURING THE PREPARATION OF THE FIRST BATCH OF SLUDGE AT THE SAVANNAH RIVER SITE

Ernest D. Lee
Michael S. Hay
Westinghouse Savannah River Company

ABSTRACT

The first batch of High Level Radioactive Sludge for the Defense Waste Processing Facility is being prepared in two 4.9 million liter waste tanks. The preparation involves removing water soluble salts by washing (water addition, sludge suspension, settling and decantation). Sludge suspension is accomplished using long shafted slurry pumps that are mounted on rotating turntables. During the sludge suspension runs in 1993 and 1994, the slurry pumps' cleaning radius was determined to be less than that expected from previous determinations using synthetic sludge in a full size waste tank mockup. Hydrogen concentrations in the tanks' vapor space were monitored during the sludge suspension activities. As expected, the initial agitation of the sludge increased the hydrogen concentration, however, with the controls in place the hydrogen concentration was maintained below seven percent of the lower flammability limit.

INTRODUCTION

Approximately 13.6 million liters of radioactive waste sludge resulting from the chemical separation of uranium, plutonium, and fission products are to be removed from twenty-one high level waste storage tanks, vitrified, and placed in canisters at the Defense Waste Processing Facility (DWPF).
Prior to sending the sludge to the DWPF for vitrification, the sludge is treated in the Extended Sludge Processing Facility (ESP). All of the sludge will undergo sludge washing. The sludge washing process uses a series of water additions and decantations to remove soluble salts from the sludge. Sludge containing high aluminum concentrations is also subjected to aluminum dissolution prior to sludge washing. The gibbsite form of aluminum can be solubilized and washed from the sludge by the addition of sodium hydroxide and heat. The first batch of sludge had previously undergone aluminum dissolution in an In-Tank Demonstration in 1982. This paper discusses the results of recent sludge washing activities in ESP with regard to sludge suspension and hydrogen evolution.
DISCUSSION
Sludge pretreatment is performed in modified type IIIa waste tanks. These tanks are 25.9 meters in diameter and 10 meters high. Each tank contains a center annulus which isolates a concrete roof support column from the tank contents. Also contained in the waste tank are 22 sets of cooling coils extending from 0.3 meter above the bottom of the tank to 0.3 meter below the tank's top. These 7.6 cm diameter carbon steel coils are located on 0.9 meter centers throughout the entire tank's cross-section. The tank's vapor space is continuously force-ventilated with outside air. Approximately 8500 liters per minute of tank vapor is continuously discharged through a HEPA filter and a centrifugal fan. The hydrogen concentration in the tank's vapor space is continuously measured by an on-line analyzer.
Suspension of the sludge lying on the tank floor is accomplished using vertical long shaft (13.7 meter) slurry pumps. This method of sludge suspension was developed using kaolin clay sludge in a full scale model of a waste tank at SRS. Kaolin clay was selected because the clay's rheological properties are similar to high level waste sludge. The slurry pumps have also been successfully used to mobilize radioactive sludge for removal of waste from other waste tanks. Two models of slurry pumps are used for ESP sludge suspension. The standard pump is a centrifugal pump containing two horizontally opposed discharge nozzles. This standard pump is designed to discharge 2300 liters per minute through each of its two 3.8 cm. diameter nozzles at a design speed of 1800 rpm. During testing the pump was able to suspend all of the kaolin clay sludge within a 7.6 meter radius. The ability of the slurry pump to remove sludge is related to the product of the pump's nozzle diameter and the nozzle discharge velocity. This quantity, designated as the VoD, is 1.27 m2/sec for the standard slurry pump.
The second type of slurry pump used in ESP is the Quad Volute (QV) Slurry pump. The QV pump is designed to discharge 7600 liters per minute through each of two 7.6 cm diameter discharge nozzles at a design speed of 2200 rpm. The VoD for the QV pump is 2.11 m2/sec. During testing with kaolin clay sludge, the QV pump was able to suspend all the sludge within a 12.2 meter radius.
A mathematical model was developed by Churnetski (1) to predict the cleaning radius of a pump based on the VoD, the Yield Stress of the sludge (to) and slurry density (SpG). The metric version of this equation is:
Eq. (1)
Where the units are:

m	for	ECR
m	for	D
m/sec	for	Vo
g/cc	for	SpG
dynes/cm2	for	to

The two tanks currently used for processing sludge at SRS are tanks 42 and 51. Four standard slurry pumps are installed in existing risers on tank 42. Four quad-volute slurry pumps are installed in existing risers on tank 51.
The first batch of sludge designated for DWPF was transferred into tanks 42 and 51 in 1987. During 1987 and 1988, four wash cycles were completed in tank 51 and three wash cycles in tank 42. During that time, the effectiveness of the pumps to suspend the sludge was not established. In 1988, the tops of tanks 42 and 51 became contaminated with low activity water that had leaked from the slurry pumps' bearing water columns. Sludge washing was suspended in 1988 and did not resume until

secondary containment enclosures could be designed, fabricated, and installed on each of the slurry pump sections that extended above the tank tops. The sludge has been settling in tanks 42 and 51 since the end of sludge washing operations in 1988.

Methodology

During 1993 and 1994, sludge washing was resumed in ESP with the initiation of the Process Verification Tests (PVT) in tanks 42 and 51. Data was collected during the PVT to determine processing parameters such as; the effective cleaning radius of the slurry pumps, the slurrying time required to suspend the tanks' sludge, and hydrogen releases. The PVT program included operating the slurry pumps for designated intervals at which time the pumps were stopped, the slurry immediately sampled, and the depth of the unsuspended sludge measured at three locations. The process was repeated with increasingly long slurring intervals. The three locations available for measuring the sludge height in tank 51 were located at risers E1, B3 and C3. For tank 42, the available risers were B2, C3 and E1.

The sludge depth is determined by lowering a stainless steel wafer attached to a steel measuring tape into the tank. The tape tension is reduced when the wafer contacts unsuspended sludge. When the tension is reduced, the length of tape below a reference point is recorded. With this information the settled sludge depth can be determined. The method indicates a general trend. However the accuracy of the measurement is dependent on the skill and experience of the operator performing the task.

Hydrogen Released During Sludge Suspension

Hydrogen is continuously generated in the waste tanks as a result of the radiolysis of water. The tank vapor space is continuously ventilated and hydrogen concentrations are nominally <100 ppm which is <0.3 % of LFL.(2) During the initial mixing of the sludge it was expected that hydrogen which had accumulated in the sludge would be released. During the 1993 initial startup of the tank 51 slurry pumps, the hydrogen concentration in the tank vapor space rose from 1% of the lower flammability limit (LFL) to a peak concentration of 6% LFL (0.24 Vol. % hydrogen). The peak concentration occurred approximately two hours after starting the third pump. At the time of peak hydrogen concentration, one slurry pump was operating at 1900 rpm, two other slurry pumps were at 1500 rpm, and the fourth pump was not operating. Due to increasing hydrogen concentration, the pump operating at 1900 rpm was reduced to 1500 rpm. The pumps remained at this speed until a power outage stopped all slurrying activities approximately 5 hours later. The hydrogen concentration and accumulated quantity of hydrogen released from the sludge are shown in Fig. 1. The release of hydrogen continued at elevated concentrations for approximately 50 hours. Included in Fig. 1 is the cumulative hydrogen released based on the hydrogen analyzer data. During the first few hours of operation the tank level dropped 2.3 cm. This drop in volume is equivalent to a release of 22.7 standard cubic meters of hydrogen. Based on hydrogen generation rate calculations for the waste composition in tank 51, the volume of hydrogen released during this initial slurrying activity is approximately 8% of the hydrogen estimated to have been generated in the tank since 1988.

The hydrogen concentration remained below 1% LFL during the remaining wash. After an idle period of five months, no increase in hydrogen concentration was detected during resumption of sludge washing in tank 51.

In May 1994, washing was initiated in tank 42. Each pump was run for four hours before startup of the next pump to minimize the hydrogen release rate. The hydrogen concentration remained below the analyzer's lower detection limit of 1% LFL (0.04 Vol. % H2) throughout testing in tank 42.

Sludge Suspension with Quad Volute Slurry Pumps

At the initiation of the PVT in tank 51, the bottom of the "B1" and "B4" slurry pumps were 1.0 meter above the tank floor, and the bottom of the G and H slurry pumps were 0.2 meter above the tank floor. During the startup of the "B1" slurry pump, it was discovered that the pump's bearing water column could not be supplied sufficient water to maintain column pressure. The high bearing water demand for this slurry pump was suspected to be a result of a failure of the mechanical seal located at the bottom of the pump's bearing housing. Washing continued without using the B1 slurry pump. In addition, the remaining slurry pumps also leaked water into the waste tank at higher than design rates. These slurry pumps were limited in speed in order to reduce bearing water in leakage.

Prior to starting the slurry pumps in tank 51, the sludge depth was approximately

two meters. The measured depths of unsuspended sludge as a function of slurrying time with three pumps are shown in Table I. The results indicate that the quad volute slurry pump's effective cleaning radius (ECR) at 2200 rpm in tank 51 is between 6.2 and 6.9 meters. Using equation 1 and a yield stress of 381 dynes/cm2, the shear stress measured for a tank 42 sludge sample, the predicted ECR is 10.9. The mean cleaning radius, 6.6 meters, is approximately 60 percent of the predicted ECR. A view of the area of the tank floor inside the ECR is shown in Fig. 2. Lowering the slurry pumps that are 1 meter above the tank floor may result in the pumps' producing a greater force on the sludge near the tank bottom and, thereby, increasing the ECR. A test is planned with the pumps in their lowest position, 0.2 meters from the tank bottom.

Sludge Suspension with Standard Slurry Pumps

At initiation of the PVT in tank 42 the sludge depth was approximately 2 meters. Much lower bearing water leak rates were observed than in the tank 51 tests even though both the standard and QV pumps have the same mechanical seals. Two of the four pumps, G and H, were elevated 68 inches off the bottom of the tank while V1 and V2 pumps were 8 inches of the bottom of the tank.

Two of the slurry pumps, G and H, did not draw their expected current during the testing. The G pump reached 40% of its expected amperage and was not operated through most of the testing out of the concern that the pump was cavitating. When the H pump was initially started, the pump amperage increased to the expected range. However, the motor current slowly decreased over the first few hours of operation. When H pump was shutdown for several hours and restarted, the pump would not load. However, if the pump was restarted after being shutdown for several days, the pump would again load to within the expected range but the amperage would slowly decrease over the period of a few hours.

The temperature measured by a thermocouple located beneath the tank floor near the location of H pump rose when the H slurry pump was operated. It is postulated that operating the H slurry pump only affected the sludge in the close vicinity of the pump's discharges. In this isolated area, the sludge temperature increased rapidly as a result of the work done. The increased temperature reduced the available net positive suction head (NPSH). Eventually the sludge temperature increased to a temperature which caused the pump to cavitate. When the pump cavitated, the pump amperage decreased below the expected range.

It is not clear why the problem only occurred with the G and H slurry pumps. Possibly the sludge was more compacted around these pumps. The G and H slurry pumps were elevated 68 inches off the floor in 1988, the last time the pumps were operated. During the same period the V1 and the V2 pumps were at their present location, 8 inches off the floor. It is suspected that the sludge in the vicinity of the H and G slurry pumps was not suspended in 1988 and may have continued to compact since the sludge's introduction into the tank.

The other two pumps, V1 and V2, maintained proper loading throughout the test. The measured depths of unsuspended sludge at the three locations as a function of pumping hours are shown in Table II. The pumping hours for the B2 riser location are based on the H pump. As a result of the problems experienced by the H slurry pump, the sludge removed at the E1 riser is attributed to the V2 slurry pump rather than the H pump. During testing, the sludge height under the B2 riser actually increased.

The effective cleaning radius observed in the tank 42 PVT is estimated to be 5.2 meters which is approximately 80% of the predicted value. Figure 3 shows the area of the tank cross section that is within the cleaning radius of 5.2 meters for the V1 and V2 slurry pumps . Approximately 30 percent of the sludge is within the ECR of these two pumps.

CONCLUSIONS

The performance of the slurry pumps during the Process Verification Tests in ESP was below expectations based on previous testing. Significantly higher bearing water leak rates were observed with the QV pumps in tank 51. The leak rate for the B1 pump in tank 51 was so excessive that it could not be operated at any speed without overriding the pump's bearing water pressure interlock. The bearing water leak rate for the tank 42 standard slurry pumps was near the expected range.

The observed ECR for both the standard and QV slurry pumps were well below predicted values. The quad volute pump's ECR was approximately 54% of the design basis of 40 feet. All four slurry pumps will be required to operate at maximum speed to fully

suspend the sludge in tank 51. The tank 42 standard slurry pumps' ECR was approximately 80% of the predicted value. However, based on the ECR of the standard slurry pump, all four of the standard slurry pumps operating at full speed will not be able to fully suspend the sludge in tank 42.
The results of the PVT indicated the majority of the sludge mobilization occurred during the first 50 hours of operation. However, sludge continued to be mobilized at reduced rates throughout testing . A steady state condition in which all of the sludge was suspended was never reached in either of the two processing tanks. The release of hydrogen during initial startup of slurry pumps was maintained below ten percent of LFL. This indicates that with the existing monitoring and control procedures, the hydrogen release can be maintained below its flammability limit in the tank vapor space.

DETERMINATION OF URANIUM DISTRIBUTION IN THE EVAPORATION OF SIMULATED SAVANNAH RIVER SITE WASTE (U)

Mark J. Barnes
Gregory T. Chandler
Westinghouse Savannah River Company

ABSTRACT

The results of an experimental program addressing the distribution of uranium in saltcake and supernate for two Savannah River Site waste compositions are presented. Successive batch evaporations were performed on simulated H-Area Modified Purex low-heat and post-aluminum dissolution wastes spiked with depleted uranium. Waste compositions and physical data were obtained for supernate and saltcake samples. For the H-Area Modified Purex low-heat waste, the product saltcake contained 42% of the total uranium from the original evaporator feed solution. However, precipitated solids only accounted for 10% of the original uranium mass; the interstitial liquid within the saltcake matrix contained the remainder of the uranium. In the case of the simulated post-aluminum dissolution waste; the product saltcake contained 68% of the total uranium from the original evaporator feed solution. Precipitated solids accounted for 52% of the original uranium mass; again, the interstitial liquid within the saltcake matrix contained the remainder of the uranium. An understanding of the distribution of uranium between supernatant liquid, saltcake, and sludge is required to develop a material balance for waste processing operations. This information is necessary to address nuclear criticality safety concerns.

INTRODUCTION

Carbon-steel tanks are used at the Savannah River Site (SRS) for the interim storage of nuclear waste. The waste consists of two phases: a sludge and its associated supernate. The solution is strongly alkaline with a high salt content (i.e., sodium nitrate, nitrite, aluminate, etc.). To minimize the volume of waste, the supernatant solution is evaporated and stored as a mixture of concentrated liquid and crystalline solids (i.e., saltcake). The evaporation process consists of successive heating and cooling of the solution. During heating, water is evaporated resulting in salt saturation of the solution. Upon cooling, salts, in excess of their solubility at the lower temperature, crystallize forming a saltcake layer. The residual supernate is then reprocessed to repeat the cycle. This process is repeated with the supernate solution until the waste tank is filled with saltcake and a minimal volume of saturated supernate. Final disposal of the saltcake will be accomplished by dissolution of the saltcake and processing through the Defense Waste Processing Facility (DWPF). Decontamination of the high-level radioactive waste solutions will be accomplished by the precipitation of cesium and potassium with sodium tetraphenylborate and adsorption of strontium by monosodium titanate in the In-Tank Precipitation (ITP) process. The slurry will be concentrated by filtration and washed. The resulting decontaminated salt solution filtrate will be stabilized in Saltstone. The concentrated slurry will be transferred for vitrification in DWPF.

Fissile isotopes of uranium are contained in the high-level nuclear waste that will be processed for permanent disposal via the ITP and sludge processing facilities (1). An understanding of the distribution of uranium between supernatant liquid, alkaline solids (saltcake), and sludge is required to develop a material balance for waste tank farm processing operations. This information is necessary to address nuclear criticality safety concerns. Two concerns are that fissile uranium, contained in the saltcake, will either not dissolve during salt dissolution or will dissolve at a much slower rate than saltcake. Either mechanism could result in uranium settling in the tank and collecting in sufficient quantity to form a critical mass. The solubility of uranium in alkaline salt solutions has been measured to better understand the behavior of the fissile material (2,3). This paper presents the results of an experimental program addressing uranium distribution behavior in an effort to provide guidance for safe dissolution and removal of saltcake. The work presented in this paper provides for an increased understanding into the distribution of uranium in saltcake and supernate for two SRS waste compositions. The two waste compositions simulated and investigated were H-Area Modified Purex (HM) low-heat and post-aluminum dissolution wastes.

EXPERIMENTAL

Simulated Waste Solutions

Simulated supernate wastes with H-Area Modified Purex (HM) low-heat and post-aluminum dissolution compositions, both spiked with depleted uranium, were used in the evaporation studies. The low-heat waste composition is based upon a 1981 waste inventory estimate (4). The post-aluminum dissolution waste composition is based upon an in-tank sludge processing demonstration in 1983 (5). The nominal compositions of the simulated test solutions are shown in Table I. For preparative purposes, aluminum nitrate, $Al(NO3)39H2O$, was dissolved separately with excess sodium hydroxide, NaOH, in distilled water to form sodium aluminate, $NaAlO2$, for the low-heat waste. Because of the lower nitrate level in the post-aluminum dissolution waste, a 65 wt % $NaAlO2$/19 wt % NaOH reagent was used instead of aluminum nitrate. For both simulants, the remaining components were mixed with distilled water and the aluminate solutions were added slowly while stirring. A 250 g U/L solution was prepared with depleted uranyl nitrate ($UO2(NO3)26H2O$) in 0.1 M nitric acid. This uranium solution was added to the waste simulants at a concentration of 100 mg U/L solution. The solutions were then allowed to stir for one week. After stirring, the solutions were filtered with a 0.45 mm filter to remove insoluble uranium solids.

