WM'95 PREFACE

With the continuing growth of these conferences has come an even greater increase in the size of the proceedings. After exhaustive cogitations, we concluded that the best solution would be to go electronic. The size of the proceedings, of the order of 500Mb, mandates a compact disc, a CD ROM and we have selected the Folio software to run the CD's. The advantages of the system are:

- Size - a single CD instead of four - eight hundred page volumes
- Processing time - about half as long to process authors' input to the CD
- Full color figures
- Fast, convenient query capability

There are some drawbacks:

- A ROM reader is required, preferably on a PC.
- How to use the Folio software must be learned even though it is extremely "user friendly"

We are including startup instructions on the CD's and will answer your questions at the conference and later at our Plumer office. There are some significant differences in CD's and hard copy. For example, instead of footnotes, CD's use "popup boxes" which are accessed by clicking on the footnote number. The "popup boxes" can provide more details, supplemental information and credits than are usually given in footnotes.

The Folio infobase uses hypertext technology which is colored and underlined. Double clicking with a mouse moves from one point of the text stream to another, to view figures and "popup boxes". The query capability is perhaps the most useful property if the infobase. The user may create a search string or use a custom template to search for a session, a paper title, an author or coauthor, a company, a country or author-defined keywords. Personal notes can be added to the infobase in use on the hard drive with "shadow files". The shadow files are saved to a disk (hard or floppy) to use with the CD at any time.

For those needing more than the CD's, we can copy a limited number of full papers from author provided hard copy, reprints may be purchased and we will publish the abstracts and provide a copy to each registrant. Later, we will evaluate putting the proceedings on the "Information Highway".

We are most optimistic about electronic publication but do anticipate problems and questions. Your indulgence and cooperation will be most appreciated.

THE EUROPEAN ORGANIZATION FOR THE CHERNOBYL'S NEW SHELTER
Colette Lewiner
Alliance consortium
Chairman of the Board and CEO of SGN (FRANCE)
ABSTRACT
Eight years ago, the fourth unit of the Chernobyl nuclear power plant was devastated by an explosion. This accident deeply undermined public perception of the nuclear industry as a safe source of energy. Faced by an urgent need to enclose the highly contaminated reactor, Ukrainian authorities succeeded in building in six months a

shelter around it. In the early nineties, the issue of constructing a second shelter to enclose the first one was raised. In 1992, a competition of ideas named Kiev 92 was organized by the Ukrainian government in order to attract suggestions from all over the world on the issue. No outright winner was selected but the Resolution consortium led by Campenon Bernard SGE was second and five other finalists were selected. Soon after, in April 1994, the European Union decided to launch a call for tenders on a feasibility study of the second shelter. It was won by Alliance, a new consortium, comprising of a group of finalists including Campenon Bernard as well as AEA Technology, Bouygues, SGN joined by Walter Bau AG and Taywood Engineering Ltd. Alliance commenced work in September 1994. The project is aimed at assessing the current situation of the first shelter, Ukritiye , and evaluating options for a new shelter. These two fundamental goals have two additional objectives : the Ukritiye dismantling strategy and the management of waste generated by the construction of a second shelter. This is why the project organization is based on four technical task groups working respectively on the stabilization of the Ukritiye, the design of a second shelter, waste management and dismantling. A fifth group, the technical support group, provides a technical consultancy role to the technical task groups. The feasibility study is divided into three phases : first, the evaluation of various options against criteria to be determined by the study. Secondly, developing the options previously approved into a concept definition report on the basis of the recommendations of phase 1 and the advice arising from a consultation process. Thirdly, conducting a validation process among various national and international authorities.

The feasibility study represents a significant step towards the construction for a new shelter for Chernobyl. This momentum must not be lost. Alliance gathers companies that have been working on the new shelter project for the past three years. The expertise gained on the site together with the good working relationship developed with Ukrainian and Russian specialists and the European and G7 funding decided in Corfu and Naples constitute a good grounding for future work.

INTRODUCTION

The Chernobyl accident, with the lives it cost and the damage it caused to the environment, has deeply undermined public trust in RBMK reactor technology and has by extension questioned the reputation of the whole nuclear industry. Since then, much has been done within the nuclear community in order to ward off the risk of a new Chernobyl : RBMK reactors today are undergoing programs of upgrading. More generally, in many countries, nuclear industries have displayed large efforts in order to fight a general public distrust by demonstrating the effectiveness of their nuclear safety approach and developing new methods in related fields (emergency planning, public information, etc.) Today, one of the major challenges on the nuclear industry is to demonstrate our ability to clean up contaminated sites and to treat and safely store nuclear waste.

The Chernobyl accident is now nine years behind us and an assessment of the situation is in process. Our objective, in this paper, is to review briefly past events as well as to describe recent initiatives taking place with respect to the Chernobyl site and specifically the damaged reactor N4.

HISTORICAL BACKGROUND

On April 26, 1986, an explosion occurred in reactor 4 of the Chernobyl power station followed by a fire. The reactor core, primary containment and enclosing structure were all severely damaged. Radioactive materials were projected outside the reactor and released to the environment resulting in an extended contamination of the environs. In the reactor hall open to the sky, highly radioactive and contaminating materials were remaining, which required the urgent reconstruction of a new containment. By December 1986, the damaged enclosing structure was incorporated into a shelter known as the Ukritiye or sarcophagus . It was intended that the Ukritiye should have a design life of at least 30 years. However, it was soon raised that the structure might be unstable.

In early 1992, soon after the independence of Ukraine, a French scientist went to visit the Ukritiye. He came back convinced that France should offer its help to the construction of a new protective shield to be installed around the first one. During the spring, a French civil engineering company, Bouygues, was working with SGN on a proposal for a new Shelter with the cooperation of Ukrainian and Russian organizations and institutes

Given the complexity of the issue and the risks involved, Ukrainian authorities

organized a competition for the project aiming to attract from all over the world the most original and the most advanced solutions. The competition named Kiev 92 was officially launched on July 8, 1992 in Kiev. The winner of the competition was supposed to be awarded the contract for the project.
Proposals were accepted until late April 1993. In total, 394 proposals were presented from Ukraine, Russia and from countries all over of the world. They included impressive proposals from major engineering groups in the world as well as some more modest ones with highly imaginative concepts. At the end of the selection process, on June the 18th, no single proposal was considered as providing a comprehensive solution, therefore, the Jury declared that there would be no winner. Yet, six final candidates were selected by the jury as those representing the best ideas and solutions for a second shelter. These finalists were :
Resolution: (French consortium led by Campenon Bernard SGE) was the best ranked solution : a prestressed concrete building with prefabricated elements remotely assembled above Shelter one.
336: (German consortium led by Kraftanlagen) : a ferro-concrete building incorporating a metallic structure poured in situ with protective screens interposed
Rainbow: (French consortium led by Bouygues and SGN) : a prestressed concrete containment assembled away from the reactor and moved onto it.
Greenleaf: (British consortium led by AEA Technology) : a two layer steel containment built away from the reactor and moved above it.
Monolit: (Russian consortium led by VNIPIET) : concrete filling all the plant's compartments and voids in the sarcophagus
Pluton: (Russian and Ukrainian consortium led by theKurchatov Institute) : a second sarcophagus using a construction similar to Shelter one.
After having provided technical support to the Ukrainian authorities during the Kiev competition, the European Union decided to fund a first study on the reactor 4. A call for tenders was organized in April 1994 by the DG I in the framework of its TACIS program. It called for the conduct of a feasibility study of the Shelter II project and invited to tender the Kiev 92 finalists as well as other European organizations. It was during this period that Alliance came into being. Alliance is a consortium of leading European organizations in the field of nuclear construction and engineering technologies. Alliance consists of the French company who lead the competition of ideas, Campenon Bernard SGE and three companies who were jointly awarded third place in the competition, AEA Technologies, Bouygues and SGN. The Alliance consortium is reinforced by the leading German consortium company Walter Bau AG, and the British consulting engineers Taywood Engineering Ltd.
Alliance was formally awarded the contract in August 1994 and commenced work on the feasibility study in September. In addition to the European organization, Alliance consists of a number of Ukrainian and Russian organizations and institutes. It was recognized during the early stages of the Kiev 92 competition that any feasible and lasting solution to the unique problem in Chernobyl would require a close working relationship with Ukrainian expertise and knowledge. In essence, an alliance of skills and ideas focused upon a single objective. The organizations working with Alliance comprise the Ukrainian Academy of Sciences, the ISTC Shelter, the Kurchatov Institute and the Ukrainian Association of Constructors. This close alliance between Ukrainian, Russian and European organizations has and continues to offer the optimum means of providing a feasible and lasting solution to the Chernobyl legacy.
DESCRIPTION OF THE STUDY
The scope of the study is to determine the optimum concept for protecting the environment from uncontrolled releases of radiation and nuclear materials [...] from the damaged remains of reactor 4 inside the current shelter . In practical terms, the above objective consists of two fundamental requirements : the assessment of the current conditions and the evaluation of options for a second shelter.
If we refer to the Terms of References we read that The existing shelter is to be strengthened and modified as may be necessary to allow the construction of a new shelter to proceed with minimum danger both from structural collapse and from radiation. This is to include securing the remains of the reactor core . Regarding the Shelter II, it is required that A new, structurally independent shelter is to be constructed to contain both the current shelter and the damaged remains of Reactor 4 . The shelter is planned to have a construction period no longer than 5 years and to last during a minimum 100 years. A condition placed upon the Alliance team is that any design must accommodate the continued operation of unit 3 and also

allow for possible decommissioning operations of unit 4.
Before any new shelter can be constructed over the existing Ukritiye, a number of important issues require careful considerations and assessment. First, the stability of the Ukritiye needs to be assessed to ensure that it will remain a viable shelter until the proposed second shelter can be designed, constructed and commissioned. Secondly, stabilization of the Ukritiye and construction of Shelter 2 should be conceived in relation to each other so that either stabilization of the Ukritiye is guaranteed in the long term, or the second Shelter is designed in order to resist possible future failures of Ukritiye. Thirdly, these two strategies should be consistent in particular with two major issues : the dismantling strategy and management of waste inside the shelter or resulting from all future activities.
Given these general objectives, the feasibility study is to be conducted in three distinct phases :

- Phase 1 : option studies ending in February
- Phase 2 : concept definitions due in June
- Phase 3 : concept validation and review

During the first phase of the project, Alliance will undertake to collect, assess, review and document information relating to the Chernobyl unit N4. It is clear that a project of this nature will rely considerably upon the availability of information. The assessment and validation of such information will also provide some of its own particular challenges. Phase 1 of the study is concerned with the generation of options for the design of a second shelter. These options will require evaluation against agreed criteria and will also need to consider the requirements for the eventual decommissioning of unit N4. During phase 1, assessments will be undertaken to review, and where possible, quantify the relative risks associated with the existing conditions and the proposed solutions. At the end of Phase 1, Alliance is required to prepare a report setting out, on the basis of criteria stated in the Terms of Reference, its recommendations and the reasons for those recommendations.
During the second phase, Alliance will review and amend if necessary the recommendations set out in Phase 1. It will also integrate the results of the presentation and consultation process and develop the options previously approved into a comprehensive concept definition report.
Phase 3 will be a validation process for Phase 2 : concepts previously developed in the previous phase will undergo various peer reviews. In the end, Alliance will produce a final report containing all the findings and recommendations of the feasibility study.

PROJECT ORGANIZATION

It is recognized that one of the objectives of the study is to secure a solution for a second shelter which can be demonstrated to be effective on technical, financial, environmental and safety grounds. The project teams are based in a single office location in France and comprise a core team of twenty engineers and specialists. Since the beginning of the study, engineers and experts from various countries have been in an ideal position to exchange information and ideas. The manager of the project is Jean-Louis Le Mao from Campenon Bernard. The study during the first phase is organized into five groups as follows :

- stabilization of Ukritiye
- design of a second shelter
- Waste management
- Dismantling
- Technical support group

It is these 5 groups who will be responsible for establishing the foundations on which the concepts will be developed during the subsequent phases of the study. In support of these groups as already stated will be a number of Ukrainian and Russian organizations who will also provide technical input into the study. The role of the technical support group in the above is to provide a consultancy role to the four main groups; the group comprises of specialists in the fields of nuclear safety, civil engineering, radiological protection, pricing, scheduling and risk analysis. In addition, it is the responsibility of this group to manage the information collected and produced during the project. The technical support group is also responsible for the establishment of the design criteria to be adopted for the second shelter. These criteria will be reviewed and ultimately approved by the Ukrainian safety authorities.

A BRIEF ASSESSMENT OF THE SITE TODAY

The fourth unit of the Chernobyl power plant is extensively damaged. Walls and ceilings in the Central reactor hall were demolished, ceilings in the water separation drum premises were displaced and walls totally collapsed. The premises housing the main circulation pumps oriented to the North were completely destroyed. Two upper floors of the de-aeration stack were demolished, the columns of the building frame were shifted to the side of the turbine room by up to 1.1 meter. The ceiling in the turbine room was destroyed in many places by fire and falling debris, several building beams were deformed and building frame columns were displaced by the explosion wave.

The reactor emergency cooling system was completely destroyed from the North side of the reactor building and buried under debris from the construction elements. The upper plate of the Elena reactor biological shield and joint elements, weighing 2,700 tons together, were thrown on the rib with an almost vertical angle of inclination. The reactor base dropped 4 meters lower opening a space through which melted fuel elements from the reactor could flow and invade the maintenance corridors in the sub-reactor space as well as the rooms of the lower part of the reactor block.

The central reactor hall is filled with debris from the destructed reactor core (fuel assemblies, graphite blocks as well as metal and building constructions). Also in some places are materials which were thrown from helicopters in 1986.

The construction within six months after the accident of a shelter in order to encase the damaged reactor was undoubtedly an impressive achievement. The main parts of this structure are a separating wall, the Pioneer wall , the cascade wall, the West wall as well as several roofings.

The separating wall was built in order to isolate the operating third unit from the damaged unit. It was erected by filling a transport corridor up to the + 12 m mark in the Northern part and no higher than the + 5m mark in the Southern part. The Pioneer protective reinforced wall was erected along the perimeter of the damaged unit. The North protective cascade wall was constructed of concrete in the form of projections. The West wall was sealed from the outside by a wall with buttresses 50m high that were manufactured away from the reactor, erected and moved against the wall.

The roofing of the Central hall was made of thin steel plates covering a row of tubes based on metal beams installed along the central hall. Roofing on the Northern and Southern sides of the central hall are made from large sized metal shields. New roofing was constructed over part of the ruined turbine hall. To date it is known that voids within the Ukritiye still exist.

Waste in the reactor can be divided in four main elements :

- spent fuel assemblies originally stored in the storage pool
- fuel containing masses (lava): a mix of concrete, fuel, steel and zirconium from the melted core
- high dispersal dust
- contaminated water

Concerning the nuclear safety of the fuel containing materials in the Shelter, the Ukrainian authorities have concluded that not all experimental studies and calculation confirm guaranteed subcriticality of these materials located in the encasement, although the probability of a chain reaction is limited by natural and artificial barriers. A concern in this respect would be water penetrating into the Ukritiye. However, it is clear the criticality issue still remains a concern.

There is a lot more information to obtain in order to have a complete assessment of the site today. Retrieving and analyzing this information is one of the main objectives of the Alliance feasibility study.

TECHNICAL APPROACH OF ALLIANCE

The provision for an optimum solution for a second shelter is an extremely difficult challenge, as anyone who knows of the problems at Chernobyl will confirm. It is also evident that there is no single solution to the problem; a number of solutions could be considered as feasible. The approach of Alliance is based on the requirements of both TACIS and MinChernobyl which gives some very clear objectives.

As a start, Alliance considered the present situation regarding the stability of the Ukritiye and the location of radioactive debris both within and around the structure needed to be fully characterized before any decisions could be taken as to long term strategies. As an example, the problem of leakage through foundation slabs

into the ground water needs exploration.
The difficulties in construction on the heavily contaminated site also need to be identified as well as their consequences on building methods and cost. For this general purpose, the consortium has secured the cooperation and support of a number of Ukrainian and Russian organizations with the best knowledge of the state of the Ukritiye.
Criteria to be used in the study pay special attention to :
- stabilization of the structure
- radiological exposure
- costs
- the degree of disruption of the regular operation of the third unit
- Ukrainian supply of skills and equipment
- future technological progresses

Compliance with emerging Ukrainian regulatory framework is also a significant aspect of the study.

STABILIZATION OF THE UKRITIYE

The establishment of existing conditions within the Ukritiye is considered an essential and fundamental objective of Phase One. It concerns ground conditions (ground water levels, contamination etc.), structural stability, radiological conditions, site infrastructure and local working methods and resources.
This data is to be used in establishing the stability of existing structures, proposing concepts of remedial actions. More generally, this data is crucial in the conduct of other activities in the project, in particular the concept feasibility planning of a second shelter, the decommissioning planning and assessment and radioactive waste management, storage and disposal.

CONSTRUCTION OF A SECOND SHELTER

The concept for the design and the construction of a second shelter is required to provide an environmentally safe system and also be compatible with any derived longer term strategies for Unit N4. During Phase One, the technical team are undertaking a review, assessment and evaluation of Kiev 92 entries based upon agreed criteria. A large number of factors are considered including reactor 3 containment, waste management and decommissioning strategies, seismic criteria, ventilation systems, etc.
In Phase II, this team is responsible for the provision for general schematic designs of the recommended concept solution. These drawings are to be supported by schedules and programs of work describing the realization of the second shelter. Method statements together with procurement strategies are to be produced. All aspects of the recommended solution will be quantified in respect to safety, costs, risks and resources.

DISMANTLING

The dismantling team are evaluating Top-Down and Bottom-Up retrieval methods, in other words, methods of dismantling starting from the roof of the building or on the contrary from the ground level. It is recognized that some dismantling operations may be required in the current stabilization of Shelter I and in the construction of Shelter II. This team provides technical expertise to the Stabilization and Shelter II teams during the study. It will give special consideration to factors such as radiological safety, radioactive waste inventories, availability of remote and semi-remote technology, waste disposal routes and base budgets.

WASTE MANAGEMENT

The Waste Management team will undertake the study and evaluate the options for recovering, processing, conditioning and storing the radioactive waste arising from the Ukritiye during the construction of the second shelter. It is also to look at the waste management requirements associated with stabilization of Shelter I and the Shelter II. This will require the development of a basic waste management strategy. During Phase 1, some assessment of waste volumes and types will be undertaken together with a review of process requirements and plant capacity.

CONCLUSION

After a succession of selection processes that lasted almost three years, the feasibility study conducted by Alliance represents a key step towards the remediation of the Chernobyl issue. Both an assessment of the site and an evaluation of options for a new shelter are underway. Beyond purely technical matters, the study is required to give consideration to other issues such as environment, costs,

funding, operation of other Chernobyl units, scientific progress and Ukrainian contribution to the future project. Clearly, the Chernobyl remediation project will be closely tied to the economy and the financial sector, to the legal and regulatory system as well as to large scientific projects. In addition, the project presents several exceptional features :

- it is unique references to this project are rare and limited
- it is located in an emerging country with infrastructures that are continuing to develop
- it entails unprecedented sharing of responsibility
- it will require an exceptional financial structure

These features contribute to the unusual character of the Chernobyl project and explain the prudence of companies and institutions involved. Yet, the accident is now eight years behind and further steps need to be taken in remediating the situation.

Last June, at their Corfu summit, European Union leaders have agreed on a program of assistance and loans to help Ukraine complete and upgrade three VVER-1000 reactors in order to shut Chernobyl reactors and to close the site. Less than one month later, at the summit in Naples, the G7 partners decided to add new actions on top of the European initiative. These two institutions have thus demonstrated their will to help Ukraine deal with its energy problem.

This momentum must not be interrupted and the Chernobyl shelter issue should not drop from the world's agenda. The key elements are gathered to start the project. Alliance has made steady progress in establishing the basic requirements and has a significant expertise to provide in view of its implementation.

ACKNOWLEDGEMENTS

The authors wish to express their thanks for the cooperation and support of the European Union and in particular DG I.

1-2

RADIOACTIVE WASTE MANAGEMENT - AN INTERNATIONAL VIEW

Sren Norrby
Swedish Nuclear Power Inspectorate (SKI)

ABSTRACT

The management and disposal of radioactive waste is a matter of great concern in many countries. Even if experience of radioactive waste management and disposal exist, disposal of high-level radioactive waste still remains to be implemented. International cooperation between countries and in international organizations can help in reaching acceptance of radioactive waste management and disposal. Openness and peer review may increase credibility.

INTRODUCTION

Nuclear power has been used to produce electricity for many decades. An inevitable result of nuclear power production is the generation of nuclear waste.

The management of radioactive waste has been, and will continue to be an issue under debate for at least as long as the final disposal of, above all, high-level radioactive waste and spent nuclear fuel have not been achieved and the safety of the disposal of such waste has been convincingly demonstrated. It is a fact that this has not yet been achieved in any country.

The safe management and disposal of radioactive waste and spent nuclear fuel is a prerequisite for the full acceptance of nuclear power production.

Although radioactive waste management is mainly a concern for countries with a nuclear power program, it is also an issue for other countries using radioactive isotopes in research, medicine and industry.

The problem of radioactive waste management is shared by all of these countries and, as we live in a world where international contact and communication are increasing, there is an obvious need for a common basis for solving the problem. Cooperation is needed not only to share resources and know-how but also to improve credibility and acceptance. International cooperation between countries and through international organizations can help to formulate a common basis for measures to be taken in individual countries and enhance public acceptance of national programs.

RADIOACTIVE WASTE MANAGEMENT PERSPECTIVES

Radioactive waste management covers a multitude of disciplines that extend over different activities such as pretreatment, treatment, conditioning, interim storage,

transportation and the final disposal of radioactive waste. These activities should be viewed as separate parts that integrate into one system. Each activity should be seen in relation to each other so that the overall system can be implemented in a logical and balanced manner. All steps must lead to the final goal - the safe disposal of radioactive waste. Emphasis should also be put on the minimization of radioactive waste as well as on the recycling and the reuse of materials with a very low radioactive content (1, 2).

The release of very low-level radioactive waste to the environment is normally accepted. However, the basic concept for radioactive waste disposal is to isolate the waste, for example, by incorporating the radionuclides in matrices such as cement or bitumen and by the encapsulation of high-level radioactive waste and spent nuclear fuel in highly durable canisters. The repository, be it a repository for high-level or low- and intermediate-level waste, will normally be designed as a multi-barrier system in which the waste form is one of the barriers.

Different countries may choose different options: the reprocessing of spent fuel or the direct disposal of spent fuel; shallow ground burial of low- and intermediate-level radioactive waste or the disposal of such waste in rock caverns; the construction of repositories for high-level radioactive waste or spent fuel in granitic rock, in clay, in salt or in other geological media. Although each of these options is different, they all share the same need for basic knowledge in scientific and technical areas. The methods for assessing the long-term safety of a repository are basically the same, regardless of the waste disposal method.

Performance assessment methods are being developed as tools for assessing long-term safety and for demonstrating compliance with safety criteria. However, they can also be of use in identifying areas where further research and development work is needed.

For many years, the assessment of the impact of radioactive waste management activities has been an issue of great concern in many countries. The approaches used in assessment of environmental impact are currently being extended beyond the impact which can be directly linked to radioactivity to include also other possible impact on the environment. Environmental Impact Assessment (EIA) is a well-known concept in the USA and in many other countries, whereas in other countries it is less well-established. However, in Sweden and in other countries of the European Union, this concept is becoming increasingly important.

The management of radioactive waste covers many scientific and technical areas. There are other concerns which are also important. Public involvement is an important part of the Environmental Impact Assessment process. Although this process may be complex and time-consuming, it carries with it the hope that, in the end, not only will acceptance be gained from the technical and legal systems but also from the public.

The need for assessing the impact of a nuclear waste repository over the very long timescales involved is not only a scientific and technical challenge, it also entails ethical considerations related to the impact of the repository on future generations. The uncertainty that is an unavoidable consequence of the long timescales involved must not only be recognized but also treated in a way that provides a basis for credible impact assessments. Ultimately, impact assessments are largely based on the understanding and judgement of experts (3,4). If we maintain a policy of openness including the publication of findings which are subjected to peer review and international cooperation, we can have reasonable assurance of making well-founded, balanced decisions within this field (5).

EXISTING EXPERIENCE OF THE MANAGEMENT OF RADIOACTIVE WASTE

Nuclear power has been used for many decades. In the early days of nuclear power production, radioactive waste management issues were recognized but too little emphasis was placed on these issues for acceptable long-term solutions to be found. Today, concepts which had been previously accepted, such as very simple forms of shallow ground burial and the dumping of radioactive waste into the sea, are questioned or no longer accepted.

We have also had positive experience of the management of radioactive waste which can help us to plan for the future. Much valuable experience has been gained in the areas of treatment, conditioning, transportation and near surface disposal of waste as well as of interim storage of radioactive waste and spent nuclear fuel. Experience in these fields has been gained in many countries, for example, France, Germany, Spain, Sweden, the UK and the USA (6,7).

Regardless of the nature of the experience that has been gained within the management of radioactive waste, lessons can always be learned.
At the same time, we need to move ahead within this field. The interim storage of radioactive waste and spent nuclear fuel is only a temporary solution. A final solution must be found. In general, near surface disposal is accepted for low- and intermediate-level waste and deep geological disposal is regarded as the most promising solution for high-level waste and spent fuel. New concepts such as the partitioning and transmutation of radioactive waste are also being explored, even if there is skepticism about whether these alternatives are realistic or even desirable.

NATIONAL AND INTERNATIONAL ACTIVITIES

The general understanding is that it is the responsibility of each country to take the necessary steps for the management and final disposal of radioactive waste and spent fuel from national programs.
Comprehensive R&D programs on radioactive waste management and final disposal are being carried out in many countries. Options under consideration and methods for implementation and demonstration of safe disposal of radioactive waste can be:

- Reprocessing or direct disposal of spent fuel
- Disposal concepts
- Geological media for the construction of a repository: salt, clay, granitic rock etc.
- Site selection methodology, technical criteria or volunteerism,or a combination
- Performance assessment methodology
- Etc

There is no single answer to the question of which option should be chosen. The conditions which exist in each country as regards the scope and nature of the nuclear power program, the geological media etc. will be of importance. Each country has the responsibility for managing its radioactive waste and the solution chosen for a particular country must take into account the specific conditions which exist within that country.
Even if the management of radioactive waste is a national responsibility, there is a recognized need for international cooperation. Cooperation between individual countries or in international organizations can be effective in utilizing the know-how and facilities which exist and can also help to harmonize views and criteria.

A NATIONAL PROGRAM FOR RADIOACTIVE WASTE MANAGEMENT

The Swedish program for radioactive waste management will be presented here as an example of a fairly comprehensive national program (8). The Finnish program for radioactive waste management is quite similar both as regards the disposal concept and the legal basis. Other countries have comparable programs.
The Swedish nuclear power program comprises twelve nuclear reactors - three pressurized water reactors (Westinghouse) and nine boiling water reactors (ABB Atom). Sweden has decided to phase out nuclear power no later than the year 2010. This means that 7,000 tonnes of spent nuclear fuel will have to be disposed of.
Under Swedish law, the responsibility for radioactive waste management and the decommissioning of the nuclear power reactors lies with the reactor owners. The reactor owners must conduct an R&D program within this area in order to live up to their legal obligations. The reactor owners must also provide the funds required to cover the future costs of nuclear waste management. The reactor owners have formed a jointly owned company, The Swedish Nuclear Fuel and Waste Management Co. (SKB), in order to fulfill their legal obligations within this field. In Sweden, there is general agreement on the direct disposal of spent nuclear fuel.
Every three years, SKB must submit its R&D program to the Swedish Nuclear Power Inspectorate (SKI). SKI reviews the program and submits its evaluation and recommendations to the Government. The program has since long time focused on the KBS-3 waste disposal method, which involves the encapsulation of spent fuel in copper/steel canisters and the emplacement of the canisters, surrounded by bentonite, in drilled holes in a system of tunnels at a depth of about 500 m in granitic rock.
SKB has proposed that the encapsulation facility should be co-sited with the already existing central interim storage facility for spent fuel (CLAB) at the Oskarshamn nuclear power plant. CLAB has been in operation for ten years. 2 000 tons of spent fuel is now stored in the facility. Discussions with the authorities and with the

local municipality and community are already in progress.
SKB is now at a very early stage in the process for selecting a site for the repository. According to the time-schedule, the construction of the repository will start within ten years from now. According to SKB's plans, the first canister will be deposited in the repository in the year 2008. The repository will be constructed in stages. The first stage is intended to demonstrate handling and disposal methods and will include the possibility of retrieving the canisters, if necessary. This first stage may be important not only for validation of the technical aspects of the concept but also for assuring public acceptance and approval of the repository.
The repository for low- and intermediate-level radioactive waste from the nuclear power program is a rock cavern (SFR), situated close to the Forsmark nuclear power plant, and has been in operation since 1988 (7). The capacity of SFR, 60 000 m3, will probably be sufficient for all operational waste from the Swedish nuclear power program. So far, about 15 000 m3 of waste has been emplaced in the repository.
Since 1985, a transportation system, comprising a purpose-built ship, Sigyn, has been in operation for the transportation of spent fuel and radioactive waste. All existing nuclear facilities - the nuclear power reactors, the central interim storage facility and the repository for low- and intermediate-level waste - are located at the coast.
The Swedish nuclear waste management program includes all activities and facilities needed to fulfill the requirements under Swedish law, i.e. the final disposal of radioactive waste and spent fuel, including the decommissioning of the reactors.
The progress in the Swedish nuclear waste program may besides the scientific and technical qualities of the program be attributed to the existence of regulatory system which clearly defines the responsibilities of the nuclear industry and society. Even if there has been some opposition against nuclear waste facilities the general public has accepted these facilities. However the most critical steps remain to be taken, the siting and licensing of the repository for spent fuel.

INTERNATIONAL ACTIVITIES IN RADIOACTIVE WASTE MANAGEMENT

As previously mentioned, international cooperation between individual countries as well as within international organizations is necessary. With regard to radioactive waste management, two international organizations with many activities in this field, the International Atomic Energy Agency (IAEA) and the Nuclear Energy Agency (NEA) within the Organization for Economic Co-operation and Development (OECD), will specifically be discussed. However, there are many organizations which have substantial programs covering areas of importance for radioactive waste management.

THE INTERNATIONAL ATOMIC ENERGY AGENCY (IAEA)

The IAEA program on radioactive waste management issues covers many aspects such as the development of safety standards, the development of principles and criteria, technical assistance and advice to developing countries, services and publications on "state of the art" of technology experience in Member States to countries which request such services. An important service offered by the IAEA is the performance of international peer review services on aspects of radioactive waste management programs of its Member States. Such services are provided within the Agency's Waste Management Assessment and Technical Review Program, WATRP.

Radioactive Waste Management Safety Standards (RADWASS)

This program comprises work to develop safety standards for different aspects of waste management, principles of radioactive waste management, a national system for radioactive waste management, pre-disposal management, near surface disposal, geological disposal, decommissioning and waste from mining and milling.
The principles of radioactive waste management, also referred to as the safety fundamentals, comprise the very basic principles of the protection of human health and the environment, as regards present and future generations within and beyond the borders of the country as well as requirements on controlling radioactive waste generation and the safe operation of radioactive waste management facilities.
The safety standard "Establishing a National System for Radioactive Waste Management", defines responsibilities for the establishment of a legal framework and a regulatory body. It also defines the responsibilities of waste generators and operators of facilities.
In addition to the standards, safety guides and safety practices will be established to address relevant issues in more detail.
The RADWASS program was set up in 1990 and many safety standards, guides and technical documents are now under preparation. The RADWASS program is reviewed by an

International Radioactive Waste Management Advisory Committee (INWAC). The INWAC members are senior experts in different fields of waste management, regulators as well as implementors. INWAC also serves as the expert group that provides guidance and advice to the IAEA on the direction and implementation of the Agency's radioactive waste management program. Also, under the new terms of reference for INWAC, the Committee will consider global waste management issues and publish their opinions and recommendations on how such issues may be overcome.

There is also an INWAC Sub-group on Principles and Criteria. This Group discusses, as the name indicates, principles and criteria for radioactive waste management. Discussions concern, for example, safeguards requirements for final disposal as viewed by experts engaged in the safety aspects of disposal, the optimization of radiation protection in radioactive waste disposal and time-frames and safety indicators in assessing the safety of the final disposal of radioactive waste. This INWAC Sub-group serves as the forum for the discussion of issues on principles and criteria as related to waste disposal where international agreement has not yet been reached. The Sub-group usually publishes its finding when agreement is reached.

International Convention on Radioactive Waste Management

The RADWASS documents "The Principles of Radioactive Waste Management" (9) and "Establishing a National System for Radioactive Waste Management" have been very carefully examined since they are also intended to provide the basis for a planned international convention on radioactive waste.

According to plans, the two documents will be approved by the IAEA's Board of Governors in spring 1995. According to present planning, preparatory work will soon be started to establish a text for an international convention on radioactive waste management.

This convention will be a complement to an international convention on the safety of civil nuclear power reactors (the nuclear safety convention) that was initiated in 1991 at an IAEA conference in Vienna. The nuclear safety convention has been signed by a number of countries and is now in the process of being ratified. The implementation of the convention will be through reporting from the countries on reactor safety issues in accordance with the requirements of the convention and through discussion and peer review of the national reports.

OECD/NEA

Within the NEA, the Radioactive Waste Management Committee (RWMC) is directly engaged in radioactive waste management issues. The work within the RWMC focuses on radioactive waste disposal and performance assessment methodology for long-term evaluation.

A few years ago, the RWMC published, in cooperation with the International Radioactive Waste Management Advisory Committee (INWAC) of the IAEA and endorsed by the Experts for the Community Plan of Action in the Field of Radioactive Waste Management, Commission of the European Communities, a collective opinion document entitled, "Disposal of Radioactive Waste: Can Long-term Safety Be Evaluated?" (3). In the document, the answer to the title question is yes, although it is also noted that the methodology for safety assessment can be further developed and that site-specific data are needed to decide whether a specific disposal system provides the level of safety required.

In the RWMC, discussions are now in progress on a new collective opinion document which will discuss the arguments for deep geological disposal of high-level radioactive waste and spent fuel.

As a basis for the new planned collective opinion document, the RWMC in collaboration with the OECD Directorate of the Environment recently organized a seminar on ethical aspects of the disposal of radioactive waste. The discussions at this seminar very clearly demonstrated that there seems to be a wide international consensus on the general principles of waste management and disposal which has developed over the years.

These very basic principles address the protection of human health and the environment with regard to present and future generations within and beyond the borders of the country as well as requirements on exercising control over radioactive waste generation etc., as they are presented in the IAEA Safety Fundamentals (9).

Another observation from the seminar is the need which has been expressed for finding and implementing methods for the final disposal of radioactive waste so as not to rely on interim storage for long periods of time. The possibility of

retrieving, for a certain period of time, the waste deposited in a repository may help to promote public acceptance of the final disposal system.

CONCLUSIONS

The management of radioactive waste, notably final disposal, is an issue which is currently under debate and which will remain so until the final disposal of high-level radioactive waste and spent fuel has been implemented and acceptance has been gained not only from the technical and legal perspective but also by the public.

It is generally agreed that the management and disposal of radioactive waste is primarily a matter of national responsibility. However, there is a need for attaining an international consensus on this issue. Consensus on standards and criteria for radioactive waste management is essential for gaining the confidence of the public.

It seems that it is possible to reach a consensus on the possibility of implementing deep geological disposal for high-level radioactive waste and spent fuel. However, it should be emphasized that R&D work should be pursued in order to further improve long-term safety.

Openness, peer review and international cooperation are means of gaining confidence. An international convention on radioactive waste management may be beneficial.

Session 02 -- DOE Deputy Assistant Secretary's Panel
Co-chairs: Ed Helminski, S.I.M./EP;
Julie D'Ambrosia, EnviroTech

DAS PANEL

The Department of Energy's Environmental Management (EM) Program held a special session on Monday, February 27, 1995, addressing the responsibilities of each Office within the EM organization. The session focussed on current program status, plans for the future, and specific changes anticipated over the coming year.

Attendees at the special session were invited to submit questions in writing to the session moderator who posed the questions to panel members.

Below are some of the key points made by panel members during their introductory remarks:

Randy Scott (Deputy Assistant Secretary for Compliance and Program Coordination) discussed his Office's key initiatives, which include better definition of EM projects and decentralization to enable more decision making to be done at the Field Offices.

Jim Turi (Director, Office of Program Integration/Office of Waste Management) discussed the reality of budget constraints and the need to meet waste management treatment and disposal objectives.

Jack Baublitz (Acting Deputy Assistant Secretary for Environmental Restoration) addressed the increased flexibility to the program with pilot demonstrations and further involvement of the commercial sector, including privatization.

Carl Cooley (Technical Advisor, Office of Technology Development) described the

"Technology Focus Area" approach to developing and implementing new technologies in five areas: landfill remediation, plume remediation, mixed waste management, underground storage tank remediation, and facility transition issues.
Andy Szilagyi (Team Leader in the Office of Integration and Assessment/Office of Facility Transition) noted that finding ways to make facilities "cheap-to-keep" is the only way DOE can ensure worker safety associated with monitoring and maintenance of surplus facilities now awaiting decontamination and decommissioning.
Following introductory remarks by each panel member, specific questions from the audience were posed. Some of the questions and answers are provided below:
How will privatization be pursued, and what do you expect to result from the initiative?
Decentralization of decision-making authority will enable the Field Offices to make more decisions locally, including what specific activities may benefit from privatization. One example - remediation of Hanford high level waste storage tanks has been offered to private industry. If this initiative is successful, DOE will benefit from the infusion of a new approach and new technologies into the program, as well as potentially accelerate the remediation of these tanks. The successful private company will gain specific experience which can be applied to other DOE sites, thereby increasing their ability to compete for other work at Hanford and other DOE sites. Overall, we expect to see less reliance on the Management and Operating contractors at the sites.
How will EM safely manage the large number of facilities being transferred from other DOE programs?
EM must find ways to prioritize projects in order to save money. By approaching individual facilities and addressing them from start to finish, EM will avoid the cost of addressing numerous facilities at the same time and taking longer to complete the activity at each of these numerous facilities. Additional focus on the deactivation process is also expected to provide cost savings.
What kinds of technologies should be pursued to save money? Will these be funded exclusively from the Technology Development Program, or from all EM programs? And how will you ensure the "new technology development approach" will work?
It is clear that capping or treating in-situ (rather than exhuming and re-disposing elsewhere) saves money in treatment, transportation, and re-disposal costs. Technologies suitable for remediating or isolating groundwater will also save money, since "pump and treat" is relatively ineffective at restoring an aquifer.
Not all technology-development or technology-application funding is provided by the Office of Technology Development, nor will it be in the future. It is currently estimated that approximately $135 million from the Waste Management program and $50 million from the Environmental Restoration program is directed at waste-specific or site-specific technology activities.
To ensure the new approach is successful, the Office of Technology Development will involve the "user organizations" (i.e., Waste Management or Environmental Restoration) in the Technology Development activity. In this way, technologies will be developed to target a specific need, and they will be more likely to be successfully implemented, since the user will have been part of the development and application process.
Is there a future for "baselines"?
The rigor associated with preparing and living to a baseline is very relevant to managing a successful program. However, DOE-headquarters recognizes that development and implementation of baselines must be made simpler. One possibility may be to have the baseline cover a short time period. This would allow better data to be incorporated and reduce the effort required to incorporate changes as they occur. Baselines remain an inherent part of project management, reinforce that projects have a beginning, middle, and end, and must proceed through each stage in the most cost-effective manner.
What authorities have been delegated to the Field, and what might be delegated in the future?
Approval for Safety Analysis documentation, Operational Readiness Review completion, and most National Environmental Policy Act authority has been transferred to the Field Offices. HQ continues to look for other areas in which delegation to the Field can occur, though we have no specifics to offer at this time. However, to further reduce the impact of HQ's review process on the field, the Office of Environmental Restoration has delegated approval of Records of Decision to HQ Office

Directors, which should reduce the amount of time required for document approval. To ensure that lessons learned at one site are shared with other sites, the role of the "site coordinator" within the Office of Compliance and Program Coordination will be strengthened. It will be the responsibility of the site coordinator to ensure inter-site sharing of information. We also look to the Office of Field Management for additional sharing of information.

What is the status of updating or replacing DOE Orders?

There has been talk of changing DOE Orders to "rules", which would require publication of each proposed rule in the Code of Federal Register. We do not know what the timing of this might be. In the meantime, the "Standards/Re-quirements Identification Documents" (SRIDs) will enable program personnel to feel more comfortable about the requirements for conducting their program in a safe manner. It is expected that Orders will be circulated to Field Office personnel for detailed review prior to being finalized.

What will be the process in renegotiating compliance agreements due to budget constraints?

The Office of Compliance and Program Coordination will play a role in renegotiations as will the program offices. EM is hoping the regulators and the public will recognize that not all objectives can be accomplished within the current budget constraints, and is further hoping that the stakeholders will work with the Department to focus these limited resources on the most significant problems, leaving wastes or contaminants that pose less risk to be addressed later.

SYSTEMS COST ANALYSIS AND OPTIMIZATION OF WASTE MANAGEMENT FACILITIES

David Shropshire

Chuck Biagi
Morrison Knudsen Corporation
Environmental Services Division

ABSTRACT

This paper presents general conclusions from application of a system cost analysis method developed by the United States Department of Energy (DOE), Waste Management Division (WM), Waste Management Facilities Costs Information (WMFCI) program. The WMFCI method has been used to assess the DOE complex-wide management of radioactive, hazardous, and mixed wastes. The Idaho Engineering Laboratory, along with its subcontractor Morrison Knudsen Corporation, has been responsible for developing and applying the WMFCI cost analysis method.

The cost analyses are based on system planning level life-cycle costs. The costs for life-cycle waste management activities estimated by WMFCI range from bench-scale testing and developmental work needed to design and construct a facility, facility permitting and startup, operation and maintenance, to the final decontamination, decommissioning, and closure of the facility. For DOE complex-wide assessments, cost estimates have been developed at the treatment, storage, and disposal module level and rolled up for each DOE installation.