Evaporation Procedure

Batch evaporation of simulated low-heat and post-aluminum dissolution wastes were conducted. The starting solution volume for the evaporation tests was approximately four liters. The starting solution densities of the low-heat waste and post-aluminum dissolution waste were 1.29 and 1.24 g/mL, respectively. Successive batch evaporations were performed on the waste simulants until the density of the supernate was approximately 1.5 g/mL. The evaporations were performed in a 6 L Teflon vessel heated by resistance-heated Chromalox elements. The solutions were heated to boiling; the overhead vapors were condensed and collected in a beaker. The volume of water removed for each evaporation step was based upon the estimated amount of evaporation required to obtain a solution density of 1.5 g/mL. Once the desired volume of water was evaporated, the boiling solution was removed from the evaporator. Small (i.e., 15-30 mL) samples of the boiling solution were collected in test tubes for analysis. the remainder was collected in a volumetric flask. These solutions were cooled to room temperature to allow crystallization of sodium salts. The supernate in the volumetric flask was decanted from the solids (saltcake) and the supernate solution density was determined. If the density was less than 1.5 g/mL, the decanted supernate was returned to the evaporator as the feed solution for the next evaporation step. This evaporation and precipitation procedure was repeated until the resulting supernate density was approximately 1.5 g/mL.

Sample Analysis

Supernate from each of the 15-30 mL supernate/solid samples collected in each evaporation step was decanted and the saltcakes were centrifuged to remove as much interstitial liquid as possible. The supernate and saltcake fractions were analyzed to determine their volume, weight, and chemical composition. Saltcake fractions were prepared for analysis by dissolution in distilled, deionized water. Extensive physical and chemical data (e.g., boiling points and densities, weight percent interstitial liquid in saltcake, and trends in chemical compositions) pertaining to

each evaporation step and the resulting supernate and saltcake were collected. Uranium analysis was performed on unfiltered and filtered (0.2 mm) solutions. Uranium was analyzed by laser-activated fluorescence and by x-ray fluorescence. Unfiltered solutions were analyzed for the remaining constituents. Concentrations of aluminum (Al), sodium (Na), silicon (Si), and phosphorous (P) were analyzed by inductively-coupled plasma (ICP) emission spectroscopy. Nitrate (NO3-), nitrite (NO2-), phosphate (PO43-), oxalate (C2O42-), and sulfate (SO42-) were measured by ion chromatography. Hydroxide (OH-), aluminate (AlO2-), and carbonate (CO32-) were determined by titration.

RESULTS AND DISCUSSION

Low-Heat Waste Evaporation and Characterization Data

Table II lists the evaporation data for the simulated low-heat waste. Four successive evaporations were performed on the low-heat waste which increased the solution density from 1.29 g/mL to 1.44 g/mL. The boiling point of the starting solution was 106.3C while the boiling point of the supernate feed in the fourth evaporation was 117.9C. The total volume reduction for the low-heat waste was approximately 70% based upon the supernate remaining after the fourth evaporation plus the total volume of solids from each evaporation. The solution volume was reduced by 87%. No solids crystallized from solution after the first evaporation, but solids did crystallize from solution in the remaining evaporations. The density of saltcake from each successive evaporation increased from 1.74 g/mL to 1.86 g/mL. The weight percent interstitial liquid in saltcake was determined from the volume of liquid removed from saltcake during centrifuging. The amount of interstitial liquid in saltcake was 14 wt % after the second and third evaporations and 18 wt % after the fourth evaporation.

Table III provides the composition of the starting solution and the supernate solutions after each evaporation step for the low-heat waste. As shown, the hydroxide concentration increased with each evaporation from 1.22 M in the starting solution to 5.22 M after the fourth evaporation. Nitrate initially increased after the first evaporation and then decreased with each evaporation. Nitrite and aluminate increased with each evaporation. Uranium increased from 8.1 mg/L to 31.4 mg/L. The uranium concentrations are significantly lower at the 1-2 M hydroxide concentrations in the low-heat waste as compared to existing data (3) thus suggesting that the low-heat waste was not saturated with uranium in the starting solution. However, the uranium concentrations in the 3-6 M hydroxide range are slightly higher than the existing data. The data suggest that uranium solubility may be significantly affected by concentrations of other components of the waste. In addition, as discussed by Karraker (3), measurements of the solubility of U in strongly basic solutions depend upon the method used for solution make-up.

Saltcake was not produced during the first evaporation step because the waste components of the low-heat waste had not reached their solubility limits. Saltcake was produced after the second, third, and fourth evaporations. Table IV shows the composition of saltcake after each evaporation step. The weight percents in Table IV are based on the total saltcake weight which includes the sodium salts plus water. Weight percent water was calculated from the difference between the weight of the sodium compounds and the total weight of saltcake. The calculated weight percent water is assumed to be fairly accurate because the total sodium moles calculated from the common sodium compounds associated with each ion were nearly equal to the sodium moles analyzed by inductively-coupled plasma emission spectroscopy. As shown in Table IV, the concentration of major components in the saltcake remain fairly constant for each evaporation while the weight of solids from each evaporation decreases with each succeeding step. The major component by weight is nitrate (~50 - 70 wt % based on total saltcake weight for each evaporation). The weight percent undissolved uranium and dissolved uranium in interstitial liquid remaining after centrifuging for each evaporation is approximately 0.0009%. The weight percent water in saltcake decreased from 27 and 24% after the second and third evaporations to 8% after the fourth evaporation.

Post-aluminum Dissolution Waste Evaporation and Characterization Data

Table V shows the evaporation data for the simulated post-aluminum dissolution waste. Three successive evaporations were performed on the post-aluminum dissolution waste which increased the solution density from 1.24 g/mL to 1.47 g/mL. The boiling point of the starting solution was 104.3C and the boiling point of the supernate feed in the third evaporation was 122.5C. The total volume reduction for the

post-aluminum dissolution waste was approximately 69% based upon the supernate remaining after the third evaporation plus the total volume of solids from each evaporation. The solution volume was reduced by 80%. Solids crystallized from solution after each evaporation step and the saltcake density increased from 1.41 g/mL to 1.76 g/mL. The concentration of interstitial liquid in saltcake determined from centrifuging was 6 wt % after the first evaporation and approximately 20 wt % after the second and third evaporations.

Table VI shows the composition of the starting solution and the supernate solutions after each evaporation step for the post-aluminum dissolution waste. As shown, the hydroxide concentration increased with each evaporation from 2.75 M in the starting solution to 8.80 M after the third evaporation. Nitrate initially increased after the first evaporation and then decreased with each evaporation. Nitrite and aluminate increased with each evaporation. The uranium concentration was initially 45.0 mg/L and then decreased and remained constant at approximately 20 mg/L. The uranium concentrations, as a function of hydroxide, are comparable to the Karraker data (3) at the low hydroxide range but slightly higher in the 5-9 M hydroxide range. This suggests that the uranium solubility is strongly dependent on hydroxide concentration but may also be affected by concentrations of other components.

Saltcake was produced during each evaporation step for the post-aluminum dissolution waste. Table VII shows the composition of saltcake after each evaporation step. The weight percents in Table VII are based on the total saltcake weight which includes the sodium salts plus water. Weight percent water was calculated from the difference between the weight of the sodium compounds and the total weight of saltcake. The calculated water content is assumed to be fairly accurate because the total sodium moles calculated from the common sodium salts associated with each ion were essentially equal to the sodium moles analyzed by inductively-coupled plasma emission spectroscopy as shown in Table VII. As shown in Table VII, as in the case of the low-heat waste saltcake, the major component is nitrate (~ 35 - 50 wt % based on total saltcake weight for post-aluminum vs. ~ 50 - 70 wt % for low-heat). The concentration of undissolved uranium and dissolved uranium in interstitial liquid decreases from 0.0056 wt % to 0.0036 wt %. The amount of water in saltcake increases from 23 wt % after the first evaporation to 37 wt % after the third evaporation.

Uranium Distribution

Low-heat waste was subjected to four successive evaporations. Saltcake was produced from each of the last three evaporations. The percentage of available uranium contained in the saltcake produced by each successive evaporation (i.e., undissolved uranium and dissolved uranium contained in interstitial liquid) decreased with each successive evaporation. For low-heat waste, the fraction of available uranium contained in each saltcake is 22, 18, and 8% for the second, third, and fourth evaporations, respectively. This data trend is likely the result of a combination of two factors. First, each successive evaporation produces less saltcake than the previous one. This results in a decrease in the amount of interstitial liquid. Second, the uranium concentration in the supernate is increasing. This would indicate that the uranium solubility limit has not been reached. Therefore, the ratio of uranium contained in the saltcake to uranium in solution is decreasing. Simply stated, the salts (i.e., NaOH, $NaNO_3$, $NaNO_2$, etc.) in this particular solution have reached their solubility limit for the second, third, and fourth evaporations while the uranium has either not reached, or has just reached, its solubility limit by the fourth evaporation. This theory suggests that the majority of uranium contained in saltcake produced by the second and third evaporations is present in interstitial liquid. The effect of the four evaporation cycles, as a whole, on the low-heat waste is that 42% of the uranium is contained in the composite saltcake.

Similar to the observations with low-heat waste, the percentage of available uranium contained in the saltcake produced by evaporation of post-aluminum dissolution waste decreases with each successive cycle. For post-aluminum dissolution waste, the fraction of available uranium contained in saltcake is 49, 22, and 19% for the first, second, and third evaporations, respectively. These percentages (specifically that for the first evaporation) are higher than those observed for the low-heat waste. This is expected in light of the fact that the post-aluminum dissolution waste starting solution had a uranium concentration of 45.0 mg/L and that 78% of the uranium was contained in solids larger than 0.2 mm. The large size would suggest that the uranium was colloidal and would easily separate from solution. Therefore,

the first evaporation likely caused a large portion of the uranium to aggregate with the saltcake. A similar pattern was repeated for the second evaporation; however, a much smaller percentage of the uranium was contained in solids larger than 0.2 mm. The effect of the three evaporation cycles, as a whole, on the post-aluminum dissolution waste is that 68% of the uranium is contained in the composite saltcake. An estimate of the amount of dissolved uranium contained in interstitial liquid is discussed in the next section.

Dissolved Uranium in Interstitial Liquid of Saltcake

The amount of dissolved and undissolved uranium contained in the interstitial liquid of the low-heat waste saltcake was estimated from the experimental data. The estimate was obtained from the weight percent water contained in a saltcake sample and the composition of the supernate above the saltcake. From this data, the volume of supernate remaining in the saltcake after centrifuging was determined. Using the uranium concentration of the supernate and the volume of supernate remaining in the saltcake, it was possible to estimate the quantity of dissolved uranium that is present in the saltcake. The difference between the measured total uranium contained in the saltcake and the dissolved uranium is undissolved uranium. Using this method, it was estimated that 82, 100, and 16% of the uranium contained in the saltcake produced by the second, third, and fourth evaporations, respectively, of low-heat waste was dissolved. Data presented in the Uranium Distribution section of this document showed the fraction of available uranium contained in the saltcake produced by the second, third, and fourth evaporations of low-heat waste was 22, 18 and 8%, respectively. Coupling this data with the above estimates would predict that the fraction of available uranium present as undissolved uranium in saltcake from the second, third, and fourth evaporations of low-heat waste is 4.0, 0.0 and 6.7%, respectively. The effect of the four evaporation cycles, as a whole, on the low-heat waste is that an estimated 10% of the total uranium originally present in the salt solution is precipitated as a solid.

The fact that only 10% of the total uranium originally present in the salt solution is precipitated as a solid is not unexpected. Three pieces of evidence support this estimate. First, tests showed that 84 to 96% of the uranium contained in the low-heat saltcake from the three evaporations was removed by rinsing of the saltcake with a highly concentrated sodium salt solution (6). Second, documented information shows that precipitated uranium does not readily dissolve in highly caustic salt solutions (2,3). Third, the percentage of uranium contained in the salt solution rinses that was less than 0.2 mm in size was relatively large (i.e., 67 to 98% for the second, third, and fourth evaporations). Coupling these three pieces of evidence suggest that a large fraction of the uranium contained in the centrifuged, low-heat waste saltcake samples was in fact uranium dissolved in the interstitial liquid.

The amount of dissolved uranium contained in the interstitial liquid of post-aluminum dissolution waste saltcake was estimated. Using the method described above, it was estimated that 14, 79, and 32% of the uranium contained in the saltcake produced by the first, second, and third evaporations, respectively, of post-aluminum dissolution waste was dissolved. Data presented in the Uranium Distribution section of this document showed the fraction of available uranium contained in the saltcake from the first, second, and third evaporations of post-aluminum dissolution waste was 49, 22 and 19%, respectively. Coupling this data with the above estimates projects that the fraction of available uranium present as undissolved uranium in saltcake from the three evaporations of post-aluminum dissolution waste is 42, 4.6 and 13%, respectively. The effect of the three evaporation cycles, as a whole, on the post-aluminum dissolution waste is that an estimated 52% of the total uranium originally present in the salt solution is precipitated as a solid. This value shows that a substantial portion of the uranium is present in a solid phase.

CONCLUSIONS

Successive evaporations were performed on simulated low-heat waste and post-aluminum dissolution waste spiked with depleted uranium. Waste compositions were determined for supernate and saltcake samples. For the H-Area Modified Purex low-heat waste, the product saltcake contained 42% of the total uranium from the original evaporator feed solution. However, precipitated solids only accounted for 10% of the original uranium mass; the interstitial liquid within the saltcake matrix contained the remainder of the uranium. In the case of the simulated post-aluminum dissolution waste; the product saltcake contained 68% of the total uranium from the original

evaporator feed solution. Precipitated solids accounted for 52% of the original uranium mass; again, the interstitial liquid within the saltcake matrix contained the remainder of the uranium.

ABSTRACT
Hanford high-level liquid waste will be converted into a glass form for long-term storage. The glass must meet certain constraints on its composition and properties in order to have desired properties for processing (e.g., melt electrical conductivity, melt viscosity, and liquidus temperature) and acceptable durability for repository acceptance. The Optimal Waste Loading (OWL) models, based on rigorous mathematical optimization techniques, have been developed to minimize the number of glass logs required and determine glass-former compositions that will produce a glass meeting all relevant constraints. There is considerable uncertainty in many of the models and data relevant to the formulation of high-level glass. In this paper, we discuss how we handle uncertainty in the glass property models and in the high-level waste composition to the vitrification process.
Glass property constraints used in optimization are inequalities that relate glass property models obtained by regression analysis of experimental data to numerical limits on property values. Therefore, these constraints are subject to uncertainty. The sampling distributions of the regression models are used to describe the uncertainties associated with the constraints. The optimization then accounts for these uncertainties by requiring the constraints to be satisfied within specified confidence limits.
The uncertainty in waste composition is handled using stochastic optimization. Given means and standard deviations of component masses in the high-level waste stream, distributions of possible values for each component are generated. A series of optimization runs is performed; the distribution of each waste component is sampled for each run. The resultant distribution of solutions is then statistically summarized.
The ability of OWL models to handle these forms of uncertainty make them very useful tools in designing and evaluating high-level waste glasses formulations.

INTRODUCTION
In immobilizing high-level liquid waste for long-term storage, it is advantageous to produce the minimum volume of immobilized waste glass (for a given volume of waste),

thus minimizing vitrification and disposal costs. The Optimal Waste Loading (OWL) models, based on rigorous mathematical optimization techniques, have been developed to determine the minimum number of glass logs required to immobilize Hanford high-level liquid waste. This optimization varies the glass-formers composition to maximize the waste loading (and minimize the glass volume), such that all processing and product (durability) constraints on the glass are satisfied.

Because there is uncertainty in both the property model predictions and in the waste feed composition for vitrification, the question naturally arises as to how the uncertainty affects the calculated waste loading and resultant number of logs required. In this paper we describe our approaches for addressing this question. We discuss techniques we are developing for addressing each of these uncertainties separately. As these techniques mature, we will integrate these and other techniques to handle all appropriate uncertainties.

In this paper, we briefly describe the general constrained optimization problem, which is the basis for the OWL model. We then present an overview of the OWL model formulation, followed by a discussion of the glass property models that are used in the constraints for optimization. We then describe our techniques for handling property model and waste composition uncertainties, and present some results for each. We end with some brief concluding comments.

THE GENERAL CONSTRAINED OPTIMIZATION PROBLEM

In the general constrained optimization problem, the objective is to find the multidimensional point x that produces the maximum (or minimum) value of some function f and meets a set of criteria called constraints. The problem would be stated as:

maximize f(x)
subject to h(x) = 0
g(x) 0

where

f is the objective function which we want to maximize (or minimize). It is a single (scalar) function of the unknown variables
x is a vector (x1, x2, ... , xn) of the variables over which we optimize
h is a vector function containing the equality constraints (h1(x), h2(x),..., hp(x))
g is a vector function containing the inequality constraints (g1(x), g2(x),..., gq(x))

Each equality and inequality constraint is also a function of the unknowns. In general, the objective function and any or all constraints may be nonlinear.