Discussions include conclusions reached by studies covering complex-wide consolidation of treatment, storage, and disposal facilities, system cost modeling, system costs sensitivity, system cost optimization, and the integration of WM waste with the environmental restoration and decontamination and decommissioning secondary wastes.

BACKGROUND

To provide a cost basis for evaluating Environmental Management options, the United States Department of Energy (DOE), Office of Program Integration (EM-33), has sponsored the Waste Management Facilities Cost Information (WMFCI) program, which is supported by the Idaho National Engineering Laboratory (INEL) and Morrison Knudsen Corporation (MK).

The WMFCI program has developed a method that is being used to estimate the planning level life-cycle cost (PLCC) of facilities needed for treatment, storage, and disposal (TSD) of radioactive, hazardous, and mixed wastes. The method is based on

dissecting the overall TSD facilities into several smaller functions, called cost modules, and developing a cost versus capacity relationship for the various cost elements of the modules. Using this approach, the type and input capacity of the TSD modules needed for handling a given input waste must be defined. Then, a PLCC estimate is developed by referring to a set of regression curves that contain the cost versus capacity relationship.

The WMFCI data base includes PLCC estimates for over 200 modules that cover six waste types: low-level waste (LLW), mixed low-level waste (MLLW), transuranic waste (TRUW), greater-than-Class C (GTCC) and DOE equivalent special case waste, hazardous waste (HW), and spent nuclear fuel (SNF). For each module, cost versus capacity relationships are provided for four different work breakdown structure (WBS) elements. The WBS elements are: preoperation, facility construction, operation and maintenance (O&M), and decontamination and decommissioning.

The WMFCI cost method provides a documented and flexible modular cost basis that DOE and its contractors can use to analyze what-if questions concerning alternative waste management strategies. This powerful method has been broadly used for assessing life-cycle costs associated with several waste management option evaluation tasks. Applications have included the analysis of DOE complex-wide consolidation of TSD facilities and studies covering system cost sensitivities, cost modeling, cost optimization, and integration of WM waste with the secondary waste from environmental restoration (ER), and decontamination and decommissioning.

The WMFCI cost method has supported DOE strategic planning, environmental compliance, and budget planning. Specific applications have included development of life-cycle cost estimates, staffing estimates for risk assessment, and facility design inputs for the socioeconomic analysis of the Environmental Management Programmatic Environmental Impact Statement; cost guidance documentation for preparation of the Site Treatment Plans required under the Federal Facility Compliance Act; and development and application of the System Cost Model for the Waste Management Baseline Environmental Management Report (BEMR) submittal to the U.S. Congress.

System Consolidation

The WMFCI method was applied during the economic studies of DOE facility consolidation options. This analysis included several alternative scenarios involving a different number and location of TSD facilities in the DOE complex. Options studied were grouped as decentralized, regionalized, and centralized configurations. The decentralized option proposed a dedicated TSD facility for most of the DOE installation. The regionalized option proposed a TSD facility at each major installation. The centralized option proposed one or two TSD facilities serving the entire complex. Some conclusions reached from the system consolidation studies are presented below.

Economies of Scale

The economy of scale from a decentralized configuration to a regionalized or centralized configuration is in the range of -5% to -30% savings for regionalized and -25% to -60% savings for centralized. The greatest economies are seen for MLLW and ER-LLW. (See Fig. 1.)

The greatest economies are based on configurations that regionalize at existing disposal sites (e.g., Hanford) and maximize the use of existing facilities.

Existing WM facilities, particularly under regionalized alternatives, provide significant MLLW treatment and LLW disposal capacity. Because of these existing facilities, fewer new facilities are constructed.

Disposal facilities have greater economies of scale than do treatment facilities because of

- lower fixed administrative costs
- a higher ratio of capital to operating costs (i.e., relatively less O&M).

Transportation Impacts

Transportation costs will offset some benefits of regionalization and centralization, although costs have been relatively small (0.3% decentralized, 1% average, and 5% one-site case) compared with the total life cycle costs. (See Fig. 2.)

Rail transportation costs are 1.5-3.5 times the costs for road transport for TRUW.

Total mileage differences on MLLW (implied transportation risk indicators) between decentralized and regionalized cases (factor of 11), and from regionalized to centralized cases (factor of 7). TRUW total miles are similar for all cases (all

ship to the Waste Isolation Pilot Plant).

Rail transportation may be more suitable for ER wastes because of larger loads (better rates).

Because of relatively low transportation costs, it makes more sense to ship some (special) wastes to more centralized sites.

Impacts of ER Residual Waste Going to WM

ER-LLW disposal costs were 91-97% of the total life cycle cost, indicating that only minor treatment would be required and most wastes would go directly to disposal. ER-MLLW disposal costs range from 65-75% of total life cycle cost. (See Fig. 3.)

Comparatively, the disposal costs for WM legacy and newly generated wastes have been approximately 25-40% of the total life-cycle cost.

Cost Sensitivity Studies

The WMFCI method was used to conduct sensitivity analysis of system costs versus the waste management elements. Conclusions of the sensitivity analysis are as follows.

Privatization of treatment facilities could result in a significant cost savings. For a scenario in which a private sector provides a grass roots treatment facility dedicated to DOE waste, the cost savings could be as high as 30-40%. The savings could be even higher if existing commercial treatment facilities were employed.

System Modeling Studies

A computerized tool, the System Cost Model (SCM), has been developed to apply the WMFCI cost estimation method for system modeling studies. After development was completed, the SCM was calibrated to model planning level life-cycle cost estimates at six major DOE installations: Hanford Site, INEL, Los Alamos National Laboratory, Oak Ridge Reservation, Rocky Flats Environmental Technology Site, and Savannah River Site. System cost modeling conclusions are as follows:

To model system costs adequately, the fixed and variable costs must be clearly understood and delineated. Variable costs are a function of the waste feed rates. Fixed costs are those expenditures incurred even if waste is not treated or disposed of. Figure 4 shows the relationship between fixed costs and variable costs.

Existing aqueous waste treatment facilities may not support future treatment needs of sites. Aqueous waste treatment is generally dedicated to specific waste streams that may be different to support processing future waste streams.

The extent that some high cost WMFCI modules are used may impact cost estimates. The open, dump, and sort; characterization; and receiving modules carry high costs. Waste should be minimized to these operations to reduce costs.

Storage of legacy LLW, MLLW, and TRUW account for a significant portion of the system TSD costs. For the six major installations, the total storage costs are 10-25% of the total TSD costs.

Review of System Cost Optimization Opportunities

Through the WMFCI method and system modeling tool, not only can life-cycle, costs be estimated but also opportunities for costs optimization can also be evaluated. Currently, several waste management operations are being reviewed to identify cost reduction potentials and areas that could be studied in the future. The following are some ideas proposed for such studies:

Maximize the use of existing TSD facilities. Using the WMFCI method, life-cycle cost estimates can be developed for scenarios that make maximum use of existing facilities. This scenario involves analyzing excess capacity and configuring the waste shipments for regional TSD accordingly. Whereas current waste management strategies designate regional treatment sites for all waste streams within a particular waste type category, this modified scenario will consider sending different waste streams to various sites, depending on existing facility capacities. Costs for these modified scenarios can then be compared with the costs previously developed for DOE strategic planning to demonstrate the order-of-magnitude potential for cost savings.

Optimize facility operating periods. The DSTP's reflect a wide range of facility operation assumptions (hours of facility operation per year and the number of shifts). The differences in operating hours will influence the sizing of the facility, and the number of shifts will impact the total work force that must be paid.

Site regionalized and centralized facilities where capabilities exist (e.g., compactable or incinerable materials).

Build disposal facilities as needed versus overbuilding capacity up front.

Use commercial facilities. Many sites are currently evaluating options for commercial treatment versus on-site DOE treatment and disposal.

Build facilities with larger throughput so that the backlog waste can be treated in a shorter time. Savings that result from eliminating backlog waste and shifting those dollars to reduce operations and maintenance cost could prove that this approach is more cost effective than sizing the facilities and processing backlog waste over a 10-20 year operating period.

Combine different waste types to use common TSD facilities and reduce the need for construction and operation of additional waste management facilities. Some waste management strategies under consideration specify separate TSD facilities for each of the major waste type categories (LLW, MLLW, TRUW, etc.). This study will combine waste types, where technically feasible, for treatment, storage, and disposal, and provide cost estimates for these optimized scenarios. Again, the optimized costs will be compared with previously developed cost estimates to demonstrate the potential for cost savings.

Consolidate special waste streams for processing. Small quantities of wastes (e.g., remote handled) at more than one site may be handled best in a centralized location, rather than regional alternatives.

Use treatment technologies that reduce pretreatment sorting and characterization.

Substitute vitrified waste forms (e.g., iron enriched basalt) with shallow land disposal rather than building expensive engineered disposal.

Integration of WM, ER, and D&D Waste

Life cycle activities and waste loads relative to the ER and D&D programs are being defined for inclusion in the Baseline Environmental Management Report. This report will be submitted to the U.S. Congress by DOE in March of 1995. The WMFCI method and system modeling tool are being employed to integrate ER and D&D waste with the WM waste, which is the waste generated during the normal operation of the DOE production facilities. Several options for cost-effective integration of WM, ER, and D&D waste are being considered. Some of these options are discussed below.

Use existing and new WM facilities for processing ER wastes

Use lag storage to allow combined WM and ER waste processing.

Reduce ER (LLW and MLLW) residual waste loads to WM by volume reduction technologies.

Use new ER technologies (e.g., in situ vitrification) that produce less residue for WM to process or dispose.

SUMMARY

The INEL and MK have developed and applied a systems cost estimating approach that has yielded several key waste management cost conclusions. These conclusions have helped to identify the areas of high cost sensitivity that require further evaluation by the DOE to develop effective management policies. The most viable options should also consider risk, socioeconomic, regulatory, and other concerns before adoption.

ABSTRACT

The U.S. Department of Energy (DOE) Headquarters and associated contractors have developed an IBM-PC based automated computer model for estimating the life cycle costs of different DOE mixed-waste management alternatives. The model has been designed to estimate the complete cradle-to-grave costs of implementing a waste management alternative. The current version of the model includes capabilities to estimate the cost of managing mixed low-level waste. Capabilities for other waste

types are planned to be included in later versions of the model. The model can estimate the cost of most potential mixed low-level waste management activities beginning with waste characterization before and after treatment, waste treatment by different technologies, pretreatment activities such as inspection and sorting of waste where required, storage of waste, certification and shipping of waste, transportation of waste, and disposal of treated waste in different types of disposal facilities. The model interfaces with a database that is based on the DOE mixed waste inventory projections and facility data. This paper discusses the various features of the automated model related to the estimation of costs of different options for management of DOE's mixed low-level waste.

INTRODUCTION

The Automated Systems Analysis Model (the Model), which is being developed by the U.S. Department of Energy (DOE), is an IBM PC-based computer model that will assist users of widely varying expertise in evaluating and comparing options for managing mixed waste generated and stored at various DOE sites. The Model is based on the premise that comparisons between options should include the entire waste handling process, from initial treatment ("pre-treatment") to final disposal because all of these waste management activities are interdependent.

At present, the Model (Version 2.0) provides the capabilities for projecting the life cycle cost and its yearly allocation (schedule) for evaluating options for contact-handled (CH) mixed low-level waste (MLLW). The term "life cycle cost" as used in the Model refers to the sum total cost of four different phases in the life cycle of a waste management facility. These include the preoperations phase consisting of activities such as studies, demonstration, design, etc., the construction phase, the operations phase, and the decontamination and decommissioning phase. The Model could be applied in the future to address public health, worker risk, and the long-term performance of final waste forms in the disposal facility. This paper describes the current version of the Model with reference to its overall structure, user inputs, steps used for estimation of cost and schedule of a waste management option, available formats for presentation of the final cost and schedule results, and also the hardware and software requirements of the Model.

DESCRIPTION OF THE MODEL

Databases Used in the Model

Figure 1 represents the overall structure of the Model. As shown in Fig. 1, the Model includes two databases that are based on the information in the latest revision of the Mixed Waste Inventory Report published by DOE. The information in these databases assists the user in configuring options for a specific waste stream. The Facility Database contains specifications and capabilities for both existing and potentially new MLLW treatment facilities within the DOE Complex. The Inventory Database contains information on the characteristics of MLLW generated within the DOE Complex on a waste stream basis. This includes the latest available information about the existing and projected volumes and masses of each waste stream and the site at which it is generated, waste matrix (e.g., aqueous liquids, organic liquids, soils, etc.), generalized hazardous waste designations based on the presence or absence of hazardous metals, organics, and PCBs, and the radioactive characteristics of the waste stream (i.e., alpha versus non-alpha, contact- versus remote-handled).

(Put Fig. 1 1 here)

User Input Required for Option Configuration

In general, application of the Model involves user input for configuration of an option or a set of options. The user configures an option by accessing the Inventory Database and selecting the MLLW inventory to be considered in the option (e.g., waste stream, group of waste streams, entire site inventory, or entire DOE inventory). The user then specifies the complete waste management train (i.e., the desired sequence of waste management activities) for each waste stream or related group of waste streams included in an option. Specifically, the Model requires user input regarding the following activities:

Primary treatment (user must either select an appropriate facility from the list of existing facilities in the MLLW Facility Database, or in the case of hypothetical facilities, specify a treatment technology and facility location). The Model can estimate the treatment cost for the following treatment technologies:

- Aqueous waste treatment
- Incineration

- Thermal desorption
- Wet air oxidation
- Vitrification
- Deactivation
- Lead recovery
- Mercury separation and amalgamation
- Soil washing
- Debris washing
- Sludge washing
- Polymer encapsulation
- Cementation

Stabilization (user must either select a stabilization facility from the list of existing facilities in the MLLW Facility Database, or in case of hypothetical facilities, specify a stabilization technology and facility location). The Model can estimate the cost for the following stabilization technologies:
- Grout stabilization
- Polymer stabilization
- Vitrification

Disposal (user must select disposal facility location and the type of disposal facility). The Model can estimate cost for the following types of disposal facilities:
- Above ground disposal in engineered vaults
- Below ground disposal in engineered vaults

Storage (user must specify whether storage is required prior to treatment, between treatment and stabilization, or between stabilization and disposal). The Model assumes that a reinforced concrete structure will be used for storage.

Once the user has configured an option by providing the above inputs, the number of shipments for transportation and the capacity requirements for treatment support activities such as facility administration, receipt and inspection of off-site waste, sorting of waste prior to treatment, maintenance, and certification prior to shipping are automatically calculated by the Model based on the waste inventory for each option and do not require user inputs.

Mass Balance Calculations

After completion of option configuration, the Mass Balance section of the Model performs calculations to determine the total quantity of waste to be processed by each waste management activity at each site. This takes into account the reduction or increase in the waste volume due to either primary treatment or stabilization, as well as the generation of secondary wastes on the basis of treatment technology characteristics. The results from the Mass Balance section are used as input to the Cost Estimation section of the Model.

Cost Estimation

The Cost Estimation section of the Model estimates the cost of each facility on the basis of its capacity requirements in kilograms per hour (except for storage and disposal cost, which are based on cubic meters) and also on the basis of cost data for each waste management activity. Based on the output of the Mass Balance section, the total quantities of waste to be processed by each waste management activity (treatment, storage, disposal, etc.) is divided by an assumed 4,032 hours of operation per year to determine the capacity requirements for each facility. The Model sums the quantities of all wastes to be sent to a particular facility and calculates the required size of each facility (if it is a "hypothetical" or "planned" facility) based on the amount of waste to be treated there. For an "existing" facility, the Model uses the capacity reported for that particular facility in the Facility Database for cost estimation. The cost data are based on the cost curves published in support of the Programmatic Environmental Impact Statement that is currently under review by the DOE (1). For each planned facility, costs are calculated for four operational phases during the life cycle of a facility. These phases are preoperations (facility design, permitting, etc.), construction, operations and maintenance (O&M), and decontamination and decommissioning (D&D). For existing facilities, only O&M and D&D costs are calculated.

Schedule Estimation

Based on the life cycle cost estimated for each facility, and the projected operational start-up dates and the inventory work-off periods specified in the

Facility Database for treatment and stabilization facilities, the Schedule section of the Model automatically determines the projected expenditure for a particular option during each fiscal year. The user also has the choice of estimating yearly expenditure both with or without the use of cost escalation factors.

Report Generation

The Report Generation section of the Model enables the user to specify a desired report format for presenting the estimated cost of an option in either tabular or graphic form. Flexibility is provided by allowing the user to select from six primary presentation formats of which up to three can be included in any one report. The following is a list of the six primary formats that can be selected by the user:

- Cost by facility operational phase (i.e., preoperations, construction, O&M, and D&D)
- Cost incurred by each DOE site
- Cost by fiscal year (i.e., results from the Schedule section)
- Cost by each treatment and stabilization facility used for an option
- Cost by each waste management activity (e.g., transportation, treatment, disposal, etc.)
- Cost by waste matrix (e.g., aqueous liquids).

Thus, depending on the purpose of the analysis, it is up to the user to select a reporting format (or a combination of one or more of the above formats). As an example, the cost can be reported by each waste management activity incurred at a given site during each operational phase. The Report Generation section also enables the user to compare cost results from more than one option in a single report.

HARDWARE AND SOFTWARE REQUIREMENTS

At a minimum, this IBM PC-based automated model requires the following hardware:

- PC with a 486 DX-33 processor
- 4 megabytes of RAM
- Hard drive with 120 megabytes or a network drive
- 1 floppy drive
- VGA video display
- Mouse.

Minimum software requirements include MS-DOS (Version 6.0 or later), Microsoft Windows (Version 3.1 or later), and Paradox for Windows (Version 4.5). Due to the calculational and disk access requirements of the Model, faster processors, additional RAM, and fast access hard drives with hardware disk cache will improve performance (in terms of response/action time) of the Model. Currently, once an option configuration is completed by the user, the Model takes an average of approximately 1 hour for calculating mass balances, estimating cost and schedule, and generating reports for an option.

PLANNED IMPROVEMENTS

Since the development of the Model is an ongoing process, it is in a state of continuous improvement in many areas. The major improvements include the following aspects of the Model:

- Updates to the Facility and Inventory Databases as additional data become available from the DOE sites regarding the precise waste acceptance criteria of each facility and the hazardous and radionuclide characteristics of each waste stream.
- Inclusion of cost data for additional treatment and stabilization technologies, especially innovative technologies that are currently in the research and development stage.
- Restructuring of some of the cost data currently used in the Model to allow more user flexibility in selection of technologies. For example, the cost data for aqueous waste treatment will be subdivided into its subsystems such as evaporation, neutralization, ion-exchange, gross organic removal, etc. so that the user can select only those technologies that are necessary for a particular waste stream.
- Inclusion of facility, inventory, and cost curve data for other types of waste such as transuranic and high-level waste to enable automation of options analysis for these wastes.

ABSTRACT

Results from two separate studies are presented to illustrate cost savings that can be achieved using detailed planning to support waste characterization activities. Data Quality Objectives were developed for an operable unit and a waste treatment system at the Hanford Site. The 200-BP-11 operable unit is a CERCLA site that contains multiple treatment, storage, and disposal units. Over $4 million was saved in sampling costs alone for the 200-BP-11 operable unit. The 242-A Evaporator is a mixed waste evaporation system designed to concentrate mixed waste solutions associated with high-level radioactive waste tanks. Identification of critical sampling requirements for the 242-A Evaporator resulted in cost savings in excess of $65K.

INTRODUCTION

There is a need for rigorous, defensible, and easily implemented cost savings evaluations of waste characterization activities in environmental restoration (ER) and waste management (WM) programs. Cost savings must be expressed in terms of both the costs of program implementation and the effectiveness of potential program outcomes. Budgetary constraints are forcing programs to interact in such a way that reciprocal cost savings in characterization are realized.

A particular challenge facing all US Department of Energy (DOE) sites is how to plan and implement cost-effective sampling and analysis activities for (i) treatment, storage, and disposal units that must comply with the Resource Conservation and Recovery Act (RCRA), and (ii) RCRA Past Practice waste management units that must comply with the Comprehensive Environmental Remediation, Compensation, and Liability Act (CERCLA). As remedial actions or tank waste retrieval/treatment operations mature, a historical database will be required to identify those sampling and analysis programs that offer the greatest cost-effectiveness in support of program-specific activities.

STATEMENT OF THE PROBLEMS

The 200-BP-11 Operable Unit

The 200-BP-11 operable unit (OU) is comprised of 1,175 acres in the 200 East Area of the Hanford Site. The 200-BP-11 OU must, in general, comply with CERCLA requirements associated with Interim Remedial Measures (IRMs) or presumptive remedies. Specifically, the treatment, storage, and disposal units in the OU must meet RCRA closure requirements. The problem addressed for the 200-BP-11 OU was how to design a sampling and analysis program that would support RCRA closure decisions while simultaneously meeting CERCLA/RCRA past practice decisions.

The 200-BP-11 OU is one of the largest waste management units at the Hanford Site. Performing sampling and analysis to satisfy CERCLA requirements, and then, performing a similar effort to meet RCRA requirements is intuitively unreasonable. Stakeholders identified the need for an integrated sampling and analysis program. All stakeholders needed to be able to clearly understand the relative advantages and disadvantages of several sampling and analysis programs in meeting the multiple requirements.

The 242-A Evaporator

Several waste characterization sampling and analysis programs for the 242-A Evaporator at the Hanford Site needed to be evaluated for mid-FY-95 operations. Characterization of specific radionuclides and chemical constituents was required for selected evaporator process streams. Each program needed to provide sufficient analytical data to meet process control, operations safety, and compliance with the RCRA requirements.

A major purpose of the 242-A Evaporator is to support delisting of various RCRA constituents. Sampling and analysis at the evaporator, therefore, needed to support similar requirements at the Effluent Treatment Facility which receives process condensate from the Evaporator.

TECHNICAL APPROACH

A reasonable method for determining the relative cost savings of alternative sampling and analysis programs is cost-effectiveness analysis (Quade, 1984; Redus,

1981). Such an approach forces a complete and concise definition of the cost parameters and the effectiveness parameters of each program. Both the 200-BP-11 OU environmental restoration group and the 242-A Evaporator operations management needed easily understood information to select among sampling and analysis programs for current and future system or site activities.

Cost and effectiveness were modeled separately. The baseline waste characterization program was first defined. Alternative programs were then identified. The cost and the effectiveness of each alternative were determined and compared to the baseline program. Programs that were dominated, i.e., both the cost and the effectiveness parameters were less than at least one other program, were eliminated from further evaluation. The remaining programs were then evaluated. The program with the greatest effectiveness-cost ratio was selected as the optimal program. Sensitivities to cost thresholds and effectiveness parameters were examined to determine the influence of these factors in the selection of the optimal alternative.

Baseline cost estimates were determined using sampling data, analytical services data, and quality control data from previous sampling events. Baseline effectiveness was estimated based on the statistical factors associated with the number of samples and the type of analyses performed.

The Data Quality Objectives (DQO) process (US EPA, 1994; Redus and Sheriff, 1994) was used to identify critical decisions, the decision variables, and the risk associated with the sampling and analysis program alternatives for the 200-BP-11 OU (Tranbarger, 1994) and the 242-A Evaporator (Von Bargen, 1994).

200-BP-11 OPERABLE UNIT

The 200-BP-11 is composed of five RCRA Past Practice Waste Management Units and two RCRA TSD Waste Management Units. The Past Practice Units consist of two ditches, one contingency pond, and two unplanned releases. The TSDs consist of one main pond and three expansion ponds.

During the period 1945 through 1985, the OU received mixed fission products, heavy metals, and organic chemicals from 200 East Area operating facilities. Active parts of the OU still receive waste water and process condensate from other treatment systems or processes in the 200 East Area.

A sampling plan was developed to combine a RCRA Past-Practice strategy with a CERCLA Limited Field Investigation. The sampling plan was included as part of a Limited Field Investigation Work Plan (Tranbarger, 1994). The plan identified, and described in detail, field screening requirements, sampling locations, and constituents of concern. Stakeholders who participated in the 200-BP-11 DQO to develop the sampling plan were from the US Environmental Protection Agency (US EPA), US Department of Energy (DOE), the Washington State Department of Ecology, and Westinghouse Hanford Company (WHC). Program managers and key personnel represented both RCRA and CERCLA organizational interests.

A phased characterization approach was developed to implement the sampling plan. The objective of first phase is to determine i) if hazardous waste exceeded Washington State Model Toxics Control Act (MTCA) Industrial Cleanup Standards, ii) if radionuclide contamination was greater than that prescribed in the Hanford Site Baseline Risk Assessment Methodology, or iii) both. Phase I supports a clean closure or modified clean closure for the inactive TSD in the OU. Regardless of the results of first phase, Phase II is required. The objective of Phase II is to confirm the results of the first phase to support modified closure or closure in place. Phase II also supports identification of additional remedial actions.

A Limited Field Investigation Report of the sampling results is planned. If contamination concentrations are between Residential and Industrial Cleanup Standards, then Phase II sampling will be required to confirm the absence of hazardous waste and radionuclide contamination above Industrial Cleanup Standards. This supports a modified clean closure or closure in place decision. If contamination concentrations are below Residential Standards for hazardous waste and below Industrial Standards for radionuclides, then sampling is performed to clean close the TSDs. If contamination is above Industrial Standards, the extent of contamination above these cleanup standards is determined and further discussions with the stakeholders will be held to determine if site-wide background concentrations will be acceptable as cleanup standards.

The stakeholders reached consensus on the decision logic for determining if contamination concentrations meet or exceed threshold requirements. If any one observation exceeds the threshold, then the specific decision is made that the

standard is not met. Thus, the parameter of interest is the maximum value of a sample, rather than an average or an upper 95% confidence limit on the average.

200-BP-11 OU Sampling and Analysis Program Alternatives

Two sampling and analysis programs were identified as described below.

Baseline: The Baseline sampling and analysis program was really two programs: one for the RCRA Past Practice Waste Management Units examined under CERCLA and another program for the RCRA TSD Waste Management Units. Each program required an extensive sampling effort of a total of 39 boreholes to groundwater, test pits, surface samples, and samples for lithological changes and for radionuclide identification. The number of samples per location ranged from one to 10. Over 200 total samples were to be collected, and virtually all compounds identified in 40 CFR 264, Appendix IX Groundwater Monitoring List, were to be analyzed and the results validated completely.

Alternative: The proposed sampling alternative to the baseline combined the two programs so that data collected for the RCRA Past Practice Waste Management Units examined under CERCLA would support the data requirements for the RCRA TSD Waste Management Units, and vice-versa. The alternative program required a total of 23 boreholes to groundwater, test pits, surface samples, and samples for lithological changes and for radionuclide identification. The number of samples per location ranged from two to 13. A total of 148 total samples were to be collected under this Alternative. A significantly reduced set of compounds identified in 40 CFR 264, Appendix IX Groundwater Monitoring List, were to be analyzed. Validation was reduced to 20% for all data packages from test pits and surface samples, and validation of results remained at 100% for all borehole samples.

Cost Savings Evaluation

The cost savings evaluation for the 200-BP-11 sampling and analysis program alternatives was performed using cost only. An effectiveness-cost ratio, ECi, is computed for each of the waste characterization sampling alternatives. For convenience, we will denote the effectiveness-cost ratio as the EC ratio. The EC ratio is simply the ratio of effectiveness to cost. The alternative with the largest EC ratio was selected as the preferred alternative. The utility of this approach is that large values of cost, regardless of the effectiveness, will push the ratio close to zero. Small values of effectiveness, regardless of cost, will force the ratio to behave in a similar manner.

Baseline cost information was obtained from the proposed 200-BP-11 OU Work Plan. Direct costs were estimated based on sampling and analysis, sample preparation, and data package costs. Costs were broken out as sampling costs and analysis costs. Several methods were employed to arrive at cost figures when data was either unavailable or suspect. Cost estimating relationships were used to relate costs to operations variables. Specific analogy methods were used to estimate costs by comparison with known costs of similar items or services. Included in this cost factor are estimates for complexity factors or scaling laws. Expert assessment was used as a last resort when cost information was unavailable. Cost estimate uncertainty was determined to be + 10%.

Effectiveness is defined as the difference between number of samples proposed for the Alternative and the Baseline. A larger positive value was preferred. This indicates that a reduced number of samples is required for the Alternative. If the difference were negative, this would indicate the Alternative required more samples than the Baseline. Both the Baseline and the Alternative employed a biased sampling approach, i.e., a statistical sampling plan was not generated. Thus, there is no tolerance for risk in either sampling alternative, and each alternative represents a deterministic sampling approach.

TABLE I.

The Alternative is clearly preferred to the Baseline, since the EC ratio is positive. Examination of relative percent differences indicates the sampling costs for the Alternative are 73% less expensive than the Baseline, and the analysis costs for the Alternative are 64% less expensive than the Baseline. Examining the marginal EC ratio (i.e., the ratio of the effectiveness difference to the cost difference), we see that the Alternative offers a marginal gain of 5.8 times the Baseline. Increasing the total number of samples for the Alternative to 80% of the Baseline, i.e., from 148 to 326, changes the marginal gain by more than 165% to 15.6 times the Baseline. There is no difference between the Baseline and the alternative when the total number of samples for the Alternative is 108 or less.

THE 242-A EVAPORATOR SYSTEM

The 242-A Evaporator, also located at the Hanford Site, uses a conventional forced circulation and vacuum evaporation system to concentrate mixed waste solutions. Candidate waste feed tanks must be characterized, pumped to the Evaporator feed tank and processed. The feed stream is separated into a slurry stream, a process condensate, and a gaseous process exhaust stream. Two non-hazardous effluent streams, steam condensate and cooling water, are produced and discharged to an evaporative pond.

The slurry stream consists of the concentrated bottoms and contain the majority of the radionuclides and inorganic constituents. The slurry stream is recycled until it is concentrated to target levels. It is then pumped to double shell tanks to be stored for further treatment. The condensed boiloff, or process condensate, contains primarily water, trace organic material, and a greatly reduced concentration of radionuclides. The process condensate is stored at the Liquid Effluent Retention Facility awaiting treatment capacity in the Effluent Treatment Facility. The process exhaust, or vessel vent stream, consists primarily of non-condensible gases drawn from the condenser system, is filtered and discharged through an exhaust stack.

Stakeholders from the US DOE, Ecology, and WHC collaborated in identification of data requirements, sampling methods and technologies, and statistical process control decision criteria to support waste characterization, waste management, environmental compliance, and safety decisions required for operations of the 242-A Evaporator and the subsequent discharge to the Liquid Effluent Retention Facility and the Effluent Treatment Facility. The resulting product was a set of decision documents addressing waste analysis planning, sampling and analysis planning, process operations, and scheduling of operations, (Von Bargen, 1994).

242-A Evaporator Waste Characterization Program Alternatives

Four sampling and analysis program alternatives were identified as described below.

Baseline -- The Baseline case was the 94-1 evaporator campaign that utilized an extensive sampling effort to determine the contents of certain feed tanks for processing. The sampling consisted of seven samples in the process streams. The baseline data was used as a historical estimate of constituent variability. A comprehensive suite of analyses was performed on the samples with extensive quality control checks.

Alternative 1 -- Alternative 1 was based on the waste characterization program used in evaporator Campaign 94-2. Five samples were taken in the process streams for this alternative. A comprehensive suite of analyses was also performed on the samples with equally extensive quality control checks.

Alternative 2 -- This Alternative has a reduced set of analytes, reduced number of samples, and fewer quality control checks. This Alternative was derived during the Evaporator DQO. One sample in each of the three process streams was identified as sufficient to meet process control, safety, and regulatory compliance requirements. Quality control checks were not as extensive as in the Baseline or Alternative 1.

Alternative 3 -- This Alternative also has a reduced set of analytes, reduced number of samples, and fewer quality control checks. This Alternative was also considered during the Evaporator DQO. Eight samples in each of the three process streams were identified as sufficient to meet process control, safety, and regulatory compliance requirements. Quality control checks were not as extensive as in the Baseline or Alternative 1.

Alternative 4 -- This Alternative is based on the implementation of DQO Process for Campaign 95-1 of the evaporator. Three samples taken in each of the three process streams were considered sufficient to meet process control, safety, and regulatory compliance requirements. Quality control checks were not as extensive as in the Baseline or Alternative 1.

Cost Savings Evaluation

An effectiveness-cost ratio, ECi, was also computed for each of the waste characterization sampling alternatives.

Baseline cost estimates were determined using sampling data, analytical services data, and quality control data from previous evaporator campaigns during FY-94 and early FY-95. Baseline effectiveness was estimated based on the statistical factors associated with the number of samples taken for the same campaigns. Costs associated with the Baseline and Alternative 1 are based on a comprehensive set of analyses and the maximum amount of quality control checks that would be accomplished by both the field samplers and analytical services personnel. Costs associated with Alternatives

2, 3, and 4 are based on a reduced number of analytes and a reduced quality control checks. Use of the DQO Process helped evaporator operations personnel better define their needs and the value of the data requirements relating to process control, safety, and regulatory compliance.

Effectiveness was determined as a weighted function of (i) the confidence to correctly conclude the requirements are not met , i.e., the power of the statistical hypothesis test, and (ii) the risk associated with incorrectly concluding the requirements are not met, i.e., the Type I error of the statistical hypothesis test, (Winkler and Hays, 1975). The requirements that must be met are process control, safety, and regulatory compliance. The minimum requirement is the concentration of all analytes do not exceed a predefined threshold. The general form of the effectiveness model is presented in Eq. 1.

Ei = w [min{(1-)] + v [1 - max(a)] (1)

where Ei is the effectiveness for waste characterization alternative i, w is the weight associated with the Power of the Test, and v = 1 - w, is the weight associated with the risk . Since there are usually several constituents that must be characterized for an alternative sampling program, the most conservative way to describe the effectiveness of any alternative is to use the minimum power, min (1-b), the maximum risk, max (a), and weights such that w = v = 0.50.

Three activities were performed prior to the computation of the ECi value. First, we attempted to identify and assess any other decision factors that should be included in the effectiveness or the cost measures. Second, all alternatives were examined in terms of any one alternative dominating another alternative for all effectiveness or cost values. Finally, we identified any minimum power required or any maximum risk allowed to screen alternatives that did not meet minimum requirements. This resulted in Alternative 2 not being included in the evaluation.

Results of the waste characterization sampling program effectiveness and cost evaluation are presented in Table II. The effectiveness value, the cost value, the EC ratio, and the marginal change between the baseline cost and the baseline effectiveness for each alternative is provided.

Using only the EC ratio, the preferred alterative is Alternative 4 (EC = 21.1). The next preferred alternative is Alternative 3 (EC = 10.0). Alternative 4 is preferred over all alternatives because it requires the least number of samples (three) and displays the smallest cost.

Alternative 4 offers a relatively small marginal change over the Baseline (DE/DC = 2.0) when compared to Alternative 3, (DE/DC = 4.5). This indicates that Alternative 4 is the preferred waste characterization alternative in the absolute sense, but Alternative 3 offers the greatest marginal return. Interpreted in terms of the effectiveness and cost measures, this implies that the alternative with the smallest risk is preferred given i) equal weights for power and risk, ii) if the power is the same for all alternatives, and iii) if the cost model remains the same.

CONCLUSIONS

We have presented a cost-savings approach based on intuitive effectiveness measures and expected costs of candidate sampling and analysis programs. planning to support waste characterization activities. Over $4 million was saved in sampling costs alone for the 200-BP-11 operable unit. A sampling and analysis program was developed that provided a marginal effectiveness-cost contribution over five times the original 200-BP-11 sampling and analysis program. Identification of critical sampling requirements for the 242-A Evaporator resulted in sampling and analysis cost savings in excess of $65K with marginal benefits of 100% over the baseline 242-A Evaporator sampling and analysis program.

A VALUE OF INFORMATION APPROACH TO DATA QUALITY OBJECTIVES FOR THE HANFORD HIGH-LEVEL WASTE TANKS
Thomas W. Wood
Valeria L. Hunter
Pacific Northwest Laboratory
Jacob W. Ulvila
Decision Science Associates
ABSTRACT
This report summarizes a Pacific Northwest Laboratorya review of the organic-nitrate reaction safety issue in the Hanford single-shell tanks. This study employed a decision analytic method known as Value of Information (VOI). VOI analysis is a special form of decision analysis that has an information collection alternative as one of the initial decision choices. This type of decision analysis, therefore results in the ability to specify the preferred information collection alternative, taking into account all information gathering and other relevant alternatives. For example, the risk reduction benefit associated with further sampling to quantify total organic carbon inventory or to improve information on energetics can be compared to the risk reduction benefit of better temperature monitoring, operational restrictions, or mitigation by moisture control. This approach allows freedom from built-in assumptions, e.g., that all tanks must be sampled to some degree or that all tanks must be deemed intrinsically safe by some means or another. It allows for each tank management decision to be judged in terms of risk reduction from the current state of affairs, and for that state of affairs to be continuously updated to incorporate new information on tank contents, the phenomenology of safety issues, or the effectiveness of mitigation schemes.
ORGANIC-NITRATE SAFETY ISSUE IN HANFORD HIGH-LEVEL WASTE TANKS
This report summarizes a study conducted by the Pacific Northwest Laboratory of the organic-nitrate reaction safety issue in the Hanford single-shell tanks (SSTs). Production of nuclear weapons materials began at the Hanford Site in 1944 and continued until 1990. Radioactive wastes from the reprocessing operations were stored as alkaline liquids and slurries in near-surface underground tanks. One hundred forty-nine SSTs, ranging in capacity from 208 m3 to 3,800 m3 (55,000 to 1 million gallons), contain approximately 14,000 m3 (36 million gallons) of waste damp saltcake (predominately sodium nitrate and sodium nitrite), metallic hydroxides, other insoluble metal salt sludges, plus about 2,300 m3 (600,000 gallons) of supernatant liquid.
Organic materials were used in several applications in the separations of nuclear materials at the Hanford Site, and many of the waste types generated included organic materials. These included ethylenediaminetetra-acetic acid (EDTA), N-hydroxy-ethylenediaminetetra-acetic acid (HEDTA), sodium citrate, sodium acetate, normal paraffin hydrocarbon (NPH), tri-butyl phosphate (TBP), and hundreds of miscellaneous compounds used in small-scale applications at the Site. (1) An estimated "average chemical composition" of these organic materials approximates

sodium acetate. (2) The waste materials have been degraded by radiolytic and chemical attacks in the waste tanks but still retain significant potential fuel value. (3)

The presence of the organic materials in the waste tanks is of concern because of the following: 1) saltcake wastes are rich in $NaNO_3$ and $NaNO_2$;, 2) efforts have been expended to remove the bulk of drainable liquids from most tanks, and 3) several tanks contain wastes with significant decay heat. Taken together, these factors could create conditions favorable for an organic-nitrate reaction.

DATA QUALITY OBJECTIVES

Data quality objectives (DQOs) are specifications that describe data that are adequate for a particular purpose. In a typical waste characterization problem, DQOs would specify the analytes to be measured, the sensitivity required (detection limits), the accuracy of individual measurements, the spatial volume of material for which measurements are deemed representative, and other such features. In addition to a generic label for this type of data specification, "DQO" has also been used to describe a specific process for deriving these specifications. (4) While some benefit has accrued from applying this method to tank waste problems, the organic-nitrate reaction risk issue was sufficiently complex in terms of phenomenology, number of options, and statistical issues to require structured decision analysis tools.

These decision analysis and risk management tools enhance the standard DQO methodology and allow it to be more responsive to the needs of tank waste characterization. In addition, these methods allowed an integration of the DQO domain (what and how to sample) into a much broader set of risk management decisions: what criteria are appropriate, how conservatively should they be applied, what mitigative actions are "risk-effective," and what incentives exist for developing more effective mitigative measures.

ORGANIC-NITRATE REACTION RISK

The following section describes the organic-nitrate reaction risk. The chemical reaction is introduced with potential initiators and propagation requirements. The reaction risk model is presented with all components. Consequences of the reaction are discussed as well as mitigation measures.

Reaction Initiation and Propagation

The primary hazard of the organic-laden waste is that both fuel and oxidizer are present and intimately mixed. The key mitigative feature is the moisture content of the waste. Waste energetics are characterized by the total organic carbon (TOC) content, expressed as weight percent carbon in the fuel on a dry-waste basis. The reaction of sodium acetate and sodium nitrate is considered a first-order surrogate for the reaction of actual waste (Equation 1) with an ideal heat of reaction of about 7.5 MJ/kg sodium acetate.

$$NaC_2H_3O_2 + 1.6NaNO_2 \rightarrow 1.3Na_2CO_3 + 1.5\ H_2O + 0.7\ CO_2 + 0.8\ N_2 \qquad (1)$$

Stoichiometry for this reaction corresponds to 11 wt% TOC. The reaction cannot take place unless appropriate energy is supplied as an initiator.

Measurements for dry waste have demonstrated that the reaction does not become exothermic unless the waste is at, or above, the relatively high temperature of about 200C. The reaction will not propagate through a medium unless the TOC exceeds 6 wt% and the temperature is about 300C. Moisture in the waste inhibits reactions. Based on the energy release of a stoichiometric mixture, a heat balance indicates that moisture content of 17 wt% would prevent a propagating reaction in mixtures with TOC less than stoichiometry.

The consequences of a hypothetical reaction of organic-nitrate waste involve the heating and pressurization of the tank headspace by hot reaction-product gases and the entrainment of vapors or aerosols from the waste that may be radiologically active. For a TOC value of 6 wt% (the value at which sodium acetate fuel reactions are observed to propagate), a dry reacting volume of 1 m^3 would pressurize the tank headspace to 1.50 atm, or 7 psig overpressure, which is enough to blow out any filter in the system and release gases and aerosols outside the tank through any tank orifice. A 6 wt% TOC dry reacting volume of 2 m^3 would cause a final pressure of about 2.1 atm, or 15 psig overpressure. Structural analysis indicates that a pressure of 14 psi would cause extensive cracking of the concrete dome of a half-million gallon tank, and the failure limit for a million gallon tank is 11.6 psi. This result is important since it indicates that a relatively small reacting volume could be a significant hazard and, thus, that spatial distribution of fuel

within a tank is important.

Reaction Risk Model

Although risks of organic-nitrate reaction are thought to be low in most SSTs, the consequences of a major release are high enough to warrant significant investment in ensuring safe storage. In this framework, information on the organic constituents, moisture level, and temperature status of tank becomes a risk management tool. By using a risk model that embodies uncertainty about the organic constituents, it is possible to show how risk management for a tank benefits from better information on fuel or moisture. Thus, the basic concept of a reaction risk model is to predict the risk of various significant release events as a function of tank fuel, moisture, and temperature (FMT) status, and the uncertainty about them.

The concept was implemented using estimates for probabilities of reaction initiation events and conditional probabilities of reaction propagation (given an initiator was present) expressed as functions of fuel content and moisture level. The basic probability structure of the model is shown in Equation 2.

Pr(Eij Ik) = Pr[F1 , Mm, Tn]p (2)

where

Pr(Eij Ik) = probability that a reaction event will proceed from stage i to stage j given that initiator Ik has occurred in tank p

Fl = fuel state l (one of several discrete states defined by fuel concentration)

Mm = moisture state m (one of several discrete moisture states)

Tn = temperature state n (one of two discrete equilibrium temperature states).

In practice, the probability of an event is a sum of these conditional probabilities weighted by estimated probabilities that a tank is in a given FMT state:

Pr(Eij) = lmn [Lp(F1, Mm, Tn) x Pr(F1, Mm, Tn)] (3)

where

lmn = summation over all FMT states

Lp = estimated probability that tank p is in a given FMT state.

This model was developed using four initiators believed to account for most of the risk of initiation during storage in SSTs. Four event-severity classes were used to define the range of possible consequences of release events. All of the probabilities in this model were estimated by a group of experts familiar with the following: the organic-nitrate reaction, a series of adiabatic calorimetry experiments on waste stimulant mixtures, and SST safety issues. Elicitation was conducted by a trained elicitor and confirmed in three separate meetings. Even with experimental basis and consistency checks, the resulting model has substantial judgmental content. The resulting risk model is not intended to accurately represent the absolute risk of uncontrolled releases from the Hanford tanks, but to capture the sensitivity of risk to FMT variables, and uncertainty about these variables.

The overall structure and function of the risk model is schematically shown in Fig. 1. This figure illustrates how the probabilities are used in conjunction with statistical estimates of TOC, moisture, and temperature to calculate the risk of a given severity class event. Also shown is the effect of various mitigation measures, which were represented by changing the position of a tank in the FMT space, the initiator probabilities, or both.

Fuel, Moisture and Temperature Definitions

The fuel status for a tank was defined using the following ranges:

0 wt% TOC 2.5 wt%
2.5 wt% TOC 5 wt%
5 wt% TOC 7.5 wt%
7.5 wt% TOC 10 wt%
10 wt% TOC.

The model incorporated uncertainty in the spatial variability of TOC within the tank and the uncertainty in specific energy content by using the concept of Maximum Total Fuel Value (MLFV), defined as the product of three independent, lognormally distributed factors (Equation 4):

MLFVp = TOCp x EDF x SCF (4)

where

TOCp = mean TOC concentration in wt%, dry basis, tank p

EDF = energy density factor, [(cal/g)p/(cal/g)NaAc]

SCF = spatial concentration factor, [TOCmax m3/TOC]
This model structure accounts for the risk that a small volume of waste, enriched in organic content, can sustain a propagating reaction given a sufficient initiator. It allows for a separate measurement of the VOI on average TOC inventory in a tank, the degree of spatial heterogeneity in the TOC concentration, and the speciation (and energy of reaction) of the TOC.
The moisture status of a tank was represented in the risk model as a set of discrete moisture states analogous to the fuel status. Reaction propagation probabilities were estimated using an assumption that the moisture variable was the moisture of the potentially reacting waste. The number of moisture states were limited to three:
M 6 wt%
6 wt% M 17 wt%
17 wt% M.
The temperature status of a tank was defined with two states:
T < 149C
T 149C.
Initiator Definitions and Probabilities
In a wet, low temperature condition, organic-nitrate mixtures of even high TOC content are stable to shock and sparks. It is possible, however, for a small spark to initiate a dry mixture. There is also the possibility for a runaway reaction if a source of heat is supplied to some waste volume. These considerations led to the use of four initiators in the risk model. The initiators and the probabilities assigned to them are shown in Table I.
A life cycle of 25 years was chosen for analysis as it would represent a reasonable upper limit for tanks that are retrieved late in the retrieval and treatment program and be conservative as an average for all SSTs. These estimates reflected the strong belief of the expert group that a very small spark was essentially unavoidable during routine tank operations (e.g., sampling and waste retrieval operations).
Event Severity Classes
An organic-nitrate propagating reaction in a SST, if initiated, could result in a wide range of event severity cases because of the possible variation in fuel concentrations, the spatial extent of fuel concentration to support propagation, and the moisture concentration in and near the reacting region. Also, the amount of free headspace volume in the tank and the configuration of headspace ventilation would be important in determining the pressures reached and the severity of structural damage and release. Five severity classes were defined in the risk model to represent the potential range of events. The event severity classes are shown in Table II.
The five severity classes were used as a framework for estimating reaction probabilities and developing estimates of possible consequences.
Mitigation Measures
The final component of the reaction risk model is the development of potential mitigation activities to achieve control of FMT. Fourteen potential corrective actions were studied. The eight shown in Table III were selected as the range of activities that provided the range of information required for this study.
The total cost includes the number and length of time each intervention would take during the 25-year life cycle.
DECISION ANALYSIS FRAMEWORK
The decisions on how to sample and classify tanks, determine whether any mitigative measures should be applied, and decide which are most effective were represented in a decision tree or decision analytic model. Such a model allows assessment of the best decisions according to some decision rule, based on the probabilities of various outcomes given that certain decisions are made. Data on mitigative measures include effectiveness and cost, where effectiveness is measured by the reduction of either the probability of an initiation event or the probability of a propagating reaction given that an initiator event has occurred; and cost of implementation includes the direct costs of the engineering measures plus, in some cases, indirect or intangible costs. Data required on consequences included at least one measure of value or costs that can be associated with each possible outcome in the decision tree.
The risk model was employed in a decision analysis mode to predict the expected costs of each possible path. Expected costs are calculated using the probabilities of release events given that each of the possible mitigation measures was implemented. All calculations depend on the assessments of fuel and moisture status,

i.e., the probabilities that a given tank is in each of the possible fuel and moisture states. The simplest decision rule for such a problem involves minimizing the statistically expected cost (or maximizing the expected value) of the outcomes resulting from a mitigation decision. This risk-neutral decision rule may not be the appropriate one for actually making risky decisions. The appropriate stakeholder (U.S. Department of Energy, State of Washington, the public, etc.) may be willing to pay a premium beyond the statistical expectation of reduced cleanup and social costs saved. However, the focus in this study was on defining the value of different types and qualities of characterization data. For this application, using an expected cost minimization (risk-neutral) decision rule resulted in a lower boundary for VOI estimates, which allows us to determine the minimum that should be spent on efforts to ensure safety through characterization or mitigation.

The value of a given set of information is the decrease in the optimal (minimum expected) cost resulting from making a decision with the information rather than without it (Eq. 5).

V(I) = Min[E(C(xi) I0 - Min[E(C(xi) (I0,I)] (5)

where

V(I)	=	value of the information, I
Min	=	minimum operator (over all possible decisions)
E	=	expected value operator
C	=	cost of option xi
xi	=	decision options
I	=	information to be valued
I0	=	base case or starting information.

In the case of the organic-nitrate reaction problem, the reference information I0 corresponds to the historical assessments of TOC, moisture, and temperature, and the judgmental evaluations of energy density factor (EDF) and spatial concentration factor (SCF) in this study. The right hand term contains both I and I0, indicating that the base case is not discarded in making the least cost decision after the prospective information, I, is available. In practice, some synthesis of base case and new information is attempted to take maximum advantage of both. In this VOI application, this was accomplished with a Bayesian updating calculation in which the information set I0 is the prior distribution and the set (I0,I) is the posterior distribution.

Figure 2 shows the schematic decision tree structure of the model for evaluating the value of characterization about each tank's organic and moisture contents to support the management of the organic-nitrate safety issue. This tree follows all of the same conventions of any decision tree model. Reading left to right, the first decision is whether and what information to gather. This decision is followed, for choices that involve information gathering, with reports on the tank's moisture and fuel (TOC or MLFV) contents. Next comes a decision node that contains the possible mitigative actions, which range from no action to an emergency retrieval and transfer of the tank's contents. Each mitigative action is followed by an uncertain event node of the tank's actual moisture and fuel contents (before mitigation). The final node is an uncertain event node of outcome severity, which ranges from no event to a major release of the tank's contents.

VALUE OF INFORMATION RESULTS

The model described was used to prepare VOI assessments under several sets of assumptions during the study. The general strategy was to begin with analyses of the value of "perfect" information (e.g., no statistical uncertainty) of various kinds. Following these studies of VOI for perfect information, studies were performed for "realistic diagnosticity" measurements. These studies calculated VOI for MLFV and moisture measurement sets with parametrically defined standard errors (10% to 50%) to assess the sensitivity of VOI to measurement quality.

In general, the results indicate substantial VOI for high TOC, indeterminate moisture tanks, and higher VOI for high-heat tanks than low-heat tanks for a given moisture level. An important observation concerns the degree of discrimination between tanks of significant interest for detailed characterization and those for which tank safety factors and associated risks may not warrant extensive characterization studies. The top 50 or so tanks studied in the case where prior distributions are adjusted for both spatial and energy of reaction factors have a high VOI such that the significant investment in sampling and analysis is a good investment for a risk-neutral stakeholder. The bottom 60 to 70 tanks may not warrant

detailed study for this issue. There are 30 tanks in the questionable region. Thus, the study discriminated fairly well among those tanks with high payoff to sampling and those not worth the cost.
Studies separating the VOI for MLFV and moisture showed that perfect information about TOC alone is always worth essentially as much as that about both variables together. However, this should not be taken to mean that priority should go to MLFV determination over moisture measurements. The factors determining MLFV (via its components TOC, SCF, EDF) are much more difficult to measure accurately than the minimum moisture content. Also, from a starting point of considerable uncertainty about both MLFV and moisture, definitive information about either variable will dramatically improve decision-making and is, therefore, of high value.
The VOI statistic for the entire population of 149 SSTs is illustrated in Fig. 3 for each of the TOC inventory values and the pertinent adjustments. This figure also shows that the upper limit to the risk-reduction benefit of information is the cost of the least-cost, but substantially effective mitigative action.
Imperfect diagnosticity cases were studied to determine how measurement precision affected the VOI, and, therefore, arrive at acceptable laboratory measurement curves. The standard errors studied are for the tank-scale indicators of MLFV and minimum moisture, and had to be translated to results for individual assays. In general, tanks with high VOI for perfect information retained a high percentage of this VOI as the standard error of MLFV and moisture estimation increased. For standard errors of 20% of the true value for both MLFV and moisture, the VOI was typically at, or near, 90% of the value of perfect information. The results showed that there was not much incentive to estimate MLFV more accurately than about 20% standard error (as a fraction of true mean). Moisture measurements were shown to be tolerated as crudely as 30% to 40% standard error.

CONCLUSIONS

The following bullets summarize the findings of using the VOI approach for applying DQOs to the organic-nitrate safety issue in Hanford high-level waste tanks.

- The decision-making value of tank waste information on moisture and fuel value is substantial.
- Almost all of the information value is concentrated in the top 50 tanks.
- The lowest-cost mitigation option limits the VOI for a tank.
- Extremely accurate predictors of MLFV and minimum moisture (at the tank scale) are not required.
- Fuel information alone is worth almost as much as fuel and moisture information together.
- Moisture information alone is worth about three quarters of the information on fuel value and moisture together.
- It may not be economical to conduct fuel assessments in wet tanks.
- The uncertainty about spatial distribution of fuel and specific reaction energy warrants investment in tank characterization.

In addition to these specific conclusions, it became clear during and after the study that the VOI model is a general risk management paradigm. With this model, decisions about developing and deploying mitigative measures, restricting operations, and other factors can be integrated and addressed in terms of overall risk reduction and cost minimization.

ABSTRACT

The Department of Energy (DOE) is currently proceeding with actions to provide cost-effective, safe, long-term interim storage of DOE-owned spent nuclear fuel (SNF) in preparation for permanent disposition. Integral to these actions is the identification, implementation, and verification of the quality assurance (QA) requirements associated with the management of this DOE-owned SNF. The potential for multiple and, perhaps, conflicting QA requirements from varying sources complicates this process. Requirements contained in 10 CFR Part 830.120, 10 CFR Part 72, DOE/RW-0333P, and DOE Order 5700.6C all have potential application to SNF activities during the course of proceeding from existing conditions to final disposition. As a result, the DOE Office of Spent Fuel Management (EM-37) has undertaken an evaluation of these different QA source documents to assess the equivalency of their requirements. This paper presents the methodology of this evaluation and the resulting conclusion that, with minor modifications, a QA program based on the requirements of DOE/RW-0333P meets or exceeds the requirements of the other QA source documents. The implementation of a DOE/RW-0333P-based program can be used to ensure compliance with all current QA requirements and ensure the ability to comply with potential requirements for long-term interim storage and final disposition of DOE-owned spent nuclear fuel.

INTRODUCTION

The Office of Spent Fuel Management, EM-37, has recognized that there are multiple quality assurance programs that may be applicable to the management of DOE-owned SNF. All DOE activities, including SNF management, are subject to DOE Orders including the QA requirements specified in DOE Order 5700.6C, Quality Assurance and the analogous requirements for contractors provided through 10 CFR Part 830, Nuclear Safety Management, Section 120, Quality Assurance Requirements. The increasing concern of the nation, in both government and private sectors, over the disposition of DOE-owned SNF has resulted in a growing constituency in favor of subjecting DOE-owned SNF storage facilities to the same management and technical standards imposed upon commercial fuel regulated by the Nuclear Regulatory Commission (NRC). The QA requirements associated with NRC regulation of interim storage facilities are promulgated in 10 CFR Part 72, Licensing Requirements for the Storage of Spent Fuel in an Independent Spent Fuel Storage Installation. Additionally, DOE-owned SNF could eventually come under the jurisdiction of the Office of Civilian Radioactive Waste Management (OCRWM) requiring a QA program governed by Quality Assurance Requirements and Description, DOE/RW-0333P. This QA program would be applicable if the fuel is to be disposed in a geologic repository. Thus the potential exists for multiple and perhaps conflicting QA requirements associated with the management of DOE-owned SNF. As a result, EM-37 has undertaken an evaluation of the QA requirements that may be applicable to DOE-owned SNF management.

This evaluation compared the requirements contained in four source documents, 10 CFR Part 830.120, 10 CFR Part 72, DOE/RW-0333P, and DOE Order 5700.6C, and assessed the equivalency of these requirements. The results are intended to support, through formal evaluation, the policy decision to utilize the applicable portions of DOE/RW-0333P as the baseline for developing and implementing a DOE-owned SNF QA program. The evaluation further identified modifications that would be needed for a QA program based on the requirements of DOE/RW-0333P to ensure the requirements of other QA source documents are, as a minimum, met.

EVALUATION

To perform a realistic and meaningful evaluation of the source requirements, it was necessary to first review the basis, intent, and background of the four source documents. This is especially relevant since each was developed to meet the needs of different organizations and activities. Additionally, equivalency of QA requirements can be assessed more meaningfully if the requirements are evaluated in the context of the regulated activities of interest. For DOE-owned SNF, a systems engineering

approach1 has been used to establish technical functions, and thus regulated activities, that define all aspects of managing the SNF. These technical functions are defined as "Ensure Safe Existing Conditions," "Achieve Interim Storage," and "Prepare for Final Disposition." Addressing the potential applicability of the four QA source documents to the three technical functions assisted in the evaluation. The relationship of the four QA source documents to each other and the SNF Program's technical functions is depicted in Fig. 1.

DOE Order 5700.6C

The most recent major revision to this DOE Order was issued on August 21, 1991. The revision of DOE Order 5700.6B emphasized the establishment of a QA culture to improve the safety and reliability of the Department's programs, projects, and facilities. This revision represented a departure from a NQA-1-based rigorous compliance program and reflected the concept that all work is a process that can be planned, performed, assessed, and improved. This culture encourages setting and maintaining high standards, identifying and resolving problems, continuous improvement, and fostering effective communication between DOE and its contractors. The Department is responsible for meeting the requirements of this Order and to continuously pursue enhancements to safety and reliability. Compliance with this order for DOE-owned SNF requires a QA program that meets or exceeds 5700.6C requirements for all SNF activities and technical functions (see Fig.1).

The Order's ten basic criteria are broken into the three categories of Management, Performance, and Assessment. These three categories capture the range of activities associated with work processes from the initial planning and organizing activities to continuous process improvements. The requirements specified in the Order were established to assist all levels of management and workers to focus on their unique responsibilities in carrying out the provisions of the QA program.

The Order's requirements apply to virtually all DOE activities. This application includes planning and conduct of basic and applied research, scientific investigation, engineering design and operations, maintenance and repair of facilities, project close-out, and environmental restoration. The requirements and guidance provided in the Order apply to DOE and are applied through contract mechanisms to management and operating (M&O) contractors. Exemptions to activities under this Order are limited to work associated with nuclear weapons administered by the Assistant Secretary for Defense Programs, work done by the Energy Information Administration, work conducted under the Naval Nuclear Propulsion Program, NRC-licensed work, and research and development work results that undergo peer review for publication.

10 CFR Part 830.120

Quality assurance requirements for nuclear facilities were promulgated on May 5, 1994 as part of the Final Rule on Nuclear Safety Management, 10 CFR Part 830. The Quality Assurance Requirements, section 120 of this rule, mandate the development and implementation of a formalized QA program. These requirements are subject to enforcement under the Price-Anderson Amendment Act, which includes civil and criminal penalties. Compliance with this rule for DOE-owned SNF requires a QA program that meets or exceeds the 10 CFR Part 830.120 requirements for all SNF activities and technical functions (see Fig.1). The QA requirements of the rule apply to DOE management and operating (M&O) contractors at DOE nuclear facilities. Exemptions to these requirements are limited to NRC-regulated activities, Naval Nuclear Propulsion Program activities, and activities conducted under the Nuclear Explosives and Weapons Safety Program.

The rule establishes three QA categories; Management, Performance, and Assessments, which contain ten criteria that are identical to DOE Order 5700.6C. Use of a graded approach is specified for the application of the requirements to facilitate a value-added process. The implementation of the rule requires M&O contractors to develop and submit to DOE for approval a QA Program applying the criteria specified in the rule.

10 CFR Part 72

The requirements for obtaining a NRC license for an Independent Spent Fuel Storage Installation (ISFSI) are promulgated in 10 CFR Part 72. Subpart G of this rule describes the QA requirements necessary for obtaining the license. These QA requirements apply to all aspects of the design and operation of an ISFSI that are important to safety. Since DOE-owned SNF may potentially be subjected to NRC licensing or licensing reviews for interim storage, 10 CFR Part 72 has potential

applicability to SNF activities associated with the technical function, Achieve Interim Storage.
Each licensee is required to develop, maintain, and implement a QA program satisfying the requirements delineated through 18 criteria. These criteria are based on the 18 criteria of NQA-1. The rule further specifies that a QA program approved by NRC under 10 CFR Part 50, Appendix B, is acceptable (see Fig. 1). The QA program must cover all activities throughout the life of the licensed facility from site selection to decommissioning. The NRC must approve each licensee's QA program prior to receipt of spent fuel.
DOE/RW-0333P
The Quality Assurance Requirements and Description (QARD), DOE/RW-0333P, was issued on December 18, 1992 to support the OCRWM Program. This includes the transportation, interim storage, and disposal of civilian spent nuclear fuel after it has been transferred to DOE custody. The OCRWM Program also includes the disposal of defense high-level waste (HLW). The QARD requirements are based on regulatory requirements from 10 CFR Part 50, 60, 71, and 72. Since DOE-owned SNF may eventually be disposed in a geologic repository, DOE/RW-0333P has potential applicability to SNF activities associated with the technical function Prepare for Final Disposition.
All organizations performing work for OCRWM must use and comply with the QARD to develop and implement QA programs. The QARD applies to: acceptance and transportation of spent nuclear fuel and defense HLW; the Monitored Retrievable Storage facility; the Mined Geological Disposal System, including site characterization activities; and HLW immobilization and waste form acceptance. The line organization responsible for the implementation of the QA program shares responsibility with the QA organization for the verification of quality activities. The OCRWM Program Director retains ultimate responsibility for the QA program.
The QARD is organized into 18 sections, four supplements, three appendices, and a glossary of terms. The 18 sections contain requirements common to all OCRWM activities. The supplements contain requirements for specialized activities, such as software, sample control, scientific investigation, and field surveying. The appendices contain requirements specific to individual OCRWM Program elements. The glossary defines the terms common to the QA Program.
Methodology
This evaluation reviewed and assessed the equivalency of the QA requirements from the four source documents in a series of three comparisons. The first comparison assessed the equivalency of DOE Order 5700.6C requirements with analogous requirements contained in 10 CFR Part 830.120. A similar comparison was then performed between the QA requirements specified in 10 CFR Part 72 and DOE/RW-0333P. Finally, a comparison was made between 10 CFR Part 830.120 and DOE/RW-0333P. These three comparisons allowed for identifying, comparing, and documenting areas of difference between the various source documents. This approach resulted in identifying applicable QA requirements which would not be implemented for DOE-owned SNF through a QA program based solely on strict compliance with DOE/RW-0333P. The process of assessing equivalency consisted of several activities. First the requirements contained in a given criteria were evaluated and summarized. This summary was then cross referenced to the analogous requirements of another document. The cross-referenced requirements were then evaluated, summarized, and compared to the evaluated requirements of the initial criteria. The process was repeated for all three comparisons.
The evaluation compared the source documents at the level of detail necessary to establish differences between the criteria. This allowed determination of the differences and an assessment of equivalency with the minimum appropriate level of detail. A line by line compliance evaluation was therefore not performed. This technique of comparing requirements at a criteria level was adopted based on previous experience with similar comparative analyses that used both criteria level and line by line approaches (2, 7). These previous evaluations indicated that although line by line evaluations will provide detailed compliance verification, such level of detail was not essential in determining the equivalency between directives.
Results
The evaluation showed that the requirements specified by 10 CFR Part 830.120 are, at a minimum, equivalent to those of DOE Order 5700.6C and that all requirements in the DOE Order have corresponding requirements in 10 CFR Part 830.120. A similar

conclusion was obtained that the QA requirements for commercial spent nuclear fuel under DOE/RW-0333P meet or exceed those for storage under 10 CFR Part 72. The evaluation between the ten criteria of the DOE QA directives with the 18 criteria of the NRC-based programs revealed that the QA requirements of the different programs were essentially equivalent. Only the requirements of DOE/RW-0333P associated with quality improvement would need modification to meet or exceed all 10 CFR Part 830.120 requirements. Additionally, numerous examples were found exemplifying the more rigorous, activity-based nature of the requirements of DOE/RW-0333P. For example, DOE/RW-0333P provides detailed records protection requirements, including design criteria for the facilities in which they are stored, whereas 10 CFR Part 830.120 provides only general requirements on retention of records. The evaluation results between these two programs are summarized in Table I.

The requirements of DOE/RW-0333P establish the need to perform trend analysis to detect and prevent problems associated with product or service quality. While these activities are essential elements of any continuous improvement program, they emphasize only the negative aspects of quality management, such as nonconformances and deficiencies. A 10 CFR Part 830.120 continuous improvement program includes observing, tracking, and acting on both positive and negative results. In short, the basis of the RW-based QA program is to ensure achievement of designated levels of performance, whereas, the 10 CFR Part 830.120 also seeks perpetual evaluation to increase the level of performance, i.e. continuous improvement. Thus a RW-based program would require modification to expand the aspects associated with trend analysis and forecasting to include the broader aspects of quality improvement contained in 10 CFR Part 830.120.

SUMMARY

The Office of Spent Fuel Management compared the source QA documents and assessed the equivalency of their requirements. This evaluation concluded that implementation of a RW-based QA program, with minor modifications, meets or exceeds all current QA requirements. Furthermore, this modified RW-based QA program would ensure the ability to comply with all foreseeable QA requirements for long-term interim storage and final disposition of DOE-owned spent nuclear fuel.

SOME QUALITY ASSURANCE ASPECTS OF TRU WASTE CHARACTERIZATION

Ruth F. Weiner
Sandia National Laboratories
Albuquerque, New Mexico 87185

INTRODUCTION

The Waste Isolation Pilot Plant (WIPP) is a planned geologic repository for permanent disposal of defense transuranic (TRU) waste generated by the U.S. nuclear weapons production program. Waste retrievable stored at defense facilities since 1970 is planned for shipment to WIPP, and about two-thirds of the waste intended for WIPP has yet to be produced. Both contact-handled (CH-TRU) and remote-handled (RH-TRU) waste are currently stored at a number of Department of Energy (DOE) facilities and are intended for disposal at the WIPP. CH-TRU is in 0.21 m3 mild

carbon steel drums that have a maximum surface dose rate of 200 rem/hour. RH-TRU waste will be emplaced in 0.85 m3 capacity cylindrical canisters with unshielded surface dose rate greater than 200 rem/hr but no greater than 1,000 rem/hr. The 50-hectare repository has been designed to hold 176,000 m3 (850,000 drums, nine million curies) of CH-TRU waste and 7,100 m3 (7,500 canisters, five million curies) of RH-TRU waste. Quality assurance (QA) programs for the characterization of these mixed wastes pose some challenging problems.

WASTE SAMPLING AND ANALYSIS

The WIPP is intended as a repository for approximately a million waste containers, most of them 55-gallon carbon steel drums. Invasive sampling of every container is not only prohibitively expensive, but poses considerable risk of occupational radiation exposure, and therefore contravenes ALARA. On the other hand, adequate characterization and assurance that data quality objectives will be achieved when only non-invasive characterization methods are used is difficult at best. Quality objectives can be met if a robust statistical sampling procedure can be combined with non-invasive analysis. Such a robust system has been developed in the Quality Assurance Program Plan (QAPP) (1). for the WIPP.

Specification of a single standard sampling procedure to be used at all sites is not only logical but cost-effective. However, a single procedure may not be appropriate for all waste streams. The waste streams at some sites like INEL are relatively homogeneous, while others, like the Hanford mixed wastes, are heterogeneous. In cases where a single standard sampling procedure may not be appropriate, consistency in quality assurance and the planning for quality assurance is important. The TRU waste characterization program is trying to achieve standardization or, at least, a normative measure for different sampling procedures. Even though different waste streams at different sites require different sample preparation methods, the trend toward a normative procedure can compensate for standardized methods or one of a standard suite of methods. The goal of the program is to make measurements at one laboratory comparable with those made at another laboratory.

Contamination of CH-TRU waste by volatile organic compounds (VOCs) includes a wide range of VOC concentrations. In addition, non-radioactive metals and inorganic compounds may be present in very small quantities, and these quantities may be so small that existing chemical methods and instrumentation cannot detect them. The minimum detection limit (MDL) is a function of the instrumentation and analytical methods used. Measurements smaller than ("below") the MDL can only be reported as such, and incorporation of less-than-MDL data into statistical analysis poses a problem. Although it is possible and relatively straightforward to substitute half the MDL for a measurement below the detection limit, such a substitution may not be suitable. Appropriate statistics such as those given by Helsel2 might be considered. Helsel plots a lognormal distribution of measurements above the detection limit and determines the summary statistics that best fit the measured data. The reporting limit is then the concentration below the median and mean that occurs with the maximum frequency. In applying a method like this one, it is important that all sites define the method detection limit consistently.

Sampling techniques for solid process residues and soils are critical for the accurate determination of total volatile organic compounds (VOCs). Inaccuracies are much more likely to occur, and be taken into account, in sampling of heterogeneous mixtures than in well-established, repeatable analytical procedures on homogeneous material. A method for relating sampling errors to analytic inaccuracy is important to any quality assurance plan, as well as being part of good laboratory practice. Although a quality assurance objective (QAO) for total uncertainty could be determined from an evaluation by an expert panel, use of expert panels is fraught with pitfalls (e.g., panel bias, questionable expertise, questions about completeness of the information presented to the panel) and is undertaken only very carefully and as a last resort. Because total uncertainty is propagated throughout the sampling system, the decision to use an expert panel is critical. In the event that a panel is used, the process can be assisted by describing in detail how the panel is selected, how it operates, what information will be presented to panel members and in what format, and how the results of the expert panel elicitation will be aggregated. Alternatively, total uncertainty could be defined as the propagation of all quantifiable uncertainties, and the result would be benchmarked against a quality assurance objective.

Reporting data in fundamental units is preferred to other reporting protocols. For

example, reporting gas concentrations in mole percent, partial pressure, mole/liter, or grams (micrograms)/liter is more readily understood than reporting in volume percent or parts per million by volume (ppmv). Moreover, the precision of the analytical method used might well serve as a goal or the overall method precision. For example, gas chromatography and mass spectroscopy have a considerably better potential precision than +/- 25%, given as the relative standard deviation or difference, and should have considerably better recovery than +/- 30%. The imprecision and inaccuracy inherent in the sampling methods used may limit the precision and accuracy of the overall method. The error band specified for any method properly does not include extreme outliers or excursions. To include them defeats the purpose of quality control and quality assurance.
The equilibrium vapor pressure of volatile organic compounds (VOCs) provides a quick and easy check on the measured concentrations: i.e., the measured headspace concentration of the gas phase of any particular VOC should be about the same as that given by the Raoult's Law calculation from the measured concentration of the total VOC in question. This check could be incorporated into the data validation system. VOC analysis generally includes an organic solvent blank as well as a water blank, since not all analyses are done in or from water solution. High concentration samples are diluted to bring them within the maximum instrument detection limits (IDL). Dilution is the time-honored method for making concentrations to be measured congruent with instrument capability. Measurements that exceed the maximum IDL are usually meaningless; most instrumentation is reliable only well below the maximum IDL.
DATA HANDLING
Quality assurance includes, at least by reference, methods and documentation for qualifying "old" or existing data. For the WIPP, as for other projects, measurements were made and data accumulated before any quality assurance procedures were in place -- indeed, in some cases, before quality assurance had been well defined. Quality assurance is not quality control, and the lack of quality assurance procedures is not a comment on the scientific validity of past investigations and existing data. A number of methods are available for qualifying old data that are considerably short of repeating the experiments. We should remember that quality assurance is a relatively new protocol, and that most of the valid and valuable scientific discoveries of the nineteenth and twentieth centuries were made in the absence of quality assurance. Moving forward with science calls for a rational application of methods to ensure quality for past, present and future data development.

LEISA - VALIDATING THE MODEL OF THE REFERENCE CONCEPT FOR THE EMPLACEMENT OF ILW(Q) AND HTGR FUEL ELEMENT WASTE PACKAGES IN VERTICAL BOREHOLES
Walter Feuser
Eike Barnert
Hendrik Vijgen
Forschungszentrum Jlich GmbH (KFA)
ABSTRACT
The semihydrostatic model has been developed in order to assess the mechanical loads acting on heat-generating ILW(Q) and HTGR fuel element waste packages to be emplaced in vertical boreholes according to the borehole technique. In this model, the borehole filling composed of emplaced packages and crushed salt is treated as a homogeneous medium with a density averaged according to the volume fractions, in order to derive the basic equations. The calculated pressure components depend both on the axial and the radial borehole coordinate.
For the experimental validation of the theory, laboratory test stands simulating the bottom section of a repository borehole are set up as part of the LEISA test program

(Lastabtragung durch EInbettung in SALzgrus - load diversion by embedding in crushed salt). For a unique interpretation of the measured data the test stands are optimized for minimum thermal and mechanical self-deformation.
A comparison of the measurement results with the data computed by the model, a correlation between the test stand results, and a systematic determination of material-typical crushed salt parameters in a separate research project will serve to derive a set of characteristic equations enabling a description of real conditions in a future repository.
Initial experiments at a prototype test stand confirm the tendency to load reduction by embedding in crushed salt derived in the semihydrostatic model.

INTRODUCTION

Apart from the safe operation of nuclear power plants, the disposal of radioactive wastes is an essential prerequisite for the civil uses of nuclear energy. It must be ensured that neither present nor future generations will be jeopardized by a release of radioactivity. The central component of the safety criteria established by the Federal German Government implies that the definite isolation of radioactive substances in a repository must be ensured by a multistage system of natural (rock formations containing the repository) and technical barriers (treatment, packaging and solidification of wastes, final closure of the repository).
According to the emplacement concept currently applicable in the Federal Republic of Germany, it is intended to emplace heat-generating high- and intermediate-level wastes in vertical boreholes or, alternatively, in horizontal drifts in underground rock salt mines. For emplacement according to the borehole technique the waste packages are lowered from the floor of drifts at 800 m depth into 300 m deep boreholes. Each package having been emplaced is completely covered by crushed salt so that the packages completely rest in crushed salt. This type of emplacement constitutes the current reference concept for final disposal according to the borehole technique.
Crushed salt has to fulfill the following functions:
Complete embedding of the waste packages in crushed salt is to ensure that, with progressing emplacement, the stacking forces acting on the bottom packages emplaced are limited due to load diversion to the surrounding borehole wall.
Backfilling with crushed salt of the cavities left should prevent any uncontrolled dispersion of radiolytic hydrogen and krypton-85 hy free convection into the upper borehole section not yet filled.
The danger of propagating flame fronts in the borehole by an assumed ignition of radiolytically formed hydrogen should be restricted by the quenching effect of crushed salt.
In the Federal Republic of Germany, the Bundesamt fr Strahlenschutz (BfS Federal Office for Radiation Protection) is responsible for the construction and operation of plants for the final disposal of radioactive wastes. The BfS may use the services of third parties (university institutes, national research centers, industry) to fulfill these tasks.
Within the framework of the LEISA experimental program (Lastabtragung durch EInbettung in SAlzgrus - load diversion by embedding in crushed salt) as part of the ILW(Q) and HTGR fuel element experimental program financed by the BfS, it is incumbent on the KFA to experimentally validate the reference concept, the semihydrostatic model (1) for calculating the pressure distribution in vertical repository boreholes filled with crushed salt and waste packages.

THE SEMIHYDROSTATIC MODEL

The semihydrostatic model is mathematically based on the assumption that there are only steady relationships between the components of the pressure tensor with progressing borehole filling. Unsteady gliding and slipping motions occurring in real beds are not contained in the model. Steady relationships between the axial, radial and tangential pressure components pzz, prr and pzr may only be assumed for steady borehole filling with constantly plane bed surface. Analytical methods such as the semihydrostatic model can only be used on these assumptions. However, this does not imply a restriction in the sense of a restricted transferability of the model calculations to real beds. The semihydrostatic model rather provides the theoretical frame for experimental studies at laboratory test stands reduced in size.
In order to derive the basic equations, the filling of crushed salt and embedded waste packages is approximately regarded in the model as a homogeneous bed with a

density rm averaged according to the volume fractions of crushed salt and packages. Rotational symmetry is assumed. With the radial and axial borehole coordinates r and z, the balance of forces in the axial direction (1) reads:

r dr df [pzz(r,z) - pzz(r, z + dz)]
+ r df dz pzr (r, z + dz/2) - [r + dr] df dz pzr (r + dr, z + dz/2)
+ r dr df dz rm g=0 (1)

Assuming that:

prr = kpzz, (2)
pzr = mprr, (3)

which is confirmed by experimental studies (1), expanding the functions in eq. (1) to their Taylor series and neglecting fourth- and higher-order differentials, the following partial differential equation is obtained:

See Eq. (4)

where k is the lateral pressure coefficient and m the coefficient of friction between crushed salt and the borehole wall, which are regarded as parameters typical of crushed salt.

Assuming certain physically meaningful boundary conditions, the solution of the differential equation for the vertical pressure component pzz from eq. (4) reads:

See Eq. (5)

Figure 1 shows the variation in pzz(r,z) for a 400-1 waste package mk = 0.054, rm = 2366 kg/m3) for a borehole radius of RB = 0.5 m.

The maximum pressure in the borehole:

See Eq. (6)

is limited and reached at a depth of:

See Eq. (7)

The depth z0 is called conversion depth because the pressure in the borehole remains constant at pzzmax from depth z0 to the borehole floor according to eq. (6) despite further progressing emplacement. The waste packages are thus not subjected to any further increasing mechanical load from depth z0 (= 9.3 m with the parameters selected above) downwards.

Conversely, this means that the mechanical load on the bottom package emplaced in the borehole only increases until the emplacement horizon has risen by z0 = 9.3 m during borehole filling. The pressure acting on the bottom package will then remain constant at pzzmax despite further borehole filling. This statement for the bottom package can be transferred to any other package in the borehole.

STRATEGY

In order to experimentally validate the semihydrostatic model, laboratory test stands reduced in scale are constructed and set up to simulate the bottom section of a repository borehole. The aim is to formulate a transference law by means of which the experimental results obtained for smaller models (laboratory models) can be transferred to real conditions (repository) without knowing the exact boundary conditions and geometrical dimensions in a future repository. This will be achieved by comparing and matching the experimental data with the model calculations and by correlating the test stand data.

The experiments are carried out varying all decisive test parameters (borehole depth, borehole diameter, crushed salt grain distribution, crushed salt temperature, borehole wall surface, time etc.) in order to define an optimum parameter combination for low package loads.

REQUIREMENTS FOR THE TEST STANDS

The LEISA I and II test stands consist of tube segments with wall thicknesses decreasing from 12 mm (bottom) to 5 mm (top) placed into each other to form a tubular column. The following requirements are fulfilled by selecting carbon-fibre-reinforced plastic (CFRP) as the wall material:

- The thermal deformations of the wall are almost zero in the entire temperature range up to 200C examined.
- Mechanical wall deformations due to bed pressure can be structurally minimized.
- The inner surfaces of the CFRP tube segments can be reconfigured after construction.

The stability of the test stands with respect to thermal deformation is of particular significance for tests at high temperatures (HAW packages reach surface temperatures of about 200C (2)) and also for long-time experiments at room temperature over several days or weeks. Even slight dimensional changes of the tube

segments due to temperature variations in the laboratory will cause considerable pressure changes in the bed. This was shown by experiments at a prototype test stand made of steel. Such dimensional changes should be avoided as far as technically feasible since otherwise no unique interpretation of the test results is possible. It must be ensured under all circumstances that variations in the pressures measured are not caused by self-deformation of the test stands, but solely by pressure changes in the crushed salt bed.

The inner structure and inner configuration of the CFRP test stands were reproduced in a finite-element computer program prior to construction in order to simulate the most extreme thermal and mechanical loads acting on the tube segments. In comparison, calculations were performed for segments made of INVAR steel (steel variety with very low thermal expansion coefficient). Other materials such as quartz glass, graphite, silicon nitride and aluminum titanate were also under discussion as wall materials with low thermal expansion coefficient. They were not used, however, for technical or practical reasons.

The calculations show a deformation of the CFRP cylinder structure (ovalization), which is lower by about a factor of 5 compared to INVAR steel for the assumed load case of 3 bar internal pressure and 150C temperature difference. Figure 2 shows the radial deformations of the CFRP tube segments for the above load case. The CFRP segments are reinforced by a circumferential stiffening ring of CFRP in the region of the flange mounting for the sensors. A cylinder wall thickness of 10 mm was assumed for the steel segments and of 12 mm for the CFRP segments in the FEM calculations.

Compliance with the maximum permissible deformation of the CFRP segments according to FEM calculations was experimentally confirmed in preliminary specimen tests. They only give a linear thermal expansion coefficient of:

See Eq. (8)

This low value cannot be achieved with any other candidate wall material so that the higher technical and financial outlay for CFRP is justified.

The prototype test stand of steel (diameter 250 mm, height 2.5 m) has been completed and put into operation, the test stands of CFRP, LEISA I and II, with diameters of 250 mm and 600 mm and heights of 2.5 m and 5.5 m, respectively, are under construction.

MECHANICS, MEASURING ELECTRONICS AND DATA ACQUISITION

The test stands rest on steel platforms of 800 mm and 1200 mm height and are integrated into accessible working platforms. They are open at the top and closed by bottom plates.

Specifically designed pressure gauges directly measure the pressure components in the axial direction towards the bottom plate and in the radial direction towards the cylinder walls. The pressure plates accommodating the bed pressure are circular and their surfaces are adapted to the cylindrical inner wall of the tube segments. The bed pressures are transmitted to electronic sensors by sensitive mechanics. The mechanical load caused by the bed is converted into an analog electrical signal by a device which is elastically deformed by the load to be measured. The deformation is recorded by strain gauges (3).

Temperature sensors are installed on the inner and outer walls of the tube segments to continuously record the temperature within the crushed salt bed. The pressure and temperature data are registered and processed by a multi-digit measuring instrument. The instrument functions are controlled and the measured data stored by an external IBM-compatible computer.

Crushed salt is reproducibly filled into the test stands in a defined manner using a feeder. For the LEISA II test stand of CFRP (diameter 600 mm) it is planned to emplace electrically heatable inactive dummy packages reaching a surface temperature of 200C from above into the test stand using a crane.

Measuring results from the CFRP test stands are not yet available. However, all essential technical components of the test stands (mechanics and electronics) have already been successfully tested, matched and optimized under operating conditions at the prototype steel test stand. The measuring results presented below are taken from this test stand.