GLASS FORMULATION OPTIMIZATION MODEL

In the simple glass formulation problem, frit (glass formers) is added to a single waste composition, and the mass fraction of waste in the glass (waste loading) is maximized such that all the constraints are satisfied. The frit composition is varied as part of the optimization. The problem formulation is shown in Fig. 1 and briefly described below. More detailed information on the model can be found in Hoza (1).

FIG. 1

The simple waste optimization problem can be generally stated as follows:

minimize number of glass logs required
  or
maximize waste loading in the glass

subject to mass balance constraints
  property model component bounds
  solubility constraints
  glass property constraints

The objective function and constraints will be discussed in the next two sections.

Objective Function

The goal is to minimize the number of glass logs necessary to immobilize a waste of the specified composition. This can also be achieved by maximizing the waste loading

(fraction of the glass that is waste).
Constraints
There are four classes of constraints in the model.
The first, the mass balance constraints, are equalities which define the relationships involved in the formation of glass from its components. These include an overall balance and component balances for all components.
The second, the property model component bounds, limit the range of the composition (mass fraction) values each component can have in the calculated glass composition. They reflect the composition region over which the glass properties were experimentally determined, as part of the Composition Variation Study (CVS) (2), and define a polyhedron in composition space that specifies the region over which the glass property models are considered valid. Compositions outside these limits will not necessarily produce unacceptable glasses. Rather, these compositions represent regions for which the glass property models must be extrapolated. Promising glasses outside these limits would have to be evaluated experimentally to determine their acceptability.
The third, the solubility constraints, limit the maximum value for the mass fraction of selected components (Cr_2O_3, F, P_2O_5, SO_3, and noble metals). They are intended to represent solubility limits for the specified components. These limits cover component species not included among the species used in the glass property models. Eventually these solubility limits will be replaced with thermodynamic calculations that predict insoluble species.
The fourth, the glass property constraints, utilize the glass property models developed in the CVS. These are discussed in the next section.
GLASS PROPERTY MODELS
The glass property models are equations empirically fit to data, i.e., glass compositions and property values (melt viscosity, melt electrical conductivity, and durability in this work). Liquidus temperature models have also been developed but were not used in this work. The modeling approach and the calculation of uncertainty are addressed in the balance of this section.
Modeling of Properties
The property models are empirically fit linear and nonlinear (in composition) models. The models were developed as part of the Composition Variation Study (CVS) and are described in Hrma, Piepel, et al. (2). The CVS has been performed in five phases (CVS-I and CVS-II Phases 1-4). The models used in this work were based on data obtained through CVS-II, Phase 2.
The CVS used statistical mixture experiment design and optimal experimental design methods and software to select the glass compositions tested throughout the CVS. The glass composition region included is expected to contain glasses that might be made from various waste types expected to be processed at Hanford.
The model of each property is of the form
Eq. (1)
where bi and bij are the coefficients of the first- and second-order terms, respectively; xi is the mass fraction of component i; and 10 is the number of components considered in the study. The components included in the models are SiO_2, B_2O_3, Na_2O, Li_2O, CaO, MgO, Fe_2O_3, Al_2O_3, ZrO_2, and Others, which accounts for all species other than the nine specifically included. For the linear property models, all bij are zero.
The glass properties used in this work were viscosity, electrical conductivity, and durability (actually rate of release of boron) by either the Product Consistency Test (PCT) or Materials Characterization Center Test (MCC-1). The current version of OWL includes PCT Li and Na releases, and no longer uses MCC-1 releases.
Calculation of Uncertainty
Predictions made with a fitted property model are subject to uncertainty in the fitted model coefficients. The uncertainty results from the random errors in property values introduced during testing and measurement as well as minor lack-of-fit of the empirical model relative to the true relationship.
The uncertainty in a predicted property value for a given glass composition is defined as
Uncert=M[xTSx]0.5
Eq. (2)
where
M = multiplier, which is usually the upper 95th percentile of a

t-distribution
[t.95(n-p)], where n is the number of data points used to fit the model and p
is the number of fitted parameters (coefficients) in the model
x = glass composition vector expanded in the form of the model
x T = transpose of glass composition vector expanded in the form of the model
S = covariance matrix of the estimated parameters (coefficients)

For linear (first-order) property models, x is the usual glass composition vector. For nonlinear models, the vector is augmented by second-order terms. For example, if there are two second-order terms, x12 and x2x4, the usual composition vector (x1, ... ,x10) becomes (x1, ... ,x10, x12, x2x4).

OPTIMIZATION WITH GLASS PROPERTY MODEL UNCERTAINTY

The method used to account for glass property model uncertainty in the glass optimization and results of optimization calculations with property model uncertainty are given in the next two sections.

Method

This model accounts for uncertainty in the glass property constraints by using uncertainty to narrow the feasible region determined by glass property models. This approach changes the form of the glass property constraint to

Eq. (3)

When Uncert = 0, this constraint is the same as for the model that does not account for property model uncertainty. Figure 2 shows the effect on a ternary diagram (for a waste + frit + recycle mixture. The idea is the same for a waste + frit system, but a ternary diagram better helps visualize the concept). A single linear glass property constraint with upper and lower limits is shown on the figure. The regions in the triangle with dark shading are infeasible (the constraint cannot be satisfied in those regions). The unshaded region is feasible. The lightly shaded regions represent those compositions that become infeasible when property model uncertainty is considered. Alternately, it can be viewed as the shrinkage of the feasible region due to uncertainty. The shading around the glass composition point represents the uncertainty in the glass composition resulting from uncertainty in the waste composition. Methods for dealing with this uncertainty will be discussed in the section on waste composition uncertainty.

Fig. 2.

Results

The effect of property model uncertainty on maximum waste loading was examined for four Hanford double shell tank waste types. Table I summarizes the results of calculations that explore this effect for two constraint sets.

TABLE I

When the full constraint set is used (first and second rows in the Table I), there is no difference between the waste loading with uncertainty and the waste loading without uncertainty in the glass property models. This is not surprising. The uncertainty in the glass property constraints effectively tightens the glass property constraints, but not enough to make a difference. The binding constraint for each case is still the same as for the case without uncertainty, so the glass property constraints and their uncertainties are irrelevant (for these cases; this will not always be the result).

When only the glass property constraints (viscosity, electrical conductivity, and durability) are used (third and fourth rows in Table I), the following occurs:

Waste loading is reduced. As expected, the uncertainty in the glass property constraints makes a difference. The percent reduction in waste loading as a result of considering the uncertainty is on the order of the uncertainty in the binding constraints.

The uncertainty in the glass properties is much greater than it is for the full-constraint case. Because the calculated uncertainty is a function of where the point is located in composition space, this indicates that these points are in composition regions where less experimental data are available and may even be outside the experimental region. Examination of the glass compositions for these cases (which are not in the table) confirms this. Several of the component compositions are outside the upper and lower limits on the ten components (because those limits were dropped for these cases).

OPTIMIZATION WITH WASTE COMPOSITION UNCERTAINTY

The method used to account for waste composition uncertainty in the glass optimization and results of optimization calculations with waste composition uncertainty are given in the next two sections.

Method

The basic approach taken to address the optimization in the presence of waste composition uncertainty problem relies on the stochastic modeling method (3). Using this method, the strategy is to generate a large number of possible waste compositions based on the composition error structures, and for each of these, to generate a waste loading. The distribution of waste loadings can then be analyzed. The main steps in this method, as applied to this problem, are:

Develop probability distributions for the masses in the high-level vitrification feed of each of the components followed in the OWL models, based on estimates of means and standard deviations. For this work, all mass distributions were assumed to be normal (Gaussian).

Sample the above distributions and developing N waste composition input sets (mass fraction basis). Sampling the distributions provided masses for each of the species tracked. Latin Hypercube Sampling (4) was used because it provides better coverage of the composition distributions than simple random sampling with fewer samples. Given these masses and the total mass of the waste, the mass fractions of all species were determined and normalized to 1.000.

Run the N waste composition sets through the OWL glass formulation model to calculate the optimal waste loadings for each waste composition set.

Analyze the resulting distribution of waste loadings for the N input sets.

For this work, uncertainties in waste components were assumed to be statistically independent (i.e., uncorrelated). This is likely an unrealistic assumption, but knowledge of composition uncertainty correlations was insufficient to account for them in this work. Future efforts will account for them once they are adequately quantified.

Results

The method described above takes distributions in the masses of all relevant species, performs a series of calculations, and produces a distribution of waste loadings. This section looks at how the waste loading distribution is related to the input distributions, and what one can conclude from the output distribution?

The relationship between the output distribution and the input distribution depends on the constraints--which constraint(s) is/are binding and whether the same constraint is binding for all cases or the binding constraint changes for different runs. The following situations are possible; they are listed in order of increasing complexity.

The same single-component constraint is always binding.

The same multiple-component constraint (e.g., durability) is always binding.

The binding constraint is different for different runs.

No feasible solution is possible for some runs.

The waste selected for the sample calculation represents the least complicated situation. For this case, the binding constraint was consistent over all generated waste composition sets. This binding constraint was the upper limit on a single waste component (P_2O_5). As expected for this case, the waste loading varied inversely with the mass fraction of P_2O_5. Because the upper bound on P_2O_5 was the binding constraint for optimization, higher concentration of P_2O_5 causes a lower maximum waste loading fraction (WLF).

What can one conclude for this single-component-limited case? If the generated waste component mass distributions reflect reality, and if N is set appropriately high, then the sample input sets are increasingly likely to cover the range of possible waste composition sets. Each WLF is the highest WLF that will produce glass meeting the property constraints for an input waste composition set. Therefore, the distribution of optimal WLFs represents the possible range of optimal WLFs given the uncertainty defined for the input high-level waste stream.

Figure 3 shows the distribution of the optimal WLF and the reverse cumulative distribution of the optimal WLF, with cumulative probability increasing as WLF decreases. The cumulative distribution can be interpreted as follows: for any WLF calculated by maximizing the WLF subject to constraints as per OWL optimization, the cumulative distribution represents the probability that that WLF can be achieved given the waste composition and its associated uncertainty and error structure. For

example, if the WLF is 0.038, the probability of being able to achieve that WLF is 0.85.
Fig. 3.
The above analysis was for the simplest case; the same single-component constraint is always binding. How would the results change for binding multiple-component constraints or for changing binding constraints? Subsequent work will have to examine this issue, but a cumulative distribution (as in Fig. 3) could still be developed and used as described above.

Issues

Because this was a preliminary look at the application of stochastic modeling, many assumptions were made to simplify calculations. These assumptions, which are addressed below, will be revisited in future work.

Two independent (and inconsistent) determinations of the total mass are available, the sum of the sampled masses and the measured mass (actually measured volume and density). Some technique to reconcile the two is needed.

The distributions for each component were assumed to be independent. This is unlikely to be true for several reasons (e.g., relationships of components in frit, waste, and recycle; correlations in analytical uncertainties; and imposed correlations among component mass fractions because they must sum to one).

The simple case examined had the same binding constraint for all N samplings. This will not generally be the case. Accounting for statistical dependence between components may also change binding constraints.

CONCLUSIONS

The techniques presented here address the uncertainty in property models (which are used in specifying constraints in the optimization model) and in waste feed composition. The latter technique needs further development to address the issues identified. Combining the two techniques would allow formulation of glasses in the presence of both types of uncertainty.

ABSTRACT

An advanced waste management of HLLW, in which super high temperature treatment is conducted by using an induction cold wall crucible, is proposed. In this process, calcined HLLW added with minimum amount of reducing agent is heated, melted and chemically reduced, resulting in the partitioning of platinum group metals from oxide residue in the form of high volume reduced ceramics. Validity of the process concept was confirmed by the fundamental experiment. Solidified and group partitioned materials of 150-250g were obtained both by continuous and batch type treatment at the temperature of 1600C in Ar gas atmosphere. A few blocks of metal were obtained in a dark green glass material. Alkaline earth, zirconium and lanthanide elements were in volume reduced oxide. Platinum group elements, including corrosion products were successfully partitioned into metal.

INTRODUCTION

The development of the nuclear industry has reached a stage where reprocessing is an established technology. Vitrification, the first strategy, is considered as the reliable method of high level waste treatment to ensure safe immobilization of radionuclides for the final disposal into deep geological formations (1). However, current vitrification characterized by concentration involves neither recovery of by-products nor high volume reduction.

The second strategy, which is characterized by the separation of high level actinides and long lived fission products from the high-level liquid waste (HLLW) and destroy them by nuclear transmutation, has been investigated as future technologies (2). Such a strategy would favor the recovery of potentially useful fission products, such as caesium and strontium. Platinum group metals, especially rhodium and palladium, could also be recovered. However, the second strategy, based on the wet treatment involving such as the solvent extraction, adsorption on iron exchangers, etc., inevitably leads to the increased amount of secondary wastes and high reprocessing cost (3). Moreover, the partitioning nature is different from that occurring in the Purex process, so this partitioning technique is not acceptable for the current Purex process.

An advanced strategy is to have both characteristics compatible with the current Purex process and enjoying the most of the fruitful partitioning of nuclides aimed in the second strategy accompanied with neither generation of the increased amount of secondary wastes nor high reprocessing cost. A super high temperature method (SHTM) is one of the promising such strategies (4). In this method, calcined HLLW added with minimum amount of reducing agent is heated, melted and chemically reduced, resulting in the partitioning of platinum group metals from oxide residue in the form of high volume reduced ceramics. In the process, melting in a conventional furnace with high temperature wall cannot be adopted, because melting in the furnace surrounded with refractory wall inevitable leads to the generation of a fair amount secondary wastes. An induction melting in a water cooled vessel can solve this problem. However, previous investigation using an induction cold crucible was aimed at applying it to the vitrification of HLLW or volume reduction of cladding hulls (5, 6).

Objectives of the present study are to confirm the process concept of melting, smelting reduction and group separation of simulated HLLW through fundamental experiment using an induction cold crucible.

SUPER HIGH TEMPERATURE METHOD OF HLLW

Concept of the super high temperature method (SHTM) of HLLW is shown in Fig. 1. together with the conventional one.

Fig. 1.

In the current treatment, nitric acid solution which are produced during the solvent extraction of uranium and plutonium in the reprocessing of spent fuels by means of Purex method are first calcined. Then, the solution is evaporated, concentrated and oxidized, followed by the decomposition of nitrates. Usually, it is dissolved into melted borosilicate glass materials and solidified in the canister vessel. Vitrified solid containing major fission products are finally disposed into deep geology.

On the other hand, SHTM branches off the conventional vitrification method after calcination without adding any glass materials. Two kinds of scenarios, A and B, can be considered as shown in Fig. 1. They are connected in branch, so this method completes in each scenario in accordance with the development of associated technology. SHTM consists of the following concepts, regardless of the scenario:

1. Immobilization of fission product elements in HLLW by heating at high temperature without adding any glass materials.

2. Partition of easy to sublime elements, especially the highly exothermic element caesium, by heating calcined HLLW.
3. Reduction of platinum group elements to the metals followed by their separation from the oxide residue by heating calcined HLLW in an inert gas atmosphere.
4. Solidification of the residue to high volume reduced materials.

In scenario A, calcined nitric acid solute is first sublimated at approximately 1000C. During the sublimation, metals with relatively low boiling temperature and high exothermic elements, such as caesium and rubidium are evaporated. Then the residuals are heated approximately up to 1600C after the addition of the reducing agent. It is essential that the reduction takes place in a furnace accompanied with a minimum amount of secondary waste generation. After chemical reaction, elements including the platinum group are reduced to metal. Alloys containing the platinum group elements are separated from residual oxide by certain method, such as electromagnetic separation After this, separated alloys and oxides are solidified. Finally, high active waste oxides containing alkaline earth, lanthanide, actinide, yttrium and zirconium are disposed to an absolutely isolated environment from human beings.

In Scenario B, which is connected with scenario A after "Separation A", oxides containing alkaline earth, lanthanide, actinide, yttrium and zirconium are heated after the addition of a certain reducing agent. After heating, alkaline earth, actinide, and zirconium oxides are reduced together with the evaporation of high exothermic and relatively low boiling element of strontium. After this, high active waste containing actinide and zirconium alloys are separated from lanthanide and yttrium oxides. Finally, actinide and zirconium alloys are disposed.

An object of the present study is confined to "Smelting reduction A" and "Separation A" of scenario A. Smelting reduction and successive separation is realized based on the key technologies such as, induction heating in a cold crucible, control of thermodynamic stability of oxides, effective use of the difference in electromagnetic force working toward metal and oxides.

An induction cold crucible is a furnace, stirrer, electromagnetic confinement equipment of the melt out of contact with the cold wall, and solidifying mold. Usually, the crucible comprises water cooled copper wall which is segmented and electrically insulated by slits, induction coil, withdrawal machine, atmospheric chamber, etc. An induction cold crucible has long been used for casting of chemically active metals with high melting temperature, such as titanium alloys (7). This technique would be capable of applying to the melting of radio-active materials in the industrial scale in the course of recent development of surrounding technology.

There are so many parameters concerning the cold crucible process, such as the structure of the crucible, arrangement of the coil, dome height, output of the generator, frequency of the alternating current, withdrawal velocity, species or dimension of the raw material to be melted, etc. Combination of appropriate parameters results in stable melting and excellent quality of the solidified ingot (8).

Relation between atomic number and standard free energy of oxidation of fission products and corrosion products at 2000K are shown in Fig. 2. In general, actinides have lower free energy of oxidation than platinum group metals and higher than the majority of lanthanide and yttrium. This difference in thermodynamic stability allows actinide to be separated from most of the other fission products.

Fig. 2.