EXPERIMENTAL RESULTS

Crushed salt with a grain size of 0 - 10 mm is used for measurements at the prototype test stand made of steel (Fig. 3). Investigations are to reveal the maximum possible pressure in the test stand filled with crushed salt. The fine

particle fraction, XF, which is defined here as the bed fraction in the range of 0 - 2 mm, varies between 0 - 90 wt%.
The test material is produced by sieving out the 0-2 mm fine particle fraction from the total 0 - 10 mm fraction and adding it proportionally to the 2 - 10 mm fraction, depending on the requirement (10, 30, 60 and 90 wt%). The test material is then homogeneously mixed using a turbulence mixer and filled into the tube segments using the feeder. All experiments are carried out at room temperature.
Figure 4 shows the measured axial pressures pzz as a function of depth z below the crushed salt surface at the radial position r = 0.095 m for increasing fine particle fractions XF. As can be seen, the measured axial pressure initially increases almost linearly with depth z for all grain fractions. After reaching a certain depth (0.2 - 0.3 m), the increase in axial pressure decreases with increasing depth. From a depth of z = 0.5 m the pressure pzz assumes a constant value. At maximum depth of 0.5 m, load diversion for the substitute borehole of steel with a diameter of 250 mm is so effective that nearly unrestricted emplacement is possible above this depth. No further pressure increase is observed on the borehole floor. Waste packages are thus not subjected to any further increasing mechanical load in this location.
Without load diversion, a vertical pressure of about 35 kN/m2 would arise on the bottom plate for a test stand height of 2.5 m. The vertical pressures are 12 to 15 times smaller in the case of load diversion. The measurements are tendentially in full agreement with the theoretical predictions of the semihydrostatic model.
Figure 4 also shows that the measured axial pressures increase with growing fine particle fraction from pzz = 1.4 kN/m2 for XF = 0 wt% to about pzz = 3.0 kN/m2 for XF = 90 wt%. This is only attributable to a minor extent to the larger packing density of crushed salt with elevated fine particle fraction. The density only increases by 10% when the fine particle fraction is increased from 0 to 60 wt%. It is even lower again for XF = 90 wt% compared to a fine particle fraction of XF = 60 wt%.
The increase in pressure with growing fine particle fraction is probably caused by a decrease of the friction coefficient with increasing fine particle fraction. A smaller friction coefficient causes less wall friction and thus a higher axial pressure. In order to quantitatively elucidate this phenomenon, the friction coefficients of crushed salt are systematically determined in a separate research program.

CONCLUSION

The measurement technique used and the mechanical setup are suitable for determining the pressure distributions within a crushed salt bed in tube segments simulating the borehole wall. The experimental studies show good agreement with the calculations according to the semihydrostatic model. The equipment components used prove to be extremely reliable. Measurements to date have shown that the pressure distribution in vertical boreholes decisively depends on the grain distribution of crushed salt and on the filling process. After construction and commissioning of the CFRP test stands (LEISA I and II) extensive further studies varying all essential parameters (borehole radius, borehole depth, grain distribution, mechanical crushed salt parameters, time, temperature, etc.) will be carried out to obtain a more comprehensive picture concerning load diversion in vertical boreholes backfilled with crushed salt.

ABSTRACT
A possibility for underground disposal of low- and medium-radioactive waste is emplacement in a dry salt cavity. In connection with the long-term safety and the quality of the natural sealing, it is advantageous to consider the use of deep-lying cavities. To limit the convergence of such cavities during the filling-up phase it is necessary to maintain an internal gas pressure for the duration of this phase. This paper gives results of numerical calculations on the convergence behavior of a cavity as a function of depth, internal gas pressure and cavity radius during the filling-up phase. Results for a cavity radius of 30 m are, that for depths of 1500 and 2200 m the necessary internal gas pressures are about 10 and about 30 MPa, respectively. Furthermore it was established that the convergence rate increases with increasing cavity radius. The convergence behavior in the abandonment phase, during which the gas pressure will be atmospheric, has also been investigated. Calculations show that in this phase the convergence rate changes from very rapid in roughly the first 2 years to very low after more than about 10 years.
INTRODUCTION
An option for underground disposal of solid, non-heat-generating radioactive waste is emplacement in a salt cavity. Both a brine-filled cavity and a dry cavity can be considered. The brine-filled cavity has two disadvantages: i) potentially a large amount of liquid can be contaminated and ii) after cavity abandonment and sealing the permeability of the cavity roof can be enhanced considerably (1). Therefore the dry cavity is to be preferred above the brine-filled cavity. Unfortunately, the dry cavity has an important disadvantage. As a consequence of, mainly, the increasing convergence rate with depth, only depths down to about 1000 m can be reached. Larger depths could be attained, however, if the internal cavity pressure is increased by compressing the air in the cavity during the filling-up phase. During the abandonment phase the cavity is depressurized.
A paper on this disposal technique was presented at the Waste Management '94 Conference (2). The advantages and drawbacks were discussed and preliminary results on cavity convergence and stability were presented. The main advantage of the technique is, that disposal of waste would be realized at a relatively large depth. It can be argued that the quality of the isolation increases with depth. Moreover, at such a depth the natural sealing of the waste within the salt body occurs much more rapidly. Disadvantages are that the cavity has a considerable internal pressure for a period of a few years and that the waste has to be emplaced in a pressurized cavity. Details of the emplacement technique and procedure have still to be worked out (2).
In the current paper the attention is focused on the convergence behavior of the cavity. Numerical calculations have been carried out on cavity convergence at different depths, both for the filling-up phase and for the abandonment phase. This paper summarizes the most important results of these calculations.
SYSTEM PARAMETERS
Depth range, in-situ stress and geothermal gradient
Depths between 1500 m and 2200 m have been investigated. Within this range two specific depths received special attention: 1700 m and 2000 m.
The in-situ stress at a depth of 1400 m was taken as 30 MPa. Below this depth the principal stresses far away from the cavity were supposed to increase linearly with depth according to:

$$\sigma_{xx} = \sigma_{yy} = \sigma_{zz} = 30106 + \rho g D h \ [Pa]$$

The rock-salt temperature was assumed to increase with depth according to:

$$T = 281.7 + 0.03h \ [K]$$

Cavity pressure
The internal cavity pressure during the filling-up phase was taken as 10, 15, 20, 25 or 30 MPa. During abandonment the cavity pressure was assumed to be atmospheric.
Cavity shape
The cavity shape was supposed to be spherical. This shape was chosen because, in an isotropic lithostatic stress situation, the sphere is the most favorable (i.e. the most stable) configuration. Most calculations have been carried out for a radius of

30 m, a rather arbitrary choice. However, also calculations with cavity radii of 10, 20, 40 and 50 m were performed.

CALCULATION PROCEDURE

The simulation program FLAC

The convergence calculations were performed using the finite difference code FLAC (Fast Lagrangian Analysis of Continua), version 3.2. This software package has been developed by Itasca Consulting Group, Inc., Minneapolis, Minn.

To simulate the creep behavior of salt the "WIPP creep model" (WIPP: Waste Isolation Pilot Plant, Carlsbad, N. Mex.) is available in FLAC. This model is based on a reference creep formulation developed in earlier waste isolation studies (4). FLAC also incorporates an experimental model which simulates volumetric hardening and non-linear irreversible compaction. This "double-yield model" was used to represent the mechanical properties of the solid waste.

Filling-up phase

During the filling-up phase the convergence behavior of the cavity is determined by the system parameters (depth, cavity diameter, internal pressure) and the mechanical properties of rock salt. The shear and the bulk modulus of rock salt were chosen as 9.84 and 18.1 GPa, respectively (3). These values correspond with a modulus of elasticity of 25 GPa and a Poisson ratio 0.27. For the convergence calculations it was convenient to use the WIPP creep model (3,4). Two creep regimes can be distinguished:

$$\dot{\varepsilon} = \dot{\varepsilon}_s + (A - B\varepsilon_p)\dot{\varepsilon}_s \quad \text{for } \dot{\varepsilon}_s \geq \dot{\varepsilon}^*_{ss}$$

$$\dot{\varepsilon} = \dot{\varepsilon}_s + [A - B(\dot{\varepsilon}^*_{ss}/\dot{\varepsilon}_s)\varepsilon_p]\dot{\varepsilon}_s \quad \text{for } \dot{\varepsilon}_s < \dot{\varepsilon}^*_{ss}$$

The secondary strain rate is a function of stress and temperature:

$$\dot{\varepsilon}_s = D\sigma^n e^{-Q/RT}$$

Since the cavity is assumed to be perfectly spherical and to be embedded in an infinite isotropic medium, this cavity and its immediate surroundings can be simulated by an axisymmetric configuration. This two-dimensional model is thought to be rotated along a vertical central axis, is 300 m wide and 600 m high (thus having boundaries at about 10 times the cavity radius) and is divided into 200 concentric zones.

Prior to the calculations proper the model is brought to an elastic equilibrium with negligible displacements. Then creep calculations are started, with initial time-steps of 100 seconds. These time-steps increase automatically when the creep rate decreases.

Abandonment phase

During the abandonment phase the convergence behavior of the cavity is determined by the system parameters (depth, cavity diameter and internal pressure; this last parameter is now assumed to be atmospheric), the mechanical properties of salt (see above) and the mechanical behavior of the solid waste, simulated by the double-yield model. This model is intended to represent granular (lightly cemented) materials that show irreversible compaction when placed under pressure, and increase in stiffness as the material becomes more compact. To our knowledge no information is available on the convergence behavior of solid waste in a salt cavity, but is seems reasonable to assume that the waste will decrease with, say, 20-25 vol. % before fully withstanding the converging cavity walls. Therefore the mechanical properties characteristic for 30:1 sand-cement fill material are used here, viz. bulk and shear modulus of 450 and 600 MPa, respectively, a friction angle of 40 and zero cohesion and zero tensile strength. Table I gives data on the assumed, strongly non-linear, stress-strain behavior of the cavity contents.

In the abandonment phase the calculation procedure is simular to that in the filling-up phase, the only difference being the different boundary condition at the cavity/salt interface, which is now a strain-dependent (and, consequently, time-dependent) pressure.

CONVERGENCE BEHAVIOR DURING THE FILLING-UP PHASE

Figure 1 gives the results of the convergence calculations for a depth of 1700 m. The volume convergence decreases significantly with increasing internal gas pressure. E.g. after 5 years the volume convergences for pressures of 15 and 25 MPa are 9.9 and 1.1 %, respectively. Corresponding values for a depth of 2000 m are 34.0 and 7.3 %, respectively, see Fig. 2. The relationship between volume convergence and time is non-linear. The tendency is that the increase in convergence decreases with time.

Fig. 1. Convergence of a spherical cavity, radius 30 m, with the cavity center at

1700 m depth, for different internal gas pressures.
Fig. 2. Convergence of a spherical cavity, radius 30 m, with the cavity center at 2000 m depth, for different internal gas pressures.
For the operation of a pressurized cavity it is required that the total volume convergence is kept below a certain limit, so that during the filling-up phase the cavity volume is kept reasonably constant. If for this limit a convergence of 10 % in 5 years is chosen, this implies the existence of a specific minimum pressure for each depth. For the chosen depth interval the calculations yield that these minimum pressures vary from 9.2 MPa (cavity center at 1500 m) up to 29.1 MPa (cavity center at 2200m).
The results given above are valid for a cavity radius of 30 m. The influence of the cavity radius on the convergence rate has been investigated. Figure 3 gives the results of the calculations, which show that the volume convergence increases with increasing radius. We cannot provide a satisfactory explanation for this scale effect. Possibly it is caused by the rock-mechanical properties of rock salt. For a small cavity the zone around the cavity undergoing significant deformation is relatively small and growing only slowly. This may imply that, for a small cavity, there is a larger tendency of the rock-salt formation as a whole to resist deformation, leading to a smaller cavity convergence than in the case of a large cavity.
Fig. 3. Convergence of a spherical cavity, with the cavity center at 1700 m depth and with an internal gas pressure of 15 MPa, for different cavity radii.

CONVERGENCE BEHAVIOR DURING THE ABANDONMENT PHASE

Once the cavity has been completely filled up, it is no longer necessary to maintain the internal pressure. In practice the pressure will be gradually decreased by letting the cavity air slowly escape during a period of, say, a few months. It may or may not be necessary to filter the escaping air. For the purpose of our calculations it was assumed that, at the end of the filling-up phase, the internal pressure was instantaneously reduced from the prevailing pressure to atmospheric pressure.
Figure 4 gives the data for the cavity convergence during the abandonment phase for a cavity depth of 1700 m. Again it was assumed that the cavity radius was 30 m. Because the internal pressure has been drastically reduced, we see initially a very rapid convergence in the first 2 years of cavity abandonment. This behavior corresponds with the rapid reduction of the porosity of the solid waste. With decreasing porosity it will become more difficult to compact the waste even more, with the result that the convergence rate decreases significantly with time in the next years. After about 10 years the convergence rate has become relatively small. The convergence rate keeps decreasing in time, but does not approach the value zero in the investigated time period (0-20 years).

DISCUSSION

The calculations presented here were based on the mechanical properties of WIPP salt. It is well-known that the mechanical properties of rock salt vary with formation type and location, see e.g. Lux (5). Therefore the results of the calculations must be regarded as being indicative rather than uniformly valid.
The influence of the cavity radius on the convergence rate has been investigated (see Fig. 3), and this yielded that this influence is surprisingly strong. A possible explanation has been suggested above, but more fundamental insight concerning this phenomenon is necessary. In future activities attention will be given to this aspect.
In this paper no specific attention was given to the stability phenomenon. The calculation of the convergence rate makes only sense in cases where one has to do with a stable cavity. In the WIPP creep model this aspect is not incorporated. This means that - in a specific situation of cavity depth, cavity radius and internal pressure - the convergence rate is evidently of importance, but that always must be checked whether one has to do with a stable cavity in a rock-mechanical sense. Also to this aspect attention will be given in future activities.
Finally we point out that, in the framework of waste disposal in a pressurized salt cavity, also attention should be given to subjects not mentioned up till now: subsidence as a result of cavity operation, final cavity and borehole sealing, and analysis of the safety consequences of this disposal design.

CONCLUSIONS

1. For a spherical cavity with a radius of 30 m the minimum gas pressure necessary during the filling-up phase varies from about 10 MPa (1500 m depth) to about 30 MPa (2200 m depth).
2. The cavity convergence rate increases with increasing cavity radius.
3. During the first 2 years of the abandonment phase the cavity convergence rate is very rapid, but this rate decreases quickly and becomes very low for times of about 10 years and more.
4. Some aspects of the disposal method treated in this paper, such as waste handling and abandonment procedure, have still to be worked out.

OPTIMIZATION OF ENGINEERED BARRIERS FOR DEEP DISPOSAL

S. V. Barlow
C. S. Mogg
United Kingdom Nirex Limited

ABSTRACT

United Kingdom Nirex Limited (Nirex) is owned by the major organizations in the UK nuclear industry. The company is responsible for developing and operating a deep repository for disposal of solid intermediate-level and some low-level radioactive waste. Nirex is concentrating its investigations on a site close to the BNFL Sellafield works in Cumbria in the North-West of England.

Nirex in common with many other disposal agencies has developed a concept of deep geological disposal for radioactive waste which uses a multi-barrier containment system. The concept makes use of both engineered and natural barriers, working in conjunction, to achieve the necessary degree of long-term waste isolation and containment. An important component of the engineered system is the disposal package comprising waste container and solid wasteform.

The principal type of container for ILW is an unshielded stainless steel drum of

nominal 500 liters capacity. Such containers are currently being filled with immobilized waste in readiness for eventual disposal to the Nirex repository. Research has demonstrated that such waste packages will be suitable for 50 years on-site storage before transport to the repository. Once emplaced in the repository and surrounded by cementitious backfill grout, waste packages will make a significant contribution to the engineered component of the multi-barrier containment system.

INTRODUCTION

United Kingdom Nirex Limited (Nirex) is owned by the major organizations in the UK nuclear industry. The company is responsible for developing and operating a deep repository for disposal of solid intermediate level and some low-level radioactive waste (ILW and LLW). Nirex is concentrating its investigations on a site close to the BNFL Sellafield works in Cumbria in the North-West of England.

Nirex in common with other disposal agencies has developed a concept of deep geological disposal for radioactive waste which uses a multi-barrier containment system. The concept makes use of both engineered and natural barriers, working in conjunction to achieve the necessary degree of long-term waste isolation and containment. An important component of the engineered system is the disposal package comprising waste container and solid wasteform.

For the Sellafield site, attention is being focused on disposal at a depth of about 650m below Ordnance Datum (about 750m below the surface), in the Borrowdale Volcanic Group (BVG) of rocks. Nirex aims to bring a repository into operation by the year 2010.

MULTI - BARRIER CONTAINMENT

The Nirex concept for deep geological disposal is similar to that being considered in several other countries. Caverns will be excavated at depth in a suitable geological environment. Wastes, cemented into steel or concrete containers, will be placed in caverns which will inturn be backfilled with a cement based material. The multi-barrier concept is illustrated schematically in Fig. 1.

This concept makes use of both engineered and natural barriers to provide the necessary long-term isolation and containment of the waste. The steel or concrete packaging is of importance during the operational phase and for several hundred years after closure. However, the long-term containment properties of the engineered system with regard to radionuclides dissolved in groundwater will stem from the establishment of uniform chemical conditions and high sorption capacity across the repository. This will be achieved by surrounding waste packages with the required amount of special cement based backfill (1). The Nirex vault backfill has been carefully specified to fulfil a number of requirements, namely:

a) long-term maintenance of alkaline pore water chemistry in order to suppress dissolved levels of key radionuclides under the prevailing conditions of groundwater flow and geochemistry;

b) long-term maintenance of a high active surface area for sorption of key radionuclides;

c) relatively high permeability and porosity to ensure homogeneous performance, in order that localized concentrations of materials in wastes do not exhaust the desired chemical conditioning and thereby locally reduce the containment performance.

With this concept a source term for dissolved radionuclides in repository pore water can be derived in a manner that is relatively simple and therefore easily understood. The natural barrier provided by the deep geological setting serves to control the rate of access of groundwater to the waste, to delay and spread radionuclide migration to the biosphere and to limit the probability of disruption by human-initiated or natural events.

Long-term containment properties of the engineered system therefore rely on the establishment of appropriate chemical conditions in the near-field. The physical barriers, provided by the disposal container and wasteform, do not contribute to containment in the long-term but are important in the short-term, during the operational period of the repository and in the years immediately following closure. Thus the performance of the waste package (ie container and wasteform) has to be specified to provide adequate containment in the repository environment whilst also being suitable for waste processing, interim storage, handling and transport.

WASTE PACKAGE SPECIFICATIONS

Working in conjunction with producers of radioactive waste, Nirex has defined a

range of standard containers suitable for accumulations and future arisings of waste in the UK. The standard containers specified by Nirex are listed on Table I. Each has been justified on the basis of an identified need for packaging a particular range of wastes.

Waste Package Specifications have been produced for each of the standard packages. Each Specification defines dimensional, functional and performance criteria for waste containers and wasteform. These criteria include activity content, dose rate, surface contamination, heat output, dimensions, shape, handling features, venting and filtration, impact performance, integrity, stackability and identification. The Specifications incorporate the various requirements for disposal and transport and are compatible with the requirements for waste packaging, storage and handling at the sites of origin. In the absence of Conditions for Acceptance, which cannot be issued until much closer to repository opening, Waste Package Specifications provide an essential link between waste package design and repository design. The Specifications have enabled waste producing organizations to design containers and build waste packaging plants. At the beginning of 1995 some 6,000 standard 500 liter drums had been filled with conditioned waste and are in store awaiting disposal to the Nirex repository. For Nirex, the Specifications have provided a key element of the basis of design for the repository and transport system and also for the various safety cases to be made to the regulatory authorities.

500 LITER DRUM

The 500 liter drum is the principal type of container for ILW. It will be used for the greater part of operational wastes arising from day-to-day operations of nuclear facilities. Within the UK, intermediate level operational wastes mainly include fuel cladding and fuel element debris, sludges and ion exchange materials, miscellaneous solid waste and plutonium contaminated materials. The 500 liter drum can also be used for the packaging of decommissioning wastes, but larger containers such as the 3m3 box or 4m box may be more appropriate.

A typical 500 liter drum is shown in Fig. 2. The drum has a diameter of 800mm and an overall height of 1200mm. Its nominal capacity is 500 liters. A cylindrical shape was chosen to facilitate in-drum mixing using a paddle. This shape ensures that there will be no 'dead' volumes where mixing of the cement and waste will not take place. Likewise it has been found that a ratio of height to diameter of 1.5 is good for in-drum mixing although this ratio may be varied considerably. An overall diameter of 800mm is considered optimum on transport efficiency grounds. It will allow transport within the British Rail W6A loading gauge with the required amount of shielding. In addition to in-drum mixing, the drum may also be used for in-drum grouting of solid waste items.

The drum is not intended to provide radiation shielding. This was a decision taken as a result of an analysis of the options of disposable shielding and reusable shielding for ILW containers (2). It was shown that relatively cheap materials for disposable shielding, such as concrete, would mean high disposal charges because of the large volumes being disposed of along with the waste. Denser materials such as steel, although incurring lower disposal costs owing to their smaller volume, would have higher waste container costs. Reusable shielding was thus the most economical solution and Nirex is developing a family of reusable transport containers to meet this need (3). The transport container will carry four 500 liter drums in a handling stillage or one 3m3 box or drum. The transport containers are being designed to meet IAEA Type B requirements (4) and will be manufactured in a range of nominal shielding thicknesses up to a maximum of about 285mm. One consequence of the decision to adopt reusable shielding for drummed ILW is that the waste containers will need to be handled remotely both during and after unloading at the repository. A transport container carrying four 500 liter drums is illustrated in Fig. 3.

It has not proved possible to standardize on one single design of 500 liter drum because the processes for immobilising different wastes require variations to the drum, mainly in the lid area and in the internal drum 'furniture'. A limited number of drum shapes has been adopted, each shape allowing variations on lidding and internal arrangements, but all having common lifting and handling arrangements. As shown in Figure 2, the lifting feature is provided by a rim of diameter 800mm at the top of the drum. The dimensions of this lifting feature are specified to permit all drums to be lifted by the same handling equipment.

Typically drums are filled with waste to within 100 - 200mm of the top of the drum.

A gap is left at the top to prevent the spread of contamination by splashing and spilling of the waste or grout introduced for immobilization. An inactive grout cap is then placed above the waste, leaving only a relatively small air gap at the top of the drum. The size of this air gap varies between a few millimetres to about 40mm.

Methods of closing drums include bolting and welding. For wastes which generate gases a vent is provided. If it is expected that sufficient quantities of gas will be produced to entrain particulate material, the vents will be filtered. This allows gases to escape, preventing pressurization and build-up of flammable gas mixtures.

All current 500 liter drums are manufactured from AISI 316L stainless steel, typically using grade 316S11 (5) for the body and sometimes grade 304S11 in the lid area. The thickness of the stainless steel body is between 2 and 3mm. The use of thin-section stainless steel sheet permits drums to be fabricated using conventional spinning and pressing technologies. The actual wall thickness adopted is not a Nirex specified requirement but is the choice of the drum designer in response to the Nirex specified design lifetime for the container.

DRUM INTEGRITY REQUIREMENTS

The Waste Package Specification defines minimum requirements for waste package integrity. Requirements cover a period of interim above-ground storage and the period post-emplacement in the repository when the package contributes to the engineered barrier.

The specification is worded so as to provide flexibility to drum designers, to enable designs to be optimized to suit the requirements of particular wastes and storage conditions. The specification calls for drum material, thickness, corrosion properties and sealing method to be such that following storage at the producer's site for 50 years, the drum will provide containment during:

- transport and handling at the repository
- post-emplacement for a minimum period of 50 years in an alkaline environment

The 50 year interim storage period is specified to account for the fact that wastes packaged now may have to be stored for that length of time before they can be accepted for disposal. Following emplacement in the repository, the specification calls for a minimum lifetime of 50 years to ensure that containment is maintained during the repository operational period. For wastes containing short-lived soluble activity, best practical means are to be employed to extend package integrity beyond the 50 year operational period.

In practice, packages manufactured from grade 316L stainless steel and backfilled with the Nirex backfill material, are expected to exhibit corrosion characteristics significantly better than the minimum requirements specified.

WASTE CONTAINER CORROSION PERFORMANCE

In order to determine the corrosion performance of waste packages following disposal and to assess the contribution of waste packages to the engineered barrier, Nirex has carried out a substantial research program to examine the performance of grade 316L stainless steel under a range of conditions.

During interim storage the waste containers will be held in purpose-built storage buildings in which the temperature and humidity levels will be controlled. Some storage buildings will be located near the coast and consequently there is a possibility of chloride-containing particulates being present in the atmosphere. 316L stainless steel is resistant to atmospheric corrosion; long term exposure to marine conditions may lead to slight staining but no significant metal loss. The most likely form of corrosive attack is crevice corrosion around the lids of the containers, but this should be slight provided condensation can be prevented.

Repository Environment

Provided the correct environmental controls are maintained during storage, the waste containers will be free of significant corrosive damage at the end of the storage period, at which time they will be transported to the repository, where they will be emplaced and covered with the cement based backfill described previously. The corrosion performance of stainless steel drums, and hence their contribution to the engineered barrier will largely be determined by the environmental conditions within the backfilled waste stack. The principal environmental factors controlling the extent of corrosion are oxygen availability, presence of chloride, temperature and the chemical conditioning provided by the backfill.

Concentrations of oxygen and chloride in repository porewater will change as a

function of time. The oxygen concentration will fall as a result of consumption by microbial activity and corrosion of structural carbon steel and eventually the repository will become anaerobic. On the basis of current models it is expected that anaerobic conditions will be achieved after a period of ten to a few hundred years. The chloride concentration in the repository will increase as it resaturates with groundwater. The chloride concentration measured in the groundwater depends on the site where it is sampled, but is typically up to 15,000 ppm (6). It is expected that resaturation will occur gradually as groundwater enters the pores of the backfill. The groundwater has a very low oxygen content and resaturation will not therefore lead to an increase in the oxygen inventory of the repository. Groundwater entering the backfill will be chemically conditioned and the porewater will be alkaline. The temperature in the repository will peak at around 80oC shortly after closure, then decay back to the background temperature of approximately 50oC (7). Corrosion behavior of stainless steel during this period will depend on the relative timescales for oxygen depletion, water availability, chloride ingress and temperature variation.

Corrosion Mechanisms

Several different forms of corrosion can affect metals when they are immersed in a corrosive environment. General corrosion refers to removal of material over a broad surface area. The general corrosion rate of stainless steel is determined by the properties of the oxide film on the surface (the passive film) and is less than 1mm/year in both aerobic and anaerobic conditions. Measurements of passive current densities indicate that the corrosion rate may be as low as 0.01mm/year (7). Localized corrosion includes such phenomena as pitting, crevice corrosion and stress corrosion cracking. Although these forms of corrosion do not lead to the loss of large amounts of metal they can lead to rapid penetration, which may result in the formation of leakage paths if experienced in waste containers. In order to examine the potential for these mechanisms to occur under expected repository conditions Nirex has carried out extensive experimental and theoretical studies.

Pitting Corrosion. Studies have shown that the chemical conditioning provided by the Nirex vault backfill plays an important role in limiting the occurrence of pitting corrosion, even in environments where this mechanism would normally be anticipated. The controlling factor appears to be the ratio of chloride ions to hydroxyl ions. Nirex studies to understand the mechanism are continuing but initial results indicate that pitting corrosion is not expected where this ratio is less than 10. This result suggests that chloride levels of 20,000 ppm could be tolerated in the repository groundwater where this has been conditioned by the Nirex vault backfill.

Crevice Corrosion. Crevice corrosion is the most difficult form of corrosion to study and predict because it is sensitive to such parameters as crevice geometry and surface finish. The most likely regions to be affected are the crevices formed around the lids of waste containers. The restrictions on the mass transport of materials into the crevice result in the development of micro-environments inside the crevice which can be highly acidic, even when the external environment is alkaline. Further experimental research is planned to investigate this phenomenon. Mathematical models (8), have also been developed as an aid to assessing whether a crevice of a particular geometry will activate in particular environmental conditions. The model simulates the evolution of the chemical and migration processes within a passively corroding rectangular crevice.

Stress Corrosion Cracking. The likelihood of Stress Corrosion Cracking (SCC) occurring in waste containers has also been assessed (9). From a literature review it is concluded that at temperatures below 100oC, and therefore in the absence of concentration effects caused by boiling, alkaline-induced SCC can be ruled out. However, chloride-induced SCC is considered to be a possibility and the likelihood of its occurrence predicted to increase with increasing temperature. Further research work in this area is in progress.

Microbially Influenced Corrosion. In conditions where microbial growth can occur, for example where there is a supply of organic nutrients and trace elements, microbially influenced corrosion (MIC) of metals can sometimes occur. Such corrosion often takes the form of bottle-shaped pits. A number of species have been implicated in MIC and each has its own specific nutritional requirements. MIC is unlikely to occur in the high pH and high radiation flux conditions which will prevail in cemented ILW wasteforms (10) but it cannot be ruled out for uncemented LLW wastes with a high proportion of organic wastes.

Corrosion Performance

From the above discussion of corrosion mechanisms it can be seen that stainless steel waste containers will experience very low rates of general corrosion. At the time of transport to the repository, perhaps after a period of 50 years above-ground interim storage, stainless steel waste containers should be unaffected by corrosion given appropriate storage conditions. Following emplacement in the repository, waste packages will initially experience aerobic conditions and even in the presence of chloride, general corrosion rates of less than 1mm/year are predicted. The typical stainless steel drum shown in Figure 2 can therefore expect a lifetime in excess of 1000 years.

The effect of localized corrosion is however more difficult to predict. Stainless steel can be susceptible to localized corrosion mechanisms under the combination of aerobic conditions and chloride. The alkalinity provided by the Nirex vault backfill is beneficial and will control pitting by the provision of hydroxyl ions. Nirex work to examine the effect of localized corrosion and its variation with oxygen availability, chloride level, pH and temperature is continuing. When the repository environment becomes anaerobic, localized corrosion mechanisms will cease, leaving corrosion to proceed at the general rate.

The choice of stainless steel as the material for the manufacture of 500 liter drums has a number of advantages. The drums can be made from thin-section sheet enabling manufacture using conventional spinning and pressing techniques. The drums can be used as process vessels during waste conditioning and because they are unshielded, enable efficient use to be made of interim storage facilities. When waste packages are despatched to the repository, they should be unaffected by corrosion, given appropriate conditions during the storage period, and following emplacement and backfilling will corrode very slowly. The long-term containment properties of the repository do not rely on a physical barrier but the drum will nevertheless provide a significant barrier to the movement of radioactivity.

CONCLUSIONS

The Nirex concept for deep geological disposal makes use of both engineered and natural barriers to provide the necessary long-term isolation and containment of waste. The principal element of the engineered system is the establishment of appropriate chemical conditions in the near-field. This is achieved by surrounding waste packages with a special cement based backfill.

The physical barriers provided by the disposal container and wasteform do not contribute in the long-term but are important in the short-term during the operational period of the repository and in the years following repository closure. The principal container for ILW, the 500 liter drum, fullfils various functions throughout its life, from process vessel and interim storage container through to eventual disposal container in the repository. The selection of grade 316L stainless steel for the manufacture of drums has permitted wastes to be packaged in advance of the opening of the repository and to be interim stored in a cost-effective manner. Research studies indicate that these packages will be materially unaffected by corrosion during interim storage and can make a significant contribution to the engineered component of the multi-barrier containment system following disposal.

UNDERGROUND CONCEPTUAL REPOSITORY DESIGN AT YUCCA MOUNTAIN, NEVADA

Dean Stucker
U.S. Department of Energy
Bruce T. Stanley
Morrison Knudsen Corporation

ABSTRACT

The Yucca Mountain Project, which is located approximately 175 km northwest of Las Vegas, Nevada, is the site that Congress has directed the U.S. Department of Energy to characterize to determine its suitability for disposing up to 70,000 tonnes of radioactive waste. This amount is comprised of approximately 63,000 tonnes of Spent Nuclear Fuel (SNF), and about 7,000 tonnes of High Level Waste (HLW). The Department of Energy (DOE) is scheduled to begin taking possession of SNF in 1998, but is not scheduled to actually dispose waste packages until the year 2010 if the site proves suitable for repository purposes.

The project schedule as shown in Table I is based upon a number of major products or milestones. High Level Findings (HLF) of a scientific nature will collectively support the determination of Technical Site Suitability (TSS) scheduled for 1998. TSS will supply an initial reading on the technical suitability of the site, and, if found suitable, will allow further development of program activity.

The overall project is comprised of two major phases: the Exploratory Studies Facility (ESF), and the potential repository. Both phases will make extensive use of mechanical excavation techniques in the development of main accesses, test alcoves, long term underground test rooms, and ultimately, emplacement drifts.

PROGRAM APPROACH

The Site Characterization Plan issued in 1988 contains an extensive testing, design, and performance assessment program that provide a comprehensive understanding of Yucca Mountain. The original intent of the Nuclear Waste Policy Act and of the Nuclear Regulatory Commission was to create a site characterization program that provides sufficient information for decision making, realizing that some uncertainty must exist. The series of decisions to be made in the various licensing stages imply an increasing knowledge base much of which is gained after the construction authorization. In fact, the 1990 report, "Rethinking High-Level Waste," by the National Academy of Sciences stressed that it is unrealistic to assume that all information can be available before constructing a repository. The Program Approach represents a fundamental change in the site characterization approach. Whereas the Site Characterization Plan described a program that attempted to provide answers for all possible questions related to the site, the Program Approach recognizes that the resources required to carry out such a program have not been and are unlikely to be available. The Program Approach is consistent with the original intent of the legislative and regulatory framework, as well as recommendations of the National Academy of Sciences.

Under the Program Approach, the site characterization program initially will focus on those tests and analyses most critical to suitability evaluation and licensing issues. If the site appears to be suitable, the focus of the Program Approach will shift emphasis to acquiring the additional site characterization data and developing the analyses needed to submit an application to the Nuclear Regulatory Commission for a Construction Authorization. These data and analyses will seek to provide confidence in the safety of repository operations and waste package containment. The data and analyses needed to support compliance with requirements related to longer-term radionuclide release and transport will likely be of a probabilistic nature, conservative, and flexible enough to accommodate many possible site conditions. Additional confidence in the certainty of these data and the demonstration of the long-term performance of the site will be achieved through the performance confirmation program. The repository will be designed to permit waste retrieval for up to 100 years from the start of waste emplacement, twice as long as the 50-year retrieval period required by the Nuclear Regulatory Commission.

The D.O.E. must develop those necessary data and analyses to enable the Nuclear Regulatory Commission to make findings with reasonable assurance with regard to the performance of the site. This process is manifested by a maturing understanding of the performance of the natural and engineered components of the system as well as the system's sensitivities to the performance of its individual components. Iterative performance assessments will serve to drive and document the maturation of this understanding.

WASTE PACKAGE DESIGN

Waste Package/Engineered Barrier (WP/EB) system design options are being developed and evaluated for applicability to the component design, performance, and MGDS design requirements. The EB Segment is comprised of the emplaced WPs and any other engineered devices or material required to provide waste isolation. Several different concepts for WP/EB packaging were considered for evaluation: Multi-Purpose Canister (MPC) and Disposal Container, Uncanistered Spent Nuclear Fuel (SNF) WP, and defense high level WP. These were subjected to parametric evaluations which included thermal response of the WP and repository with respect to a number of variables such as: age of SNF, burnup, initial U-235 enrichment, repository thermal mass loading and Area Power Density (APD), drift spacing, WP spacing, properties of the WP and repository material, and SNF receipt rate. Included in the evaluations was the attempt at understanding the long term criticality behavior, which investigated different initial enrichments and configurations, and ultimately contributed heavily to the understanding of long term disposal requirements.

Of the different options available, the MPC concept has received the most attention for immediate development and implementation. This concept has refined the method of packaging the waste for transportation and disposal. The MPC is currently undergoing design and fabrication, which will allow SNF to be packaged at the source location and handled using various overpacks for transportation and disposal. (See Fig. 1). This concept greatly affects design and operations for transportation, interim storage, surface repository facilities, and ultimate underground disposal. As structured, this "cradle-to-grave" strategy reduces the necessity for extensive hot cell facilities at the repository surface location, since the packages will not have to be opened at the site before disposal

Several different WP capacities have been evaluated, but recent interest has centered on the large multibarrier WPs with capacities up to 21 Pressurized Water Reactor (PWR) assemblies or 40 Boiling Water Reactor (BWR) assemblies. PWR assemblies are considered limiting because of their higher decay heat output compared to BWR assemblies. Higher capacity WPs are more likely to exceed thermal goals than smaller ones in the same repository thermal environment. The choice of design-basis fuel is important because it will directly limit the number assemblies that can be loaded into a WP or MPC and still meet thermal goals; the limiting thermal goal for large WPs is 350 degrees C at the SNF cladding. For the MPC conceptual, design-basis fuel characteristics of 10 years aged with 40 GWd/MTU burnup, the 21 PWR capacity is considered at or above the maximum allowable temperature for a metallic multibarrier WP such as the MPC with disposal container. All these factors affect the timing of peak temperatures as well as the magnitude. Host rock temperatures will peak between 20 and 500 years depending on the thermal loading, but is largely independent of the individual WP design. The WP will experience its peak temperature between initial emplacement and the repository peak depending on the design-basis fuel and the basket/container design. For the large WP, higher conductivity SNF baskets will lower and delay the peak temperatures experienced. The choice of the design-basis fuel is of key importance to the timing of peak temperatures. Younger fuel types produce high peak temperatures within the first few years, but then temperatures drop off quickly. Older fuel (at the same APD) produces lower temperatures and later peaks with more stable and higher long-term temperatures.

REPOSITORY DESIGN

Repository design on the Yucca Mountain project is made up of two primary components, surface and subsurface, and is currently in the Advanced Conceptual Design (ACD) phase. This phase will define major program elements which are necessary for integration with the ESF, testing, MPC development, transportation and environmental concerns. Significant concepts will be established for future development and design definition in the License Application Design (LAD) and Final Procurement and Construction Design (FPCD). The various phases of design are

scheduled to coincide with major program milestones as indicated on Table I. Information from products developed during these design phases will be used to support High Level Findings (HLF), Technical Site Suitability (TSS), the Environmental Impact Statement (EIS), and License Application (LA). An appropriate amount of information that is necessary to define systems, subsystems and components is scheduled for completion prior to each of the major milestones.

Surface repository facilities consist of two major areas: the general support facilities area, and the more closely controlled and secure geologic repository operations area (Fig. 2). The general support facilities area will provide normal service functions such as offices, warehousing, maintenance shops, utilities substations, and miscellaneous installations. These will be of normal commercial quality, and will not involve any nuclear related design or subsequent interface with nuclear materials.

The geologic repository operations area is adjacent to the general support facilities, and will be the center for receipt and handling of nuclear waste shipments. Conceptually, the area contains the following basic structures: performance confirmation building, waste handling building, waste treatment building, cold canister storage building, and possible lag storage area. As the program has developed, significant changes to the functional concept, size and location of these facilities have been made, due mostly to the incorporation of the MPC concept.

As an example, the Waste Handling Building (WHB) design is affected by factors involving waste forms, transportation mode, shipments, function, and operations. Current approaches have drastically reduced the amount of bare spent fuel to be handled at the site. Transportation has shifted from primarily truck transport to almost exclusively rail. The use of the MPC has reduced the number of casks scheduled to be received per year to about 25% of the previous estimate by increasing the number of assemblies contained in each container. Functionally, the effect of using MPCs minimizes the need for rod consolidation, making the resulting facility smaller, cleaner, less expensive, and safer.

The surface operations area dealing with receipt and handling of waste is immediately adjacent to the north ramp portal, thereby facilitating transfer of waste packages to the underground storage area. Underground accesses consist of two ramps and two shafts, with the ramps serving as main access for personnel and materials, and the shafts primarily serving ventilation needs. Ramps are designed to be less than three per cent grade from portal to the emplacement area, and are 7.62 meters in diameter. Each ramp is outfitted with concrete invert and double rail sets allowing efficient and safe handling of large heavy waste packages.

Conceptual layout of the subsurface emplacement area can be seen in Fig. 3. Main features include two primary areas that are crossed by parallel emplacement drifts which will be used for final disposal. The emplacement drifts will be excavated by tunnel boring machines (TBM) at approximately five meter diameter. The target horizon for the emplacement area is in the TSw2 formation comprised of low lithophysal welded tuff. Rock properties of the area are shown in Table II, and are anticipated to be consistent throughout the block. Most major structural features have been identified and marginally characterized from surface investigations. Remaining features will be delineated during the course of subsurface site characterization and construction, with specific interest being focused on the identification of major fault structures.

Subsurface repository layout has been affected to the greatest extent by physical limitations brought about by MPC size and weight, and the issue of thermal loading. With MPC weight approaching 125 tons (with emplacement overpack), previous concepts of vertical and horizontal borehole emplacement became impractical, and led to the concept of in-drift emplacement. Variations on this theme were considered (in- drift on center; in-drift off center; in-drift in alcove; etc.); however, the current schemes favor the in-drift on center concept. Emplacement is relatively fast and efficient, and waste packages can be left on rail cars or pedestals as shown in Fig. 4. Using this method, careful consideration must be given to drift size. Heat generated by the waste package is dissipated through the wall rock which acts as a heat sink. However, if too closely confined, the rocks efficiency to dissipate heat is maximized, and ultimately may reflect heat back toward the package. As a requirement, the core temperature of the package must not exceed 350 degrees C, resulting in the need for an accurately engineered near field environment. This

constraint, coupled with the large size and weight of the waste package, effectively eliminated consideration for borehole emplacement and small confined openings. Another significant driver of subsurface design is the issue of thermal management. As mentioned before, limits exist on temperatures both within the waste package and in the surrounding rock. Some of the physical parameters that affect both near field and total system thermal profiles include: fuel age, burnup, number of assemblies per MPC, waste package spacing, drift spacing, and drift size. It can be readily understood that while package spacing may be altered, drift spacing cannot. Further, the optimum drift spacing for thermal loading is not consistent across multiple scenarios, thereby eliminating the flexibility of alternate drift emplacement. Other means of thermal management may be employed in the use of ventilation, aging of the waste, and rearranging the emplacement spacing after a certain period of time in the pre-closure period. These management tools are currently under investigation as to their effectiveness in achieving uniform thermal loading.
Current strategies for thermal loading are focusing on a "minimal disturbance" scenario which means that thermal loads are low enough not to cause any temperature induced changes to the rock and hydrologic ambient conditions. This would result in loading at the rate of approximately 25 MTU (Metric Ton Units) per acre. As such, the defined repository emplacement area that is currently targeted for site characterization would only be able to accommodate about 27,000 tonnes of the total inventory. This would trigger the need for characterization of additional area for repository expansion. Another alternative is under investigation to apply for initial license to construct based upon the maximum known thermal loading limit to date. After confirmation testing is completed in actual underground environment, the license application may be updated to increase the loading limit based on new confirmed data, resulting in an increased capacity for the repository, and decreasing the need for expansion area. With this in mind, it is conceivable that underground emplacement designs may be altered up until the final application for license to operate is submitted.

NEW PUBLIC HEALTH AND SAFETY STANDARDS FOR YUCCA MOUNTAIN AND THEIR IMPACT ON THE CARBON-14 ISSUE
Steven P. Nesbit
Duke Engineering and Services, Inc.
Stephan J. Brocoum
United States Department of Energy
ABSTRACT
Preliminary performance analyses of a geologic repository in the unsaturated zone have indicated that carbon-14 releases and release rates may exceed limits set by the Environmental Protection Agency (EPA); however, those releases appear to pose negligible health risks to individuals in the vicinity of the repository. The carbon-14 issue is discussed in the light of the Energy Policy Act of 1992 and the associated study by the National Academy of Sciences (NAS) on health-based standards for a repository at Yucca Mountain. First, the technical and regulatory background of the carbon-14 issue is summarized. The health risks posed by carbon-14 released from a potential high-level waste repository at Yucca Mountain are discussed, along with the rationale for the cumulative release limits in the EPA's regulation 40 CFR Part 191. Second, the ongoing process to develop health-based standards for a repository at Yucca Mountain is reviewed, including the roles of the NAS Committee on Technical Bases for Yucca Mountain Standards, the EPA, and the various affected organizations. Third, the recommendations by four specific organizations - the Department of Energy (DOE), the EPA, the Nuclear Regulatory Commission (NRC), and the Electric Power Research Institute (EPRI) - to the NAS committee are examined. The potential impacts of those recommendations, if adopted, on meeting regulatory limits related to carbon-14 releases are evaluated. The DOE and EPRI recommendations are different, but either, if implemented, would address the compliance concerns associated with carbon-14 releases. The recommendations from the NRC and the EPA input are less specific in nature than the input from the DOE and EPRI, so the implications with respect to carbon-14 are not as straightforward. The NRC notes

that releases of carbon-14 pose a problem in complying with 40 CFR Part 191, and states a preference for a health-based regulation, as opposed to one based on technical achievability. The EPA appears to favor following the current precedent of 40 CFR Part 191; that "status quo" approach would not address carbon-14 related concerns.

BACKGROUND

The ability for a geologic repository in the unsaturated zone to comply with the carbon-14 release limits has been a controversial issue for many years. Pflum (1), Park (2), and others have pointed out the potential high costs and negligible health benefits of complying with the EPA regulations on the carbon-14 radioisotope. The ongoing process to develop health-based environmental standards for a geologic repository at Yucca Mountain has focused renewed attention in this area.

In 1985 the EPA promulgated 40 CFR Part 191, Environmental Standards for the Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Radioactive Wastes (3). At that time the regulation applied to all United States geologic repositories for high-level nuclear waste. The EPA regulation established cumulative isotopic release limits into the accessible environment for 10,000 years after permanent closure of a repository. The limits were based on the number of curies released from a hypothetical 100,000 metric ton heavy metal (MTHM) repository that would correspond to 1,000 premature cancer deaths in 10,000 years, or 0.1 fatality per year. The EPA justified the limits being achievable by comparing this level of health effects to simplified performance assessments of several hypothetical geologic repositories in different geologic media. The EPA also analyzed the health risks from the amount of unmined uranium ore that would be required to produce 100,000 MTHM of reactor fuel. The unmined uranium ore analysis indicated between 10 and 100,000 premature cancer deaths over the 10,000 year period of regulatory concern.

In 1987, the U. S. Court of Appeals for the First Circuit responded to challenges to 40 CFR Part 191 by vacating and remanding the regulation. Later that year, the court restored administrative and preclosure portions of the regulation on appeal. In 1992 the Congress of the United States, through the Waste Isolation Pilot Plant (WIPP) Land Withdrawal Act (LWA) of 1992 (4), reinstated the postclosure cumulative isotopic release limits of the remanded regulation. The WIPP LWA also stipulated that the EPA would repromulgate the remaining portions of the regulation, those related to individual and groundwater protection, within a year. Finally, the WIPP LWA specified that 40 CFR Part 191 would not apply to repositories being characterized under the Nuclear Waste Policy Act, i.e., Yucca Mountain. In 1993 the EPA repromulgated the remaining parts of 40 CFR Part 191. The resultant 1993 version of 40 CFR Part 191 retains the cumulative release limits from the 1985 version; however, the 1993 regulation specifically does not apply to a potential geologic repository at Yucca Mountain. The Energy Policy Act of 1992 (5) directed the EPA to promulgate environmental standards specifically for Yucca Mountain, based on the recommendations from a National Academy of Sciences (NAS) study.

As previously noted, the cumulative release limits in the 1985 and 1993 versions of 40 CFR Part 191 are based on analyses performed by the EPA on a set of hypothetical repositories and equivalent uranium ore bodies. Klett (6), Duguid (7), and others have pointed out that the EPA analyses, and the resulting isotopic release limits, were significantly affected by the simplified EPA model and its assumptions. The EPA assumed repositories and ore bodies located in the saturated zone, discharging to a large, diluting river near the site; all releases were aqueous in nature. By contrast, the potential repository at Yucca Mountain is located in the unsaturated zone, far from any diluting surface water; gaseous releases must be expected from such a site. Therefore, the link between the 40 CFR Part 191 cumulative release limits and health effects for a Yucca Mountain repository are tenuous at best. While the current version of 40 CFR Part 191 does not apply to Yucca Mountain, William Gunter of the EPA indicated at the December 16-17, 1993 meeting of the NAS Committee on Technical Bases for Yucca Mountain Standards that the EPA would like to make the Yucca Mountain standards as consistent as possible with that regulation. Therefore, it is prudent to consider the 40 CFR Part 191 cumulative release limits as potential requirements for Yucca Mountain.

40 CFR Part 191, Appendix A, prescribes a cumulative 10,000 year release limit of 100 curies of carbon-14 per 1,000 MTHM in the repository, assuming that no other radionuclides are released. For a 70,000 MTHM repository, that corresponds to an

average yearly release of 0.7 curie. Compliance with the carbon-14 cumulative release limit is not unduly difficult for a repository located in a favorable saturated zone environment; once radioactive carbon, in the form of carbon-14, is released from the waste package, it is dissolved in the groundwater, and significant releases to the accessible environment do not occur. However, a repository located in the unsaturated zone (like Yucca Mountain) offers faster pathways for gaseous releases of carbon-14, and compliance with the EPA limit is not assured. A 1993 total system performance assessment of the potential Yucca Mountain repository indicates that the total normalized release (based on all radioisotopes) may exceed the EPA limit, and that virtually all of the normalized release is attributed to carbon-14 (8). Compliance with the cumulative release limit at an unsaturated site like Yucca Mountain will require exceptional long-term performance from virtually all waste packages in the repository; demonstrating such performance would be very expensive and may not be practical (9).

While it may be challenging for a repository in the unsaturated zone to comply with the cumulative EPA release limits due to the gaseous release pathway for carbon-14, it is not at all clear that a failure to comply with the limits would translate to any significant health risk to future populations. In contrast to the average yearly release of 0.7 curie allowed for a 70,000 MTHM repository, the annual releases from a typical nuclear power plant and a typical reprocessing plant are approximately 10 curies and 850 curies, respectively (9). If the entire repository inventory of carbon-14 were released in one year (an extremely conservative assumption) the inhalation dose to an average members of the global population is estimated to be less than 0.0003 mSv/yr (0.03 mrem/yr). In that same scenario, a maximally exposed individual near the repository would receive less than 0.005 mSv (0.5 mrem). In contrast, the average individual dose due to only the carbon-14 constituent of natural background is estimated to be 0.013 mSv/yr (1.3 mrem/yr), out of a total United States average background dose of 3.6 mSv/yr (360 mrem/yr), including the dose from radon (10). The National Council on Radiation Protection and Measurements has recommended a Negligible Individual Risk Level that corresponds to an annual effective dose equivalent of 0.01 mSv (1 mrem) (11).

Due to gaseous releases of carbon-14 it is difficult for a repository located in the unsaturated zone to comply with the cumulative EPA release limits in 40 CFR Part 191. However, gaseous carbon-14 releases well in excess of those limits would lead to very small doses to the public. Postulating health effects from carbon-14 releases can only be done by integrating very small doses (typically considered negligible) over very large numbers of people and over very long periods of time. The 40 CFR Part 191 cumulative release limits for carbon-14 should not preclude the use of otherwise attractive waste disposal sites in the unsaturated zone.

DEVELOPMENT OF HEALTH-BASED STANDARDS FOR YUCCA MOUNTAIN

As noted earlier, pursuant to the Energy Policy Act of 1992 the NAS is conducting a study to provide findings and recommendations on reasonable standards for protection of the public health and safety from the radiological hazards associated with a geologic repository at Yucca Mountain. The 1992 law also directed the EPA, based on the recommendations of the NAS, to promulgate public health and safety standards for protection of the public from releases from radioactive materials stored or disposed of in the repository at the Yucca Mountain site. Furthermore, the NRC was directed to modify its requirements to be consistent with the EPA standards.

It is apparent that the U. S. Congress did not intend for the EPA to reinstate a slightly modified version of 40 CFR Part 191 for use at Yucca Mountain. If that had been the congressional intent, then there would have been no need for separate pieces of legislation (WIPP LWA and Energy Policy Act) addressing repository standards. The carbon-14 issue was one of the concerns that prompted the Congress to initiate the NAS study and to direct the EPA to issue a dose-based standard, consistent with the recommendations of the NAS.

The NAS formed the Committee on Technical Bases for Yucca Mountain Standards to prepare its recommendations to the EPA. The committee held a series of public meetings between May of 1993 and April of 1994. A number of interested and affected organizations made recommendations to the NAS pertaining to standards for a geologic repository at Yucca Mountain. The NAS committee is expected to issue its report, containing recommendations to the EPA, during the first half of 1995.

SPECIFIC RECOMMENDATIONS

The recommendations of four organizations, the DOE, the EPA, the NRC, and EPRI, to

the NAS are considered below, in the context of how those recommendations would, if implemented, address the concern that carbon-14 releases are regulated at an unreasonably low level.

U. S. Department of Energy

The DOE submitted six specific recommendations pertaining to a standard for the potential repository at Yucca Mountain (12). Of those six, the following three are particularly pertinent to the carbon-14 issue.

1. The standard should be health-based.

2. The standard should focus on protecting those people who will be living in the vicinity of the potential repository.

6. A standard expressed in terms of individual dose would be appropriate, provided that certain aspects are clearly specified in a regulation or associated guidance. Those aspects are:

a. The individual dose limit should be commensurate with current dose limits for individual members of the public as specified in 10 CFR Part 20, and with recommendations of national and international advisory groups.

b. The dose limit should be applied to an average individual in the population living in the vicinity of Yucca Mountain.

c. Assumptions related to the future biosphere should be specified. These should include a water use scenario for the average individual which is based on the current practices of people living in the Amargosa Valley.

The DOE recommendations, if implemented, would address the concern that carbon-14 release limits are overly stringent, without providing commensurate benefits to the health and safety of the public. Yucca Mountain standards would not include cumulative radioisotope release limits that attempt to provide some arbitrary level of protection to the entire population of the world for the next 10,000 years. The current overly stringent carbon-14 release limits (as well as all of the other release limits) in 40 CFR Part 191 would be removed. However, the DOE would have to demonstrate a sufficiently low probability of significant adverse health effects from carbon-14 (or any other radioisotope) on the people who might be living near the repository. One means of doing so might be demonstrating compliance with a dose standard that is commensurate with other present-day radiation protection limits. Most studies have indicated that carbon-14 doses to individuals near a repository located in the unsaturated zone would be negligible compared to such limits.

The DOE recommendations are based on the fact that Yucca Mountain is a non-diluting site, located far from any significant bodies of surface or ground water. Gaseous releases provide the only reasonable pathway for dispersion of radionuclides to the world population, and bounding calculations indicate that the doses that would result from carbon-14, the major gaseous radioisotope, would be negligible.

U. S. Environmental Protection Agency

The EPA did not provide specific recommendations to the NAS committee. This is understandable, since the Energy Policy Act requires the NAS to provide its recommendations to the EPA, not vice versa. However, the EPA did provide the NAS with the EPA views on the context within which the NAS advice will be used (13). Two points that are pertinent to the carbon-14 issue are discussed below.

The EPA restated its concern that a standard for Yucca Mountain must deal with the precedent set by 40 CFR Part 191, the general standard for geologic repositories. The EPA maintains that if it sets standards for Yucca Mountain that are different from the existing 40 CFR Part 191 standards, they will be legally required to explain the difference.

The EPA also expressed the opinion that having only an individual dose standard is not sufficiently protective and cannot replace the need for other requirements. One of their concerns is that an individual dose standard could encourage dilution by failing to cap total releases.

The implication of these points is that the EPA would like to retain the 40 CFR Part 191 release limits in a standard for Yucca Mountain. This would remove the need for them to defend the differences between a Yucca Mountain standard and the general standard for repositories.

While the "status quo" approach that is apparently preferred by the EPA may be the easiest for them to implement, it does not address the concern that carbon-14 limits might disqualify an otherwise suitable repository site, or significantly increase the cost of compliance with no commensurate public health benefit.

U. S. Nuclear Regulatory Commission

The NRC did not provide the NAS committee with specific recommendations on Yucca Mountain standards, but it did provide its staff views on environmental standards for the disposal of high-level waste (14). The NRC first discussed the "Societal Pledge to Future Generations," a philosophy that this generation should do what is necessary to ensure an adequate level of radiation protection for those in the future. Then the NRC discussed seven major issues, three of which pertain to the carbon-14 issue.

First, in the area of health-based versus technology-based standards, the NRC specifically cited the failure to recognize the potential for gaseous release of carbon-14 from an unsaturated zone repository as one of the problems with technology-based standards like 40 CFR Part 191. The staff recommended that more emphasis be placed on health-based reasoning in the development of high-level waste standards.

In addition, in the area of individual versus population protection, the NRC noted that the EPA's decision to use cumulative release limits based on the impacts to the entire world population was "... EPA's most significant departure from the traditional concepts of radiation protection, from the recommendations of advisory groups like the International Commission on Radiological Protection, and from the practices of other nations." The NRC further noted that "There are strong arguments in favor of an individual protection standard, either as a supplement to EPA's cumulative release limits, or as a replacement for those release limits."

Finally, in the area of fundamental versus derived standards, the NRC noted advantages in a standard expressed in terms of a derived quantity, such as the cumulative release limits in 40 CFR Part 191. However, the NRC also observed that the EPA's 1985 cumulative release limits "... were controversial, at least in part, because the release limits were derived using a 'world-average' biosphere that bore little resemblance to the biosphere likely to exist near Yucca Mountain."

The NRC made no recommendations to the NAS on the specific characteristics of a standard for Yucca Mountain. However, their views noted some of the problems with 40 CFR Part 191, and the carbon-14 issue was specifically cited as one of those problems. The NRC expressed a preference for health-based standards over a technology-based approach. It was clearly implied that the NRC is not satisfied with the way that 40 CFR Part 191 treats potential health impacts from carbon-14 at a potential Yucca Mountain repository.

Electric Power Research Institute

EPRI provided the most detailed recommendations of any individual or organization that provided written input to the NAS committee. EPRI proposed a two part standard, with each part pertaining to a specific time period in the lifetime of the repository. A strict, quantitative release limit would be applied for approximately 1,000 years after emplacement. For the time period after 1,000 years, the standard would be a design objective that the health risks from the repository do not constitute a significant incremental addition to other sources of health risk with which future average individuals in a local population group will have to contend. Probabilistic analyses would be used to assess performance with the second part of the standard, which would be treated as a guideline, not a strict licensing requirement. In addition to their detailed recommendations, EPRI provided a report containing supporting analyses and discussions of important issues (15).

Section 4.2.1 of the EPRI report discusses release versus dose criteria. EPRI states "Release-based standards are appropriate during a time scale for which there is a very low probability that radionuclides will even enter the biosphere, let alone provide much of an opportunity for individual dose accumulation. This time scale at Yucca Mountain is the first few hundreds to perhaps thousands of years after loading of the repository." EPRI supports a strict release standard during that time frame "... when the health risk is already vanishingly small ..." because it "... provides an additional factor of safety." For longer time periods, EPRI favors dose minimization over release minimization.

The EPRI recommendations, if implemented would effectively address the carbon-14 concern. The EPRI proposal would apply strict release limits on all radioisotopes (including carbon-14) during the first approximately 1,000 years after waste emplacement in a repository. However, that time frame is short enough so that it should be feasible to rely on robust waste packages to preclude significant releases to the environment. After 1,000 years, carbon-14 releases would be a concern only to the extent that they contribute to projected doses to individuals in the local

population near a repository. Since most analyses indicate that carbon-14 is not a significant contributor to the dose (or health risk) to nearby inhabitants at any time following emplacement, the carbon-14 issue would not pose significant limitations on a Yucca Mountain repository.

SUMMARY

40 CFR Part 191, the current environmental standard applicable to geologic repositories other than Yucca Mountain, imposes a release limit on the radioisotope carbon-14 for a period of 10,000 years following permanent closure of the repository. A repository located in the unsaturated zone, like Yucca Mountain, may have great difficulty meeting the carbon-14 release limit. However, the consequences from exceeding the repository carbon-14 release limit have been shown to be exceedingly small. Current activities such as operating nuclear power plants or fuel reprocessing plants expose the world population to much greater amounts of carbon-14 than are anticipated to be released from a Yucca Mountain repository.

A number of organizations and individuals provided input to the NAS Committee on Technical Bases for Yucca Mountain Standards. The recommendations from four organizations - the DOE, the EPA, the NRC, and EPRI - were considered, in the context of how those recommendations would, if implemented, address the concern that carbon-14 releases are regulated at an unreasonably low level. The EPA and the NRC did not make specific recommendations to the NAS. The input from the EPA indicated that they would prefer to apply the existing general environmental standard for repositories (40 CFR Part 191) to Yucca Mountain - an action that would not address the carbon-14 concern. The NRC expressed some dissatisfaction with the application of 40 CFR Part 191 to Yucca Mountain, specifically citing the carbon-14 issue as one of the problems with that regulation. The DOE recommended that standards for Yucca Mountain should focus on the health risk to individuals in the vicinity of the repository. If implemented, this approach would effectively address the carbon-14 concern. EPRI recommended a two-part standard for Yucca Mountain, with strict release limits for approximately 1,000 years, followed by a probabilistic design objective, based on individual risk, thereafter. Since it is anticipated that demonstrating compliance with the release limits for the first 1,000 years should be feasible, the EPRI recommendations would also address the carbon-14 concern.

ABSTRACT

Gaseous 14CO2 originating from buried Low-Level Radioactive Wastes (LLRW) in a near-surface disposal site are released to the environment via two major paths: gas-phase diffusion through soils to the atmosphere, and dissolution in groundwater, followed by aqueous migration. Aqueous migration is the path giving a higher dose to an individual, especially if C-14 is converted to an organic form and ingested. Gaseous diffusion would give a lower dose, largely because of atmospheric dispersion and dilution.

The objective if this study was to develop the capability to estimate which of the two paths will likely be dominant for typical near-surface disposal facilities. The mass transfer coefficient (KL) of 14CO2 to groundwaters was determined experimentally using a large sand box. The KL thus determined was approximately 10 to 20 times smaller than for an open liquid surface, thus creating a potential resistance to mass transfer. The value obtained was incorporated into a simple model of CO2 transport around a typical near-surface disposal site. The model suggests that CO2 transport via both gaseous release and aqueous migration paths are of similar magnitude for a repository located ~2 m above the water table.

INTRODUCTION

Most of the Carbon-14 present in near-surface Low-Level Radioactive Waste (LLRW) repositories is expected to be as carbonate and released as 14CO2 (1,2). The latter is displaced by CO2 from microbial degradation of the wastes and volatilization. Carbon dioxide can escape the repository via two main pathways: gas-phase migration through soil and into the air, and aqueous transport, which involves the dissolution of 14CO2 and its mass transfer to groundwater. Conservative assumptions are applied for dose assessment where the total inventory is assumed to enter both the gaseous and aqueous pathways. Using that approach, a significantly lower dose would be expected from gas-phase diffusion (dose mostly due to inhalation) as opposed to the aqueous migration (dose caused by ingestion). A more realistic estimate can be generated if the split between the two pathways is quantified.

Gaseous migration of CO2 is the dominant transport mechanism in the vadose zone because of the high gas diffusivity (3). In a humid climate, however, aqueous transport may be important if the 14CO2 source is located near the water table. The capillary fringe, located above the water table, may create a resistance to mass transfer to the groundwater (4,5), thus possibly favouring gas-phase migration. Conventional gas-liquid exchange with an open liquid surface applies to some extent, but specific values must be obtained experimentally in soils because the process is complex due to the capillary fringe acting as an interface.

The primary objective of the work reported here is to determine which path, gaseous migration or liquid-phase migration, is dominant for CO2 release from a typical near-surface disposal site. A secondary objective was to determine experimentally the mass-transfer rate of CO2 to groundwater using a large sand box, as this parameter is currently unknown and is needed to make C-14 transport calculations.

In an earlier study (4), the mass transfer rate to groundwater was determined using bench-scale sand columns. In the columns, the porewater was static and there was no fluctuations in the position of the capillary fringe. Subsequently, the experiment was scaled up using a large sand box with a moving aquifer. We are reporting preliminary results from this experiment. We have also incorporated scoping calculations of carbon-14 transport around a near-surface repository as an example. The example is applicable to AECL's proposed IRUS (Intrusion-Resistant Underground Structure) waste disposal vault (6). The facility features an impermeable roof and walls, with an engineered open bottom to allow drainage of any water that may enter the vault by infiltration (Fig. 1). The open bottom also allows gas release. The vault will be located below the ground surface in unconsolidated material (sand), and the foundation will be approximately 2 m above the average level of the water table. Although the calculations performed here are specific to IRUS, equivalent calculations can be performed for any near-surface storage or disposal facility.

EXPERIMENTAL

Description

A steel box (3.6m long 2m wide 1m high) was used to determine the mass transfer coefficient of CO2 to a moving aquifer (Fig. 2). The box was filled with sand to approximately 0.8 m. Probe sets consisting of pre-cleaned porous ceramic samplers [4] were placed in the sand along the length of the box to sample the vertical profile of dissolved inorganic carbon (DIC). In addition, plastic probes were installed on the sand surface and 15 cm below the surface to monitor the gas composition. An adjustable water inlet and outlet allowed the establishment of a saturated zone which controlled hydraulic gradients and flow rates. A 100 L plastic tank equipped with a float valve served as a source of water to the box. The tank was sparged with CO2-free N2 gas to minimize and maintain a constant background DIC.

A gas mixture of fixed composition (10% CO2 and 10% O2 in N2) was fed under a polyethylene sheet which was placed and sealed above the sand surface.

Sampling and Analysis

A plastic line was connected to a peristaltic pump from each ceramic cup sampler. One dead volume of solution was slowly withdrawn from each probe and discarded, and a 1-mL water sample was collected and analyzed immediately for pH and DIC. The DIC was measured with a Dohrman DC-80 carbon analyzer. Only a few probes were pumped at one time to preserve the vertical profile of the aquifer, and to optimize analysis time with the instrument. The DIC concentrations were monitored at the inlet and the outlet of the box at each sampling episode.

TREATMENT OF THE EXPERIMENTAL RESULTS

A fitting routine to model the DIC vertical profile is very complex because the vertical groundwater velocity is not constant throughout the aquifer, especially in the tension-saturated region. A complete solution will be published at a later date.

An alternate approach is to calculate a mass-transfer coefficient KL (in metre/annum, or m/a) using a mass balance approach. The basic equation of mass transfer through a gas-liquid interface is given by (7):

Eq. 1

where FGW is the direct mass transfer flux of gaseous CO2 to groundwater through the capillary fringe (mole/time), Cg and Cl are the CO2 concentrations (mole/volume) in the gas phase and the liquid phase, respectively, Hc is the pH-dependent Henry's law coefficient (dimensionless; (4)), and AR is the diffusional area under the repository (m2). The value of FGW can be obtained independently using the difference in the total DIC mass in the box at two time periods, plus the total mass that has left the box through the outlet in the same time period. This amount has to be equal to the influx to balance the mass passing through the system. The other parameters in Eq. (1) are known, thus KL can be calculated (Table I). Note that Hc was calculated for pH 6.1 and 6.4, representing the two extremes observed near the diffusion interface, at the top of the capillary fringe. This is strictly an interface condition and it does not have any chemical significance. If KL is a measure of mass conductance across the capillary fringe, then its reciprocal is analoguous to resistance. A dimensionless resistance factor Rf is defined here for convenience:

Eq. (2)

where KL (open surface) 20. This value is smaller than the Rf of ~20-50 obtained for columns (4), but larger than for an open water surface (Rf = 1). This

difference is attributed to the moving aquifer.

TRANSPORT OF 14CO2 AROUND THE REPOSITORY

The information needed to calculate the fate of 14CO2 around the repository is readily available from the literature except for KL, which was obtained in this experiment. The approach presented here constitutes a preliminary estimate of the relative contributions of different transport mechanisms.

Gases expected to be produced in a LLRW vault are CO2, CH4 and H2. We will simplify gas generation by assuming that only CO2 is produced from degradation of organic material. Methane production can be neglected because its assimilation rate is high in dry environments (8,9), such as expected in the vault. We also assume that CO2 gas is unreactive with the soil components. There is a small retardation factor for gaseous CO2 in wet soils (10), but this is unimportant since the source of CO2 is constant.

The transport model is based on a steady-state flux of CO2 generated in the vault (ST; Figure 1), equal to the flux released to the atmosphere (FA) and the total flux to groundwater, FGW and FWO, for the direct mass transfer to groundwater and the flux of CO2 equilibrating with the infiltrating water, respectively (in moles/a):

See Eq. (3)

FA can also be represented as:

See Eq. (4)

where FGD is the flux of CO2 (moles/a) due to gas diffusion in the unsaturated soil. A term for advection caused by gas generation is assumed to be negligible as CO2 accounts for most of the gas produced. Each one of these fluxes can be expressed with simple equations:

Eq. (5)

Eq. (6)

Eq. (7)

The definition and the values for most of these terms are given in Table II. Equation (1) is the flux to groundwater for which KL was determined using the sand box. The term Hc is used here assuming a groundwater pH of 6. Equation (5) is analoguous to Fick's Law, using the gradient between the concentration at the bottom of the vault (Cg) and the air above ground (Ca). To simplify the calculations, we have assumed that the lateral diffusion area under the vault AD (that is 2 m above the top of the capillary fringe and the vault foundation the total length of the four walls) is also equal to the diffusional area from the vault to the surface. In other words, CO2 will diffuse out to the atmosphere via the shortest path through a "chimney" made of unsaturated sand. The term Dg is the gas diffusion coefficient of CO2 in soils corrected for tortuosity (11). In Eq. (6), the washout term, Vc is the volume of the dispersion "chimney", and (I/nl L-1) constitutes the fraction of the infiltrating water reaching the aquifer per annum. The term CT is the DIC upper limit in the pore water, equal to:

Eq. (8)

In this situation again, the pH of the infiltrating water is assumed to be 6, giving the same value for Hc as above.

We have assumed that Cg in the soil volume below the repository is constant, because the distance from the bottom of the repository to the water table is short. By combining Eqs. (1) and (3-7), the variable Cg can be determined manually on a spreadsheet. Using a KL value of 4.1 (Rf = 10), the CO2 gas released from the vault would travel via gas phase diffusion and aqueous migration in a relative proportion of 35-65%, respectively (Table II).

DISCUSSION

The influence of the capillary fringe as a barrier to diffusion is an important component of the model. The KL value used corresponding to Rf = 10 still allows for a large amount of CO2 to transfer to groundwater. A relatively small change in KL leads to a fairly large change in the flux to groundwater because of the large diffusion area under the repository.

The lateral area under the repository is the principal restriction for gaseous transport. It was assumed that diffusion towards the surface was in one direction and the cross-section of the soil "chimney" was the same as the lateral area under the vault. This is somewhat restrictive as diffusion takes place in a 3-dimensional pattern, and CO2 has the tendency to settle due to its molecular weight. This limitation suggests that the current calculation underpredicts gas diffusion. On the other hand, unrestricted diffusion in soil would probably give a higher figure

for gas-phase migration but this, along with CO2 layering, would imply a larger contact area with groundwater, thus increasing CO2 transfer to groundwater. The overall result of these competing effects is not clear. Increasing the distance between the repository bottom and the water table would allow a higher proportion of gas to diffuse to the atmosphere. The use of drain pipes or channels instead of an open-bottom configuration would have a similar effect due to a smaller contact area with groundwater. More detailed calculations would be needed to obtain a better estimate of these fluxes.

The washout flux from groundwater infiltration has a small impact relative to either of the other two fluxes. This parameter is not very sensitive, as also noted elsewhere (11). In practice, this term may be neglected.

This approach for determining the major CO2 path around the repository is essentially independent of the CO2 production rate, ST, and its concentration below the vault, Cg. A 10-fold increase in ST does not appreciably change the relative proportion of FA and FGW. Other estimated parameters such as Dg, etc., (Table II) could vary by a factor of 2-3, but in our example, one would not be able to clearly demonstrate the dominance of one path over the other. Consequently, for the purpose of performance assessment calculations, the full 14CO2 inventory may have to be considered for both pathways (gas-phase diffusion, liquid phase migration) in the situation of a near-surface site, located near the water table.

Finally, the approach given here is generic. The capillary fringe provides a physical barrier, and the findings of this study should be applicable to other volatile unreactive contaminants. Only H (Henry's law coefficient) needs to be known to apply this approach.

CONCLUSIONS

The mass transfer coefficient obtained experimentally for the transport of CO2 across the capillary fringe gave a value of 1.9 to 3.2 m/a, which is approximately 10-20 times smaller than for an open water surface.

This mass transfer coefficient was incorporated into a scoping model for CO2 transport around a near-surface repository. Our calculations indicate that the gaseous and the aqueous paths for 14CO2 release from a repository are of similar magnitude. The calculations would have indicated a near-quantitative transfer to groundwater if the open-surface value of the mass transfer coefficient had been used. In our example, even in extreme but realistic cases, one would still expect a significant proportion of 14CO2 to transfer to groundwater.

The distance between the contaminant source and the groundwater is important. If the source is remote from the groundwater, then there is a gradient to the groundwater and lateral diffusion through soil is higher. Both these factors would favor gaseous migration.

This calculated result is nearly independent of the gas generation rate (i.e., source term) and the CO2 concentration in the repository. This approach is generic and it could be extended to other unreactive volatile contaminants.

ACKNOWLEDGEMENTS

Contribution from COG (CANDU* Owners Group) Working Party #49 is gratefully appreciated. The authors wish to thank R.W.D. Killey, J.H. Rowat, M.E. Stephens (AECL, Chalk River), and R. Dayal (Ontario Hydro Technologies) for their comments on this manuscript. We also thank R.W.D. Killey for the loan of the steel box, and the Chemical Engineering Branch, Chalk River, for providing us with a suitable location for the experiment.

RETENTION OF INORGANIC 14C IN SURFACE SOILS

S.C. Sheppard
W.G. Evenden
AECL Research
Pinawa, Manitoba
Canada, R0E 1L0

ABSTRACT
The 14C reaching the biosphere from deep disposal facilities is likely to be inorganic, and in many cases will be lost rapidly in the gas phase from surface soils. This is especially true when the surface soils are acidic. However, even in these soils, the potential exists for photosynthetic fixation of some of the 14C into relatively stable forms of soil organic matter. In non-acidic soils, there is also the potential for retention of the inorganic 14C, either sorbed or isotopically exchanged with indigenous carbonate minerals. Isotopic exchange could lead to the formation of relatively stable pools of inorganic 14C. In previous studies, the volatilization rate of 14C in soils was determined, and a stable fraction was observed. The present investigation was directed toward this stable 14C. Soils spiked with inorganic 14C were incubated up to 24 months in buried outdoor containers. Along with incubation time, we included treatments that allowed comparisons of the original soil with soil where carbonates or organic substrate were added, and where the microbial population was left unaltered or was decreased with gamma irradiation to 10 kGy. A range of analyses were performed, centered on a sequential extraction method designed to investigate isotopic exchange of 14C. The results indicate a small fraction of the 14C was incorporated into organic material, perhaps by non-photosynthetic autotrophs. Isotopic exchange appears to have progressed throughout the incubation times, and was likely not complete even after 24 months. Analyses are continuing.

INTRODUCTION
Carbon-14 is one of the most important radionuclides in used CANDU fuel. Sheppard et al. (1) describe the biosphere model developed to assess the impacts of geological disposal of 14C. In soil, 14C is largely regarded as a transient, and Ewing and Sheppard (2) and Sheppard et al. (3) report half-times ranging from minutes to 62 days. However, not all of the 14C may be transient, some may be retained in the pools of stable carbon (C) in the soil.
The objective of this study was to investigate the rate of incorporation of inorganic 14C into stable forms of soil C. In calcareous soils, mineral carbonates reside with half-times of up to millennia, depending on both soil and climatic conditions. In all soils, some amount of organic C resides, and the mean ages range from days for the labile, newly added materials, to centuries for the more recalcitrant fractions. There has been almost no research effort to measure the rate at which inorganic14C becomes incorporated into these pools of stable C in soils. Sheppard et al. (4) investigated the plant uptake of 14C from two soils, an acidic sand and a calcareous sand. Inorganic 14C was applied and the gaseous loss rate was almost identical for both soils. The half-time for gaseous loss was 17 d. The difference between the soils was that this rapid gaseous loss was operative on the

full inventory of 14C in the acid soil, but only on 98% of the inventory in the calcareous soil. The remaining 2% in the calcareous sand stayed in the soil, and contributed 14C to the plant tissues, over the two years of the field study. It is likely this 14C had undergone isotopic exchange with the native carbonate minerals. The present study investigates this process more fully.

METHODS AND MATERIALS

The key aspects of the methods are presented here, with more details given by Sheppard and Evenden (5). The experiment was a factorial design of three soil amendments and two levels of sterilization repeated over four incubation times. There were duplicates of every treatment. The soil amendments were none, calcium carbonate (laboratory grade at 10% by weight) and ground alfalfa (at 10% by volume). The sterilization treatments were none and irradiation (to 10 kGy with 60Co). The Gleyed Rego Black (Aquic Udic Calciboroll) soil was the same as the calcareous sand used by Sheppard et al. (4). The amended soils were spiked with inorganic 14C at 1000 Bq g-1 dry soil and placed in 1-L glass jars. The irradiated jars were sealed, and the unirradiated jars were open and covered with a mesh. All jars were buried 20-cm deep, upside down, outdoors for their respective incubation intervals. The jars were prepared and buried at six-month intervals so that incubation times were 6, 12, 18 and 24 months. Exhumation of all jars was at the same time, and they were stored frozen until extractions could be done.

On exhumation, the open jars were sealed. When each jar was processed, the first step was to obtain two samples of the headspace gas. One was used for gas chromatographic analysis and the other for 14C analysis. The 14C gas sample was collected in contact with NaOH, which trapped the 14C ready for analysis by liquid scintillation counting (LSC). After the jars were opened, samples of soil were collected aseptically for microbial assay by biological activity reaction tubes (BART). These confirmed that the microbial populations were still impeded by the irradiation treatment even at the end of the incubations.

The soils were extracted using a slow, sequentially sampled titration procedure. Under a CO2-depleted N2 gas stream, acid was added to a sample of soil and the offgas was trapped in NaOH. The rate of acid addition was adjusted so that the procedure took over two hours for the soil to change from pH > 7 to pH 1. The strategy was that the most labile inorganic soil C would be degassed first, and the most occluded carbonate minerals dissolved and degassed last. By measuring both 14C and 12C in the offgas, it was possible to determine how much of the soil inorganic 12C had undergone isotopic exchange with the applied 14C. After the acidification series was complete, the acid infusion was replaced with 30% peroxide, the NaOH trap was renewed, and the procedure repeated. A similar strategy was involved, with the idea that the more labile organics would be oxidized first and the most recalcitrant oxidized last, if at all.

Another set of extractions was done to investigate the organic C. Extractions were done with distilled water and NaOH, and with KCl with or without prior treatment with chloroform. The difference in the KCl extractions was a measure of the14C in microbial tissues. All the extracts were acidified below pH 2 to remove inorganic C, and a sample of the unacidified NaOH extract was also analyzed to measure humic acid 14C. All analyses were by LSC.

Analyses of total inorganic 14C on the soil solids followed the method of Sheppard and Schwartz (6). Analyses of total organic 14C in the soils was with a Packard Oxidizer. These methods of analysis were confirmed by independent methods, including thermal release of organic C at 500C and of inorganic C at 1100C in a tube furnace.

RESULTS AND DISCUSSION

Mass balance calculations showed large losses of the original spike in all jars, including the irradiated/sealed jars. This was because of degassing in the few minutes these soils were open after spiking. The degassing losses were largest for the alfalfa-amended soils (>98%), but still as high as 50% for the carbonate-amended soils. The various analyses made throughout the study were sufficient to develop a two-phase first-order loss-rate model to describe the degassing losses (equation 1). This is the same model used previously (4, 5). The fraction of 14C remaining in the soil, F, was described as:

$$F = A\, e^{-(0.693 \times \text{time} / \text{thalf1})} + (1 - A)\, e^{-(0.693 \times \text{time} / \text{thalf2})} \quad (1)$$

where A is the fraction of 14C lost rapidly with the half-time thalf1, and the remaining fraction (1 - A) was lost slowly with the half-time thalf2. The relationship was fit iteratively to the data, and the R2 value was 0.86 (P <

0.0001). The degassing rate constants were assumed equal for all the soil amendments, but the fraction of inventory subject to each rate constant varied. The two phases had half-times of 2.4 min (thalf1) and 1720 d (thalf2). The rapid loss affected 98% of the 14C in the alfalfa-amended soils, 76% in the unamended soils and 56% in the carbonate-amended soils. The balance of the 14C in each soil was lost at the slow rate, if at all.

The effect of incubation time was most evident in the 14C concentrations in the headspace gas. For the open jars, there was no meaningful trend with time, and very little 14C was present in the headspace gas. For the irradiated/sealed jars, the concentration of (and fraction of total) 14C was significantly ($P<0.05$) less in the jars incubated the longest time (Table I). This is consistent with our initial hypothesis that, with time, the 14C becomes more fully incorporated into the stable C pools in the soil. The lower fractions of the total 14C found in the headspace gas indicated that with time more of the 14C was isotopically exchanged with stable C in the soil.

The sequential extraction method clearly showed that isotopic exchange with the mineral 12C was not complete. The release of 14C was relatively rapid and usually reached an asymptote before half of the final amount of acid was added to the soil. In contrast, the 12C was often still being released at the end of the titration when all the acid had been added. This indicates, as expected, that the 14C was present in the more labile fractions of soil inorganic C. If isotopic equilibrium was complete, then the relative release rate of 14C and 12C would be the same. Sheppard and Evenden (5) used linear interpolation to estimate the fraction of the total inorganic 14C in the soil that was released when 20% of the total inorganic 12C was released. This value, REL20, could in theory range from 100%, implying little isotopic exchange, to 20% at full isotopic equilibrium.

The value of REL20 was lowest and was not significantly ($P > 0.05$) different from 20% in the alfalfa-amended soils at any incubation time (Table II). This indicates that isotopic equilibrium was essentially reached in these soils, and within the shortest incubation time of 6 months. The alfalfa may have caused periodic fluctuations in the soil pH and gaseous CO_2 and accelerated the isotopic exchange as minerals dissolved and reprecipitated over time.

The values of REL20 in the unamended soils were intermediate and again did not vary with incubation time (Table II). In contrast to the other amendments, the REL20 values decreased with incubation time in the carbonate-amended soils (Table II). They were also significantly higher in the open jars than in the irradiated/sealed jars for this amendment. After 6 months, the REL20 was 95% in the open jars, indicating isotopic exchange with only a small part of the total soil inorganic 12C. The decrease in REL20 with time is as expected, indicating that isotopic mixing was progressing and that REL20 would approach 20% if the incubation were long enough. Even after 24 mos, REL20 was equal to or above 50%. It would be a very long time before isotopic exchange would be complete in this soil. The higher values for REL20 in the open jars are probably, as suggested above, related to the continuous diffusive loss of 14C our of the jars that essentially competed with isotopic exchange as a sink for 14C.

The acidified soil extractions and the peroxide titrations contained some organic 14C, in amounts that were not clearly linked to treatment. The presence of organic 14C was been confirmed by thermal oxidation of the soils (5).

CONCLUSIONS

Mechanisms exist to retain inorganic 14C in soils, even though most of it will be lost by gaseous evasion. Isotopic exchange may be accelerated by specific conditions, but was shown to be far from complete even after a 24-month incubation. The 14C retained in soils by isotopic exchange and by autotrophic fixation can be expected to reside for very long times, perhaps approaching the residence times of stable carbonates and organic matter in soil.