A reduction agent is chosen taking the following condition into account.
1. Reducing ability is necessary and sufficient for the partitioning of platinum group metals from other residual oxides.
2. Reduction takes place by adding as small an amount of reducing agent in mass and volume as possible.
3. Melted and solidified oxide after reduction has absolutely small leach rate
4. Reducing agent is cheap and poisonless.
5. Reducing agent is not the isotope of the fission products.

EXPERIMENTAL METHOD

Oxides of the simulated liquid waste were synthesized from elements containing larger than 1g/Mg-U amounts through calculation by the ORIGEN code as shown in Table I. Corrosion products such as iron, chromium and nickel were added. Those elements

with an atomic number of 35, 36, 41, 53, 54, 61 were not added mainly because of the difficulty in obtaining. A 5 mass % boron compound was added to decrease the melting point of calcined HLLW.
Silicone nitride is one of the promising reducing agents satisfying the requirements described in the previous section, since solidified glass is used as the stable material in the current strategy.
An induction cold crucible is 45mm in inner diameter with 12 number of slits, width and length of which are 0.2 and 150mm, respectively. Graphite wall of 3mm thickness was inserted into the cold crucible to promote heating low conductive HLLW. Insertion of graphite is not essential to this process, because a high frequency generator on the order of GHz enables the induction heating of low conductive HLLW without insertion of graphite. A multi turn induction coil surrounds a water cooled crucible made of copper. After carbon steel, which was the primary and was used as the pulling rod, was inserted from the bottom into the crucible where the electromagnetic field was most effective, atmosphere in a chamber was replaced with Ar gas.
The crucible, coil, high frequency generator, etc., are provided with cooling water, then power is gradually supplied. With an increase in supplied power, the primary melts to rise in a dome shape. A melt is electromagnetically stirred and the top of the melt is out of contact with the wall. Simulated HLLW, which was agglomerated in advance to prevent from spreading over a chamber by free convection, was supplied on the melt dome by a vibratory feeder.
Major experimental condition in continuous treatment is shown in Table II. This was determined by the scientific approach using a precise numerical model (9). Batch treatment is almost the same as that of a continuous one except that the withdrawal equipment is not installed and larger crucible of 70mm diameter is used.
RESULT
In a batch treatment, simulated HLLW materials were initially melted on the crucible bottom and steadily on the viscous melt surface agitated slowly. After cutting the solidified materials longitudinally on the plane including the symmetry axis, they were observed being separated into two lumps, metal and oxide, when the temperature is 1600C. Generally, metal was observed on the bottom and oxide was above. The separation is not solely responsible for the gravity. Cohesion due to agitation of the melt or interfacial tension between metal and oxide, followed by macro separation by the electromagnetic force, would also be responsible. Up to 250g simulated HLLW was processed in batch type treatment.
When the treatment temperature was lower, reduction and melting were insufficient. Metal and oxide were mixed in the form of small particles and the macro separation was not established.
In a continuous and high temperature treatment, the material was melted first by the heat of the primary. Successive feed of materials results in the macro separation of metal on the center and oxide near the wall. With an increase in fed material, macro separation was not clearly observed from the top opening and the melt was stirred accompanied with the foaming probably due to the generation of nitrogen gas during the reaction.

$$6MxO + Si3N4 = 6Mx + 3SiO2 + 2N2 \quad \text{Eq. (1)}$$

However, after cutting the solidified material, macro separation of metal by the electromagnetic levitation provided to be established below the foaming.
In a steady state, raw materials were melted by the heat conduction from inductively heated metal and graphite wall. Reaction continued successfully and 150g simulated HLLW was treated.
Wearing of graphite was small in the experiment. However, it will become a problem when the equipment is enlarged to an industrial scale and works long run. This would be overcome by using high frequency generator on the order of GHz.
One of the longitudinal sections of the solidified material obtained from the continuous treatment is shown in Fig. 3. A few blocks of metal were obtained in a dark green glass material. Two small metals in the oxide seemed to be produced as a resultant of falling of droplet, which cannot be sustained as a large amount of metal in the oxide melt by the electromagnetic force, on the solidification front of oxide. Densities of oxide and metal are measured as 4.1x103 and 8.4x103kg/m3, respectively. From the mass conservation during the chemical reaction, volume ratio between oxide and metal are estimated as 4.5:1.0. Meanwhile, the experimentally

obtained ratio is between 3.5:1.0 and 5.0:1.0. Experimentally obtained ratio was approximately in agreement with that of calculation.
Fig. 3.
Mass fraction of simulated elements into oxide and metal phase obtained by chemical analysis using inductively coupled argon plasma spectroscopy, together with that theoretically obtained on the assumption of stoichiometric reaction, are shown in Fig. 4 as a function of atomic number. Generally, experimental results agree with that of theory. Some discrepancy would be responsible for the shortage of the reducing agent on account of free convection during feed. From thermodynamic calculation, oxide of Te is expected to be reduced to metal. However, Te was not observed neither in metal nor in oxide. Boiling temperature of metal is 990C, so the element seemed to be evaporated during reaction.
Fig. 4.
Alkaline earth, zirconium and lanthanide elements were contained in volume reduced oxide. On the other hand, platinum group elements including corrosion products were successfully partitioned into metal. From this result, it is expected that the long lived fission products of actinide having similar thermochemical properties with lanthanide could also be separated from the metal including the platinum group.
CONCLUSION
Concept of SHTM, which is an advanced waste management of HLLW, was proposed. SHTM is comparable with the current vitrification process and enjoying the partitioning of elements without adding any glass materials. In the process, an induction cold crucible was used, resulting in the minimum amount of secondary wastes.
Validity of the process concept was confirmed by the fundamental experiment. Solidified and group partitioned materials of 150-250g were obtained both by continuous and batch type treatment.
A few blocks of metal were obtained in a dark green glass material. Alkaline earth, zirconium and lanthanide elements were in volume reduced oxide. Platinum group elements including corrosion products were successfully partitioned into metal.

ABSTRACT
A program has been in place at the Idaho Chemical Processing Plant for the past two years to identify and define technologies for treating and disposing of sodium bearing liquid radioactive waste, high-activity radioactive calcine, and irradiated spent nuclear fuel (SNF) stored at the Idaho National Engineering Laboratory (INEL). The sodium bearing waste (SBW) and calcine have resulted from past ICPP reprocessing operations and cleanup conducted since 1953. The irradiated spent fuel consists of various fuel compositions and ranges from complete fuel elements to fuel pieces for which no reprocessing flowsheet has been identified. The development program has resulted in a very successful systems analysis approach affecting final disposal of the waste and spent fuel. Use and integration of all applicable waste treatment and disposing technologies currently available within the DOE complex, at universities, and in private industry are described.
INTRODUCTION
Between 1953 and April, 1992, when DOE announced curtailment of reprocessing, irradiated nuclear fuel had been reprocessed at the ICPP. As a result of the decision to curtail reprocessing in 1992, the ICPP put in place a Technology Development Plan to identify and implement acceptable technologies for disposing of sodium-bearing liquid radioactive waste, radioactive calcine, and irradiated spent fuel stored at the INEL.
A unique and practical systems analysis program was developed to allow immediate assessment of technical treatment and disposal options by calculating high and low level waste volumes, near-term and life cycle costs of processing options, and required time lines for a given scenario. Extensive repository performance assessment and preliminary waste acceptance criteria were developed. Hundreds of waste and disposal treatment options were evaluated; available technologies developed throughout the DOE complex, at universities, and with private industry through partnerships, cost sharing, and contracts were integrated to create the options. Separations technologies, HLW vitrification technologies, and LLW grout technologies were included in the development. A strong program for stakeholder involvement was developed. The long-term spent fuel treatment plan was largely superseded by high priority fuel transfers to new underwater storage basins and expanded evaluations of strategies for handling all DOE owned spent fuel.
PROGRAM OBJECTIVES
The nation's radioactive waste policy has been established by the Nuclear Waste Policy Act (NWPA), which requires the final disposal of SNF and radioactive waste in accordance with U.S. Environmental Protection Agency (EPA) and Nuclear Regulatory Commission (NRC) standards. In accordance with these regulations and other legal agreements between the State of Idaho and the DOE, the DOE must, among other requirements, 1) complete a final Environmental Impact Statement by April 30, 1995, 2) evaluate and test sodium-bearing waste pre-treatment technologies, 3) select the sodium-bearing and calcine waste pre-treatment technology, if necessary, by June 1, 1995, and 4) select a technology for converting calcined waste into an appropriate disposal form by June 1, 1995.
The primary objective of the Waste Management Technology Development Program (WMTDP) is to develop and demonstrate safe, cost-effective, and environmentally responsible methods for the conditioning, interim storage, qualification, and final disposition of SNF and radioactive wastes. The program will, ultimately, recommend and implement technologies and processes to facilitate the conditioning and certification of SNF and radioactive waste for permanent disposal. The program will also provide technical support to resolve current SNF and radioactive waste interim storage issues, such as SNF characterization and removal of sodium bearing waste from the existing tank farm. Success will be measured in terms of safety, life-cycle cost, regulatory compliance, and waste volume. Emphasis will be placed on process robustness to ensure that processes will apply not only to INEL SNF and radioactive waste, but will also foster transfer of technologies to address the conditioning of a broad range of SNF and radioactive wastes throughout the DOE complex.
Assumptions made in developing the WMTDP include: 1) Treatment and immobilization processes must accommodate radioactive liquid and calcine wastes, 2) Existing facilities will be utilized to the extent practical, 3) Actinides and fission products will be collected into a HLW stream for disposition approaches involving

constituent separation, 4) Low-activity waste will meet NRC Class C, or lower, limits, and 5) Funding will be available to support signed agreements, consent orders, and Federal Facility Compliance Agreement mandates.

SYSTEMS ANALYSIS

DOE Order 4700.1 outlines a logical systems engineering approach to problem evaluation and resolution. This process consists of six principle steps (3):

Define the problem and establish the program goal
Determine the functional (baseline) requirements
Identify alternatives that meet the functional requirements
Develop and evaluate the alternatives
Recommend preferred alternatives for selections and implementation

The WMTDP is taking a systems engineering approach to the development of technologies for the treatment and disposition of radioactive waste. The system engineering process considers all aspects of systems requirements from the earliest stages of design through development, testing and operation. The process supports project management by ensuring that technical control is on a level and integrated with funds, cost, schedule, and performance controls. The fundamental philosophy is the systematic narrowing of a large number of candidate process options through identification and evaluation, laboratory and component-scale testing, non-radioactive and radioactive pilot-scale testing, and implementation.

The evaluation employs systems analysis tools and techniques and considers process development technical data and test results. Ultimately, process options that best meet the stated criteria will be selected by decision makers for development into an operating facility to condition and prepare SNF and radioactive waste for placement in a final storage facility. In selecting processes for further evaluation and testing, candidate options are evaluated against the following criteria: 1) Safety of process to workers, the public, and the environment; 2) Life-cycle cost (i.e., development, construction, operations, decontamination and decommissioning , disposal, etc.); 3) High-activity and low-activity waste volumes generated; 4) Final waste forms; 5) Flexibility of the process to handle multiple input streams; and 6) Compliance with all applicable regulations.

Through mid 1993, using program goals and baseline requirements as guides, extensive investigations were conducted to identify potential technologies that could be employed at the ICPP to treat and dispose of radioactive liquid and calcine wastes. Identified technologies were then sub-divided into pretreatment , separations, and immobilization categories and combined into process systems (flowsheets) capable of handling ICPP radioactive liquid and calcine waste. Additionally, an analysis of alternatives for removing sodium waste from the existing tank storage volume was performed and recommendations were made to DOE concerning processes for treating sodium waste inventories without having to construct additional storage tanks. Processes that did not meet the baseline requirements, could not be developed in time to meet regulatory requirements, or were viewed as technically inferior to other technologies were eliminated from further consideration. Processes that still showed promise following initial development were advanced to the next stage of analysis. These technologies have resulted in 27 viable waste treatment process combinations.

Mass balance calculations resulting from laboratory testing and literature data were made with radioactive waste compositions of current and projected inventories being used as inputs. Mass balances were then used to evaluate candidate technology flowsheet performance relative to ICPP radioactive waste streams and to develop estimates of cost, schedule, throughputs, and radioactive waste volumes.

This approach to analyzing the processing , storage, and disposal of radioactive liquid and calcine waste at the ICPP was implemented to facilitate informed decision making and understanding in the resolution of stakeholder issues. This approach evaluates candidate processes and disposal forms using a consistent set of assumptions and data. Additionally, the potential impacts of existing uncertainties are being evaluated, resulting in the recommendation of programs to investigate and resolve those uncertainties.

SEPARATION TECHNOLOGIES

There are many treatment and disposal options which can be potentially applied to the ICPP radioactive sodium-bearing liquid and solid HLW calcine wastes. However, those which include separation processes to split the high activity, low volume components (actinides and fission products) from the inert, high volume, low

activity fraction are greatly desirable in order to reduce the volume and, therefore, cost of the final, high activity, repository-destined waste. The Modified Consent Order between the State of Idaho and the DOE required that the ICPP contractor LITCO select and investigate three base separation technologies possibly applicable to both SBW and calcine. This investigation must occur prior to the required 1995 EIS Record of Decision to choose preferred treatment and disposal options for both waste streams. However, due to the nature of the waste streams, these base technologies must be complemented with auxiliary upstream and downstream technologies such as mercury and cesium removal and/or calcine dissolution. These base technologies are necessary if: 1) secondary waste is to be minimized, 2) desired fission product decontamination factors are to be achieved, and 3) desired low activity waste classifications (e.g., NRC A, B, or C) are to be obtained. The following sodium-bearing waste and calcine base separation and auxiliary technologies (as tabulated in Table I) were tested with surrogate and/or actual wastes at laboratory, bench and small pilot-plant scale levels.

TABLE I

The majority of the testing was accomplished at ICPP facilities, but for cases where the technology was immature or not part of the previous ICPP experience (i.e. freeze crystallization), the development work was subcontracted to private firms. Detailed test results of those technologies listed in Table I can be found in Ref. 1, 2, 3, and 4. Brief status descriptions of key base and auxiliary technologies still under ICPP investigation are as follows.

Freeze Crystallization (FC) is applicable only to sodium-bearing waste. Freeze Crystallization is a developing technology which concentrates liquid waste by removing heat and thereby freezing one or more components of the liquid to a solid phase. In the case of sodium-bearing waste, this solid phase is water in its pure form (ice). When the ice forms, the mother liquid becomes supersaturated in sodium nitrate which is then precipitated and separated from the remaining contaminated SBW. Since the presence of sodium causes caking and agglomeration difficulties in calcination, the depleted sodium liquid becomes amenable to calcination with less cold additives. Non-radioactive testing has shown the process to be technically plausible, but equipment difficulties pose likely challenges which may be insurmountable for full-scale operation.

The freeze crystallization concept is also the principle in the evaporation/precipitation separation technology. However, the difference is in the method by which the water is removed from the waste. By heating the sodium-bearing waste water is evaporated and sodium nitrate is precipitated upon reaching saturation. Like freeze crystallization the evaporation/precipitation concept is not applicable to calcine.

The simple precipitation/neutralization process, applicable to both SBW and dissolved calcine, involves increasing the pH of the acidic aqueous wastes to levels that promote heavy metal and polycation precipitation. Testing shows that when pH levels are increased between 8 and 10, TRU components, toxic metals and a large fraction of the strontium also precipitates to the sludge, leaving a low activity supernate highly concentrated in sodium. Additional fission product (Cs, Sr) removal from the supernate would be necessary, sludge quantities would be large, and chemical conditioners, flocculants and coagulators would be required to improve liquid-solid separations.

After precipitation, the low activity, high sodium, supernate fraction could then be treated further via electrohydrolysis (EH), an auxiliary technology employing both electrohydrolysis and membrane separation concepts. EH utilizes cation and anion selective membranes and an electromotive force to split waste into hydrogen and hydroxide ions and is applicable to both the treated low activity fractions of sodium-bearing waste and/or dissolved calcine. As a result, the waste is substantially diluted, and relatively pure sodium hydroxide and nitric acid are recovered for recycle and reuse in future ICPP decontaminations. Development efforts continue to focus on feed chemistry to eliminate the presence of ions that cause frequent membrane fouling.

The base technology of radionuclide partitioning via the TRUEX process developed by Argonne National Laboratory is recommended for both sodium-bearing waste and dissolved calcine. This technology consists of continuous counter-current solvent extraction performed in centrifugal contractors and a solvent (organic phase) of 0.2 M CMPO and 1.4 M TBP in a hydrocarbon diluent. The TRUEX process has shown excellent

decontamination factors on actual SBW and dissolved calcine wastes, and is currently the recommended base treatment option for the EIS Record of Decision. A pilot plant is currently available for studying the process parameters. International collaborations are also in progress for developing a radionuclide partioning concept utilizing phosphine oxide as an extracting agent.

As with the precipitation and freeze crystallization technologies, TRUEX will also require auxiliary technologies to remove high concentration fission products such as 90SR and 137Cs. For 90Sr, the SREX process is being developed and studied extensively at both laboratory and pilot levels. Like TRUEX , SREX is a counter-current solvent extraction method utilizing a crown either extractant. Cs137 removal is accomplished by ion exchange technology. Testing to date indicates that the most promising is ammonium molybdophosphate (AMP). One engineered form of this material, suitable for radiological use, is on a modified polyacylonitrile (PAN) resin. However organic supports are known to be less thermally and radioactively stable than inorganic supports.

Despite these development challenges, the TRUEX, SREX, Cs ion exchange series of separation technologies yield the most cost effective, technically proven, and flexible train of unit operations for sodium-bearing waste and calcine treatment. These operations, pending stakeholder approval, will be the EIS Record of Decision recommendation for ICPP waste separations.

HLW VITRIFICATION TECHNOLOGIES

Throughout the United States and the rest of the world, the accepted vitrified HLW form is borosilicate glass. The French began developing this technology in the 1950's and the British and Japanese have patterned their vitrification processes after the French. West Valley, Savannah River, and Hanford are each in various stages of implementing glass technology to vitrify their waste. The INEL, historically, has pursued a different technology. Essentially all of the INEL HLW is stored at the ICPP in the form of calcine. Because of the composition of the calcine (high in cladding materials), a significant reduction in the immobilized calcine volume could be achieved by immobilizing it as a glass ceramic rather than as a glass. The volume decrease results from a combination of higher waste loading and higher density for the glass ceramic form. During the last 15 years, a small HLW Immobilization group has developed very durable glass ceramic waste compositions for all types of ICPP calcines (alumina, zirconia, fluorinel, zirconia-sodium, and fluorinel-sodium).

Although the glass-ceramic form produces a minimum volume for the ICPP calcine, the structured systems analysis described above showed that life-cycle costs for treating ICPP HLW could be minimized if the calcine were redissolved and separated into high- and low-activity fractions and these fractions immobilized into high-level glass and low-level grout forms. The final decision on technology implementation will occur as part of the INEL EIS Record of Decision to be issued in June 1995. However, since the glass form now seems to be a likely candidate for immobilization of the ICPP HLW, the development effort is now focussing on this waste form. The major waste form development objectives for this activity include:

Develop durable glass waste forms for ICPP wastes using laboratory-scale equipment and waste simulants.

Demonstrate vitrification flowsheets on pilot plant scale using waste simulants.

Identify process control requirements for waste qualification.

Demonstrate waste immobilization with radioactive wastes.

In parallel with the above items, establish programs for quality assurance, records management, and waste form qualification.

Demonstrate process equipment at near full scale.

Provide recommendations and process data for a waste treatment facility design.

The most comprehensive suite of glass waste form fabrication experiments to date has been performed to demonstrate direct vitrification of zirconia calcine. The approach used in conducting this experimental program illustrates the general approach used by the ICPP HLW Immobilization Program to develop waste forms.

The experimental program included preparation of laboratory-scale waste glass samples from simulated (non-radioactive) zirconia calcine, fabrication of glass waste forms using a pilot-scale melter, and preparation of laboratory-scale waste glass samples from actual (radioactive) zirconia calcine. The laboratory experiments were used to develop and test waste formulations. This work is performed most efficiently and economically at a small scale. However, there is technical risk

inherent in scaling a process up from bench-scale to production. Pilot-scale tests were used to gather data for process scaleup, thereby reducing the technical risk. Hot tests were used to confirm the results obtained from cold testing, thus further reducing technical risk.
Performance of the experimental waste glasses was compared using standardized static leach tests (MCC-1). The results of these tests showed the leach rates from the glass samples were consistently less than 1 gram/m2 day. The similarity of results obtained from waste glasses prepared in different ways using simulated and actual calcine validates the approach being pursued.
Significant work remains to be done at the ICPP to meet these objectives. To date the following have been achieved:
Specified waste streams for immobilization from proposed processes
Developed predictive programs for glass waste formulations
Prepared glasses from surrogate wastes for proposed processes
Measured leach resistance of surrogate waste glasses
Prepared glass from radioactive zirconia calcine (archived for durability studies)
Procured and modified equipment for additional hot tests
Prepared a performance assessment for disposal of INEL wastes in a geologic repository
Completed feasibility studies for the HLW glass plant process
Significant milestones planned for the remainder of FY-1995 are:
Issue the first draft of the Waste Compliance Plan
Prepare and test simulated waste glasses from feed streams currently being identified by separations process development.
Complete installation of equipment for hot tests
Determine equipment needs for pilot-scale demonstration

LLW GROUT TECHNOLOGIES

Following separations, the low activity fraction, like the high activity portion, will require stabilization prior to interim or final disposal. ICPP investigators have employed laboratory scale testing and system analysis techniques over the past year and, as a result, have chosen to concentrate stabilization efforts on grouting techniques (as opposed to glass). These techniques will ensure a low cost, high waste loading waste form that can be readily transported from interim to final storage. Furthermore, analyses have indicated that Portland cement, due to its availability and performance record, is the preferred grout over other encapsulating thermosetting and thermoplastic materials. However, small development efforts are ongoing with both sulfur-polymer and polyethylene cements.
Non-radio-active laboratory testing at ICPP with cement grout has concentrated on optimizing grout waste formulations in terms of performance (leach resistance and compressive strength) and high waste loadings. This optimization is being accomplished by varying parameters such as the water-to-cement ratio, the addition of admixtures for rheology and leaching control (plasticizers, slag-fly, clays, etc.), the curing time, and the waste loading. Early results indicate that the water-to-waste ratio is probably the most significant single parameter affecting chemical and strength resistance of hardened cement mix. Current test data show that a 10% waste loading (by weight under a dry bases) passes initial strength tests and waste loadings as high as 70% may be achieved depending on the waste source and pretreatment methods. Contracted studies have also been conducted at Pennsylvania State University to determine waste loadings possible for ICPP surrogate waste originating from the radionuclide separation of both calcine and sodium-bearing. Prior to grouting, preconditioning through either chemical or thermal methods may also improve waste loadings and grout performance. Because highly soluble nitrate salts in the waste will easily leach, denitration and the addition of mineral like compounds may be required upstream of the grout process. Bench scale thermal tests methods such as high-temperature calcination (via a rotary kiln dryer or evaporation on a production scale) will reduce and remove all the nitrates in the waste to an oxide form. This same testing has also indicated that the addition of clay or silica during thermal denitration may help form insoluble, leach resistant sodium-alumina silicates within the formulation, thereby greatly enhancing its performance.
Extensive development of the low-level grout process will continue through the use of a comprehensive low-level grout pilot plant which is currently in the design phase. The pilot plant will accommodate three methods of mixing waste with cement, since mixing is considered one of the key equipment challenges facing the grout

process. High quality mixing is available via batch mixing, but large volumes of rinse solution would be generated. In-line mixing would provide high throughput with high quality, but process control would be difficult. In-container mixing, on the other hand, provides a low cost simplified alternative, but the drums may not be completely filled. Completion of the initial pilot-plant test phase will determine both the optimum mixing method as well as define the thermal denitration equipment for preconditioning.

Development efforts related to the polyethylene encapsulation of low activity waste are currently under review to ensure a suitable alternative to the preferred Portland cement grout process. Formed through the polymerization of ethylene gas, low density polyethylene provides a matrix with a relatively open structure. This matrix can be processed at relatively low temperature and pressures to produce final formulations of 70 wt% waste loadings that meet all performance criteria. However, continued development is required to ensure that the matrix can handle the higher radioactivity and heavy metal concentrations existing with ICPP wastes.

Like polyethylene, sulfur polymer cement (SPC) is under investigation as an alternative to base Portland cement grouts. As sulphur polymer cement concrete has gained popularity as a construction material, it became evident that it would be capable of immobilizing low activity wastes. Produced by combining elemental sulfur with dicyclopentadiene, SPC behaves similarly to polyethylene, except SPC will react with certain chemical species in the waste. Advantages of SPC include possible high waste loadings (50%), relatively low processing temperature, recovery from out-of-specification batches via remelting, and resistant to acids and corrosives. Disadvantages include the existence of adverse chemical reactions, incompatibly with bases and oxidizers, and potentially poor thermal and radiation stability.

INTEGRATED FACILITY

The integrated facility which incorporates the above technologies has been named the Waste Immobilization Facility (WIF). The WIF will house a combination of technologies for processing liquid sodium-bearing waste, other decon and process solutions, and calcine. The technologies include calcine dissolution, transuranic extraction (TRUEX), strontium extraction (SREX), cesium ion-exchange (CslX), low and high activity waste immobilization, and interim storage for the immobilized waste forms. Amalgamation of recovered mercury will also be included. A vitrification plant will be built for immobilizing high-activity waste and a grout plant for immobilizing low-activity waste. This process is designed to minimize the volume of the high-activity waste stream and the cost of producing the low-activity waste stream. When the WIF is operational, it will have surge storage tanks to collect and characterize any liquid waste generated at the ICPP.

WIF buildings are arranged in a complex of six structures co-located on a common site.

- Separations Building
- HLW Vitrification Building
- LLW Grouting Building
- Vitrified HLW Interim Storage Building
- Grouted LLW Interim Storage Building
- Bulk Chemical Storage Building

The process and storage buildings are designed for a 40-year life. The facilities provide for remote operations and maintenance of the process with appropriate radiological and biological shielding for operator safety. Heating, ventilation, and air conditioning (HVAC) systems provide additional confinement barriers to limit spread of radioactive contaminants. The storage facilities are sized for a seven-year production period. The interim storage facilities' layout allows storage capacity to be increased to accommodate an additional fourteen-year production of vitrified HLW canisters and grouted LLW drums.

WIF process systems are designed to handle a range of waste streams including liquid SBW and HLW calcine materials currently held in ICPP inventory and similar radioactive waste materials anticipated to be generated from future ICPP activities, and in particular from D&D operations. Process flow streams within WIF vary as the feed streams change; therefore, unit operations within the facility are designed to handle the maximum flow rate of liquids and/or solids that would occur in the plant if it were processing each of the feed streams on a dedicated campaign basis.

The design throughput of the facility is based on being able to treat the calcine inventory in 30 years. This requires the facility to be sized for 185 gallons per

hour liquid throughput. The actual facility throughput will vary based on the feed material being processed. For example, processing SBW will produce approximately 1/10 canister of HLW glass and 44 drums of LLW grout per day. Processing 100% zirconium calcine feed will produce approximately 1/2 canister of glass and 14 drums of grout per day.

WIF is divided into eleven functional areas:

1. Calcine transport, receiving, dissolution, and solids separation
2. Liquid waste receiving, storage, solids separation, and dissolution
3. TRUEX, SREX, ion-exchange, and organic mixed waste thermal oxidation
4. HLW evaporation, pretreatment, condensate treatment, and solids separation
5. HLW calcining, vitrification, and offgas treatment
6. HLW canister filling, handling, decon, transfer, and storage
7. LLW denitration, pretreatment, and grout mixing
8. LLW drum filling, handling, transfer, and storage
9. Mercury collection, washing, amalgamation, packaging, and storage
10. WIF PEW collection, storage, evaporation, and acid recycle
11. Hot and cold process offgas treatment; service and hazardous waste collection

Ultimately, WIF will contain all of these functional areas; however, to minimize cost impacts to the DOE budget while still meeting the waste treatment schedules required by the State of Idaho, the facility will be constructed in two phases. Phase 1 will consist of functional areas 2, 3, 7, 8, 9, 10, and 11. This will enable the facility to process SBW into a liquid HLW and a grouted LLW. Interim storage for both fractions will be provided. Current plans are for this phase to begin operation in approximately 2009 which will result in the ICPP Tank Farm being emptied of SBW by the Consent Order date of 2015. Phase 2 will add the remaining functional areas to enable the facility to treat calcine, vitrify the HLW, and store the resulting glass waste form. This phase will begin operation in approximately 2014 and operate for approximately 30 years to treat the inventory of calcine at the ICPP.

STAKEHOLDER INVOLVEMENT

One of the six major goals of the DOE Environmental Management Program is to develop a strong partnership between the department and its stakeholders. As stated by Tom Grumbly, "Stakeholder involvement was one of the key activities that lead recently to the successful conclusion of negotiations of changes to the Hanford Federal Facility Agreement and Consent order..." The public involvement programs at other sites were benchmarked, resulting in defining some lessons learned such as providing stakeholders with clear information, involving them as early as possible, and keeping the working meetings small and informal. A public participation plan has been developed based on these principles to involve stakeholders in the evaluation of technologies for immobilizing calcine and liquid sodium-bearing waste. As part of the plan, workshops are held with various interested stakeholder groups to discuss the technology development options, potential stakeholder concerns, and establish the relative importance to each outside interest group of the concerns. The resulting determination of stakeholder values with regard to future processing options will be incorporated in the final recommendation to the State of Idaho of a preferred technology as required by the December 22, 1993 Court Order of the DOE/Navy/State of Idaho agreement.

CONCLUSIONS

1. After 2 years, the ICPP Technology Development Program has been highly successful in identifying cost effective, environmentally acceptable, and safe options for treatment and disposal of ICPP sodium-bearing liquid and calcined solids radioactive wastes. Due to deteriorating spent fuel, the emphasis on spent fuel management has largely shifted to near-term storage improvements rather than long-term treatment and disposal actions.
2. A successful systems analysis program has been developed to allow immediate evaluation of near-term and life cycle costs, waste volumes, and related information.
3. Separations has been identified as cost effective and required technologies have been demonstrated using hot laboratory and cold pilot plant techniques for both sodium-bearing and calcine radioactive wastes.
4. Immobilization methods for HLW by glass formation and low-level waste by improved grout have been identified as leading options for processing ICPP radioactive wastes.
5. Required facilities necessary to implement waste treatment and preparation for

disposal in the required time frame have been identified.
6. Maximum use has been made of available technology through DOE Complex sites, private industry, and technical universities.

RECOMMENDATIONS

1. Continue to apply the elements of the ICPP technology Development Program to the ICPP and expand applicable program elements to the INEL and other DOE sites.
2. Continue to work with other DOE sites, universities and private industry to utilize applicable, available technologies and transfer technologies as appropriate.

ABSTRACT

Partitioning of radionuclides from Idaho Chemical Processing Plant wastes has been demonstrated using aqueous separations processes. The two major waste streams consist of an acidic liquid waste high in sodium content (1.3 M) and a solid calcine which is readily dissolved (greater than 98%) in 5M nitric acid to produce an acidic aqueous stream. Actinides are removed from the aqueous feed streams by a solvent extraction process utilizing organophosphate compounds such as CMPO, DHDECMP or phosphine oxide derivatives. The raffinate from this process is then treated to remove strontium by another solvent extraction process utilizing selective crown ethers or treated to remove strontium and cesium using chlorinated cobalt dicarbollide. The raffinate from the crown ether strontium removal process is subjected to cesium removal by use of inorganic sorbents or solvent extraction using crown ethers. All of the above processes have been demonstrated, on the laboratory-scale, using actual high-activity waste streams. Based on the results of tests with simulated and actual wastes, the acidic waste streams have been decontaminated to levels below NRC Class A Low Level Waste. The concentrated high-activity radionuclide product streams would be immobilized as a glass waste form. The effect of inert materials from the separations processes, primarily Zr, P and Mo as well as radionuclides on glass waste loadings has been evaluated.

INTRODUCTION

The Idaho Chemical Processing Plant (ICPP), which is located on the Idaho National Engineering Laboratory (INEL), has reprocessed irradiated nuclear fuel since 1953 to recover uranium-235 and krypton-85 for the U.S. Department of Energy. The resulting acidic liquid radioactive waste was solidified to a high-level waste (HLW) calcine, and stored in stainless-steel bins enclosed in concrete vaults. About 3800 m3 of radioactive HLW calcine is currently stored at the ICPP. In addition to the HLW calcine, approximately 6.9 million liters of high-activity acidic-liquid waste are stored at the ICPP. This liquid is a result of decontamination activities, evaporator bottoms and solvent wash activities and cannot be calcined directly because of its high sodium content. In the past, this waste was blended with extraction cycle raffinates and calcined. Since October 1993, all extraction

raffinates available for blending with the sodium-bearing waste (SBW) have been calcined.

Reprocessing activities at the ICPP were halted in April 1992, and since that time an aggressive development effort has been underway to evaluate technologies for processing and immobilizing the liquid and calcine radioactive wastes. A rigorous systems analysis approach was used to develop a model for evaluating and comparing waste treatment technologies. This model was used to evaluate several technologies and combinations of technologies (1). The key criteria used to evaluate technologies included: life-cycle cost (with and without HLW disposal costs), five-year cost, cost-time profile, HLW volume, total waste volume, and capability of meeting regulatory requirements. Aqueous separation processes were selected as having the highest probability for meeting regulatory requirements for processing SBW and also resulted in the lowest life-cycle costs for all treatment options considered.

The HLW calcine is composed primarily of metal oxides from inert materials such as Zr and Al (from fuel claddings), Ca (added for fluoride corrosion control in the calciner), and B and Cd (used as soluble nuclear poisons in the dissolution process). Radioactive materials including the TRU elements and fission products (primarily Cs and Sr) comprise less than 1 wt% of the calcine. Aluminum and zirconium based calcines represent the greatest inventory of the calcine at approximately 20% and 80% respectively. A summary of calcine compositions is given in Table I.

TABLE I

The average composition of SBW is given in Table II. The liquid SBW has an average nitric acid concentration of 1.4M, a nitrate concentration of 4.5 M and a sodium concentration of 1.3M. Radionuclides in the SBW that will require treatment and/or immobilization are U, Np, Pu, Am, Cs, Sr, and possibly Tc. Other hazardous constituents in the SBW that may require treatment are mercury, lead, chromium and cadmium.

TABLE II

The SBW is readily amenable to aqueous separation processes, but the calcine must first be dissolved prior to treatment. Dissolution of most calcines can be achieved using 5 M HNO_3 at 90o C in about 30 minutes. The calcine/acid mixture must be continuously mixed to facilitate effective dissolution. The heel of undissolved calcine from a batch dissolution is left in the dissolver and mixed with fresh acid and a new calcine charge. Laboratory and bench-scale data indicate that greater than 98% of the calcine can be dissolved in 10 sequential batch dissolutions. This suggests that a calcine heel will not build in the dissolver and that undissolved calcine, which will be fed directly to the glass melter, will not be a significant factor in glass composition or waste loading.