Monday, February 27, 1995 Lunch Address
Address by Hon. Mike McCormack
Director, The Institute for Science and Society

THE IMPERATIVE SOCIETAL NEED FOR SCIENTIFIC LITERACY

Thank you, Dr. Post. Good afternoon Ladies and Gentlemen.
I'm certainly flattered to be invited to address this meeting of so many experts in the sciences and technologies related to the management of radioactive and mixed wastes. The work you are doing, and will do, will make a significant contribution, not only to environmental restoration, but also to building healthier attitudes among the people of this country with respect to future challenges involving nuclear power, food irradiation, the transportation, storage and processing of spent fuel, and the permanent storage of vitrified waste.
I congratulate Roy Post and all of you who have organized this conference, and all who are participating in it. Certainly the broad scope of research and technology you will review this week will leave little occasion for questions about handling radioactive or mixed wastes that won't have been thoroughly studied, and for which there will not be credible answers.
It is my sincere hope that we have reached a time when the lessons learned and the technologies and techniques for managing and cleaning up radioactive and mixed wastes, and for environmental restoration, can be implemented with aggressive programs to complete the various projects without further delays.
My comments today, however, do not relate directly to waste management or environmental restoration. Instead, I shall use this time to propose that you have an additional obligation to society beyond the excellent work you are already doing. I will discuss the need for enhancing the level of Science Literacy throughout society, but especially within our educational systems and our news media, and among our public officials. I have focused on this subject because I believe science literacy is essential to the development and growth of healthy attitudes among our fellow citizens in their consideration of subjects related to public health and safety, energy supply, industrial development, environmental protection, and adapting to a rapidly changing technological world; and indeed, to waste management.
Most scientists live within their own professions, and only a few venture far into the greater society -- in terms of public service, for instance. This is natural and traditional, and you are justified in claiming that scientists serve society well by their professional accomplishments. I submit, however, that we must all do even more -- for our professional respect, and indeed for our children and our nation.
During my twenty-four years' service as an elected official, including the decade of the 1970s in the U.S. congress, I frequently found myself working with colleagues who were uneducated about -- literally ignorant of -- the scientific or mathematical foundations required for the realistic consideration of policy issues involving such subjects as environmental protection, energy production, health and safety, industrial growth, risk assessment, and basic research, among others.
This inability to handle such issues rationally constitutes a dangerous malaise that is pandemic across our nation. It afflicts all too many public officials, members of the news media, and the entertainment industry. It has, most disturbingly, afflicted much of the educational community, where one would traditionally expect to find high standards of excellence and intellectual vitality.
For instance, a faculty member of a major university recently related to me an incident in a chemistry class for non-science majors. The students were asked for their reaction to the suggestion of having a nuclear power plant in their region of the state. The reaction was essentially unanimous and vigorously negative. They were then asked to define or describe radiation. Of a large class of university students, only three hands were raised, and these tentatively.
The message this incident brings to us is one that should be disturbing to all

thoughtful citizens. These students have been frightened into a state of irrationality without the slightest understanding of the feared subject, to say nothing of understanding who was responsible for manipulating their minds to create behavior inconsistent with their own best interest; inconsistent with the very concept of an institution of learning.

This is the most striking aspect of anti-nuclear and chemophobic attitudes. Many average, well- intentioned citizens -- including teachers, students, and even many professional men and women -- behave essentially as if they are members of a brainwashed cult, unwilling or unable to face the truth about a subject on which they have accepted misinformation, and have adopted attitudes and opinions without thinking, and which they will militantly defend without even trying to understand the simplest fundamentals about that subject; or who has poisoned their minds about it, or why.

This phenomenon provides a frightening demonstration of the fact that of all the ancient enemies of mankind, ignorance is the most menacing -- the most dangerous. It is the insidious source of fear and superstition -- the vehicles for the enslavement of human minds. Throughout the history of mankind, clever men and women have cynically exploited their fellow humans, perpetuating ignorance, generating fear and superstition, and profiting from the willingness of their exploited subjects to think and behave in a manner contrary to their own best interests -- contrary to their own health, safety and welfare.

Today, one can rarely pick up a newspaper or magazine that does not contain at least one article about health hazards presumably originating from some technology; or articles presuming to expose the hazards of "chemicals" -- almost always with the adjective "toxic". So it is, too, with anything connected with the words "electromagnetic fields", "nuclear", "radiation", or "radioactive". It becomes extremely difficult for any public official who wishes to make sense of societal issues involving these subjects. He or she may be immediately exposed to attacks from sensationalist elements of the news media, from gleeful demagogues running for public office, and from activist organizations pretending to protect the public -- or some aspect of the environment -- from industry, technology, or even scientific or medical research.

I encountered this phenomenon throughout my years of public service, and I was increasingly disturbed as the education community failed to provide the bulwark of intellectual integrity that I assumed was the hallmark of that profession. Even worse, I found that many members of the education community were actually perpetuating the mythology of this fear and encouraging hostility with respect to science and technology.

After leaving the Congress, I determined to try to help strengthen our education system, especially in science and mathematics, because I believe that a reasonable level of familiarity and comfort with these subjects (not to mention others) is essential for responsible citizenship and rational decision making on public issues involving science and technology. I have become ever more convinced that an understanding of at least a modest amount about the major scientific disciplines, a respect for the scientific method of problem solving, and an appreciation for science must be essential elements in the education of every child in this nation, starting in the primary grades. To accomplish this goal, all teachers must be at least scientifically and mathematically literate, unafraid of teaching science and mathematics, and inspired to excite their students about the fun of science and the promise of careers in science.

The Institute for Science and Society, of which I am director, was created to help accomplish these goals. Its mission is to enhance the level of Science Literacy throughout society; and within that mission, to provide non-threatening courses in Science Literacy for K-12 (primary, elementary and secondary) teachers. I am pleased to report that 390 K-12 teachers have completed our primary course in Science Literacy , "Stars, Bugs, Molecules and You". In addition, we are oversubscribed in special one-weekend, single discipline courses in "Science Literacy for Educators;" and this spring we will offer "Stars and Bugs" as part of the University of Washington's Master's Degree program in Education being offered at the University's satellite campus in Tacoma.

We are clearly enhancing the level of Science Literacy of the teachers who experience these courses, and changing their perspective about science, their place in the universe, and their obligation to their students. Teachers' comments after

completing the course include such statements as:
"I'll never be the same again."
"I'm a better person." "Now I care."
"I know now that I was cheated in college."
"Thank you for the wonderful intellectual kick in the pants."
"Every teacher should take it."
". . . now I'm aware of the consequences of scientific ignorance."
"Now I can teach the excitement of science."
These remarks are by teachers who are interested enough to take the course -- presently about one percent of the K-12 teachers in Washington State. This afternoon I will participate in the Teachers" Workshop under the chairmanship of Jim McCray. At that time I will discuss in detail our science literacy program.
Most teachers of grades one through six, except those specializing in some selected subject (art, music, P.E., etc.) are required to teach some science and mathematics as part of the students' daily studies. Most of these teachers have completed very few science or mathematics courses (some almost none), either in high school or the university; and this in spite of published requirements at most universities that some number of credits in laboratory sciences must be earned as a prerequisite for a teaching certificate. In addition, many of these teachers have received their training, and work within a culture where science illiteracy is the norm, and where fear of and hostility toward science and mathematics are prevalent.
This should be a matter of serious concern, and alarm bells should be ringing in the minds of all U.S. citizens, as we learn that most 14-year-old U.S. students lag far behind their contemporaries from all other developed countries in science and mathematics test scores. Ten-year-old students in the U.S. do much better when compared to other nations. This should cause serious questions, and the first one is "What happens to U.S. students -- or what doesn't happen -- between the ages of 10 and 14?"
A disturbing explanation for this phenomenon has been suggested -- one that appears to have been generally overlooked in some current campaigns to improve the quality of science education in U.S. schools. That relates to the stultifying impact that primary and elementary scientifically-illiterate teachers can hardly avoid having on their students.
Most children under 10 years of age are naturally "good scientists." They poke, probe, try to operate or take apart almost anything they encounter, and they ask endless "why" and "how" questions. Their teachers -- and their parents also -- are frequently intimidated or simply overwhelmed by questions in a subject in which they may be illiterate, and they may cut sincere kids off with criticism or rebuke. Thus, students are "turned off" or, as Carl Sagan has observed, "dumbed down". At the same time, a teacher may be forcing the kids to memorize material that neither teacher nor student understands, while the teacher "stays one day ahead" in the text. The result, all too frequently, is that the students are alienated from school or science, or both. Even when scientifically illiterate teachers think they are doing an adequate job of teaching, and are sincerely trying, they may be unintentionally turning off their students by their body language or facial expressions. This may be especially true for female and ethnic minority students. Thus, it should be no surprise that optional registration in science or mathematics courses at and beyond junior high school is so low. Many of these students are lost before they are contacted by a trained science teacher or by exciting special programs to improve the quality of science education. Again, this may be especially true for female and ethnic minority students.
It should be obvious that any program to upgrade the level of science education among U.S. students is doomed to failure if the primary and elementary teachers -- who have the attention of the young students most of the time -- are themselves scientifically illiterate, or are frightened of, or hostile to science and mathematics. The students will absorb the message of their role model, even if it is unintended.
This points directly to the problem of public understanding of subjects related to nuclear energy and waste management. If our fellow citizens of any age are frightened of and hostile to science itself, and to the scientific approach to problem solving, they will easily fall victims to misinformation and appeals to emotionalism about technologies which they do not understand and about which they may be suspicious. The goal of rational public consideration of issues involving

modern technology must be built on a campaign of scientific literacy for the majority of our citizens.

We have concluded that the most important undertaking in any effort to upgrade the quality of science education at any level must be first to provide attractive continuing education programs in Science Literacy for all K-12 teachers. Such programs must first focus on primary and elementary teachers, and should be accompanied by strong inducements that the courses be successfully completed. Such courses should -- and can -- be made exciting, fun, and rewarding; and should, above all, avoid the trap of frightening or threatening teachers with abstract and valueless material to memorize.

In addition, the schools of education throughout the country should include successful completion of a comprehensive curriculum in Science Literacy as a prerequisite for a teaching certificate; and these courses in Science Literacy should be made available to all non-science majors, rather than requiring completion of academic level courses in science disciplines.

I have proposed that a department of Science Literacy be created at Central Washington University, with which The Institute for Science and Society is affiliated. I have suggested a curriculum of 20 quarter credits in Science Literacy for undergraduates, and suggested that this be made a prerequisite for obtaining a teaching certificate. Under this proposal, Science Literacy classes would be taught by faculty from the various science disciplines. Thus the University would offer an academic curriculum in each science discipline as at present, and a program in science education for students who wish to qualify to teach science, and third, a comprehensive curriculum in Science Literacy. Our Science Literacy curriculum includes a brief overview of the major physical and biological sciences, an understanding of what science is, a course in mathematics for understanding science, one on societal issues involving science and technology, and one on the relationships of science and technology to industrial growth and economic stability.

I assume that some states and some schools of education are doing better than others in this matter, and you may wish to find out about yours. You should be aware, however, that there are land mines lying in wait for anyone recommending changes in any level of our educational systems. One is the resistance one would expect to proposing any change in the activities of any organization. This may be reinforced by the apprehensions of many members of the education community who themselves are scientifically illiterate and possibly frightened of, or hostile to including any study of science, however superficial, in their curriculum.

There will also be resistance among those who object on philosophical grounds to teaching any education course with "content" rather than simply in "methodology." There will be those who have difficulty understanding the distinction between Science Literacy and Science Education. There may also be resistance among some members of the science faculty at some institutions who may object to teaching Science Literacy to teachers because they consider it to be "watered- down science," and beneath their dignity. These obstacles, where they exist, must be cleared away if a comprehensive program in Science Literacy can be made a requirement for certification to teach.

There is yet another obstacle. It lies within some federal agencies that fund science education programs. It is born partially because of inertia, and partially because some of these agencies appear to have difficulty recognizing that all primary and elementary teachers are "science" teachers. I suggest that such federal agencies reconsider the need for Science Literacy training for all teachers, rather than primarily for those who teach science in middle and high schools; and that science education is essential for all students, starting with kindergarten.

I suggest that you who share the concerns I have expressed may wish to survey the level of Science Literacy among the teachers of your state, and the curriculum requirements at your state's schools of education. You may come to recognize your obligation to work to enhance the level of Science Literacy among your state's teachers, and within its schools of education. You may wish to enlist the participation of scientific societies in which you are a member. I consider this to be a critically important aspect of the societal obligation of all scientists -- but especially experts in the sciences related to radiation, because this is a raw nerve in the emotion-ridden minds of too many of our scientifically illiterate fellow citizens today.

Nor is your obligation limited to working with your education communities. Many

elements of the news media and entertainment industry are guilty of flagrant violations of their responsibilities to society. Their tendency to sensationalize real or imagined issues involving science and technology is causing terrible damage to our country, especially in the minds of the scientifically illiterate. It is the responsibility of every individual scientist and every scientific society to keep the pressure on the news media and the entertainment industry, insisting that they be responsible and accurate when dealing with any subject related to science and technology.

Most public officials -- especially state legislators and Members of Congress -- are scientifically illiterate, and thus functionally crippled with respect to their responsibility to legislate intelligently on societal issues involving subjects such as health, safety, energy, environmental protection, and others. There are countless stories, many of them true, about legislative bodies enacting bills that violated mathematical rules, changed mathematical constants, denied exponential growth, and attempted to repeal the Second Law of Thermodynamics. Members of the scientific community who are concerned that such incidents are possible need only look in the mirror to find the reason. In short, if you are frustrated with the apparent inability or unwillingness of your legislative body to treat issues involving science and technology rationally and with appropriate respect, you may wish to organize a non-partisan, or bi-partisan group of scientists to meet regularly with your legislators when they're at home. If this fails, you may wish to run for office.

In fairness, I should observe that most elected officials will welcome constructive assistance, especially from their constituents. They cannot help but respond to what they believe to be their constituents' wishes. If you and your scientific associates make it abundantly clear that you expect responsibility from your elected representatives in the consideration of issues involving science and technology, your requests will be heeded.

In summary, the obligation of all scientists is to accept their roles in society, and thus to accept the critical need for their involvement in all levels of education, public communication, entertainment, and government. It seems to me that each of us who has benefited from a good education has a positive obligation to give back to society something of ourselves -- something beyond just earning a living -- to help build a better world.

I frequently use a story about a man who fell off a cliff. As he fell, flailing his arms, he caught hold of a tree root protruding into space. There he hung, bouncing up and down. After yelling for help several times and getting no response, he shouted, "Is anyone up there? After a moment a voice seemed to come from space, and said, "I'm here." "Help me", yelled the man. "Have faith", the voice said, "and let go." The man looked down a thousand feet to jagged rocks, and up the sheer cliff for dozens of unclimbable feet, hesitated, and shouted, "Is anybody else up there?"

♀

The reality is that there isn't anyone else to help do what is necessary to improve the level of science literacy and rational consideration of public issues involving science and technology, except those of us who understand the issue and understand what must be done. I challenge each of you to accept that obligation to help overcome this problem. In addition to what you are doing, you must do more.

It may be that in the future you will be able to look back and know that because of your efforts, some of the major problems we face today have been corrected; and that this country is once again moving forward with a citizenry that is unafraid and vibrantly challenging the future. I hope this will happen. It's easily worth a lifetime commitment.

ABSTRACT
This paper addresses the plans and strategies for remediation of the Liquid Low-Level Waste (LLLW) system tanks that have been removed from service at the Oak Ridge National Laboratory (ORNL).
The Superfund Amendments and Reauthorization Act of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) requires a Federal Facility Agreement (FFA) for federal facilities placed on the National Priorities List. The Oak Ridge Reservation was placed on that list on December 21, 1989, and the agreement was signed in November 1991 by the U. S. Department of Energy Oak Ridge Operations Office (DOE-ORO), the EPA-Region IV, and the Tennessee Department of Environment and Conservation (TDEC). The effective date of the FFA is January 1, 1992. One requirement of the FFA is that LLLW tanks that are removed from service must be evaluated and remediated through the CERCLA process.
The Environmental Restoration Program intends to meet this requirement by using a "streamlined" approach for selected tanks. This approach will combine the CERCLA Site Investigation, Remedial Action, Feasibility Study, and Proposed Plan requirements into a single Interim Proposed Plan document. This streamlined approach is expected to reduce the time required to complete the regulatory process while attaining acceptable risk reduction in a cost-effective way.
OAK RIDGE NATIONAL LABORATORY BACKGROUND
Oak Ridge National Laboratory (ORNL) is a multidisciplinary research facility operated for the Department of Energy by Martin Marietta Energy Systems, Inc. ORNL began operation in 1943 as part of the Manhattan Project. The original mission of the laboratory was to develop a prototype graphite reactor and reprocess the reactor fuel for plutonium recovery. After World War II, the primary functions of ORNL were fuel reprocessing research; radioisotopes production and applications development; and nuclear reactor concepts development, testing, and operation. More recently, the laboratory has increased its role in biological, environmental, energy, and materials research. As a consequence of these multidisciplinary research activities, heterogeneous wastes, including liquid low-level radioactive, hazardous, and mixed wastes, have been generated in varying amounts over time.
Since its establishment, ORNL has operated numerous facilities that generate LLLW. LLLW originates from radioactive liquid discarded into sinks and drains in research and development laboratories and from facilities such as the Radiochemical Processing Pilot Plant, nuclear reactors, radioisotope production facilities, and the Process Waste Treatment Plant.
The LLLW system is a complex system with multiple facilities, users, and operators. The system is used for collection, neutralization, transfer, and concentration of aqueous radioactive waste solutions from generator facilities. Waste solutions are typically accumulated at source buildings, often in collection tanks located inside the buildings, and discharged to below-grade collection tanks that may receive wastes from several different source buildings. However, in many instances, LLLW is transferred from laboratory and hot cell drains through unvalved piping directly to underground collection tanks or to the central waste collection header. A network of below-grade piping interconnects the various system components. The collected LLLW is transferred to an evaporator, where it is concentrated. The concentrates are transferred to storage tanks.
Most of the LLLW system was installed more than 30 years ago. The original system, installed during the early 1940s, and its subsequent modifications were designed to minimize radiation exposure to LLLW system users and operators. The system includes features such as unvalved, gravity-drained transfer lines to prevent waste backup

into generator areas; shielded lines and tanks; and provisions for remote operations. As-built drawings for some of the older tank systems do not exist. Over the years, tank systems were removed from service as their integrity degraded or as programs were terminated. New tank systems installed during the past 10 to 15 years incorporate secondary containment and improved leak detection features. The LLLW system is thus a mix of singly and doubly contained tank systems. The portions of the system that have been removed from service consist almost exclusively of tanks without secondary containment.

OBJECTIVES

The objectives of the Environmental Restoration Program for the inactive LLLW tanks complement the objectives for a comprehensive environmental restoration of the Oak Ridge Reservation in keeping with the overall program mission.

ENVIRONMENTAL RESTORATION MISSION

Our mission is to remediate contaminated sites and contaminant releases to reduce current and future risk to human health and the environment. Early actions focused on reducing current or potential off-site risk are conducted in parallel with efforts to select, implement, and verify final remedies for contaminated sites. Remedial efforts are prioritized and innovative approaches are developed to support cost-effective risk reduction. All efforts are conducted with an emphasis on worker health and safety and with the goals of meeting regulatory requirements and the expectations of the public.

As stated in the FFA,

DOE shall remediate all tank system(s) removed from service. To the extent practicable, DOE shall remove or decontaminate or otherwise remediate all residues, contaminated containment system components (liners, etc.), contaminated soils, and structures and equipment associated with the tank system(s).

A primary objective of the Environmental Restoration Program is to remediate all LLLW tanks that have been removed from service to the extent practicable in accordance with CERCLA requirements. In addition to risk and risk reduction, applicable or relevant and appropriate requirements (ARARs) will be addressed in choosing a remediation alternative. Preference will be given to remedies that are highly reliable and provide long-term protection. Efforts will be directed toward permanently and significantly reducing the volume, toxicity, or mobility of hazardous substances, pollutants, and contaminants associated with the tank systems. Where indicated by operational or other restraints, interim measures short of full and complete remediation may be taken to maintain human health and ecological risks at acceptable levels until full remediation can be accomplished.

Environmental restoration requires decision making with available data containing uncertainties and traditional approaches can sometimes be very time consuming, expensive, and inefficient. Therefore, the environmental restoration process for LLLW tanks that have been removed from service will consider 1) employing innovative and technically sound approaches to tank remedial actions; 2) balancing short-term needs to protect health and the environment with long-term future use objectives for the Oak Ridge reservation; 3) remediating the inactive tank systems in a logical order that is integrated with other remedial actions; 4) attaining cost-effective risk reduction; 5) meeting environmental regulations; and 6) addressing the expectations and requirements of all stakeholders.

REMEDIATION STRATEGY

Background

The management strategy for timely and efficient remediation of all sites at ORNL is to divide the waste units into waste area groupings (WAGs), which are areas that are either geographically contiguous or hydrologically confined units. Within each WAG, one or more operable units (OUs) have been defined. These OUs are smaller, more manageable units chosen on the basis of contaminant pathways analysis, application of similar remediation technology, geographical consideration, assessment of early or time-phased action, and remediation efficiency or simplicity considerations. The designation of all OUs for the Oak Ridge Reservation is shown in the FFA.

Remediation Plan

As of December 1994, FFA Appendix F identified a total of 55 tanks that had been removed from service and designated these tanks as Category D. Eighteen tanks considered to pose the highest risk were assigned to WAG 1 OU 1, Gunite and Associated Tanks (GAAT), which will be remediated under a separate project. These 18 tanks will undergo the complete remedial action process including a remedial

investigation and feasibility study (RI/FS) leading to a proposed plan and a record of decision (ROD) as required by CERCLA. Treatability studies are currently being conducted on these tanks.

In parallel with the ongoing activities associated with remedial actions for the GAAT OU, a "streamlined" CERCLA process is being applied to the remaining 37 Category D tanks. These 37 tanks were preliminarily screened according to risk, remediation technology required, interferences with other piping and equipment, location, and available sludge removal techniques and storage requirements. On the basis of this preliminary screening, the tanks were assigned to one of five "batches" (I through V) for consideration of remedial action alternatives and these batches were tentatively scheduled for remedial actions. This prioritization will be further refined on the basis of results from the prioritization risk assessment and site investigation results.

For each batch of tanks, documentation will be prepared that incorporates all the requirements of the CERCLA remediation process leading to an expedited record of decision (ROD). The specific remediation alternative will be chosen on the basis of risk as described in EPA guidance manuals. This streamlined approach will combine the CERCLA Site Investigation, Remedial Investigation, Feasibility Study, and Proposed Plan requirements into a single Interim Proposed Plan document. The Interim Proposed Plan will clearly define the tank system components, both piping and containment (tank, vault, etc.), that will be included in the interim remedial action. The Interim Proposed Plan will also describe the means taken to safely secure the components not immediately remediated and will clearly indicate to which OUs these components will be assigned. Following the selection of a preferred remedial action alternative and its documentation in the ROD, remedial design and remedial actions will proceed. The goal will be to arrive at final remediation for each tank system, although in some cases interim actions may be indicated.

The Environmental Restoration Program recognizes that other tanks are scheduled to be removed from service as projects are completed to bring the active LLLW system into full FFA compliance. Active tanks whose removal from service is pending have also been tentatively assigned to batches. The same preliminary screening factors that were used for the initial batch assignment of the inactive tanks were applied to these currently active LLLW tanks. As they are removed from service and transferred to the Environmental Restoration Program, the tanks will be emptied and made to meet program acceptance criteria. As the program moves forward and more information becomes available, these tanks may be reassigned to other batches or they may be remediated as a separate batch or batches.

A team has been assembled to address remediation of the Batch I tanks. The team is a group of technical representatives from all involved organizations. The team, which meets regularly to coordinate and plan remedial action activities for the tanks that have been removed from service, provides a mechanism for integrated responses on remedial action issues to DOE, EPA, and TDEC.

The approach to remediation of each tank or batch of tanks can and should be viewed as a dynamic, flexible, customized process that must be adapted in response to the specific circumstances of individual tank and sites. Thus, the approach will be tailored to accommodate feedback on lessons learned from previous remediation actions and will not be a rigid step-by-step approach that must be conducted identically for every tank system.

Tank parameters have been examined and an initial ranking made to determine the first tanks or batches of tanks to undergo remediation through the CERCLA process as required by the FFA. Remedial actions for the Batch I tanks are scheduled to begin in FY 1995. All of the tanks in Batch I have previously been emptied and are thought to have no inflow.

Although the specific remedial action alternatives for a tank system, which will reduce the risk to acceptable levels, will be described in the Interim Proposed Plan, four general alternatives that are applicable to both direct-buried tanks and tanks located in vaults have been identified.

Alternative	Merits and limitations
Remove and dispose of tank and isolate piping.	Remediation of the tank will be complete. Adverse impacts on other OUs will be minimized. Risk reduction or other cost/benefit ratio must justify

	cost of removal and disposal. Removed tank may require treatment to meet appropriate waste acceptance criteria.
Leave tank in place and isolate piping.	To complete successful CERCLA remediation, risk posed by tank must be below EPA risk acceptability range. Future deterioration of tank could cause problems. Tank may require acceptance into the remedial action program of other OUs. Tank may require continued surveillance and maintenance.
Fill tank with stabilizing medium.	Stabilizing medium could minimize the accumulation of liquid in the tank. The tank must be cleaned prior to placing stabilizing medium. Any remaining contaminants could be leached from stabilizing medium if tank wall is breached. Added mass and volume of stabilizing medium might increase future excavation and waste disposal costs.
Leave tank as is.	If tank risk falls below EPA acceptable range, the tank can be removed from CERCLA consideration. The tank could remain under CERCLA, a surveillance and maintenance program, or both because of potential for inleakage and contamination.

Following successful remediation of the Batch I tanks, and using the lessons learned in these projects, as well as lessons from the GAAT OU project, the plan is to proceed to increasingly more complex or difficult tank or tank site remedial actions on the basis of knowledge and skills developed on these initial tank remedial action projects.

CHEMICAL MECHANISMS DISCUSSION - INEL: CESIUM IN GROUNDWATER INNOVATIVE TREATMENT

Philip N. Baldwin, Jr.
Louis E. Reynolds
J. E. Day
ADTECHS Corporation

ABSTRACT

The removal of cesium 137 from waste and groundwaters is a subject that has been approached by several investigators. The REFERENCE section provides some examples. Although there are approaches that have been shown to work there appears to be a limit of the applicability of these approaches when the generation of secondary waste is considered. This paper provides a possible new approach to the removal of low levels of Cesium 137 from water. The approach depends upon chemical oxidation, iron chemistries and bicarbonate additions under controlled pH parameters. The proposed mechanisms that could explain the limited data obtained to date, shows an ability to reduce the Cesium levels by about 93%.

BACKGROUND

ADTECHS Corporation was engaged in treating heaving metals and low levels of selected organics in a groundwater stream at a DOE site at the Idaho National Environmental Laboratories. During this work, an unanticipated analyte, Cesium 137, began to appear in low levels in the influent. Work was commenced on finding a suitable method of removing this Cesium from the stream. This goal is supported by the fact that Cesium-137 is found at many DOE sites and a practical solution to its removal would have additional benefits. As of this paper's writing, a fully approved methodology for Cesium removal and treatment has not been approved by the site prime contractor. It is anticipated that a process and site standard will be in place before the end of 1995.

The data provided in the Summary below, is based on pilot work performed at the site on the actual groundwater. At this time, full scale pilot treatment has not been permitted pending the decisions noted. However, it is felt that the results seen to date do warrant further study.

TESTING INFORMATION

The groundwater native pH was measured to be 8.88 +/- 0.2 at 20oC. The general levels of chemistry and type used is shown in TABLE I.

When the pH is raised into the 7.0 to 7.5 range with the base addition, an initial white tinged with umber precipitate is formed which when filtered turns mostly organe-umber. When air dried the filter cake becomes essentially white.

The light but large flock precipitate is readily filtered. Both a sand filter and a 1 micron cartridge filter work equally as well.

DATA SUMMARY

TABLE II includes a summary of the data taken on "before" and "after" treatment. On average, the samples tested were reduced by greater than 93% with some samples reduced to non-detect. Based on the standard deviation differences, a reduction of at least 90% seems apparent.

MECHANISMS DISCUSSION

(A) Conversion of monovalent Cesium into a Cesium Oxide (Cs2O) is accomplished by the addition of the oxidant. Also Cesium superoxide or Cesium trioxide may also form. The combination will produce a blend of colors of dark brown to dark orange/umber.

(B) The very low levels of Cesium requires a mechanism to remove it into a filterable cake. This step is accomplished by the judicious use of iron chemistries. FIGURE 1 shows that freshly precipitated Fe(OH)3 at various pHs will yield Hydroxo Iron complexes that range from Fe+3 to Fe(OH)2+1, Fe(OH)+2 , Fe(H2O)6+3 and others. Optimizing the iron chemistries in the pH range indicated in Fig. 1 assists in the formation of polymeric iron compounds which can engage the cesium oxides to form a co-coagulant/precipitant. While insufficient work has been done to optimize the conditions, it is known that polymerization and precipitation kinetics are effected by the concentration of the iron solution, the type, concentration and method of base addition; ionic strength; temperature and specific anion effects.

(C) The adjustment of the pH into the "optimal range" allows for the potential formation of carbonate or bicarbonate complexes that could be ensnared in the polymeric iron matrix. The appearance of orange-umber crystals when subjected to the air drying could be due to the conversion of cesium/iron oxide/hydroxide complexes into bicarbonate/carbonates which would be white. TABLE IV demonstrates the statistical experimental design proposed for evaluating the sensitivities and strength of the effects of each step in the chemical precipitation process. In this way, both first order and second order potential effects and strength of correlation to Cesium removal can be evaluated.

FIGURE 1

The equilibrium concentrations (Log C = Y) of selected hydroxo iron +3 complexes in contact with freshly precipitated Ferric hydroxide (Fe(OH)3 @ 25oC versus solution pHs were graphed above. The descriptive equations that relates the Log C to pH (X) are shown in TABLE III.

CONCLUSIONS

The usefulness of chemical precipitation for low levels of Cesium-137 appears to have merit. Preliminary bench work utilizing actual ground water has indicated a high percentage of removal is possible with a low generation of solid waste. The mechanisms for this removal are based around the ability of iron to form polymers and to engaged and entrap other oxides even when present at very low levels. Further work appears to be warranted.

CENTRALIZED CEMENT SOLIDIFICATION SYSTEM FOR RADIOACTIVE WASTES

Tukashi Nishi
Masami Matsuda
Makoto Kikuchi
Tatsuo Izumida
Hitachi Ltd.

ABSTRACT

A centralized cement solidification system has been developed to solidify various radioactive wastes such as liquid waste, spend ion exchange resin, incinerated ash and miscellaneous solid waste using a single solidifying facility and agent. This system is simple and highly reliable regarding the equipment and treatment process. Since it used high performance cement (HP-cement), waste loading can be raised and deterioration of waste forms after land burial is prevented. The HP-cement consists of slag cement, reinforcing carbon fiber, natural zeolite and lithium nitrate ($LiNO_3$). The fiber allows waste (spent resin) loading to be increased from 25 to 60kg-dry resin/200L drum. The zeolite, whose main constituent is clinoptilolite, reduces radiocesium leachability from the waste form to below 1/10. Lithium nitrate reacts as an inhibitor for corrosion of aluminum contained in the incinerated ash, which allows ash content in the waste form to be raised from 10 to 30wt%. This inhibitor is applicable to cement solidification of miscellaneous solid waste containing Al pipes and foil. Laboratory and full-scale experiments were performed to evaluate properties of the waste form and industrial applicability of this solidification system.

INTRODUCTION

The amount of radioactive wastes generated from nuclear power plants is decreasing annually, as advanced treatment processes have been developed. Recently a simple waste solidification system with low cost is highly desirable. We have developed a "centralized cement solidification system" in order to reduce the volume and cost of the solidifying facility. This is system allows several kinds of wastes to be solidified using a single solidifying facility and single agent. Our goals in developing the solidification system are:

1. reducing the number of solidified waste forms produced by increasing waste loading;
2. reducing release of radionuclides release into the environment;
3. obtaining a stable waste form for final land disposal; and
4. minimizing secondary waste generation.

Liquid waste, spent ion exchange resin, incinerated ash, and miscellaneous solid waste comprise the major fraction of low-and intermediate-level radioactive wastes generated in nuclear power plants. This research work was mainly aimed at developing a universal solidifying agent for all types of waste (High Performance cement, HP-cement) in order to realize the above four goals. Fundamental experiments were performed to optimize the composition of HP-cement, especially selection of additives for the cement. Simulated wastes were solidified, on a laboratory scale, using the HP-cement. Water resistance and leachability of waste forms were evaluated to predict their long-term stabilities after land burial. Furthermore, full-scale pilot plant tests, in which emphasis was laid on solidification of spent resin, were carried out to confirm an industrial applicability of the solidification system.

OUTLINE OF SOLIDIFICATION SYSTEM

A schematic of the centralized cement solidification system is shown in Fig. 1. Four features ensure the system is simple and highly reliable:

1. Several kinds of radioactive wastes can be solidified simply by mixing with cement paste using a single mixer.
2. Only one cement storage tank is necessary, because HP-cement is supplied as a ready-mixture containing carbon fibers (an reinforcing agent), clinoptilolite (an adsorbent for radiocesium), and lithium nitrate (an inhibitor for aluminum corrosion).
3. Wash drain generated from the mixer is reused as mixing water for the next batch. This significantly reduces the amount of secondary radioactive liquid waste.
4. Installation of a slide valve ensures the mixed paste of waste and cement is discharged without plugging the outlet.

In the case of spent resin, the solidification process consists of three steps. The

spent resin is first dewatered to a water content of about 50% using a centrifugal liquid/solid separator. The resin is transported into a mixer by use of a screw feeder. It is then mixed with HP-cement and water. Finally the mixed paste is fed into a steel drum and cured at room temperature after capping. When ash or liquid waste is solidified, the dewatering process is unnecessary. In the case of miscellaneous solid waste, the waste is put into a drum in advance. Then the open space in the drum is filled by the mixed paste of HP-cement and water. HP-cement can simplify the solidification process, because it needs neither pretreatments of wastes before solidification nor special equipment.

FEATURES OF HP-CEMENT

The main purposes and developed techniques, which solve the problems expected to be encountered during cement solidification and after land burial of the waste forms, are summarized in Table I. We concluded from the basic experiments described below that the HP-cement should contain slag cement, carbon fibers (a reinforcing agent), natural zeolite (an adsorbent of radiocesium), and lithium nitrate (an inhibitor for aluminum corrosion).

Solidification of spent resin

Water resistance: Main concerns in cement solidification of spent resin are water resistance of the waste form and leaching of radionuclides, especially Cs. Therefore, resin content in conventional waste forms has been controlled below 25kg-dry resin/200L drum (1). When resin content is higher, resin-containing waste forms tend to crack after water immersion due to resin swelling. Fundamental studies on the cracking mechanism led to development of a fiber reinforced cement which allows the resin content to be raised (2,3). The measured swelling pressure of solidified resin by cement was approximately 2.5MPa, which generated a maximal tensile stress of about 4MPa in the cement matrix. The tensile strength of fiber reinforced cement increased in proportion to fiber content. The hardened cement paste with 3vol% of carbon fiber (15 mmf 3mm long) had a tensile strength (about 5MPa) high enough to resist the resin swelling pressure. Figure 2 shows the relation ship between waste (mixed bead resin) loading and compressive strength of cementitious waste form, containing 3vol% of carbon fiber, before and after a 30-day water immersion test. The waste form reinforced by carbon fiber did not deteriorate during water immersion, even with as high a resin content as 60kg-dry resin/200L, while the waste form without fiber (con ventional cement) cracked in water and its strength decreased to about 0MPa within a few days.

Leachability: The distribution coefficients of cementitious waste form with and without mixed bead resin for the five main radionuclides are summarized in Table II. The waste forms with resin, except for Cs, showed much higher values than those without resin because of adsorption onto resin. Therefore Cs leachability from the resin-containing waste form is much higher than that of other radionuclides. The distribution coefficient of cement is relatively low for radiocesium (4), further the Cs selectivity of resin is lower than that for Ca in cement. Enhanced Cs retention ability in the waste form would be necessary for high waste loading. Although high pH and coexistence of Ca ions limits the possible choices of Cs adsorbent which can be added to cement, the fundamental experiments showed a natural zeolite, whose main constituent was clinoptilolite, had suitable adsorption ability for Cs. Figure 3 shows increases in Cs distribution coefficients of the hardened cement pastes with natural zeolite (clinoptilolite) and synthetic zeolites. Clinoptilolite was most effective additive for Cs adsorption among the tested zeolites because of its high selectivity for radiocesium. Cs leachabilities of resin-containing waste forms with 5wt% of clinoptilolite and without it are summarized in Table III according to the leaching rate and leachability index (5). The addition of clinoptilolite gave waste forms with a Cs leaching rate less than one-tenth that without adsorbent.

Solidification of incinerated ash and miscellaneous solid waste

When incinerated ash or miscellaneous solid waste (pipes, filters, etc.) is solidified with cement, the waste form often swells due to gas generation (6). Hydrogen gas is produced from alkaline corrosion of amphoteric metals contained in the wastes. We wanted to exclude pre-treatment or assortment of the wastes prior the solidification process. Alkaline corrosion experiments on Al metal were carried out to find an effective inhibitor which could be added in cement. We found that lithium ion helped to form an insoluble white film (about 5 mm thick) on the Al specimen which prevented hydrogen gas generation. The film was characterized by X-ray

diffraction analysis as the double salt of lithium aluminate, LiAl(OH)4Al(OH)3 xH2O. Then, lithium nitrate (LiNO3) was selected as the most effective inhibitor of Al corrosion, because the nitrate ion also showed an inhibition effect. Table IV shows that the addition of lithium nitrate (3wt% of slag cement) significantly reduced the rate of hydrogen gas generation from an aluminum plate placed in cement paste. Figure 4 shows the relationships between the ash content and the compressive strength of ash-containing cementitious waste forms. In the case of waste forms without lithium, their compressive strengths clearly decreased with addition of incinerated ash. They also swelled due to hydrogen gas generation and volume increased 20%. On the other hand, the strengths of waste forms with 3wt% added LiNO3 did not decrease notably until the ash content was as much as 30wt%. No volume expansion of the waste form was observed. We concluded this inhibitor can be applied to cement solidification of miscellaneous solid waste which contains Al pipes or foil.

The effect of lithium ion on aluminum corrosion was discussed based on the dissolution equilibrium of aluminum in alkaline solution. The equilibrium in lithium-free solution is as follows:

$$Al(OH)3 + OH- = Al(OH)4- \quad (1)$$

$$\log[Al(OH)4-] = \log K1 + pH - 14 \quad (2)$$

where the logarithmic equilibrium constant, logK1, is 0.18 for bayerite (7). In the case of disillusioning the presence of lithium ion, the amount of dissolved aluminum is limited by the deposition of Li-Al double salt as follows:

$$LiAl(OH)4\ Al(OH)3 + OH- = Li+ + 2Al(OH)4- \quad (3)$$

$$\log[Al(OH)4-] = 1/2\{\log K2 - \log[Li+] + pH - 14\}. \quad (4)$$

The logarithmic equilibrium constant, logK2, obtained in this study was 6.60. When pH is 13 (nearly the pH of cement paste), aluminum solubility in the alkaline solution is lowered below 1/100 by the addition of lithium ion (0.1M). Because the amount of hydrogen generation depends on the amount of dissolved aluminum, the addition of lithium salt reacts effectively as an inhibitor for gas generation.

PILOT PLANT TESTS

A demonstration pilot plant was constructed to confirm findings of the fundamental experiments. Its design specifications when handling spent resin were as follows.

Treatment capacity: 2drum/hour
Drum volume: 200L (net)
Waste loading: 60kg-dry resin (max)

Simulated spent resin was solidified into a 200L waste form by the following ratio,

Resin/water/cement = 100/60/140kg

where the resin was on a wet basis (water content = 43wt%). After curing for three months at room temperature, the package was cut and specific gravity was measured for core samples. Fairly good homogeneity was obtained for the actual size pack age. The package was immersed into a 1m3 water vessel and changes in its volume, weight and compressive strength were measured during more than three years.The strength was estimated from propagation velocity of ultrasonic waves in the waste form. Table V shows results after 3-year water immersion test. The weight gradually increased with time and became saturated at an increased value of 3.5wt% after immersion for about 100 days indicating water penetration into the waste form. Deterioration features such as cracking and swelling were not observed. The volume change was less than the experimental error of 0.1%, and compressive strength was more than 8.0MPa before and after the water immersion. These findings agreed with the results of fundamental experiments.

CONCLUSION

A centralized cement solidification system has been developed to solidify several kinds of radioactive wastes using a single solidifying facility and agent. It is simple and highly reliable regarding the equipment and treatment process. By using high performance cement (HP-cement), the waste loading can be raised and deterioration of waste forms after land burial can be prevented. The high performance cement consists of slag cement, reinforcing carbon fiber, natural zeolite and lithium nitrate (LiNO3). The fiber allows waste (spent resin) loading to be increased from 25 to 60kg-dry resin/200L drum. The zeolite (clinoptilolite) reduces radiocesium leachability from the waste form to below 1/10. Lithium nitrate reacts as an inhibitor for aluminum contained in the incinerated ash, which raises ash content in the waste form from 10 to 30wt%. This inhibitor is suitable for cement solidification of miscellaneous solid waste containing Al pipes and foil. A

full-scale pilot plant was constructed and 200L waste forms were prepared. The water resistance test was performed for more than three years and no deterioration was observed.

CONCENTRATION OF IRON and COPPER STEAM GENERATOR CLEANING SOLVENTS

Philip N. Baldwin, Jr.
ADTECHS Corporation

ABSTRACT

Chemical cleaning is a key method for removing metal and/or mineral build up in power plant steam generators. Such cleaning compounds are tailored to remove specific metals such as copper and iron. The formulations differ in each case, but one formulation constant can exist: Each formulation contains ethylene diamine tetraacetic acid (EDTA), a metal binding (chelation) agent. The presence of EDTA requires that the spent cleaning solution be treated to destroy this chelant. This may be done through methods such as incineration (hot oxidation), wet air oxidation, and wet oxidation (boiling water). Regardless of the method of treatment, waste reduction is an important technique to be applied to EDTA-bearing aqueous wastes, such as steam generator cleaning solutions. This paper will outline some of the details surrounding the concentration of both a spent EDTA-Iron and an EDTA-Copper cleaning solvent. The effect of Concentration on pH and specific Gravity of the solvents will be reviewed as well as the limits of the concentration process.

Table I

IDEAL SODIUM EDTA SALT SOLUBILITY - pH RELATIONSHIP

EDTA may form four (4) sodium salts, mono through tetra. The average solubility of the sodium salts as the pH changes is demonstrated in the solubility equation below. The salt solubility\ pH relationship for the free EDTA acid in water is somewhat different. However, since free acid EDTA is present only in very low concentrations, if at all, in a spent steam generator cleaning solution, the Regression Equation below gives a better insight into the solubility characteristics of an ideal solution of heavy metal EDTA chelates (Fe, Cu). NaEDTA Solubility in Water @ 25oC = 1388 - 628 (pH) + 435 (ln pH)3 R2 = ~98, Standard Deviation = ~24 solubility units.