The flowsheet for separating the actinides, strontium and cesium from the aqueous acidic feed solutions is shown in Fig. 1. This flowsheet includes solvent extraction processes for the removal of actinides and strontium and an ion-exchange process for the removal of cesium. The high-activity waste stream from the separation processes is concentrated and sent to the vitrification process. The decontaminated waste raffinates would meet NRC Class A LLW criteria and be immobilized as grout for near surface disposal. These processes will be discussed in more detail later in this report.

The advantages offered by this flowsheet include: significant reduction of HLW volume, capability to process several waste streams in one facility, and a very consistent feed composition to the HLW vitrification process. The major disadvantage of this flowsheet is the additional capital cost required for the separations process, but analyses indicate this cost may be largely offset by the reduction in the size and throughput of the HLW vitrification facility.

Fig. 1.

Figure 1. Aqueous Separations Flowsheet for ICPP Acidic Waste

Actinides (U, Np, Pu, Am) and Tc are removed from the aqueous waste streams by solvent extraction processes utilizing bifunctional neutral organophosphate compounds such as CMPO, DHDECMP or phosphine oxide derivatives. The TRUEX process, which uses a solvent comprised of 0.2M CMPO and 1.4M TBP in a paraffinic hydrocarbon diluent, has been successfully demonstrated on both simulated and actual calcine and SBW (2). In a series of 3 batch contacts with fresh TRUEX solvent in each contact, >99.995 % of the actinides were removed from actual SBW. The actinides were effectively stripped from the solvent by 0.04M HEDPA. Tests in centrifugal

contactors, with simulated SBW containing neodymium as an americium surrogate, have demonstrated >99.93% neodymium extraction in 4 stages. It has also been shown that mercury can be selectively partitioned from the acidic waste and the actinides in the TRUEX process.

Other potential actinide extractants, primarily DHDECMP and phosphine oxide derivatives have been tested with simulated and actual SBW. These solvents offer promising alternatives to the TRUEX process and will be evaluated in detail, including tests in centrifugal contactors, in the near future.

Strontium is selectively removed from the acidic raffinate from the TRUEX process by the SREX (strontium extraction) process. The SREX process utilizes a crown ether extractant of 0.2M di-(tert-butyldicyclohexo) 18-crown-6 in 1-octanol (3,4). Recent test results indicate 1.0M TBP in a hydrocarbon diluent is also an effective solvent for the crown ether. The SREX process has been demonstrated on simulated and actual SBW and dissolved calcine. The SBW poses the greatest challenge for this process as sodium and potassium, present in 4 to 5 orders of magnitude higher concentrations than strontium, will be partially extracted and reduce the amount of strontium extracted. Greater than 99.99% of the strontium was removed in six successive batch contacts with actual SBW and fresh solvent. The same degree of separation from actual dissolved calcine was accomplished with 3 successive contacts. Testing of the SREX process in centrifugal contactors is in progress, but results are not yet available.

Two more important issues relative to the SREX process have been investigated. The first is the purity of the substituted crown ether extractant. Extractant samples from two suppliers in the U.S. and one in Russia were tested. The results of one U.S. produced crown ether and the Russian crown ether were comparable. The other U.S. produced crown ether had significantly lower strontium distribution coefficients than the other two. It is postulated that differences in the isomeric composition of the extractants result in different levels of strontium extraction due to interferences from alkali and alkaline earth elements. The second issue is the availability of substituted 18-crown-6 material in commercial-scale quantities. The U.S. manufacturer of the better crown ether has developed the capability and has demonstrated production in kilogram quantities. These issues are significant for the potential future use of the SREX process on a production scale.

Cesium removal is accomplished by ion exchange using ammonium molybdophosphate (AMP). AMP is effective at removing cesium in nitric acid media, but must be placed on an engineered support for use in a fixed-bed column. AMP on a polyacrylonitrile (PAN) support developed and produced in the Czech Republic (5) has been tested with simulated and actual wastes at the ICPP. An equilibrium capacity for AMP-PAN of 150 g Cs/ kg AMP was experimentally determined. Testing of AMP-PAN in fixed-bed columns is in progress.

The disposition of the AMP-PAN has not been determined. One option is to load the AMP-PAN with cesium and then remove the bed material and send it to the vitrification process. Alternately, it may be feasible to elute the cesium from the AMP-PAN. In this case, the cesium-rich eluent would be added to the actinide and strontium-rich streams prior to concentration/vitrification.

A collaborative program between the Khlopin Radium Institute (KRI) of St. Petersburg, Russia and the INEL has resulted in testing of chlorinated cobalt dicarbollide for the removal of strontium and cesium from ICPP wastes (6). The process was effective at selectively removing the fission products Sr and Cs; however it may be difficult to implement because of safety concerns relative to the nitrobenzene-based solvent. Recent work at KRI may have produced a new solvent that would be acceptable for use in the United States. Testing of this process in centrifugal contactors is planned for 1995.

In order to meet the NRC Class A LLW criteria and to avoid operational problems with the centrifugal contactors and fixed-bed columns, the liquid feed streams must be clarified prior to the separations processes. Data from actual calcine dissolutions suggest that radionuclides are concentrated by about an order of magnitude in the undissolved solids from the dissolution process. Preliminary estimates indicate up to 99.99% solids removal must be achieved to meet the 10 nCi/g limit in the low-level grout. This level of solids removal is assumed to be more than adequate to preclude any equipment operational problems.

The amount of HLW glass produced from the concentrated radionuclide containing streams from the separations processes was estimated for zirconium-based calcines.

Zirconium-based calcines represent about 80% of the calcines at the ICPP and on a mass basis, over 70% of the total waste. Assumptions and process considerations used for this estimate are as follows:

99% Zr calcine is dissolved, undissolved solids report to HLW fraction
66 wt% of the Zr in the feed to TRUEX reports to the HLW fraction
0.04M HEDPA strip, 150 l strip/400 l aqueous feed to TRUEX, 2 moles P/mole HEDPA
60 g Cs/kg AMP-PAN, 80 wt% AMP on AMP-PAN, 1 mole P/mole AMP

Based on these considerations, the composition of the feed stream to the HLW vitrification process can be estimated. The amount of glass produced will be based on limiting concentrations of certain components to maintain solubility in the glass and not produce unacceptable process conditions such as excessive corrosion or glass viscosity. Assumptions for the limiting compositions in glass are shown below:

1 wt% loading of radionuclides in glass. If the feed stream to vitrification was pure oxides of the radionuclides, a 1 wt% loading would produce a centerline glass temperature of 3500C.
7 wt% elemental zirconium loading in glass.
1.5 wt% elemental phosphorous loading in glass.
1 wt% elemental molybdenum loading in glass.

Based on these assumptions, glass volumes were calculated for the limiting case of each element. Zirconium has the greatest impact on glass volume, resulting in about 2300 m3 of glass. Phosphorus contributes to about 1100 m3 of glass, while molybdenum contributes to 300 m3. If 1 wt% of radionuclide oxides were the only material fed to the HLW melter, only 22 m3 of glass would be produced. It is apparent from these calculations that zirconium (partially extracted in the TRUEX process) has the largest effect on glass volume and phosphorus (used as a stripping reagent in the TRUEX process) has the second largest effect.

SUMMARY

Aqueous separation processes proposed for treatment of the two high-activity waste streams at the ICPP have been demonstrated to be feasible and cost effective. The waste streams can be decontaminated to levels below the NRC Class A LLW criteria, allowing for near-surface disposal as grout. Clarification of the waste prior to processing is a very critical aspect of decontaminating the wastes. Waste loadings of key elements from the separations processes indicate that the primary driver for glass volume is zirconium and the second largest driver is phosphorus. These two elements are the focus of development efforts to 1) maximize weight percent loadings in glass and 2) minimize the amount of each element reporting to the HLW vitrification process.

ACRONYMS

AMP	ammonium molybdophosphate
CMPO	octyl (phenyl)-N,N-diisobutylcarbamoylmethylphosphine oxide
DHDECMP	dihexyl-N,N-diethylcarbamoylmethylphosphonate
HEDPA	1-hydroxyethyl-1,1-diphosphonic acid
HLW	high-level waste
ICPP	Idaho Chemical Processing Plant
INEL	Idaho National Engineering Laboratory
KRI	Khlopin Radium Institute
LLW	low-level waste
NRC	Nuclear Regulatory Commission
PAN	polyacrylonitrile
SBW	sodium-bearing waste
SREX	strontium extraction
TBP	tributylphosphate
TRUEX	transuranium extraction

A PROGRAMMATIC OVERVIEW FOR THE DOE-OWNED SPENT NUCLEAR FUEL PROGRAM

Mark W. Frei
Acting Special Associate Deputy
Assistant Secretary for Waste Management
Department of Energy
Ralph Stein
Golder Federal Services

ABSTRACT

This paper provides a programmatic overview of the current status of DOE-owned spent nuclear fuel, resulting principally from the stoppage of weapons production and the reduction in the weapons stockpile. The paper also describes how DOE will manage the effort leading to ultimate disposal, and problems and issues associated with this responsibility.

INTRODUCTION

Since the 1940's, the Department of Energy (DOE) and its predecessor agencies, have operated a complex of defense nuclear facilities for the purpose of manufacturing, testing, stockpiling, and then dismantling nuclear weapons. In recent years, as a result of the changing political situation, the United States has halted production of new weapons, and then agreed to make dramatic reductions in the size of the nuclear weapon stockpile. Because of the stoppage of weapons production and the reduction in the weapons stockpile, DOE must now deal with the nuclear materials legacy of the Cold War.

DOE currently owns and stores about 2700 metric tons of heavy metal (MTHM), most of which is stored in facilities in or near Richland, Washington; Idaho Falls, Idaho; and Aiken, South Carolina. While disposal of such a substantial amount of spent nuclear fuel (SNF) represents a significant problem, it is only a small portion of over 100,000 MTHM processed since the start of the weapons program, and will increase by only about 100 MTHM over the next 40 years.

In addition to the weapons program SNF, DOE has provided nuclear fuel to a number of research reactors, both in the United States and abroad, requiring only that the SNF from these reactors be returned to DOE for ultimate disposition.

PROGRAM OVERVIEW

This paper provides a programmatic overview of the current status of DOE-owned SNF, how DOE will manage the effort leading to ultimate disposal, and problems and issues associated with this responsibility. Because the paper is general in approach, specific details concerning issues and site-specific problems are left to other papers in the program.

The accumulation of DOE-owned SNF is, currently, resting primarily in storage pools. Some of this SNF has been in underwater storage well beyond the limits initially planned and has degraded to the point where continued storage, as is, can lead to safety problems. This situation combined with the fact that the SNF stored in multiple locations is made up of over 90 fuel forms grouped into six categories presents DOE with formidable challenges as it seeks a path forward for permanent disposal.

DOE-OWNED SNF VULNERABILITIES

In August 1993, the Secretary of Energy requested that the condition of DOE-owned SNF storage facilities be assessed. Although no conditions were identified that required immediate attention to prevent harm to the workers or to the public, 106 environmental, safety and health vulnerabilities were identified regarding the current inventory of spent fuel. In addition to these vulnerabilities, five DOE facilities and three burial grounds were identified that warranted priority

management attention to avoid unnecessary increases in worker radiation exposure and cost during cleanup.
A critical generic vulnerability identified in the assessment of the DOE SNF inventory noted that, unlike the high-level waste from the first stage of reprocessing, there was no path forward for ultimate disposition of DOE-owned SNF. In the past, DOE-owned SNF had been managed under a plan to achieve ultimate disposition by converting the liquid high-level waste resulting from reprocessing into a vitrified waste form for disposal in a geologic repository. However, in 1992, DOE discontinued reprocessing thereby leaving an inventory of spent fuel to be managed in addition to the inventory of liquid high-level waste.
In response to the assessment of storage facilities for DOE-owned SNF, a three-phased action plan was developed to resolve the identified vulnerabilities. The Phase I Action Plan addressed 31 of 33 high priority vulnerabilities, and 48 of the lower priority issues. The Phase II Action Plan released in April 1994 covered 81 vulnerabilities. As a result, all vulnerabilities were covered by a complete or partial individual action plan. The completion of the partial action plans identified in Phase II was addressed in the Phase III Action Plan released in October 1994. With this release, all vulnerabilities have now been addressed, one-quarter of the 430 corrective actions have been completed and 15 vulnerabilities have been completely resolved. The Phase III plan constitutes the final Headquarters report, and represents the completion of the Secretary's initiative to assess DOE's SNF facilities and the first step toward preparing DOE-owned SNF for interim storage.
MANAGING DOE-OWNED SNF
Using a system engineering methodology to define the program requirements, the path forward for permanent disposal has been defined as consisting of three primary functional activities:
Stabilization of existing fuels and facilities (Assure Existing Safe Conditions);
Development of stable, long-term, cost-effective interim storage pending disposition (Achieve Interim Storage);
Preparation for permanent disposition. Currently the planning base assumes disposal in a geologic repository. (Prepare for Disposition).
In undertaking these activities, DOE seeks to make its key SNF policy decisions in conformance with a process established by the National Environmental Policy Act (NEPA). As required by NEPA, the DOE is systematically evaluating the potential environmental consequences of spent fuel management and policy alternatives prior to making its management decisions.
To support DOE's decision making regarding management of DOE-owned SNF, a number of environmental documents have been or will be prepared. These documents include:
an Environmental Assessment for the return of DOE-owned SNF from foreign research reactors that have immediate significant problems with on-site storage of the SNF;
a Programmatic Environmental Impact Statement to address the management of SNF throughout the DOE complex, and
an Environmental Impact Statement for Foreign Research Reactor SNF that does not have immediate on-site storage problems.
Additional site-specific spent fuel NEPA reviews are underway or planned.
DOE also has a number of evaluations underway to consider significant programmatic or policy issues related to possible licensing by the Nuclear Regulatory Commission (NRC), and whether some of the DOE-owned SNF should be considered as Resource Conservation and Recovery Act (RCRA) material falling under Environmental Protection Agency regulations. These issues are discussed later in this paper.
In a real sense, NEPA, through the Programmatic EIS, will drive the DOE-owned SNF program strategy for some 40 years on a national level. The draft Programmatic EIS that has been issued addresses potential environmental impacts associated with alternative management approaches, e.g. regionalization which would distribute existing and projected DOE-owned SNF among certain DOE sites based primarily on fuel type. A final programmatic EIS on DOE-owned SNF is scheduled to be issued by April 15,1995, following review and revision based on stakeholder comments on the draft EIS, and the Record of Decision by June 1,1995.
Another EIS that is being prepared involves SNF from foreign research reactors that contain U.S. origin enriched uranium. This document will evaluate the potential environmental effects of establishing and implementing a policy that is consistent with the long-standing nuclear non-proliferation policy of the United States. This

EIS, scheduled to be issued in draft later this year, will defer to the programmatic EIS for siting alternatives, but evaluates the environmental consequences for a stand-alone, site- specific management approach for SNF from foreign research reactors.

PROGRAM POLICY ISSUES

The resolution of existing and potential programmatic issues will ultimately depend on the completion of the NEPA process. Until that process is completed, near-term issues and vulnerabilities must be addressed to the extent possible. At this time, the DOE-owned SNF program faces three primary policy issues:

- Should DOE-owned SNF be placed in the first geologic repository?
- Should new interim dry storage facilities be developed and licensed by the NRC?
- Should some DOE-owned SNF be regulated under RCRA?

Should DOE-Owned SNF be Placed in the First Geologic Repository?

The Nuclear Waste Policy Act of 1982, as amended, mandated that the Federal Government pursue the development of deep geologic repositories for the disposal of civilian spent nuclear fuel, high level waste and other highly radioactive waste. In 1985, the President authorized the co-location of defense nuclear wastes and civilian nuclear waste. Although the statute was silent on the disposal of DOE-owned SNF, in 1994, the DOE General Counsel concluded that the NWPA authorizes disposal of DOE-owned SNF in the civilian repository conditioned upon an intra-agency agreement that requires payment of a fee adequate to cover the full cost of the disposal. This conclusion is consistent with Act's stipulation that the EIS accompanying the repository site recommendation to the President does not need to consider alternatives to geologic disposal for spent fuel.

It is important to note that the NWPA limits the first repository to 70,000 MTHM until a second repository is in operation. The Office of Civilian Radioactive Waste Management has allocated, as a planning basis, 10 percent of the first repository for defense materials. Within this 10 percent allocation, DOE may include some DOE-owned SNF. While there is currently no consensus on a method of assigning metric ton heavy metal equivalence to high-level waste, it is anticipated that the total inventory of high-level waste will exceed the 7,000 metric ton heavy metal planning allocation set by the Office of Radioactive Waste Management. The Department is evaluating an option of placing both DOE SNF and Defense HLW in the first repository, up to the 7,000 MTHM limit, with factors like risk, safety, cost, etc. determining how much and what type of each would go when.

Should New Interim Storage Facilities be Licensed by the NRC?

Management of DOE-owned SNF until its disposal is expected to require new interim storage capacity to span the time period until the geologic repository is available. However, since the current statutory framework does not allow licensing of new DOE interim storage facilities for DOE-owned SNF by the NRC, a decision must be made regarding whether DOE should proceed toward implementation of NRC licensing requirements and reviews for new facilities. One option available under the current statutory framework is to conduct a "licensability review", which would provide an independent technical review by the NRC of the adequacy of the proposed facility. This approach will require DOE to agree to pay a fee to the NRC for the review. Other options are also under evaluation.