The pH range found in the spent steam generator cleaning solvents is typically between 8.3 and 9.5 prior to concentration. After concentration, the pH range found for the iron and copper cleaning solvents was from about 5.6 to 7.9. Apparently, due to factors such as variance in ionic strength and the presence of other chemicals such a trace peroxide and ammonium hydroxide as well as metal salts, the observed solubility of the EDTA chelates in the concentrates was higher than initially predicted and higher than might be anticipated by reviewing the data generated from the Ideal Salt Solubility equation above.

pH CHANGE IN IRON SOLVENT

In Fig. 1, the effect of the concentration step upon the spent iron solvent is demonstrated. The relationship shown is based upon averaging all of the batches. Each batch of cleaning solvent varied and the curve for the change in pH versus the concentration level was, therefore, not the same for each batch; but the data in the graph adequately presents the pH change effects observed.

The relationship of Concentration Factor (CF) and change in pH from the beginning of

the concentration step until the stopping point can be generally described by:
CF = -1.2 - 2.3 * pH Difference from Beginning to Stopping R2= .98
pH CHANGE IN COPPER SOLVENT
In Fig. 2, the variation in the copper concentrates at the end of the concentration step versus the initial waste cleaning solvent pH is compared. Again, as with the Iron solvent, this data represents an overview. The individual batches of copper solvent differed; but, on average, the relationship shown in Fig. 2 is a reasonable representation. The relationship of the Concentration Factor to the change in pH during concentration is expressed by the mathematical equation:
CF = ~ -125 + 15 * ln pH + 13 * pH R2= >0.95 [pH = difference in pH from beginning to stopping point]
SPECIFIC GRAVITY CHANGES- Fe SOLVENT
As the iron solvent is concentrated, the specific gravity changes. This can be used to determine when to stop the concentration process and, thereby, minimize the risk of salting out the concentrator. The information in Fig. 2 indicates how this process works.
The relationship of the iron Concentration Factor to the change in specific gravity is expressed by mathematical equation:
Natural Log of CF(Fe) = 10.7 + 17.9 * Sp. Gravity + 8.3 * (Sp. Gravity)2 -or-
CF(Fe) = e(10.7*Sp. Gravity) + 8.3 (Sp. Gravity)^2 R2 =>.95
Fig. 3
SPECIFIC GRAVITY CHANGES-Cu SOLVENT
As with the iron solvent, the Concentration Factor can be controlled through the use of changes in the specific gravity. Figure 4 shows this relationship. The mathematical expression that described this is:
CF = ~ -0.87 + 61 * Nat. log * (Sp. Gravity) R2 => 0.95
CONCLUSIONS
The concentration of iron and copper cleaning solvents based on EDTA chemistries is possible to accomplish with reasonable and useful efficiencies. The level of concentration before and after rising is shown below in Table II. The utilization of a large, "already in place 30 gallons per minute" evaporation system (upon which this data is based) created a much larger amount of clean-up water than would have been required had a specialized more compact evaporator been used. This reduced the total "net" Concentration Factors. For the Iron solvent this CF reduction was about 19% and for the copper, the final solvent concentrated, the percentage reduction was about 25%.

SOLID RADWASTE FACILITY IMPROVEMENTS AT DIABLO CANYON POWER PLANT
J.D. Nevins
C.C. Miller
E.D. Strassman
Pacific Gas & Electric
ABSTRACT
Diablo Canyon Power Plant (DCPP) is located in Central California on the Pacific coast. Pacific Gas and Electric Company (PG&E) owns and operates the two Westinghouse 1100 Mwe PWR units. The commercial operation dates for Units 1 and 2 were May 1985 and March, 1986, respectively.
In 1981 the NRC issued Generic Letter 81-38 which anticipated the need for utilities to store radwaste due to interruptions in the flow of radwaste to burial sites. At that time PG&E decided to make the investment and provide additional interim storage at Diablo Canyon. DCPP decided it was necessary to provide onsite storage for radwaste as an insurance policy in the event that burial site access was cut off. By 1983 the design was issued on a plan to extend the walls of the small existing storage facility. Although the initial design was issued in 1983, the design was

scrapped in favor of building a completely new building. The design for this new building was issued in 1985.

DESCRIPTION OF RADWASTE FACILITIES

The radwaste storage facilities at DCPP are composed of two buildings. The old storage building was built during the original construction. It was intended to provide storage for palletized drums of cement solidified boric acid and boxes of DAW. Figure 1 shows the layout of the old storage building. The old storage building is separated into six bays. Bay 1 was intended to be a truck bay, but is now used for storage of Radiation Protection equipment. Bay 2 is used to store highly radioactive drums containing cartridge filters, odd sized parts and valves. This bay also contains an air pallet, a spent filter storage cask, a processing shield and an area for sampling filters. Bay 3 an bay 4 were intended to provide storage for drums. Bay 5 originally contained tanks for accumulating oil. Bay 6 was intended for box storage.

It became clear in the early 1980's that the original facility was inadequate to meet the radwaste storage needs and an upgrade of the original facility was planned. This plan encompassed the demolition of the interior shield walls of the building and installing new cranes to enable high activity waste to be handled remotely. The largest size container that could fit in the low head room design was an 80 ft3 liner. New 5 ton bridge cranes were procured based upon this design. DAW storage was to be provided by a metal butler building erected on the roof of the old facility.

Reconsideration of this storage expansion design resulted in the construction of a new storage building. The old facility would be retained. The metal building would be added but serve as an on site laundry facility. The new building would utilize the 5 ton cranes already procured for storing liners of resin or filters and provide a vault for boxed DAW storage. The new building consisted of a control room, an HVAC fan room, a truck bay, two liner storage vaults each serviced by a separate bridge crane and a large DAW storage vault. The new building configuration is shown in Fig. 2.

A shielded rail car is provided to transport 80 ft3 liners from the solidification pad (east of the auxiliary building) into the truckbay. A closed circuit television (CCTV) system for remote operation of the rail car and each crane is provided. A remote liner inspection station and decontamination station is provided in the east liner vault. At the inspection station container weight and radiation and contamination surveys can be obtained remotely. Two CCTV cameras in this station and a turntable allow visual inspections of high activity liners to be performed remotely. The truckbay provides access for trailer mounted shipping casks. The shipping casks must be loaded using the east vault crane.

The south end of the new building is the location of the separate DAW storage vault. This vault has fire protection sprinklers and boxes can be stacked four high. All container handling in this vault is by forklift.

Construction of the building was started in 1985 in anticipation of disposal site closures at the end of 1986. With the extension of disposal site access, the bulk of the installation was not finished until 1987. Since the building was not needed until burial site access was lost, the startup and operational testing were given a low priority. In 1989 disposal site access was again at risk and an intensive testing program was initiated. These tests were completed and the facility was turned over to the plant. Neither crane had been certified by a state inspector, however, and disposal access was extended again. In 1992 and several attempts were made to certify the cranes. These attempts failed and resulted in physical damage to the cranes. In 1994 a team of individuals was assembled to provide operating cranes for certification and enable liners to be stored on site.

PROBLEMS WITH THE NEW BUILDING DESIGN

Soon after the physical building was erected problems with the design started to emerge.

Shipping Cask Access

The 80 ft3 liners were designed to fit into an 80 ft3 Type B shipping cask. These

casks lost NRC certification. The truckbay door opening is only eleven feet high. This opening will permit access of LSA greater than Type A casks but not the new Type B casks mounted on trailers. Various options were considered to resolve this including the enlarging the concrete door (too expensive), purchasing our own cask (expensive, but feasible if the cask could be rented out), purchase of a lowlift trailer or bare liner transfer from rail car to shipping cask outside the truckbay. No decision has been finalized since shipping is no longer an option and Type B cask shipping regulations are due to change again.

Remotely Operated Bridge Cranes

Two 5 ton bridge cranes traveled the length of the vaults and move liners to and from the vaults into casks or the rail car. Heco Pacific Corporation provided the crane and control room design and fabrication. Many problems evolved with the complicated design.

1. limit switches. In order to control the crane from a remote room, the crane was fitted with many limit switches. These limit switches provide three different speed zones and protection from banging liners into the walls or obstructions. Different crane speeds were necessary. Slow speeds are required to provide control while grappling an object. Fast speeds are needed to traverse long distances. The limit switches became a nightmare of complexity when modifications to the original design were needed. First, installation of the cranes in the new building added the twist of the inspection and decontamination stations for one of the cranes. The addition of a slow zone encompassing these stations created the need for more limit switches which made the design more complicated, prone to failure and much harder to trouble-shoot. During the startup testing in 1989 the hoist limit switches were replaced by programmable units to enable stacking of liners two high in the vaults.

2. festoon cable trolleys. The originally supplied bridge crane cable trolleys failed the 1989 startup testing. Since the cranes were originally procured for the low head room constraints of the old building, flat ribbon cable was not used. Round festoon cable was supplied and this cable was mounted in a coiled horizontal orientation. This design was an asset for truckbay shielding since no notch in a vault wall was required to permit the festoon cable to pass. This cable passed over the vault wall guided by a channel track. The channel track design included a curve section in the truckbay to stow the coiled cable when the crane was parked in the truckbay. Unfortunately, the cable trolley trucks would stick in the channel track. The entire cable track and trolley were replaced with a triangular track with external truck trolleys for each crane.

3. control cabinet. The crane control cabinets originally contained inverter boards. When the west vault crane was damaged in 1992, a fuse blew and damaged one of these boards. The boards were not readily available an the damaged one had to be sent off site for repair. When the east vault crane was damaged in 1993 and it was determined that the board had been damaged again, it was decided to replace the boards with digital inverters. These new inverters were installed in the first quarter of 1994.

4. Festoon cable. During the functional testing of the new crane inverter controls in 1994, the crane experienced control problems. The cause of the problems was traced to short circuits between conductors in the circular festoon cable. Friction between the individual conductor insulation sheathing developed as the cable coiled and uncoiled during bridge movement. Several short circuits were noted over the length of the cable. The festoon cable was replaced for both cranes with circular multi-conductor cable with smooth and hard insulation sheathing. The new cable eliminated the friction and short circuit problem.

5. liner grapple device. During the 1989 startup testing it was noted that improved indication of remote grappling would be helpful to crane operators. Installation of mechanical flags attached to upgraded grapple limit switch pins in 1994 enabled the existing CCTV system to provide the operator with this indication.

Crane Retrieval System

The original crane retrieval system was a manual ratchet on a wire tow rope. Although it was proven to work in 1989 it was very slow and labor intensive. A system that could be powered by a portable electric drill was requested. This modification was approved, installed and successfully tested in 1993.

High Rad Barriers

In 1991, NRC regulations on high rad barriers were enforced under a new interpretation. Since the building was not designed with this interpretation in

mind, modifications were required to bar and lock any potential access point. It was decided that the easiest items to lock were the truckbay shield door and personnel door. A keyed hand switch was added to the control console and a ventilation penetration 20 feet high in the truckbay wall was barred.

Building Roof

The roof of the new building was concrete with a built-up coating. In 1992 leaks in the roof of the DAW vault were noted. Inspection of the roof determined that cracks had developed in both the liner and DAW vault roof sections due to seasonal thermal cycling. These cracks were leak repaired in 1992. In 1993, the DAW vault roof leaked again through two leak repaired cracks. A new polyisobutylene (PIB) membrane roof was installed over both liner and DAW vaults in 1994. This roof has withstood the recent 500 year rainfall in California.

Ventilation Ducting

During planning for roof repair in 1994, it was noted that the exterior ventilation ducting had corroded. The damaged ducting was the fan suction section which was square duct. This section was replaced by round ducting in 1994 to eliminate water pooling and subsequent corrosion.

Inspection Station

The inspection station and decontamination station were supplied by Hydro Nuclear through a competitive bid. The inspection station was to have been supplied with a remote readout scale linked to the liner turn table. The startup testing in 1989 determined that no remote scale was provided. Due to an overzealous seismic review of the preliminary drawings, the vendor was ordered to remove the proposed scale. Modification of the station to retrofit a scale with the turn table proved to costly. A portable scale was procured that could be remotely grappled by the east vault crane and set on top of the turn table. Cables from the scale must be feed through a penetration in the inspection station shield wall.

MODIFICATIONS TO THE OLD BUILDING

Conversion of Bay 6 to a Clean Waste Sorting and Hazardous Waste Handling Area.

In order to implement radwaste minimization fully, a green is clean program was established from day one at the plant. An area was needed to accumulate and sort this potentially non contaminated trash. Hazardous waste regulations in California are very onerous. A location was needed to sample and survey liquid and solid hazardous consumable generated from both contaminated and non contaminated locations within the radiological controlled area (RCA) of the plant. A sort table and a clothes dryer were added to the bay to support clean trash handling. Two hooded tables and several drum hoods were added to the bay to support hazardous waste handling.

Mixed waste storage.

Bay 4 of the old building now serves as the mixed waste storage location on site. The tanks in Bay 5 have been removed and we petitioned State of California to approve mixed waste storage in this area. Plans are to perform a hazardous waste closure on Bay 4 and return it to radioactive storage.

Remote Handling Modifications to the Filter Storage Area.

One of the upgrades which proved to be beneficial from an ALARA point of view was completed in the Bay 2 of the Old Radwaste Building. Originally, the aisles used to store highly radioactive drums were serviced by a pendant controlled hoist on a monorail system. This, combined with a simple mechanical drum grab proved to be very inefficient, therefore, resulting in unacceptably high exposure to the workers.

A new design was implemented which provided remote actuation to the hoist through a retractable cable reel installed on top of the shield wall which feeds control wires inside one cable to the hoist, trolley, new camera and new electric drum grab. With this new system, the operator can control the grapple, the hoist and the trolley from a control console outside the shield wall. The system operation can be observed on a monitor installed on the control console. This new system saved approximately 3 Man Rem of exposure during the last refueling outage.

EVALUATIONS AND MODIFICATIONS NOT ADOPTED

Decontamination Station.

The New Radwaste Storage Building was furnished with a Decontamination Station. Next to the inspection area there is a completely enclosed and water tight decontamination chamber. The decontamination for small tools and equipment can be performed by a worker standing outside the chamber and using the protruding gloves and the decontamination gun supplied with the chamber. Next to the decontamination

chamber, behind a shield wall is the control console for the remote operation of the turntable and the decontamination chamber. This station was originally designed for use with freon as the cleaning solvent. Regulatory changes on ozone depletion made startup testing of the station in 1989 with freon imprudent.
Several vendors were contacted in late 1993 about converting the station to use a different solvent. Both CO2 and hot water solvents were examined. The cost of the CO2 unit was justified by the projected need to decontaminate a liner or two per year. Experience with hot water in other services was insufficient to insure that residue on the station walls would not create an airborne radiation area. At this time other substitute solvents are being investigated.
Liner Stacking.
During the startup testing in 1989 it was noted that depth perception should be improved prior to stacking liners in storage. During crane operator training, feedback will be requested from personnel on needed improvement, if any, to improve stacking. One potential change would be to covert a fixed scan camera on each crane to a pan and tilt type to provide depth perception. Another option now available with the digital inverters would be to add a remote readout at the control console for grapple height. Based upon operator feedback we will proceed with changes for stacking liners as required.
CONCLUSION AND RECOMMENDATIONS
Numerous changes were implemented to the radwaste storage buildings at DCPP. These changes have resulted in providing adequate storage to support continued plant operation now that access to a disposal site is lost. Dry active waste and mixed waste have been stored at DCPP without incident. The first liner, actually a canned poly HIC, was placed in storage by the east vault crane on January 27, 1995. Recommendations based upon this experience are that container size selection is very important. Large containers may be too large to be shipped in new casks certified under shipping rule changes while waste is in storage. Ensure that any cranes are state certified before accepting turnover of the building.
Initially, building of interim storage facilities seemed a straightforward project. Experience has shown that due to the many regulatory uncertainties this is a complicated and time consuming project. Examples listed in this paper detail problems with containers, remotely operated cranes, saltwater environment, changing technology and unexpected needs which all contributed to the complexity, expense and delays of the endeavor.

7-7
A SYSTEMS ENGINEERING ANALYSIS TO EXAMINE THE ECONOMIC IMPACT FOR TREATMENT OF TRITIATED WATER IN THE HANFORD KE-BASIN
Antonio Villegas
Lavelle Clark
Andrew Schmidt
Pacific Northwest Laboratory
Richland, Washington
ABSTRACT
Federal and state agencies have established a Tri-Party Agreement (TPA) to address some key environmental issues faced at the Hanford Site. Under the TPA, the Department of Energy is currently under a consent order to reduce the tritium concentration in the spent fuel storage basin for KE-Reactor from 3.0 mCi/L to 0.3 mCi/L in the KE spent fuel storage basin, starting in 1996. The 100KE and 100KW Area fuel storage basins (K-Basins) at Hanford were built in the early 1950s to receive and provide temporary storage for irradiated fuel from the now shutdown KE and KW production reactors. In 1977, the KE-Basin began to leak at a rate of 13.5 gpm (51 L/min.), but decreased to 0.03 to 0.05 gpm (0.13 to 0.19 L/min.) by 1980. In 1993, the leak increased to a rate of 0.42 gpm (1.6 L/min.). This engineering analysis examines the relative costs to reduce the tritium concentration KE-Basin water using a polyphosphazene polymer membrane under development at Pacific Northwest Laboratory. The estimated cost of using the membrane to reduce the tritium concentration is compared to three no-treatment alternatives that include 1) disposing of the tritium-contaminated water directly to the Columbia River, 2) disposing of the contaminated water to the soil at the on-site Effluent Treatment Facility, and 3) disposing of the contaminated water by evaporation using solar evaporation ponds.

INTRODUCTION

The Department of Energy (DOE), other federal, tribal, and state agencies involved with Hanford Site are concerned about the KE-Basin water leakage and its possible effect on the environment. A Tri-Party Agreement (TPA) milestone has been established to remove all the spent fuel and sludge from the 100 Area fuel storage (KE and KW-Basins) in encapsulated form by December 31, 2002. In 1977, the KE-Basin began to leak to the ground at a rate of 13.5 gpm (51 L/min.), but decreased to 0.03 to 0.05 gpm (0.13 to 0.19 L/min.) by 1980. In 1993, the leak increased to a rate of 0.42 gpm (1.6 L/min.) Under the TPA, the DOE is currently under a consent order to reduce the tritium concentration in the KE-Basin to 0.3 mCi/L, starting treatment in 1996.

There are currently no commercially available methods to separate tritium from large volumes of water with relatively low tritium contamination levels. The Pacific Northwest Laboratory (PNL) is conducting a research effort to evaluate the use of membrane technology for separation of tritium from sources containing HTO as a contaminant.(1)

This engineering analysis examines the relative costs to reduce the tritium-concentration in the basin water using a deployment strategy that uses the polyphosphazene polymer membrane. The estimated cost to reduce the tritium concentration using the polyphosphazene membrane is compared to three no-treatment alternatives that include 1) disposing of the tritium-contaminated water directly to the Columbia River, 2) disposing of the contaminated water to the soil column after treatment at the on-site Effluent Treatment Facility, and 3) disposing of the contaminated water by evaporation using solar evaporation ponds.(2)

MEMBRANE DESCRIPTION

The results from the research conducted thus far indicate that the use of membranes to remove dilute tritium from water is achievable.(1) Aromatic polyphosphazenes were chosen as the polymeric material among membranes being investigated because they have been shown to possess excellent radiological, thermal and chemical stability as well as good tritium separation factors. The membrane system is similar to that of reverse osmosis and requires pressure from 10 to 48 psi (6.9 x 103 N/m2 to 3.3 x 104 N/m2). Research results have indicated that the polyphosphazene membrane within the system will provide up to 75% depletion of HTO after a single pass through the system. Additional research is being conducted to confirm and extend the usefulness of such a membrane separation procedure.

Based on an evaluation of the KE-basin treatment goals, and a knowledge of membrane system operations from research done at PNL, a membrane deployment concept has been identified that would reduce the tritium concentration in the KE-Basin. In this concept, water would be pumped from the KE-basin to a cascading membrane system made up of cocurrent multiple stages. The tritium-depleted stream from each stage would be recycled back to the basin. Concentrate would be used as the feed for the next stage. As the concentrate passes through each succeeding stage, the tritium concentration in the concentrate will increase. The total volume of concentrate leaving each stage in the conceptual scheme is set at 25% of the feed going into that stage. The tritium concentration increases in the concentrate stream to 220% of the feed to that stage and contains 55% of the tritium in the feed in 25% of the feed volume. When the concentrate leaves the final stage, it would then be solidified in cement and sent to an on-site DOE-operated low-level radioactive waste disposal facility.

To estimate the cost to reduce the tritium concentration in the KE-Basin using the membrane system, a mathematical model was developed to estimate the time required and waste volume generated during the different process scenarios. The model was based on the process configuration provided in Fig. 1. In this configuration, it is assumed that the tritium-depleted stream is continuously returned back to the KE-Basin, while the concentrated tritium stream is further processed to increase the tritium concentration and reduce the volume. A constant volume of water is maintained in the KE-Basin to ensure that any spent fuel elements that may be in the basin are not exposed to the atmosphere. Clean make-up water is added to the basin at the same rate that the concentrate stream is leaving the basin. Based on the model results, cost estimates were made for capital, operational requirements, and waste disposal.

MEMBRANE SYSTEM DESIGN CONCEPT ASSUMPTIONS

The design concept of the membrane system for removal of tritium and cost estimates

for the system are based upon the following assumptions:
1) Tritium concentration in the tritium-depleted stream is 60% of the concentration in
the feed stream entering each membrane stage for each pass.
2) Tritium-depleted stream to concentrate the stream flow ratios in each stage are
75%:25%.
3) The membrane system is configured in a cocurrent-flow series such that each
succeeding stage will increase the concentration of tritium in the brine stream (see
Fig. 1).
4) The system will operate with commercially available membrane technology.
5) The tritium-depleted stream is returned to the KE-Basin.
6) The starting material in the KE-Basin is 1 million gallons (3.8 million liters) of water.
7) The initial tritium concentration in the KE-Basin is 3.93 mCi/L.
8) The tritium concentration in the makeup water is 0.001 mCi/L.
9) No new tritium is formed or decays during the time the membrane system is operating.
A material balance was developed around the KE-Basin, pretreatment, and membrane processes to estimate the concentration of tritium in the tritium-depleted stream, concentrate stream, and KE-Basin at any time during the process.
A material balance may be estimated around any given stage:
Eq. (1)
where:
FRn = Feed rate entering the nth stage
Fpn = Tritium-depleted stream flow rate leaving the nth stage
Fbn = Concentrate stream flow rate leaving the nth stage
Based on the given assumptions for tritium removal from each stage, an equation to estimate the concentration leaving the nth stage may be derived:
Eq. (2)
where:
Cfn = Tritium concentration going into the nth stage
Cbn = Tritium concentration in brine leaving the nth stage
Co = Tritium concentration initially in the KE-Basin
To estimate the size of each stage, its feed rate must first be determined. Based on our assumptions, flow rates of the tritium-depleted stream to the concentrate stream will be 75:25, and the tritium-depleted streams from each stage will be returned to the K-Basin. Therefore, each stage receives the concentrate from the previous stage (i.e., FRn+1 = Fbn), and the feed rate at each succeeding stage is 25% of the feed rate of the stage up-stream of it (i.e., 0.25FRn = FRn+1, or 0.25Fbn = Fbn+1). An equation to estimate the flow rate from each stage can be determined by the following equation:
Eq. (3)
where:
F1 = feed rate entering first stage
Fb1 = tritium-depleted stream leaving the first stage
A differential balance was developed to indicate what is happening in the system at an instant of time. Based on the system configuration illustrated in Fig. 1 and the previous design equations, a differential balance was developed to estimate concentration of tritium in the KE-Basin at any time given initial tritium concentration and flow rate through the membrane system. This is shown below.
Eq. (4)
where:
n = number of membrane stages.
V = water volume in the KE-Basin, L.
vb = flow rate into the first membrane, L/min.
Ca = concentration of tritium in clean make-up water, mCi/L.
Cb = concentration of tritium in KE-basin water at t-time, mCi/L.
Co = initial tritium concentration in the KE-Basin.
t = time to reduce tritium concentration from Co to Cb, min.
Solving for t:
Eq. (5)
This equation estimates the time required to reduce the tritium concentration from

Co to Cb at a specified flow rate. Cost estimates can then be made based on the time required to operate the system and the volume of tritium separated, and the amount of waste resulting from the solidified tritium.

COST ASSUMPTIONS

The cost to reduce the tritium concentration in the KE-Basin using the membrane system was compared to other cost estimates made for three alternative disposition schemes for the water.(2) The membrane system concept and three alternatives considered were evaluated in terms of cost using the Equivalent Uniform Annualized Cost (EUAC) methodology that is identified in Refs. 2 and 3. These alternatives are 1) Columbia River discharge; 2) ground disposal after treatment at the Effluent Treatment Facility (ETF); and 3) solar evaporation at the 100K Area.

The KE-Basin currently has an existing pretreatment system to remove most of the dissolved materials and suspended solids and radionuclides (except tritium) from the KE-Basin prior to the any alternative action.(2) The cost for this pretreatment system was included in the total cost for each alternative. The cost for the pretreatment system is also included as part of the membrane system to provide a consistent cost analysis. The pretreatment system includes a sand filter, an ion exchange module (IXM), and an additional microfilter/ultrafilter and a polishing IXM that operates at 25 gpm (95 L/min.).

The costs for the alternatives were divided into capital costs and annual operating costs. The total purchased equipment cost for the pretreatment system is estimated to be $520,000. The estimates for the membrane system are based on the same cost factors and procedures used to estimate the cost estimates for the other alternatives. Additional costs include installation, testing, solidification, and disposal. The details for the development of the cost estimates for the other alternatives are provided by Hunacek and Gahir.(2) Cost estimates made for a membrane system were based on published information.(4,5,6,7)

To prepare the concentrate stream for final disposition, the stream is solidified into cement inside steel 208-liter containers. First, the concentrate stream is mixed with cement in a 208-liter container. Generally, 25 gallons (95 liters) is mixed with five 67-lb (30-kg) bags of cement and aggregate to obtain approximately 1 yd3 (765 L) of solidified material. The container is then transported 25 miles to the on-site disposal facility. The 1994 cost for on-site disposal of low-level radioactive waste is $49.96/ft3 ($1.76/L). The tritium concentration in the containers will not exceed the maximum concentration of 5 x 109mCi/m3 allowed at the disposal facility.

The estimated EUAC methodology estimate for disposing of the tritium-contaminated water to the Columbia River, disposing of the tritiated water to the soil at the Effluent Treatment Facility, and disposing of the tritiated water by evaporation using solar evaporation ponds was $2.25 million, $3.26 million, and $3.05 million, respectively. The cost estimates made for the membrane system range from $79 million to $2 million, depending on the number of stages used and variations in operating and feed flow rates.

The EUAC for the membrane system was calculated using a 7% time value of money and a project life of six years. The EUAC methodology estimates provides the annual operating and maintenance costs for the treatment system, including the costs associated with capital equipment investment.

The following assumptions were used to estimate the cost for the membrane system:

1) The maximum concentration of the solidified tritium does not exceed the waste acceptance criteria of 5 x 109 mCi/L.(2)
2) The 95 L/min. pretreatment system used in this analysis is the same one used in Hunacek.(2)
3) The concentrate stream is solidified using cement for final disposition.
4) The solidified tritium is transported 25 miles (38 km) to the on-site disposal facility.

The waste generated will be disposed at the Hanford Facility as DOE-generated low-level radioactive waste.

RESULTS

Three scenarios were considered to examine the costs for operating the membrane under different circumstances. The first scenario compared the cost of a 25-gpm (95-L/min.) system with a different number of membrane stages to the three alternatives identified in Hunachek and Gahir.(2) The second scenario examined the time effects with the system operated at 5-gpm (21.4 L/min.). The third scenario

examined the requirements needed to treat the tritium-contaminated water in one year for a different number of membranes stages. A brief summary of results are provided in Table I.

The first scenario assumed a constant feed water flow rate of 25 gpm (95 L/min.) that is consistent with the flow rate of the other alternatives. These three alternatives include discharge of the tritiated water to the Columbia River, ground disposal after further treatment at the Effluent Treatment Facility (ETF), and solar evaporation at the 100K Area seen in Fig. 2. The most expensive system was the one-stage membrane system. This system could reduce the tritium concentration to 0.3 mCi/L in 0.4 years with an EUAC cost of $79 million. For this option, the volume of solidified waste generated is estimated to be 4.4 million liters. Most of the cost is attributed the disposal of the solidified tritium waste. When the tritium concentration is increased in the concentrate stream, the disposal cost decreases significantly, but at the expense of treatment time. For example, to operate a 10-stage membrane system with a flow rate of 25 gpm (95 L/min.) into the first membrane, the EUAC cost is $2 million, 40 times less than the one-stage membrane system. The volume of waste generated was estimated to be 63,738 liters. But the process time needed to reduce the tritium concentration is 77 years, 190 times longer than a 1-stage membrane system. The optimum number of stages required ranges from 4 to 6 stages, with a cost from $9.4 million to $3.7 million, depending on the time specified. The cost to operate the membrane system for a different number of stages decreases asymptotically due to the increase in labor required to operate the system for a longer period of time.

The second scenario assumed that the flow rate into the first stage was 5 gpm (21.4 L/min.). The reason for this scenario was to examine the effect that the flow rate had on the membrane system seen in Fig. 3. The cost to reduce the tritium concentration in the KE-Basin was similar to the 25 gpm (95 L/min.) for the corresponding number of stages. For one- and ten-stage systems, the cost estimates were $79 million and $2.1 million, respectively. The time required to operate these systems increased significantly, 1.6 years for a one-stage system and up to 342 years for a ten-stage system. The volume of waste generated is the same for the corresponding number of stages when comparing the 25 gpm (95 L/min.) membrane system to the 5 gpm (19 L/min.) membrane system, but the process time required to generate the solidified waste increased in direct proportion to the decrease in flow rate. The cost to operate the membrane system for a different number of stages decreases asymptotically due to the increase in labor required to operate the system for a longer period of time.

The third scenario assumed a one-year processing time to reduce KE-Basin tritium concentration from 3.93 mCi/L down to 0.3 mCi/L. The economic analysis indicated that the cost ranged from $79 million to $6.5 million, depending on the number of membranes required to remove the tritium from the KE-Basin water as seen in Fig. 4. When a one-stage membrane is used to reduce the tritium concentration in one year, a flow rate of 9 gpm (34 L/min.) is required. The volume of solidified waste generated is approximately 4,400 m3. The capital and operation cost for a 1-membrane system is estimated to be $1.7 million. The disposal cost for the resultant solidified waste is estimated to be $77 million.

When a ten-stage membrane system was considered, a 1,900 gpm (7,200 L/min.) unit was required to reduce the tritium concentration to 0.3 mCi/L. The volume of solidified waste generated is estimated to be 0.4 m3. The capital and operating cost for a 10-stage membrane system is $25 million. The disposal cost for the solidified waste based on the estimated waste volume is $64 thousand.

The optimum cost for a one-year treatment to reduce the tritium concentration is estimated to be $6.6 million, and uses and 6-membranes with a flow rate of 177 gpm (670 L/min.). The estimated volume of solidified waste generated from this option is 3.9 m3. The capital and operational cost estimated for this system is $5 million. The disposal cost for the solidified material is $1.5 million.

ACKNOWLEDGMENT

Pacific Northwest Laboratory is operated for the U.S. Department of Energy by Battelle Memorial Institute under Contract DE-AC06-76RLO 1830.

APPLICATIONS OF FIBER-REINFORCED CONCRETE CONTAINERS IN FRANCE AND IN THE USA

Richard Pech
SOGEFIBRE
William Gallagher
NUMATEC

CNSI

ABSTRACT

Commercial generators, of low-level radioactive wastes in 31 states, are faced with the dilemma of unavailability of commercial low-level radioactive waste disposal facilities for some undefined period of time. Many commercial generators have developed contingency plans for on-site storage of generated waste until such time that the developing compact disposal facilities become available. Requirements for containers to be used for extended periods of on-site low-level radioactive waste storage include durability, ruggedness, shielding capability, handling flexibility and acceptability at the compact disposal facilities. Chem-Nuclear Systems, Inc. (CNSI) has developed a container, which meets the stated requirements, for use as an on-site storage container and as a final disposal container. This versatile container, known as the Multi-Use Container (MUC), is also well suited for waste processing operations and over-the-road transport.

The MUC consists of a fiber-reinforced concrete outer shell with a polyethylene inner container. The utilization of fiber -reinforced concrete as a low-level radioactive waste disposal container material was developed in France by COGEMA in the late 1980s. The use of polyethylene as a low-level radioactive waste disposal container material began in the United States in 1981. Combining the two materials provides technical and operational advantages that give the MUC superior versatility. This paper provides details on the design and operational applications of the MUC. Information on the certification of the MUC as a high integrity container is also presented.

INTRODUCTION

Chem-Nuclear Systems, Inc. (CNSI) recognized in early 1991 the potential for interruption of access to disposal facilities for many of the commercial low-level radioactive waste generators. Many commercial generators had arrived at the same conclusion, and were developing contingency plans to store generated waste on-site until such time as disposal facilities were available. In response to this, CNSI embarked on a program to develop a container that could be used by generators for on-site storage and as the ultimate disposal container.

In the late 1980s, CNSI was selected as developer and operating contractor for three of the compact disposal facilities. These included the Southeastern Compact in North Carolina, the Appalachian Compact in Pennsylvania, and the Central Midwest Compact in Illinois. Each of these disposal facilities requires that low-level radioactive waste be placed in a concrete overpack for disposal. Polyethylene containers received at CNSI's Barnwell disposal facility are also placed in concrete overpacks prior to final disposal. With this in mind, attention was focused on development of a durable and efficient concrete storage/disposal container.

In France in the late 1980s, a multiple year research effort by COGEMA, a world leader in the nuclear industry, culminated in the development of fiber-reinforced

concrete containers for containment and disposal of low and medium level wastes. These containers were certified as satisfying all French safety requirements relating to waste immobilization and disposal by ANDRA, the French national radioactive waste management agency (1). SOGEFIBRE, a subsidiary of Societe Generale pour les Techniques Nouvelles (SGN), member of the COGEMA group, began fabricating the containers on a production scale in July 1990 utilizing a dedicated production facility in Valognes, France. The containers were supplied to the French Atomic Energy Commission (CEA), COGEMA, ANDRA and others to store and dispose of low and medium level waste.

In June 1991, SOGEFIBRE made a presentation on the fiber-reinforced concrete technology to CNSI. The fiber-reinforced concrete containers developed in France fit well with the CNSI objective of developing a concrete container. However, given the differences in waste processing techniques and regulations between the U.S. and France, it was recognized that an additional element would be needed in the container design.

CNSI has been a leader in the development and utilization of polyethylene containers for use with low-level radioactive waste processing and disposal since early 1981. Polyethylene containers are well known for providing a highly corrosion resistant, virtually impermeable waste container. The polyethylene containers are familiar to the commercial generators of LLW and are simple to manufacture. The concern with polyethylene has been the structural effect of long-term sustained load. The combination of an external concrete shell to handle compressive structural loadings with an internal polyethylene container circumvents this concern. It was clear that a container composed of a fiber-reinforced concrete structural shell with a polyethylene inner container would provide a highly durable and versatile container which could be used not only for storage and disposal, but also for waste processing activities currently practiced by the generators and over-the-road transport for shipments containing Type A quantities of waste.

Moreover, CNSI was confident that such a container would be certified by the U.S. Nuclear Regulatory Commission as a high integrity container under the provisions of 10 CFR 61 and the Branch Technical Position on Waste Form. Subsequently, SOGEFIBRE sub-licensed the fiber-reinforced concrete container technology to CNSI and a joint effort was undertaken to develop a Multi-Use High Integrity Container. This paper will discuss the MUC design and its operational applications.

CONTAINER DESCRIPTION

The container is composed of a rectangular prismatic concrete shell and an inner polyethylene container. The inner polyethylene container may have the shape of a right circular cylinder or rectangular prism. The inner polyethylene container provides a
highly corrosion resistant, virtually impermeable container surrounding the contained waste. The fiber-reinforced concrete outer shell provides a high compressive strength, highly durable, and radiation-shielding structural shell. This combination of fiber-reinforced concrete structural shell and inner polyethylene container takes optimum advantage of the capabilities of both materials. The fiber- reinforced concrete shell provides the required mechanical strength, and is designed to provide durability with respect to the disposal environment as well as radiation shielding. The inner polyethylene container provides a highly effective corrosion barrier between the contained waste and the concrete shell, and since it is essentially impermeable, it also serves as an effective barrier to radionuclide migration.

This combination of materials also combined the expertise of both SOGEFIBRE and CNSI. By the end of 1994, SOGEFIBRE had produced around 30,000 fiber-reinforced concrete containers for disposal of low and medium waste in France. CNSI has provided over 7,500 polyethylene containers for disposal of low-level wastes in the United States.

The design of the MUC has benefitted from this combination of experience and knowledge gained in container production and utilization.

Figure 1 defines the MUC in its disposal configuration and demonstrates the inner polyethylene container and the fiber-reinforced concrete structural shell. Table I provides dimensions, weights and volumes of the MUC family of containers.

The inner polyethylene container is designed to be closed by means of an induction welding process which heat seals the lid to the vessel body. This feature allows the inner polyethylene container to be sealed in a remote operation.The fiber-reinforced

concrete shell is closed with a precast concrete lid for storage and transport, Fig. 2. This lid is removed, and a cast-in-place fiber-reinforced concrete lid is placed for final disposal.
Handling of the MUC is accomplished by utilizing grooves cast into the container bottom to permit handling with forklift tines, or by using lifting attachments in the topside of the container walls to permit handling with overhead cranes.The inner polyethylene container is equipped with a passive filter vent to allow venting of any gases generated in the waste, but no release of solid material. No vent is required in the fiber-reinforced concrete shell.The polyethylene container can also be equipped with an optional sample tube and seal plug. This sample tube permits sampling and inspection of the contained waste until such time as the concrete disposal lid is placed.Additional shielding can be added to the container in the interstitial space between the polyethylene inner container and the concrete structural shell. This shielding can consist of conventional concrete, high density concrete or iron/steel, and is selected to optimize shielding characteristics and economics. The size of the polyethylene inner container is adjusted to accommodate the shielding thickness required.

OPERATIONAL APPLICATIONS

The MUC is a highly versatile container well suited to the processing, storage, transport and disposal of low-level radioactive waste (Table II).

Processing Applications

Several MUC processing configurations are shown in Fig. 3. The MUC may be used to process a wide range of low-level radioactive wastes. Current dry and wet waste processing techniques may be used in conjunction with the MUC similar to current processing in conventional steel or polyethylene containers. Disposal of filters or irradiated hardware in the MUC is also similar to disposal in currently used containers.
Waste can be processed directly in the inner polyethylene container with the inner polyethylene container in place inside the fiber-reinforced concrete shell. In the event the MUC cannot be positioned to allow direct waste processing due to weight or size limitations, the MUC can be supplied with a removable cylindrical inner polyethylene container that can be loaded in a separate area and then rejoined with the fiber -reinforced concrete shell. This processing configuration would also be applicable for higher activity waste loadings when waste loading in the container was projected to require over-the-road transport in a Type B radioactive waste shipping cask. In this case,the cylindrical inner polyethylene container will be shipped separately to the disposal facility in a Type B radwaste shipping cask, and placed into a fiber-reinforced concrete shell at off-load at the disposal facility. The inner polyethylene container, cylindrical or rectangular, can be supplied with a full opening top lid for bulky waste or a smaller manway size opening for liquid waste processing.

Storage Applications

The MUC is an excellent storage container for extended on-site storage applications. The fiber-reinforced concrete structural shell has been evaluated for exposure to environmental conditions, such as precipitation, sunlight and potential accident conditions such as fire or dropping, and demonstrated to be a highly durable structure (2). Polyethylene containers have also been previously evaluated and shown to be suitable for safe storage of low-level radioactive wastes for extended periods of time (3).
The proven durability of the MUC, coupled with the shielding capability, make it an ideal storage container. Coupling this with the pending U.S. NRC certification as a high integrity container, ensures that the MUC used for storage will be acceptable for disposal at a licensed disposal facility without repackaging.

Transport Applications

Over-the-road shipment using the MUC provides both economic advantage and a high degree of operational simplicity. There are two options for use of the MUC for over-the-road transport. As noted previously with waste quantities requiring shipment in an approved Type B package, the cylindrical inner polyethylene container must be shipped separately in a U.S. NRC certified radioactive waste shipping cask. The inner polyethylene container will then be placed in a fiber-reinforced concrete structural shell at cask off-load at the disposal facility. All other waste can be shipped in the MUCin its transport configuration shown in Fig. 4.
This configuration consists of a removable energy absorbing impact limiter and

impact limiter and MUC tie-down system. The MUC and its transportation configuration have been evaluated and tested to verify conformance to Titles 10 and 49 of the Code of Federal Regulations. This evaluation demonstrated acceptability as a Type A packaging (Specification 7A container) in accordance with the U.S. Department of Transportation regulations.Successful full-scale drop testing of the MUC was performed to verify the MUC integrity under worst case accident scenarios.

Disposal Applications

The MUC disposal configuration is shown in Fig. 1. For disposal, the precast concrete transport/storage lid is removed.Any space between the inner polyethylene inner container and fiber-reinforced concrete wall is filled with a cementitious material. A fiber-reinforced concrete lid is then cast in place to close the MUC. The MUC is designed for shallow land burial to a depth of 25 feet and for engineered facility disposal with MUC stack heights up to 30 feet. As previously noted, the pending U.S. NRC certification as a high integrity container will ensure MUC acceptance at licensed disposal facilities, and provides certification of the fact that the MUC will remain structurally stable in the disposal environment for a period of at least 300 years.

HIGH INTEGRITY CONTAINER CERTIFICATION

A key element in the development of the MUC is obtaining U.S. NRC certification of the MUC as a high integrity container under the provisions of 10 CFR 61 and the Branch Technical Position on Waste Form. CNSI and SOGEFIBRE worked together to integrate the fiber-reinforced concrete methodology, test data, and industrial test results,together with the MUC design and high integrity container regulatory requirements specified in 10 CFR 61.56(b) (1) and the U.S. NRC Branch Technical Position on WasteForm (Revision 1). Included in this effort was full-scale prototype container testing which was conducted in the United States and in France by a joint CNSI/SOGEFIBRE team.