Should Some DOE-Owned SNF be Regulated Under RCRA?

With passage of the Federal Facility Compliance Act of 1992, which addresses management of mixed wastes, questions have been raised concerning the applicability of RCRA waste management regulations to DOE-owned SNF. In light of decisions to discontinue reprocessing of DOE-owned SNF, the Department is evaluating potential regulatory frameworks, but is committed to safely and responsibly managing SNF regardless of the regulatory regime, i.e. under RCRA or the Atomic Energy Act. Preliminary evaluations indicate that only a small fraction of the many types of DOE-owned SNF may potentially exhibit the characteristics of a RCRA hazardous waste. Process knowledge or more specific ongoing evaluations will be required to completely resolve this issue. Discussions are ongoing with the Environmental Protection Agency on this issue.

MASTER LOGIC SCHEDULE

As noted earlier in this paper, the DOE complex is wide-spread with a large number of fuel types residing in several sites. The management of these fuel types leading to final disposition is controlled by the several NEPA documents that are being produced for the entire complex as well as individual sites. To manage this vast

array of activities, as well as to enable the decision maker to maintain an overall picture of the on-going activities stretching out over a 40 year period, DOE has developed a Master Logic Schedule (MLS). The MLS consists of several levels of detail ranging from the Summary Chart and Logic Diagrams shown in Figs. 1 and 2 to progressively more detailed schedules.

The MLS can be thought of as a snapshot in current time, recognizing that as some of the NEPA documents are completed, and Record of Decisions issued, the activities may change. For example, the MLS was developed using the planning base of regionalization by fuel type. The MLS assumes that certain spent fuel types will be moved to selected DOE sites. Under this option, chemical processing of the DOE-owned SNF could take place at the Savannah River Plant, and possibly the Idaho National Engineering Laboratory, pending NEPA evaluations. The schedule assumes that certain DOE-owned SNF may be declared a RCRA waste, and that DOE will seek a licensability review by the NRC of new dry storage facilities to be acquired. However the MLS also assumes that RCRA and the licenseability review is done during the Major Systems Acquisition process, thus not impacting the schedule. Delays due to law suits, permit acquisitions, and various reviews could impact the schedule significantly, and will require schedule modifications.

If this is not the decision reached by the Department by June 1,1995 there will be substantial changes in the MLS. Similarly, as the Technology Integration Plan matures from its current state (as reflected in the December 1994 revision 0), activities and milestones in the MLS will change. To provide for this, the MLS is accompanied with a data base that provides ready revision of the MLS to reflect decisions as well as actual schedules. The MLS will become part of the integrated SNF Program Plan, which will be issued in FY 1995. This Plan will be a living document, being updated periodically to reflect current issues and approaches to resolve them. The Program Plan will serve as a control mechanism for the SNF program, guiding budget and other planning and decision-making activities.

CONCLUSION AND SUMMARY

Safe, efficient, and effective management of DOE-owned SNF in preparation for ultimate disposal (in a geologic repository) is a complex and difficult task. DOE needs to ensure that the necessary policies and programs, technologies, hardware, and facilities are all developed, integrated and available in a timely manner. DOE is utilizing system engineering at both the program-level and site-level to achieve this.

It is expected that as the environmental documents, studies, and findings are completed, the requirements and direction of the program may undergo changes and adjustments. The management practices and tools that DOE has put in place are considered to be sufficiently responsive and far reaching so as to enable management to make appropriate responses in a timely manner to keep the DOE-owned SNF program on track.

Because the program for dealing with DOE-owned SNF is relatively new, and is not expected to complete its mission until well into the next century, it is critical that stakeholders be actively engaged. In keeping with DOE's openness initiative, the public review process for the Programmatic Spent Nuclear Fuel EIS entailed four scoping periods, 20 public hearings, and the receipt and consideration of about 5100 public comments. Also, DOE is currently working with the Citizen Advisory Boards at Hanford, Idaho, and the Savannah River Site to secure stakeholder input on the recently issued Strategic Plan, and the Foreign Research Reactor EIS.

Through the completion of these activities:

- issuance of the Plans of Action to address vulnerabilities,
- issuance of the Programmatic SNF EIS and Record of Decision, - resolution of the 3 key program issues,
- issuance of the SNF Strategic Plan,
- preparation of the MLS and Program Plan,
- issuance of the Technology Integration Plan, and
- issuance of SNF program requirements documentation,

the DOE will have set the initial framework and planning basis for a complete path forward. With all of this in place by the end of FY 1995, the program will be focusing in FY 1996 on getting on with the job of completing the resolution of urgent health and safety vulnerabilities, developing and implementing solutions for new, dry interim storage, and tackling the technical and regulatory issues associated with complying with repository acceptance criteria. DOE believes it has

the right program in place to carry out this important task and complete the implementation of the path forward.
Whether resolving technical and regulatory issues, or interacting with stakeholders in this dynamic program, NEPA reviews will play a key role in our activities, both now and in the future. But the specific path forward will be determined in detail by the programmatic EIS and supporting program documents. These planning documents will form the basis of an overall framework that will enable us to overcome the challenges of DOE-owned SNF management and to meet our program commitments.

36-2
CRITICAL POLICY ISSUES FACING DOE WITH RESPECT TO THE STORAGE AND DISPOSAL OF DOE-OWNED SPENT FUEL

Thomas C. Elsasser, P.E.
Alan S. Cohlmeyer
VPA Corporation

ABSTRACT

The Department of Energy (DOE) Office of Spent Fuel Management, EM-37, is proceeding with actions to implement safe and cost effective long-term interim storage of its Spent Nuclear Fuel (SNF) prior to ultimate disposal. In order to address identified shortcomings in the current storage of DOE-owned SNF, EM-37 developed the "Plan of Action to Resolve Spent Nuclear Fuel Vulnerabilities." Cognizant DOE sites will implement the actions for the individual facilities that are specified in the Plan of Action. The third and final phase of this plan was issued in October 1994. This Plan of Action identified four critical policy issues that confront DOE with respect to safe and effective interim storage of SNF and preparation of SNF for final disposal. These issues are:

What is the Path Forward for Geologic Disposal of the Department of Energy's Spent Nuclear Fuel? How much, if any, DOE-owned fuel will be placed in the "first" repository? How will the selection be made? What will happen to SNF not placed in the first repository?

Should New Interim Storage and Conditioning Facilities be Licensed by the Nuclear Regulatory Commission? What will the standards be for DOE's interim storage facilities? How will DOE address concerns with respect to "self-regulation?"

Should Hanford N-Reactor Fuel be Stored in a Dry Configuration? Dry storage of N-Reactor and other DOE SNF continues to be an actively discussed topic.

What Should the Approach Be If Some DOE-Owned Spent Fuel is Deemed Unsuitable for Extended, Interim Dry Storage or Direct Geologic Disposal? The issue here is whether DOE should retain the option and capability to process certain "at risk" SNF.

This paper summarizes progress to date in addressing these issues. In all cases, a final decision has not been reached with respect to every aspect of these issues; however, in each case DOE has identified a preferred option in the form of a recommended technical approach or path forward. Each of these issues is discussed in turn, in light of the most current information available.

INTRODUCTION

In August of 1993, Secretary O'Leary commissioned a comprehensive baseline assessment of the environmental, safety, and health vulnerabilities associated with the storage of spent nuclear fuel (SNF) in the DOE complex. During October 1993, a multi-disciplinary Spent Fuel Working Group, directed by the Assistant Secretary for Environment, Safety and Health, and comprised of DOE employees and contractors, assessed 66 facilities spread across 11 sites. This assessment was performed to determine the inventory and the condition of the Department's Reactor Irradiated Nuclear Material, which includes spent nuclear fuel and reactor irradiated target material. The assessment also evaluated the condition of the facilities that store spent fuel and identified the vulnerabilities and problems that are currently associated with these facilities.

In order to address the identified vulnerabilities and associated problems, EM-37 developed the "Plan of Action to Resolve Spent Nuclear Fuel Vulnerabilities." In developing this plan, four critical policy issues were identified that significantly affected the future direction of DOE's spent nuclear fuel program. Resolution of these issues was considered necessary in order to permit important programmatic decisions to be made so that a clear path could be established to address the identified vulnerabilities and related problems. This paper presents the current status of DOE's efforts to resolve these critical policy issues.

WHAT IS THE PATH FORWARD FOR GEOLOGIC DISPOSAL OF THE DEPARTMENT OF ENERGY'S SPENT NUCLEAR FUEL?

Background

The Nuclear Waste Policy Act of 1982 and its 1987 Amendment (the Act) mandates that the Federal Government pursue the development of deep geologic repositories for the permanent disposal of civilian spent nuclear fuel, high-level waste, and other highly radioactive waste. In 1985, the President accepted the Secretary of Energy's recommendation that defense nuclear waste should be co-located with the civilian waste. General Counsel concluded in a legal opinion dated March 23, 1994, that the Act authorizes the disposal of DOE-owned spent nuclear fuel in a geologic repository, conditioned upon payment by the DOE of a fee adequate to cover the full cost of disposal. The DOE, however, has made no final decision at this time regarding the specific strategy for the ultimate disposition of DOE-owned spent nuclear fuel.

The Act limits the capacity of the first repository to 70,000 metric tons heavy metal until a second repository is in operation. DOE's Office of Civilian Radioactive Waste Management (OCRWM), however, has allocated as a planning basis 10 percent of the repository capacity for defense wastes (7,000 metric tons heavy metal, if the capacity of the first repository is at least 70,000 metric tons heavy metal). Projections of waste inventories show that the first repository, with a legislative limit of 70,000 tons, does not have adequate capacity for either all civilian, or the total civilian and defense waste.

The path forward for ultimate disposition of DOE-owned spent nuclear fuel must be addressed in a manner consistent with the three DOE-owned spent nuclear fuel program systems engineering functions: remediation of vulnerabilities in existing storage, achievement of reliable interim storage, and preparation of DOE-owned spent nuclear fuel for disposal. In addition, three assumptions are made when developing options for ultimate disposition of DOE-owned spent fuel. These assumptions are: 1) The current OCRWM program will be successful in constructing, licensing and operating repositories for the disposal of high-level radioactive waste; 2) Development of long-term interim storage, with active institutional controls in place, will be required to store DOE-owned spent nuclear fuel, pending repository availability; and, 3) There is a distinct possibility that some DOE-owned spent nuclear fuel may not be adequately characterized to support the OCRWM schedule to submit its license application to the Nuclear Regulatory Commission in 2001.

Discussion

Three planning options have been developed for consideration. Each option assumes emplacement in a geologic repository as DOE's proposed strategy for disposition of its inventory of spent nuclear fuel. These options would integrate DOE's spent nuclear fuel into the program being conducted by OCRWM for the disposal of civilian spent nuclear fuel and establish the framework within which to evaluate DOE-owned spent nuclear fuel against the requirements for qualifying spent nuclear fuel for geologic disposal. The options considered are:

Option 1 -- DOE-owned spent nuclear fuel and vitrified high-level waste would be authorized for disposal in the first repository. The total quantity of DOE-owned spent nuclear fuel and vitrified high-level waste would not exceed 10 percent of the repository capacity. Disposition of remaining DOE-owned spent nuclear fuel and vitrified high-level waste would not be decided until the DOE recommendation on the need for a second repository. In addition, under this option all DOE-owned spent nuclear fuel would be aggressively stabilized and prepared for repository disposal.

Option 2 -- All DOE-owned spent nuclear fuel would be authorized for disposal in the first repository, along with all high-level waste, assuming the 70,000 metric tons heavy metal limit is removed by Congress.

Option 3 -- All DOE-owned spent nuclear fuel would be deferred to a second repository.

Recommended Path Forward

Option 1 is recommended because it provides a path forward for the geologic disposal of DOE-owned spent nuclear fuel, while minimizing impacts on OCRWM's schedule for the first repository. Option 1 leaves undisturbed the existing repository capacity allocations for civilian spent nuclear fuel and DOE-owned materials. Option 1 also does not assume an increase in the capacity of the first repository. This option is also recommended because it would constitute a significant step toward satisfying stakeholder concerns over de facto disposal of DOE-owned spent nuclear fuel at

storage sites.
SHOULD NEW INTERIM STORAGE AND CONDITIONING FACILITIES BE LICENSED BY THE NUCLEAR REGULATORY COMMISSION?
Background
New interim storage facilities will be required for DOE's spent nuclear fuel since additional time is needed to finalize a decision regarding the location and timetable for long-term disposal of this fuel. However, it is very likely that DOE's spent fuel will eventually come under Nuclear Regulatory Commission (NRC) jurisdiction, since it will be required to meet waste acceptance criteria for geologic disposal, and given the likelihood of new legislation being enacted to address external regulation of new DOE facilities. Further, it appears that the technical standards that would be required for NRC licensability of any facility associated with spent fuel storage or disposal are reasonable. Therefore, it is prudent that DOE pursue an evaluation of the current regulatory framework and technical requirements associated with NRC licensability of new spent fuel interim storage facilities. This evaluation will provide the data and information required for a future decision regarding licensing of DOE facilities.
Discussion
A number of options exist as to how to best pursue application of NRC requirements to DOE's spent nuclear fuel facilities. Three options were formulated to capture and highlight the identified issues and address the variety of implementation approaches. These options can be summarized as follows:
DOE Directive Option -- This option would be to design future SNF interim storage facilities to comply with DOE technical requirements and proceed to construction without NRC review. This option relies on existing DOE spent fuel requirements defined in the DOE directives system.
Licensability Review Option -- This would consist of designing future SNF interim storage facilities to comply with NRC technical requirements and a confirmation of compliance through NRC licensability reviews. This type of independent technical review of a DOE facility by the NRC has been previously conducted (e.g., Fast Flux Test Facility) and can be performed within the current statutory framework. To facilitate this type of NRC review, this option adopts NRC technical and safety requirements utilized for commercial SNF.
Full Licensing Option -- This option would require design of future SNF interim storage facilities to comply with NRC requirements and begin construction once an NRC license can be obtained. This option differs from the other options primarily in that it would require external regulation of DOE facilities and thus represents a change from the status quo. While this option would result in external regulation, it would also require congressional action for full implementation.
Recommended Path Forward
The need for flexibility early in the DOE-owned SNF program and a desire to position DOE for potential future external regulation were determined to be the predominate selection criteria. The best option, which could be implemented under the current statutory framework and would assist in transitioning to external regulation, is the Licensability Review option. The Licensability Review option would also assist in verifying the implementation of NRC criteria to DOE spent fuel and facility design. Moreover, it would provide a strong independent technical review that could improve the credibility of DOE with its stakeholders and the general public. Finally, a licensability review would facilitate a detailed evaluation of the cost, schedule, and safety benefit of NRC oversight of DOE facilities.
SHOULD HANFORD N-REACTOR FUEL BE STORED IN A DRY CONFIGURATION?
Background
Facility assessments documented in the Spent Fuel Working Group Report on spent nuclear fuel vulnerabilities issued on December 7, 1993, and Defense Nuclear Facilities Safety Board (DNFSB) reports have identified concerns over continued wet storage of Hanford N-Reactor fuel. DNFSB Recommendation 94-1 in part recommended the acceleration of efforts to place N-Reactor fuel into a stable interim storage configuration with a "program to be directed toward storage methods that will minimize further deterioration." Continuing wet storage may result in continued spent fuel degradation and negative impacts on future spent fuel handling and disposal. Dry storage of spent fuel, in general, is considered superior to wet storage; however, the knowledge base for dry storage of N-Reactor spent fuel is somewhat limited. An evaluation was performed in order to determine whether

long-term wet storage or dry storage is most beneficial in minimizing further fuel degradation and potential environmental insult.

Discussion

Placement of the N-Reactor fuel into dry storage has been evaluated by an Independent Technical Assessment (ITA) team comprised of industry experts, sponsored by the DOE Richland Operations Office. Results of this evaluation indicate that the fuel can be conditioned prior to placement into dry storage, and safely managed during the dry storage period. The Assessment team defined the steps and related schedule which could be followed for demonstration that dry storage of N-Reactor fuel is safe and that the fuel degradation can be arrested.

Recommended Technical Approach

The Hanford Spent Nuclear Fuel Project (the Project), in conjunction with the ITA, has developed engineered alternatives for expedited removal of spent nuclear fuel, including sludge, from the K Basins at Hanford. Based on these evaluations, a Westinghouse Hanford Company (WHC) recommended path forward for K Basins spent nuclear fuel has been developed.

The recommendation consists of a series of projects to construct and operate systems and facilities to safely retrieve, package, transport, process, and store K Basins fuel and sludge. The overall conditioning and storage scheme is based on the ITA team's proposed passivation and vault storage process. A dual purpose staging and vault storage facility provides an innovative feature that allows accelerated removal of fuel and sludge from the basins and minimizes programmatic risks beyond any of the originally proposed alternatives.

The two-phase strategy packages and moves K Basins fuel and sludge to a newly constructed Staging and Storage Facility where it is staged for conditioning. When an adjoining facility is constructed, the fuel is cycled through a stabilization process and returned to the Staging and Storage Facility for interim (40 year) dry storage.

This recommended path forward combines aspects of several of the originally developed alternatives, thus optimizing across the most significant objectives and constraints. In general, the concept of vault storage of dried, passivated metal fuel (the ITA proposal) was used. However, temporary staging of wet packaged fuel and sludge prior to conditioning was added to improve the schedule for K Basins fuel and sludge removal. Using the dry storage vault facility for temporary fuel staging avoided the need to construct a separate basin to perform this function.

The packaging, transfer, and wet staging of the spent fuel are to be conducted under a K Basins Environmental Impact Statement (EIS); a Notice of Intent for this NEPA review was scheduled to be issued in early 1995. The necessary testing, design, and procurement of critical path items for this project are to be conducted under the Hanford SNF EIS, which is scheduled to be issued in mid-1996. Preliminary schedule projections include the start of fuel removal in late 1997, complete fuel removal by December 1999, initial placement of SNF in dry storage in 2001, and complete placement in 2005.

WHAT SHOULD THE APPROACH BE IF SOME DOE-OWNED SPENT FUEL IS DEEMED UNSUITABLE FOR EXTENDED, INTERIM DRY STORAGE OR DIRECT GEOLOGIC DISPOSAL?

Background

During April 1992, the Department of Energy approved a secretarial action directing the "phaseout of reprocessing at both the Savannah River Site (SRS) and the Idaho National Engineering Laboratory (INEL)." For Savannah River, the secretarial action included an option for processing of existing inventories of aluminum clad fuel in parallel with stabilization operations over a five or six year period. Pursuant to this policy, further DOE spent nuclear fuel processing would be limited to DOE-owned spent nuclear fuel deemed "at risk" for interim storage or potentially unacceptable for the repository. "At risk" fuels are defined as those fuels which will not, or cannot, be expected to maintain safe and non-hazardous integrity during either underwater basin storage or extended, interim dry storage.

The processing of some "at risk" spent nuclear fuel in the F and H Canyons at Savannah River site is under evaluation. Also, in recognition of the unfavorable economics and the perceived proliferation risks attendant with the conventional aqueous reprocessing technology, DOE is developing an alternative technology that could prove to be useful in conditioning certain "at risk" spent nuclear fuel types. This technology, known as "pyroprocessing," employs pyrochemical methods to separate fissile materials from fission products in such a way that there is no production of

a stream of separated plutonium. Because it recycles all of the process reagents and thereby produces minimal secondary waste streams, the pyroprocess also promises to provide improved waste management through reduced high-level waste volumes and by production of highly stable final waste forms. The feasibility of application of this process to many of the DOE spent nuclear fuel types is being evaluated.
Spent nuclear fuel at various DOE facilities has been inventoried, with data being assembled on approximately 150 fuel types (e.g., cladding, dimensions, fissile compounds and alloys, chemical constituents, uranium enrichment and mass, etc.). Data are also being assembled on the condition of each fuel type and the potential for, or existence of, serious deterioration. Vulnerability assessments have been made of existing storage facilities to identify weaknesses due to aging and to deterioration of containment for radioactive materials. For a few fuel types, the existing storage facilities and deteriorated fuel condition may place the fuel "at risk" during the period prior to transfer to dry storage or during the 40 year period of extended, interim dry storage.

Discussion

Various options are available to DOE with respect to dealing with the fuel deemed to be "at risk:"

Option 1 -- Allow no chemical conditioning of DOE-owned spent nuclear fuel prior to transfer to extended, interim dry storage facilities; limit conditioning to repackaging. Chemical conditioning may be required before ultimate disposal of the spent nuclear fuel in the geological repository.

Option 2 -- Process fuel considered to be "at risk," i.e., those fuels that will not, or cannot, be expected to maintain safe and non-hazardous integrity either during storage in underwater basins or during extended, interim dry storage.

Option 3 -- In addition to conditioning fuels considered "at risk," process other DOE-owned fuels that are believed to be unacceptable for placement in the geological repository.

Recommended Technical Approach

The option for processing "at risk" spent nuclear fuels should be retained as a means to assure public and site personnel safety, and facility and environmental protection prior to implementation of extended, interim dry storage.

Selection of "at risk" spent nuclear fuel types for conditioning should be based on a thorough systems engineering study, comparing processes, technical risks, lifetime costs, and waste form volume and stability. The systems engineering study should address stakeholder concerns and involve the stakeholders at critical stages of the management decision process.

The use of conditioning technology should be considered for fuel other than just "at risk" fuels. The effect on spent nuclear fuel storage under the Resource Conservation and Recovery Act and the waste streams for the geological repository could be affected in a positive way by this conditioning and should be evaluated in a systems engineering study.

The specific approach(es) to be taken for these "at risk" fuels is being evaluated in an EIS on interim (10 year) management of materials at SRS. A range of possible approaches is being evaluated for different fuel types and includes processing to metal or metal oxides, vitrification, or continued storage. The EIS will determine the appropriate technical or management approach for these fuels, and a decision will need to be made in the near term to ensure the availability of SNF conditioning facilities such as the F and H Canyons at SRS.

In addition, reprocessing is being considered as an option under the Foreign Research Reactor EIS which is currently scheduled for a Record of Decision in late 1995.

NATIONAL ENVIRONMENTAL POLICY ACT REVIEWS ON MANAGEMENT OF DEPARTMENT OF ENERGY SPENT NUCLEAR FUEL

David F. Hoel
EM Office of Spent Fuel Management (EM-37)

Charles Winklehaus
JUPITER Corporation
ABSTRACT
This paper gives a brief history of the origins of DOE's current inventory of spent nuclear fuels (SNF) and the effects of the end of the "Cold War" on the management of such materials. It also describes the proposed and future DOE SNF management activities, and focuses in detail on the National Environmental Policy Act (NEPA) reviews to evaluate the environmental effects of these activities.
HISTORICAL PERSPECTIVE
During the last four decades, the Department of Energy (DOE) and its predecessor agencies have transported, received, stored, and reprocessed approximately 100,000 metric tons of spent nuclear fuel (SNF). Currently, approximately 2,700 metric tons of heavy metal (MTHM) of SNF that are now stored at various locations in the United States--as shown in Fig. 1-- and overseas have not been reprocessed. This SNF is in a wide range of enrichments (that is, percent uranium 235), types, and conditions. By the year 2035, this quantity may increase by approximately 100 metric tons.
The bulk of this SNF that is now the responsibility of DOE was utilized in "production" reactors at the Hanford and Savannah River Plants that were used to produce plutonium and tritium for nuclear weapons. DOE SNF is also derived from the U.S. Navy's use of nuclear reactors for ship propulsion. Smaller amounts of SNF were generated by research reactors at other DOE facilities, such as the Oak Ridge Reservation, Argonne National Laboratory-East, Brookhaven National Laboratory, Los Alamos National Laboratory, and Sandia National Laboratory-Albuquerque, and at many non-DOE research reactors--both domestic and foreign--such as at universities, government agencies, and private firms. DOE-EM has also been assigned the responsibility for the SNF from a few special-case commercial nuclear power plants or former reprocessing facilities. Detailed listings of DOE SNF inventories at their various facilities are given in Table I (1).
It should be noted, however, that most SNF from commercial nuclear power plants--a far larger amount of SNF than the DOE SNF discussed here--is the responsibility of DOE's Office of Civilian Radioactive Waste Management (OCRWM), and such commercial SNF will therefore not be discussed in further detail in this paper. OCRWM has been studying, as authorized by the Nuclear Waste Policy Act of 1982, a site in Nevada for suitability for geological disposal of SNF and defense high-level radioactive wastes.
REDIRECTION FOLLOWING THE END OF THE COLD WAR
The end of the Cold War led DOE to reevaluate the scale of its weapons production, nuclear propulsion, and research missions. In April 1992, DOE began to phase out reprocessing of SNF for recovery and recycling of plutonium and highly enriched uranium. DOE realized the need to establish an integrated complex-wide program that provides safe and effective management of the SNF inventory, pending its permanent disposition.
Concurrently, DOE was preparing the "Environmental Restoration and Waste Management Programmatic EIS" on Department-wide waste management and environmental restoration programs, including a section on management of DOE SNF. As recently announced (60 Federal Register 4607, January 24, 1995), the DOE proposes to downscope the Environmental Restoration and Waste Management Programmatic EIS to waste management only. ["Programmatic NEPA document means a broad-scope EIS or EA that identifies and assesses the environmental impacts of a DOE program..." (definition from 10 CFR 1021.104)] When DOE committed itself to preparing a complex-wide SNF EIS as part of a court order--as discussed in more detail below--the coverage of SNF management was transferred to the more comprehensive coverage in the "Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs EIS". The scoping and timing of these two EIS documents is also discussed further below.
CURRENT SNF STORAGE ISSUES AND THEIR NEPA IMPLICATIONS
The following text describes ongoing NEPA reviews related to SNF management and discusses other factors likely to be considered in making strategic decisions regarding interim storage of DOE SNF over the next 40 years, as well as DOE plans for future tiering of NEPA reviews that may be prepared to assist in implementation of programmatic decisions. ["Tiering" refers to the coverage of general matters in broader environmental impact statements (such as national program or policy statements) with subsequent narrower statements or environmental analyses (such as

regional or basinwide program statements or ultimately site-specific statements) incorporating by reference the general discussions and concentrating solely on the issues specific to the statement subsequently prepared. ..." (definition from 40 CFR 1508.28)]
While the Environmental Restoration and Waste Management Programmatic EIS was being prepared, a lawsuit was instituted by the State of Idaho against the further importation of SNF into Idaho, specifically from the Fort St. Vrain facility in Colorado to Idaho National Engineering Laboratory, on the grounds that an EIS had not been prepared for such shipments. In settling the lawsuit by a court order in June 1993 (slightly modified in September and December 1993), DOE and the Navy agreed to suspend almost all shipments of SNF to Idaho National Engineering Laboratory (except for limited shipments of Naval SNF) while such an EIS was being prepared. DOE and the Navy also agreed to prepare a two-part EIS (1), called the "Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs EIS", and an EA on a very specific timetable as follows:

Issue EIS Implementation Plan	11-1-93
Complete Draft EIS and publish public notice of its availability in the Federal Register (FR)	6-30-94
Complete Final EIS and publish public notice of its availability in the FR	3-30-95
Issue and publish in the FR the Record of Decision based on the Final EIS	6-1-95
Prepare Environmental Assessment (EA) for storage of Navy SNF at sites other than Idaho National Engineering Laboratory	12-31-93

One part of the EIS was a complex-wide study of the management of SNF; the other part was a more detailed, site-specific study of environmental restoration and waste management programs (including SNF management) at Idaho National Engineering Laboratory. The alternatives being considered in this two-part EIS are listed below:
Volume 1--Programmatic Spent Nuclear Fuel Management Alternatives (2,1):
No Action, which is taking the minimum actions required for safe and secure management of SNF at or close to the generation site or current storage location;
Decentralization, which is storing most SNF at or close to the generation site or current storage location with limited shipments to DOE facilities;
1992/1993 Planning Basis, which is transporting and storing newly generated SNF at Idaho National Engineering Laboratory or the Savannah River Site;
Regionalization, which is distributing existing and projected SNF among DOE sites based primarily on fuel type or geographic location; and
Centralization, which is managing all existing and projected SNF inventories from DOE and the Navy at one site until ultimate disposition.
Volume 2--Idaho National Engineering Laboratory Environmental Restoration and Waste Management Alternatives (for details, see reference (1)):
No Action
Ten-Year Plan
Minimum Treatment, Storage, and Disposal
Maximum Treatment, Storage, and Disposal.
Following the court order mentioned earlier, DOE published in the Federal Register on September 3, 1993 a Notice of Opportunity to Comment on a proposal to expand the scope of the Idaho National Engineering Laboratory Environmental Restoration and Waste Management EIS to include Department-wide impacts related to: transportation, receipt, processing, and storage of DOE-owned SNF. Comments were accepted from September 3, 1993 through October 4, 1993. The EIS Implementation Plan summarized comments received and described the resulting scope of the EIS. The EIS Implementation Plan was issued on October 29, 1993 (3).
Three DOE site alternatives were identified in the October 29, 1993 EIS Implementation Plan as ones having existing, large-scale SNF management operations: the Hanford Site, the Idaho National Engineering Laboratory, and the Savannah River Site. Also, four Naval shipyards and the DOE Kesselring Site (in upstate New York) were identified as having experience in handling Naval SNF; these shipyards are: Norfolk, in Portsmouth, VA; Portsmouth, in Kittery, ME; Pearl Harbor, in Honolulu,

HI; and Pudget Sound, in Bremerton, WA.
In response to public comments generated in the scoping process, DOE decided to broaden the range of siting alternatives by considering other sites for future SNF management. DOE utilized a disciplined screening process, which resulted in the addition of the Oak Ridge Reservation and the Nevada Test Site as reasonable alternative sites for regionalized or centralized SNF management (4). The EIS Implementation Plan was amended on May 9, 1994 to include these additional sites. During this same time period, internal studies by DOE also identified environmental, safety, and health vulnerabilities in SNF-related units at Hanford, Oak Ridge Reservation, Savannah River and Idaho National Engineering Laboratory, which were described in a detailed report dated November 1993 (5). This was followed by DOE's three-phase "Plan of Action to Resolve SNF Vulnerabilities", which was finalized in October 1994 (6). These vulnerabilities are discussed in a paper by John J. Jicha, Jr. of DOE in Waste Management '95, session 52; its title is "DOE-Owned Spent Fuel Program Strategic Plan: Issues, Challenges, and Options."
The Draft "Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs EIS" published in June 1994 drew approximately 5,100 comments from stakeholders and the public. DOE is presently responding to these comments and adjusting the EIS where appropriate. No sooner than 30 days after the final EIS is published, the Department will issue its record of decision. However, any particular SNF management alternative that is chosen may affect many sites, and new SNF-related facilities may be needed; other NEPA reviews may be necessary for these, with some of the NEPA reviews "tiered from" the Programmatic SNF Management EIS. The status of many such ongoing or planned tiering NEPA documents is shown in Table II. The interrelationships of the various NEPA documents discussed herein is shown in detail in Fig. 2 (2), with the letters shown in the lower right corner of specific boxes keyed to the listing of the same documents in Table II.
Note that each non-DOE domestic research reactor has appropriate NEPA coverage, as part of the Nuclear Regulatory Commission (NRC) license requirements, for on-site storage and shipping of the SNF from the reactor.
In the 1950's and 1960's the U.S. Government, acting through DOE and its predecessor agencies, began its "Atoms for Peace" program, which included a program whereby DOE furnished enriched uranium for fuel for research reactors in various foreign countries, and agreed to take back the SNF from those reactors. This program expired in 1988 for highly-enriched uranium (HEU) and in 1992 for low-enriched uranium (LEU). The United States is considering the resumption of the acceptance of SNF from such foreign research reactors in furtherance of its fundamental foreign policy and national security objectives to prevent the spread of nuclear weapons to additional foreign countries. A key element of United States nuclear non-proliferation policy has been to minimize and eventually eliminate worldwide the use of HEU--a material usable in nuclear weapons--in civil nuclear programs. Research reactors are the major civil use of HEU; if such reactors convert to LEU fuels, HEU will essentially be eliminated from civil commerce.
An Environmental Assessment (EA) was prepared for urgent shipments from eight foreign reactors (7), and an EIS is in preparation on an acceptance policy that would involve Foreign Research Reactor (FRR) SNF from approximately 42 reactors in 26 countries. The "Programmatic Spent Nuclear Fuel Management and Idaho National Engineering Laboratory Environmental Restoration and Waste Management Programs EIS" that was mentioned earlier takes into account the SNF that might be received from these foreign research reactors. FRR SNF is discussed at length in a paper by Charles Head of DOE in Waste Management '95, session 52; its title is "The DOE Foreign Research Reactor (FRR) SNF Program and Status."
FUTURE SNF STORAGE AND DISPOSAL ISSUES AND THEIR NEPA IMPLICATIONS
The relationship of these studies with respect to planned activities by the DOE Office of Civilian Radioactive Waste Management (OCRWM) is described. These interrelated studies and actions provide a roadmap to establish a clear path forward for disposition of DOE SNF.
The main issues for the future of SNF management concern its ultimate disposition and the preparation required therefor, along with the interrelated implications of these issues for the interim storage of SNF. Because of the deteriorated condition of some of the existing DOE SNF inventory, stabilization may be necessary for interim storage as well as for packaging it for disposal. At the time of this paper,

it is uncertain whether DOE SNF would be disposed of by placement in the geologic repository now being investigated and planned by OCRWM mainly for the much larger quantities of commercial SNF from nuclear power plants. This repository is now anticipated to be available around 2010. Several related issues would need to be resolved, including: the degree of priority, if any, that DOE SNF will have vis a vis defense high-level radioactive waste; the repository's requirements on cask design and dimensions; and waste acceptance criteria. The potential disposal of DOE SNF in a geologic repository is discussed at length in a paper by Jon Thompson of DOE in Waste Management '95, session 52; its title is "A Path Forward for Geologic Disposal of DOE-Owned Spent Fuel." These latter requirements will determine the preparation and timing of the ultimate disposal of DOE SNF, but it is possible that a span of 40 years may be needed for all the DOE SNF to be placed in a repository. OCRWM is also preparing an EIS on development of a multipurpose cask design and plans to begin an EIS on the suitability of the Yucca Mountain Site in 1995. DOE's Office of Spent Fuels Management is cooperating with OCRWM on these studies to ensure that its management of DOE SNF is compatible with OCRWM's plans and requirements.

CONCLUSIONS

The end of the cold war has necessitated a change in the management of DOE SNF. The goal is to assure that all SNF management proposals are carefully analyzed through NEPA reviews to assure that the public and decisionmakers are well informed of potential environmental consequences. The numerous SNF-related NEPA documents discussed herein are illustrative of DOE's ongoing efforts to fulfill both in letter and in spirit the goals so cogently stated in section 2 of the National Environmental Policy Act of 1969, that is, "...To promote efforts which will prevent or eliminate damage to the environment and biosphere and stimulate the health and welfare of man..."