CNSI submitted the MUC Topical Report, "Multi-Use container High Integrity Container Licensing Topical Report, Docket # WM-107", to the U.S. NRC on July 23,1992. After thorough evaluation and review, U.S. NRC certification of the MUCas a high integrity container, is expected in the first quarter of 1995. Following NRC certification of the MUC as a HIC, it is CNSI's intention to use this technology to obtain approval for a cylindrical version of the MUC as well as container sizes in addition to those described in Table I.

CONCLUSION

The MUC is a versatile container well suited to commercial low-level radioactive waste generators' requirements. The MUC is designed to function as a process container, storage container, over-the-road transport container, and as a disposal container. The technology incorporated into the MUC includes the experience of COGEMA in developing fiber-reinforced concrete containers used for low and medium level waste disposal in France, the fiber-reinforced concrete container manufacturing experience of SOGEFIBRE and CNSI experience with polyethylene containers and low-level waste management services to the U.S. commercial nuclear industry.

The MUC accommodates low-level radioactive waste processing techniques currently in use and incorporates features which make it a simple easy-to-use container. Its design, incorporating high durability materials and self-shielding capability, makes it an excellent storage container. U.S. NRC certification as a high integrity container ensures MUC acceptability at licensed disposal facilities without the need for repackaging the contained wastes.

Use of fiber-reinforced concrete containers in France, their impending use in the United States, and projected use in eastern Europe demonstrate that the fiber-reinforced concrete container technology is becoming a major technology for low-level radio active waste disposal.

RADIOLYTIC HYDROGEN PRODUCTION DURING THE LONG TERM STORAGE OF SPENT ORGANIC ION EXCHANGE RESINS

Charles L. Crawford
Ned E. Bibler
Westinghouse Savannah River Co.
Aiken, SC 29808

ABSTRACT

Removal of radionuclides from contaminated process waters requires the extensive use of organic ion exchange resins at the Savannah River Site (SRS) and at Hanford. During storage of the spent resin, radiolysis from the radionuclides sorbed on the resin produces hydrogen and can create a flammable mixture in the storage container. This report presents results of radiolysis studies involving typical organic anion, cation, and mixed anion/cation resins used at SRS. These results include measurements of hydrogen production, water-soluble material formation, and changes in mass, volume, and moisture content due to exposure of the resins to gamma radiation. Hydrogen production rates, expressed in terms of G values or the number of molecules produced per 100 eV of energy absorbed by the resin, are used to estimate a minimum time to reach a flammable mixture in an actual SRS reactor moderator resin storage container. The G(H2) values determined for the anion resin, the cation resin, and 1:1 volume mixtures of the two, are in the range of 0.1-0.3 molecules/100 eV. Oxygen depletion was observed for all the resins irradiated in air-sealed systems. We have also examined the effect of liquid slurry type and the effect of varying water content on the radiolytic hydrogen production using a Savannah River Technology Center (SRTC) developed resorcinol-formaldehyde polycondensation type cation exchange resin. Total radiolytic gas production is highest for resorcinol resin-acid slurries and radiolytic hydrogen evolution is highest for resorcinol resin-water slurries. For resins irradiated with various amounts of water present, maximum hydrogen evolution occurs for the resin containing highest water content (~97 wt% water), with G(H2) = 0.7 molecules/ 100 eV. The measured hydrogen yield decreases linearly to a minimum of G(H2) = 0.1 molecules/100 eV for a pre-dried (~0 wt% water) resin.

INTRODUCTION

Organic ion exchange resins are used at Savannah River Site (SRS) and Hanford as well as many commercial nuclear installations to remove radionuclides from process waters that have become contaminated.(1-4) Contamination of reactor moderator water can occur during reactor operation or the water in basins used to store spent fuel such as the K-basin at Hanford can become contaminated. After these resins have been used to the extent that they are no longer efficient for removing the radionuclides, the resins need to be stored and eventually placed in permanent disposal. During this storage, radiolysis from the radionuclides on the resin produces hydrogen (5,6) and can create a flammable mixture in the storage container.(7,8) Recent reviews stressing the importance of understanding the effects of radiation on resins used in the nuclear industry have been published. (9,10) This report presents results of radiolysis studies designed to provide an estimate of the rate of hydrogen production from two commonly used resins so that the time to reach a flammable mixture (4% hydrogen in air) in the storage container can be estimated. We also include in this report further studies on our previously reported investigation of the radiolytic stability of a resorcinol-formaldehyde ion exchange resin.(11,12) The resorcinol-formaldehyde polycondensation-type cation exchange resin is currently being investigated for potential cesium removal applications at Hanford and the Savannah River Site (SRS).(11-13)

EXPERIMENTAL

Ion Exchange Resins

Two commercial resins that are used at SRS for moderator water decontamination were irradiated with Co-60 gamma rays. One resin was an anion exchange resin (Amberlite IRA-400-OH) and the other a cation exchange resin (Amberlite IR-120-H).(1,2) Both resins had a styrene-divinyl copolymer as the organic matrix. The anion resin contained trimethyl quaternary ammonia groups and the cation resin contained sulfonate groups. These resins are identical to those used at Hanford except the anion resin at Hanford contains ammonium groups rather than the trimethyl ammonium groups. The two resins were irradiated separately and then irradiated as a mixture. The mixed bed resin was a 5:1 anion to cation equivalent mixture formed from mixing

equal volumes of each resin. The resins are usually used in the mixed bed form because this form simultaneously removes cationic and anionic radionuclides from the contaminated water. The resorcinol-formaldehyde resins used in this study were of the potassium (K) form that results from the condensation reaction between resorcinol and formaldehyde in KOH.(11)

Irradiation Methods and Systems

The ion exchange resins were irradiated with Co-60 gamma rays and the rate of gas formation measured as a function of radiation dose. The anion and cation resins were each irradiated as received, i.e. neither resin was contacted with water prior to radiolysis. The mixed bed resin (damp) was irradiated in the swollen form (~50% water) in which they will be stored in the reactor areas at SRS. The mixed resin sample was prepared by mixing equal volumes of the anion and cation resins, rinsing with ASTM Type-I water and vacuum filtering immediately before irradiation. ASTM Type-I water is a highly purified form of water with resistivity > 18 Mohm.cm. A mixed bed resin (dry), which was not contacted with water prior to radiolysis (~35% water), was also studied. Moisture contents of the resins were determined from heating ~ 1 gram samples in triplicate at 60oC in a convection oven until no further mass change, typically for about 5 days. Higher drying temperatures were avoided due to possible thermal decomposition of the resins. (2)

Gas evolution studies involving the resorcinol-formaldehyde resins were carried out using slurries of 0.5 gram K-form resin to 1.0 ml volume of 101-AW Hanford simulant, ASTM water, and 0.5M nitric acid. (The 101-AW Hanford simulant has the composition of the caustic supernate in the 101-AW tank at Hanford. See Table I of reference 11 for its composition). K-form resin/ASTM water slurries containing varying resin to water ratios were also irradiated to investigate the effect of the resin to water ratio on hydrogen production.

Irradiations were performed using a Co-60 gamma ray source submerged beneath 25 ft. of water. All resins were irradiated in 45 ml stainless steel air-sealed vessels. Prior to sealing the systems, no attempts were made to purge air from the slurry or the void volume of the system. Two identical samples were simultaneously irradiated to provide a duplicate data set for each system studied. The vessels were connected via 4 ft. of 1/8 in. O.D. stainless steel tubing and 24 ft. of 1/8 inch O.D. nylon pressure tubing to pressure transducers outside the radiation field. The pressure transducers were equipped with digital readouts. The pressure was measured as a function of radiation dose. The dose rate was 6.6-6.9 E+05 rads/hr based on the standard potassium iodide (KI) dosimeter solution. (14,15) The temperature during the irradiations was ~ 30oC due to gamma heating. Gases were collected after the irradiation in evacuated 1 L glass bulbs that had been evacuated immediately prior to gas collection using a mechanical pump. Total collection of system gases in this manner enabled the analysis of a homogeneous gas sample. Prior gas sampling techniques involved typically 5 successive 5-10 cc aliquots that were sampled ~ 4 ft. above the radiolysis vessels using gas chromatography syringes. (11)

All the SRS reactor moderator resins were rinsed with 50 ml of ASTM Type-I water before and after irradiation. The resulting leachates were analyzed to compare the difference in water soluble products leached from both the unirradiated and irradiated resins. The 50 ml rinses were analyzed for pH, ion content (anion scan and NH4+), and both total inorganic carbon (TIC) and total organic carbon (TOC). The anion and cation rinsed resins were not irradiated in this study. The anion and cation resins were rinsed only to provide leachates for comparison to leachates derived from irradiated as received anion and cation resins.

Analytical Methods

Gas compositions were determined by gas chromatography (GC) using a previously described Varian Model 3400 gas chromatograph.11 This GC instrument was equipped with both a thermal conductivity detector and a flame ionization detector. The columns used were a Chromosorb-101 column and a molecular sieve 13X column with argon as the carrier gas. Various standard gases (Scott Specialty Gases) consisting of H2, O2, N2O, CO, CO2, and CH4 in the range of 0.1 to 20 vol% mixed with N2 were used for calibration. Trimethylamine was detected using gas chromatography / mass spectroscopy (GC/MS) instrumentation. The GC/MS consisted of a Hewlett Packard 5090 series II GC and a Hewlett Packard model 5971 quadrupole mass spectrometer. The concentrations of various anions and the ammonium cation were determined from the SRS reactor moderator resin rinses using a Dionex ion chromatography (IC) instrument. Anions were separated using a Dionex AS4/AG4 column with an equimolar

(0.002M) NaHCO3/Na2CO3 eluent and conductivity detection. Cations were separated using a Dionex CS3/CG3 column with a 0.034M aqueous HCl eluent and conductivity detection. Total inorganic and organic carbon measurements were made on the 50 ml rinses of the SRS reactor moderator resins using a previously described O. I. Co. Total Carbon analyzer.11

RESULTS AND DISCUSSION

KI Dosimetry

The standard KI dosimetry system is based on measurement of hydrogen and oxygen produced from the radiolysis of aerated 0.1mM aqueous KI solutions in the dose range of 5E+06 to 1E+10 rads. (14,15) This dosimeter was selected for use in the present study to provide 1) a dosimetry calibration system that was identical to the irradiation configuration used in all of the resin and resin/slurry irradiation experiments and 2) an accurate measure of the hydrogen yields for all the resin and resin/slurry systems studied. Figure 1 shows the average pressure changes produced when two identical aqueous 0.1mM KI solutions were simultaneously irradiated in air-sealed vessels. For the aqueous KI dosimetry system (see upper curve in Fig. 1) the pressure starts to linearly increase after a short time period during which the solution becomes saturated with the two radiolytically produced gases, hydrogen and oxygen. Table I shows the gas compositions determined for the KI dosimetry system. Rates of gas production were calculated in terms of G values or molecules produced per 100 eV of energy absorbed by the system. These G values for the KI dosimeter are shown in Table II. Also shown in Table II is the experimentally determined dose rate that is calculated from the total number of moles of gas evolved during the radiation time. (See equation #17 of reference 15). The average value of 6.93 E+05 rads/hr found for the KI system is comparable to the value of 6.87 E+05 rads/hr that was previously determined from the same irradiation source using thin film nylon dosimeters.16 As shown in Table II, our experimentally determined G values for hydrogen and oxygen production are in good agreement with the published values of Hart and Gordon.14

Gas Production From Radiolysis of SRS Moderator Resins

Figure 1 shows the average pressure changes produced when the SRS reactor moderator resins were irradiated in air-sealed vessels (see lower four curves). Two identical resin samples were irradiated simultaneously for each of the four resin systems shown. In all the air-sealed resin systems, the pressures initially decreased rapidly, followed by approximately linear increases over time. Both the anion and the mixed resin (damp) systems were pressurized at the end of the irradiation to ~ 2.0 psia above the starting pressures of 1 atmosphere, or ~ 14.67 psia. The mixed resin (dry) system final pressures were ~0.5 psia above the starting pressure and the cation system final pressures showed no significant change from the starting pressures. The initial pressure decreases observed are due to oxygen depletion from the air initially present in the sealed systems. Oxygen depletion from the irradiation of organic resins (5,6) inorganic zeolites, (17) and concrete (18) in sealed systems has been reported. Table III shows the gas compositions determined for the SRS reactor moderator resins. Hydrogen was produced in all the resin experiments. Small amounts of methane, carbon monoxide, and carbon dioxide were also produced. With the anion resin, we have also detected trimethylamine using GC/MS techniques. The irradiated anion resins had strong ammonia-like odors as well. Rates of gas production were calculated in terms of G values or molecules produced per 100 eV of energy absorbed by the system. These G values for the resins are shown in Table IV. For the mixed bed (damp), anion, mixed bed (dry), and cation resins, the G values for hydrogen are 0.29, 0.26, 0.13, and 0.12 molecules/100 eV, respectively. The precision of these results is 10% or better.

Radiation Effects on SRS Moderator Resin Properties

Radiation induced changes in mass, volume, and moisture content for the irradiated SRS reactor moderator resins are shown in Table V. Masses were obtained by weighing the radiolysis vessels containing the resin before and after irradiation. Volume changes were determined from measurements of the height of the resin columns contained in the radiolysis vessels before and after irradiation. As described above, the resin moisture contents were determined from heating ~ 1 gram samples in triplicate at 60C in a convection oven until no further mass change. The anion resin shows the largest changes in mass, volume, and moisture content. All irradiated resins decreased in volume. The mixed resin (damp) was the only resin irradiated in which an increase in moisture content was not observed.

Water-Soluble Products Leached From SRS Moderator Resins
The SRS reactor moderator resins were each rinsed with a single portion of 50 ml of ASTM Type-I water before and after irradiation. The resulting leachates were analyzed for soluble products leached from both the unirradiated and irradiated resins. Radiolytic production of dissolved ion and carbon in the irradiated resin rinses was calculated in terms of G values or molecules of dissolved species produced per 100 eV of energy absorbed by the 26-31 g samples irradiated (resin and some H2O). These G values for the water-soluble ion and carbon components are shown in Table VI.
The ion concentrations in the unirradiated and irradiated rinses from the mixed resins (damp) were all < 8E-05M. There were small amounts of organic carbon detected (3E-04M for unirradiated rinses and 9E-04M for irradiated rinses) and very little inorganic carbon detected (<1E-04M for both unirradiated and irradiated resin rinses). Similar results were found for the mixed resin (dry) rinses. These results indicate that water-soluble products released from the irradiated mixed resins are insignificant relative to water-soluble products released from the individual irradiated anion or cation resins discussed below.
The ion concentrations in the unirradiated and irradiated rinses from the anion resins were all insignificant at concentrations < 8E-05M, except for the nitrite and ammonium ions which were detected in the irradiated resin rinses at concentrations of 2E-04M and 6E-04M, respectively. These two ions were not detected in the unirradiated anion resin rinses. Three prominent chromatographic peaks at larger retention times than the ammonium ion chromatographic peak appeared in the ion chromatograph of the irradiated anion resin leachate. Comparison of these peaks with the elution pattern of substituted amines indicates that the components are most likely due to methyl-, dimethyl-, and trimethylamine dissolved in the leachate. A very large increase in the soluble organic carbon content of the anion resin rinses due to radiation was measured. The soluble carbon G values shown in Table VI were calculated using the formula weight of carbon = 12. The large amounts of dissolved organic carbon, ~ 0.2M, in the irradiated anion resin leachates are consistent with the IC data discussed above, i.e. the presence of dissolved substituted amines. Similar production of water-soluble aliphatic amines has been reported by Hall and Streat from the destruction of strong-base functional groups during the radiation-induced decomposition of aqueous slurries of organic anion exchange resins.19 The irradiated anion resin leachate also contained strong ammonia-like odors similar to the odors from the actual irradiated anion resin. The unirradiated anion resin leachate was odorless.
The ion concentrations in the unirradiated and irradiated rinses from the cation resins were all insignificant at concentrations < 8E-05M, except for the formate and sulfate ions. Formate and sulfate ions were detected in the irradiated resin rinses at concentrations of 9E-04M and 5E-02M, respectively. Both formate and sulfate ion concentrations were 3E-04M in the unirradiated cation resin rinses. Similar sulfate production from radiolytic degradation of organic cation exchange resin has been reported. (1) Large amounts of dissolved organic carbon in both the unirradiated cation resin leachate (0.019M) and the irradiated cation resin leachate (0.017M) were detected. Both the unirradiated and the irradiated cation resin leachates were noticeably yellow in color. We suggest that this color is due to soluble organic components leached from the unirradiated cation resin and soluble organic degradation products leached from the irradiated cation resin. All other leachates from the mixed resin and anion resin were colorless.
Calculation of the Shortest Time to Generate a Flammable H2 Air Mixture
During storage of the spent reactor moderator resins, H2 from radiolysis can form a flammable gas mixture in the vapor space above the resins if this space is not ventilated. Calculations involving radiolytic hydrogen generation in sealed radioactive waste containers have been reported. (7,8) From the equations given below, (7) it is evident that the times necessary to create flammable mixtures in sealed storage containers are directly proportional to the free volume in the container and inversely proportional to both the amount of resin present and the dose rate to the resin from the radionuclides sorbed on it.
Eq. (1)
with:
Partial pressure H2 for flame = 0.59 psi (based on LFL of 4% H2 in air)
Eq. (2)

with:

G(H2) = # molecules of H2 produced per 100 ev absorbed
N = Avogadro's number, 6.02E+23
dE/dt = total radiation dose rate, ev/hr
R = the gas constant, 0.043 psi ft3/mole oK
T = temperature, oK
V = volume in gas phase or free volume, ft3

Spent ion exchange resins from SRS reactor moderator purification activities are stored at SRS in ~40 ft3 stainless steel containers. Each container of dimensions ~4 ft height by ~3 ft diameter contains ~30 ft3 of resin and ~10 ft3 of free volume. Radiation measurements on the outer surface of these containers containing actual spent mixed resin indicate dose rates in the range of 0.1 to 18 r/hr at surface contact. The deionizer resins in the containers had been drained a small amount and were in the deuterated form resulting from the processing of reactor moderator water in SRS reactors. The radiation is due predominately to C14, H3, Sr90, and Cs137, all of which have half-lives
> 10 yrs, that are sorbed on the spent mixed resins.20 Using the maximum measured dose rate of 18 r/hr it has been estimated that the 30 ft3 of spent resin could have a maximum of ~4 W of activity . The total radiation dose rate for the 30 ft3 of spent resin is then calculated to be (4W x 2.25E+22 ev/hrW) = 9E+22 ev/hr. Using the measured G value for hydrogen production for the damp mixed bed resin (47 wt% water) of 0.3 molecules per 100 ev and a free volume of 10 ft3, the minimum time to reach a flammable mixture of hydrogen in air inside a sealed container at a temperature of 25oC is calculated from equation 1 above to be ~1,026 days or ~2.8 years.

Resorcinol-Formaldehyde Resins

Potassium form resorcinol-formaldehyde resins were irradiated in 101-AW Hanford simulant, ASTM water, and 0.5M nitric acid using 0.5 gram to 1.0 ml slurries. The average pressure differences produced when two identical slurries of resin were simultaneously irradiated in sealed vessels are shown in Fig. 2. Compositions of the gases produced in each system are given in Table VII. The gas compositions shown in Table VII of the present study were determined from the total collection of the gases present in each irradiated system. Table VIII shows the G values for the various gases produced. The G values shown for the resin in 101-A Hanford simulant slurries have been corrected for the dose absorbed by the resin-slurry, which has an experimentally determined density of 1.3 g/ml. Hydrogen is the predominant gas component produced for both the resin-101-AW Hanford simulant and the resin-water slurries. CO2, H2, and N2O are the main gas components determined for the resin-0.5M HNO3 slurries. It does appear that nitrogen may indeed be depleted in the resin/acid system. These gas compositions and G values presented in this study are to be compared to previous gas composition and G value results (see Tables V and VI of reference 11) that were determined from averages involving the collection of typically five successive 5 cc increments taken from a single sample using gas chromatography syringes. We suggest that while our present results are not significantly different from those previously reported for the same three resorcinol resin-slurry systems, both the accuracy and precision (typically 10% or better) with which the present results were determined is much better due to the revised gas sampling methods.

Gas Production from Different Resorcinol Resin/Water Ratios

Potassium form resorcinol-formaldehyde resins were irradiated in ASTM water at varying resin to water ratios. Additional systems consisting of 1) resin stored under ambient conditions (~20 wt% water), 2) dried resin (~0 wt% water), and 3) ASTM water containing no resin were also irradiated in this study. The change in the average system pressures as a function of absorbed dose for each set of two identical samples irradiated simultaneously are shown in Fig. 3. The systems containing slurry-like mixtures, i.e. the 1, 7, and 13.5 gram resin to 27 ml water ratios, show a linear increase of total pressure with absorbed dose (see upper three curves in Fig. 3). The two systems containing 1) 17 grams of dry resin (0 wt% water) and 2) 27 ml of ASTM water with no resin present, showed very little pressure change over the ~15 Mrad dose. The two highest resin fraction systems, the 18 gram resin / 27 ml water and the 22 gram moist resin (~20 wt% water), showed initial decreases in total system pressure indicative of oxygen depletion, followed by a gradual increase in total pressure. The measured G values for H2 from slurries containing different mass fractions of resin are shown in Table IX. The mass fraction of resin

is the approximate fraction of radiation absorbed by the resin in the resin/water slurries. These resin mass fractions were calculated using a measured starting resin moisture content of (20.80.1%). The moisture contents were determined from heating triplicate samples of the resin in a convection oven at 98oC until no further mass change was observed, typically for ~4 days.
Figure 4 shows the G(H2) values from Table IX plotted as a function of the mass fraction of resin present. With no resin present, only a small finite amount of hydrogen is produced in the radiolysis of a sealed system containing pure water.(21) The plot of G(H2) vs. mass fraction of resin in Fig. 4 indicates a sharp increase in G(H2) due to a small mass fraction (0.03 wt% resin) of resin present. The hydrogen yield then decreases linearly as the mass fraction of resin is increased. Similar results involving the decrease of hydrogen evolution with decreasing water content (or increasing resin fraction) have been reported for sulfonic acid type organic cation exchange resins.10 For all the gas compositions in which resin is present, H2 is the predominant gas produced with traces of CO, CO2, and CH4 also present.

CONCLUSIONS

Based on the data in this study we conclude the following:
1. More soluble products are leached from either irradiated anion resin (ammonia and substituted amines) or irradiated cation resin (sulfate) than are leached from irradiated mixed resin.
2. Irradiation of the anion resin or the mixed resin (damp) produces larger hydrogen yields and larger total system pressures than irradiation of either the cation resin or the mixed resin (dry).
3. The time to reach a flammable hydrogen-air mixture for storage of the mixed resin (damp), with G(H2) = 0.29 molecules/100 eV, in an actual sealed SRS spent resin storage container is calculated to be > 1,000 days.
4. Total gas production is highest for the resorcinol resin/0.5M HNO3 slurry and the hydrogen yield is highest for the resorcinol/ASTM Type-I water slurry.
5. Radiolytic hydrogen production decreases with increasing resin mass fraction for resorcinol resin/ASTM Type-I water mixtures.

ABSTRACT

Nuclear power stations, spent fuel reprocessing facilities, and radio-isotope (RI) laboratories generate wastes that have low-level radioactivity. The use of an alkali activated slag binder has been studied for the solidification and stabilization of these wastes.
The slag effectively formed waste products having good physical properties with high waste loading. Moreover, the results of this study suggest slag has the ability to become a common inorganic binder for the solidification of various radioactive wastes.
This paper also describes the fixation of radionuclides by the slag binder.

INTRODUCTION

Volume reduction of radioactive wastes and the stabilization of radionuclides are important items from the viewpoint of waste management. Currently, cementization, bituminization, plastic solidification(1) and vitrification(2) are the solidification technologies employed for the immobilization of radioactive wastes in nuclear fuel cycle facilities.
The main sources of radioactive wastes in reprocessing plants for spent fuels and nuclear power stations are low-level liquid wastes (sodium nitrate, sodium borate, boric acid, sodium sulfate, spent ion-exchange resins, incinerator ash, etc.) and dry wastes (polyethylene sheets, rubber paraphernalia, concrete debris, metal pipes, valves, etc.). By employing suitable solidification processes, these various wastes can effectively be treated and stabilized.

However, a simplified radwaste process system is needed whereby various wastes will be efficiently embedded and stabilized using a common binder solidification process. In this study, alkali activated blast furnace slag was selected as a candidate common binder because it is inorganic and is a low-cost material. Such slag is a by-product of the ferrous metal industry and is composed entirely of inorganic constituents. Several studies of alkali activation of slags and applications have been reported.(3,4) However, a detailed study addressing the use of alkali activated slag to solidify radioactive wastes has not previously been performed. This study investigated the application of slag for the solidification of various radioactive wastes. The results indicate that this technique offers high volume reduction and efficient immobilization of radioactivity.

CHARACTERISTICS OF ALKALI ACTIVATED SLAG

Hardening

A normal Japanese industrial slag was used in this study. Its composition was 39.0% SiO_2, 12.5% Al_2O_3, 6.0% MgO, 38.8% CaO, and 0.5% Fe_2O_3. Its density was 2.9 Kg/dm3. Alkalies were used to activate and harden the slag and a dispersant was added to improve the homogenization of the mix.

For normal hardening, the weight ratio of water to binder (W/B), where the binder represents the slag, dispersant, and additives, was in the range of 0.2. Hardening was promoted by increasing the curing temperature to 60-90C for about 24 hours. The effects of various chemical compounds on the hardening was investigated. The results suggested there was no retardation of hardening when a few percent by weight of any of the following chemicals were present: sodium nitrite, sodium carbonate, sodium dihydrogen phosphate, EDTA-2Na or hydrazine.

Properties

The measured compressive strengths of the hardened slag are 80 MPa with a 14-day cure at ambient temperature and 155 Mpa with a 24-hour cure at 90C. The measured bending strength of the hardened slag varies from 20-70 MPa. These properties are excellent, much better than most conventional cement binders.

SOLIDIFICATION EXPERIMENTS

This experimental study used several simulated radioactive wastes to examine waste solidification by the alkali activated slag. Pulverized sodium nitratewithout water of crystallization were prepared. Powder and bead type of mixtures of cation and anion exchange resins were dewatered to provide water contents in range of 45-60%. The specimen mixture was formed by combining the binder, simulated wastes, and water and mixing in a 3-dm3 agitator for 24 hours. The specimens were then formed by placing the mixture in molds followed by curing at ambient temperature or 60C for 24 hours.

RESULTS OF SOLIDIFICATION-SODIUM NITRATE

A large amount of low-level liquid waste containing sodium nitrate is generated in reprocessing facilities using the PUREX process. Typically, the bituminization process is used to embed the waste. Cement solidification is not commonly used because waste with a high loading of nitrate salts retards the hydration of cement. Recently, a process has been examined to drastically reduce the waste stream sources of sodium nitrate.(5)

However, this paper reports the solidification of powdered $NaNO_3$ by activated slag.

Compressive Strength and Swelling in Water Immersion

Table I shows the compressive strengths of slag products containing 8-60wt% sodium nitrate salts. These specimens were cured at ambient temperature. The strengths increased with curing times, even in the product with 60% waste loading.

To study the swelling of the product, specimens were immersed in ambient temperature water for 21 days. The weight of the specimens decreased slightly but no swelling was evident. These results were consistent for all amounts of nitrate salt loading waste.

The activated slag binder formed high-loading waste $NaNO_3$ products that had excellent physical properties.

Leachability of NO_3^-

The leachability of NO_3^- from sodium nitrate waste in the product is an important item in the evaluation of disposal safety because of the discharge limit of NO_3^- to the environment. The specimens used for the leaching test conformed to the Standard Leach Test procedure (SLT) specified by the American National Standard ANSI/ANS. 16.1-1986.

Figure 1 illustrates the relation between the cumulative fractions leached and the

leaching times for samples of products with 20, 40, and 60% nitrate salt. The testing time was about one month. From these data, the effective diffusivity, D (cm2/s), was calculated and the Leachability Index, LIX, of NO3- was obtained. As shown in Table I, the LIX of NO3- was about 7.5, which indicates that discharge of the nitrate anion is effectively controlled and limited, even when the waste loading of sodium nitrate is high.

Leachability of Tc-99

Liquid NaNO3 waste often contains Tc-99. Conventional cement binders are unable to effectively immobilize Tc-99. The leachability of Tc-99 from activated slag was examined by SLTs performed on specimens containing sodium nitrate and a radioactive Tc-99 tracer. The specimens had a weight loading of sodium nitrate of 40% and were cured at 60C for 24 hours. The test duration was 50 days.

In Table I above, the LIX of Tc-99 was 11. Thus, very low leachability was measured in a product with a high loading of NaNO3. As discussed later, reducing action by the slag (a low Eh oxidation- reduction voltage in the activated slag appeared) causes to the Tc-99 immobilization.

SPENT ION-EXCHANGE RESINS

In general, ion-exchange resins processed with conventional cement binders are difficult to solidify and to form into products having good properties. Therefore, advanced pretreatment methods(6) and the use of fiber cement(7) have been investigated.

The solidification of ion-exchange resins by activated slag was studied. The simulated wastes, mixtures of cation and anion resins, both bead and powdered type resins, were mixed and embedded in slag. The properties of products are presented in Table II. The mixture ratios of cation/anion resin were 1:1 and 2:1 for bead and powdered, respectively. Following 8 weeks of water immersion, the products exhibited no swelling and only negligible weight increases. The other characteristics were excellent. Photographs of samples taken after 4 and 8 weeks of immersion are shown in Fig. 2.

The study revealed products which can be formed without pretreatment that contain 50-60 Kg of wastes (dry based) per 200-dm3 drum. The limitation for the amount of loading waste depends mainly on the viscosity of the activated slag paste and the water content of the resin.

FIXATION OF RADIONUCLIDES

As described above, the alkali activated slag provided a high LIX for Tc-99 leachability in products containing NaNO3. To confirm the fixation of other radionuclides by the activated slag, the sorption capability has been quantitatively investigated. Radionuclides of Co, Ni, Cs, Sr, Am, and Tc were selected. The alkali activated slag was pulverized and added to an aqueous solution containing a tracer of each radionuclide. After standing for 7 days at ambient temperature, the slag powder was separated from the liquid by a filter. The radioactivity in the separated liquid was measured by a Ge-detector or a liquid scintillation counter.

The Kd value, a quantitative capability of sorption for a radionuclide, is defined as:

Kd (dm3/kg) = ([Initial radioactivity] - [residual in solution after 7 days])
/ [residual in solution] ([solution volume] / [slag weight])

Table III summarizes Kd values for each radionuclide. To compare the effect of activation of the slag, raw slag without activation was also used. For all radionuclides, the alkali activation provided more immobilization than raw slag. The alkali activated slag has high Kd values for all radionuclides except Tc-99. The Kd values of Cs and Sr are higher than those for conventional cement binders while the Kd values of Co, Ni, and Am are of the same order as for conventional cement.

The Kd value of Tc-99 was not satisfactory. But, a high Kd value was obtained with product formation under oxygen free conditions. In this condition, the Eh voltage measured was low for the alkali activated slag solution. It is shown that the activated slag initially has a reducing action. It is also suggested that the low leachability of Tc in the NaNO3 product, described above, is related to the slag's reducing action.

CONCLUSIONS

The application of alkali activated slag to the solidification of various radioactive wastes was studied. The activated slag embedded and formed a product with up to 60% loading of sodium nitrate that has low leachability of Tc-99 (LIX 11)

and no swelling. Ion-exchange resins also were effectively solidified by activated slag.
The sorption of radionuclides by the activated slag showed higher Kd values for Cs, Sr, Tc than for those associated with conventional cement binders.
This study suggests activated slag has the ability to be a common binder for solidification of various wastes and can provide a high reduction of waste volume.

PROGRAM FOR FREE RELEASE OF ZONE 3 LIKELY CLEAN SOLID WASTE AND RECYCLABLES AT ONTARIO HYDRO'S DARLINGTON NUCLEAR GENERATING STATION (DNGS)
Janice Hudson
Ontario Hydro Darlington NGS
Michael Rhodes
Scientific Ecology Group
ABSTRACT
An innovative solid waste management program developed at the Darlington Nuclear Generating Station has resulted in $1 million annual savings in avoided low level radioactive waste (LLW) processing and storage costs. The process is supported by a trained and dedicated staff and utilizes multiple checks and barriers to ensure complete segregation and thorough monitoring of waste prior to its release as clean. The program has been reviewed by the Atomic Energy Control Board (AECB), external auditors and interested members of the public. It was commissioned with $150,000 in equipment costs and no additional labour costs.
BACKGROUND
Darlington is a CANDU (Canada, Deuterium, Uranium) design, 4 unit station with a total generating capacity of 3680 MWe. The first Unit was placed in service January 1991 and the last in April 1993. It is important to note that at Ontario Hydro NGS's, contamination control is structured around the division of the Station into zones numbered 1 through 3. A clarification of the "Zone" concept follows:
Zone 1- a clean zone that is kept free of contamination. The Administration building and Powerhouse lunchroom are Zone 1 areas.
Zone 2- normally maintained free of contamination but has the potential for cross contamination from areas with radioactive systems.
Zone 3- contains radioactive systems and work areas. There are numerous Zone 3 areas widely spread throughout the four DNGS units.
ZONE 3 WASTE MANAGEMENT PROGRAM
Traditionally, DNGS has treated all solid waste produced in Zone 3 areas of the plant as contaminated. This resulted in large volumes of materials being shipped to the Ontario Hydro Bruce Nuclear Power Development (BNPD) Radioactive Waste Storage Site, located on the shores of Lake Huron 400 km from Darlington. It was recognized that a significant volume of waste collected in Zone 3 areas was potentially free of contamination. Therefore, DNGS and Scientific Ecology Group (SEG) developed a unique system to specifically address the reclassification of waste materials collected in Zone 3 areas as free of contamination. Figure 1 illustrates Low Level Radioactive Waste (LLW) volumes before and after implementation of the program.
Program Objectives

The main objectives of the Zone 3 Likely Clean Waste Management Program are:

To prevent the inappropriate release of detectable levels of activity to the municipal landfill by individually hand frisking each item for potential contamination using sensitive instrumentation and monitoring techniques that improve the probability of detection.

To prevent the inappropriate classification of clean (inactive) materials as contaminated (active) which can result in large volumes of clean materials being sent for storage to the BNPD RadWaste Site.

To minimize waste disposal at the Public landfill and comply with the Metro Toronto landfill ban criteria which prohibits the deposition of wood, cardboard, scrap metal or paper at the Public landfill.

Source Term

The first action prior to implementation of the program was to conduct a source term analysis to identify radionuclides that could potentially be present in the waste stream. Results of the analysis were used to ensure appropriate selection and calibration of instrumentation as well as define which areas of the Station should be excluded from the collection of materials eligible for monitoring for unconditional release. Routine sampling results are forwarded by the chemistry department, and a periodic characterization reviews will be conducted, to monitor for any changes to the source term. CANDU reactors contain large quantities of deuterium in the form of heavy water in the moderator and coolant which when bombarded by neutrons produces tritium. Tritium is the dominant component in some waste streams.

Waste Collection/Segregation

The original waste collection system in Zone 3 consisted of a three can set for segregation of incinerable, compactable and non-processable waste. All waste collected was treated as active. Waste collection stations were modified to provide for initial segregation of three new waste categories in Zone 3:

Likely Clean,

Presumed Active, and

Excluded Area.

For this reason, careful selection, surveillance and maintenance of waste stations is essential to the programs success. It is important to note that the "Likely Clean" waste stream may be directed to offsite landfill or recycling markets only if it is monitored and confirmed to be free of contamination.

Different coloured waste containers and bags are used to aid in identification of the waste streams during any stage of the process. Station staff are trained to ensure that only waste for which they know the radiological history, and believe to be free of contamination, is placed in the "Likely Clean" cans. Excluded area waste stations are few in number and are restricted to fuelling machine maintenance areas, hot particle areas, decontamination facilities and tritiated rooms. This waste requires a minimum of rehandling and is packed directly for shipment to BNPD RadWaste site.

Control of all 540 waste stations has been achieved by barcoding each station location and maintaining a master floor plan and database of their positions. Each bag of waste is barcoded and scanned during collection to register its point of origin, waste stream type and unique identification number.

Facility Layout/Equipment

A large room previously used for storage of active waste shipping packages was converted into the "Likely Clean" processing area. This room has a very low background, typically .05 mSv/hr or approximately 40 cpm on a pancake type frisker, and is ideal for monitoring waste for unconditional release. A second room was dedicated for handling "Presumed Active" and "Excluded Area" waste with provision for future sorting of "Presumed Active" waste up to 10 mSv/hr per bag.

The "Likely Clean" processing area was fitted with the following instrumentation and equipment:

Tritium monitor

Two waste bag monitors with barcode reader and data docking station

SEG ventilated sorting tables each with an NE Technology CM7A and traditional pancake contamination meter

Continuous air monitor

In the "Presumed Active" and "Excluded Area" waste processing area, a computer with barcode reader and data docking station was provided to track the active waste

stream until the third bag monitor is completed. A modified version of the bag monitor program is used to provide a consistent method of data collection, presentation and management. The active sorting table has been fitted with two HEPA ventilation systems to provide extra safety when monitoring the "Presumed Active" waste stream.

Barcoding System

A comprehensive barcoding and database management program has been added to the waste collection and bag monitor systems. The waste bag monitor database is accessible from the station computer network to allow daily review by the responsible system engineer. Each bag of waste processed is tracked as to its point of origin; waste classification; date and time of collection; tritium content; date and time of monitoring; weight; and total and specific activity.

This data system provides a method to:

Track waste volumes generated for each waste stream type at each Unit. This creates accountability among the Units, which function as separate businesses, and promotes further waste minimization activities. Accurate data allows each Unit to be charged for the waste it actually produces.

Identify the source of unexpected active waste and aid in investigation of the cause and resolution of the problem.

Determine waste volumes produced for a specific job by selecting waste stations associated with a particular work activity or outage.

Comply with the AECB requirement to investigate, and take action to prevent reoccurrences, of instances of contaminated Zone 3 "Likely Clean" waste exceeding specific limits for dose rate and tritium concentration.

Monitor program effectiveness and identify areas of the station where additional measures are required to further reduce waste production.

Continued improvements are being observed as the station staff become educated about the importance of waste minimization and their responsibilities associated with the waste management program. Figure 2 illustrates the effectiveness of the front end segregation step in the process.

Technical Surveillance/Quality Assurance

Technical Basis documents and instrumentation operation and calibration procedures have been developed to document instrument use in an unconditional release program. Instrumentation maintenance staff have been trained in maintenance and calibration of all associated instrumentation and are available to support the program on an as needed basis. Daily routine sheets are completed by waste processing staff to document instrument operational requirements specified by the unconditional release program. All documents are filed as permanent Quality Assurance records.

All materials determined to be clean, after monitoring at the ventilated sorting table, are rebagged into recyclable or landfill categories and directed to a second waste bag monitor for an independent QA check. These materials are barcoded to indicate their point of origin as the final step in the sorting process and are scanned into the QA bag monitor database prior to monitoring. If a bag of waste or recyclable fails this check, it is redirected back to the sorting table for remonitoring.

Waste Handling staff perform a variety of duties in the waste handling area and rotate their responsibilities periodically. The hand frisking of bag contents normally does not exceed 2 hrs per individual per day (Human Factors).

The database for waste bag tracking serves as an ongoing surveillance system to ensure any errors in the process are detected and taken care of in a timely manner. This database also provides useful information for report generation and further performance enhancement of the program.

Training of Station Staff

Formal training packages and examinations were developed and delivered to waste collection and processing staff to document their qualification for participating in a free release program. Only trained and qualified staff are permitted to collect or process waste, and operate any of the associated instrumentation. General traffic to the Waste Handling Facility is also restricted. A thorough understanding of all aspects of the process is essential to ensure that radioactive materials are not inadvertently deposited in a clean area. The Likely Clean Waste Sorting Room is secured and only accessible to trained and qualified staff.

A generic waste awareness seminar has been prepared and delivered to all Station staff to reinforce the correct use of the waste collection system. Tours of the

waste handling facility have also been provided to staff so that they may gain an appreciation of the importance of placing waste in the correct disposal containers. Ongoing training during radiation protection requalification courses and monthly safety meetings ensure that Station staff are kept informed. This method has provided us with excellent feedback on the program and further methods of improvement.

The success of this program can be attributed to the excellent cooperation and teamwork of many work groups within the Station.

INSTRUMENTATION SPECIFICS

Waste Bag Monitor

Waste bag monitors are used to monitor and track Zone 2 "Clean" and Zone 3 "Likely Clean" waste. The monitor uses seven large area plastic scintillation detectors, five for the cavity walls and one for each half of the front door assembly. The detection capability is 270 Bq/bag for Cs-137 with a 15 second count at typical background levels in the Likely Clean Waste Sorting Room. The monitor's Minimum Detectable Activity (MDA) is calculated and stored by the system software, based on user configurable parameters, each time a background update is completed. Efficiencies are determined with a calibration jig that simulates the typical density of a bag of waste and centres the source in the monitors cavity.

Each monitor includes a barcode reader to scan bag number and tritium labels and a docking station to download waste collection data into the monitor's computer. When a bag is monitored, the weight, tritium content and total and specific activity are appended to the collection data and stored in the monitor's database. Also stored is the current MDA value and whether an alarm initiated. One monitor is configured to track "Likely Clean" waste with an alarm setpoint that determines a bag's eligibility for sorting. A second monitor tracks waste that has been unconditionally released and is used as a QA check with the alarm set near the instruments MDA.

SEG Ventilated Sorting Table

"Likely Clean" waste is monitored and segregated on an SEG ventilated sorting table constructed from stainless steel and Lexan and customized for DNGS. The table includes shelves and mounting brackets for a HEPA vacuum and monitoring instrumentation. Three containers are provided for sorting waste which is confirmed to be free of contamination with an additional container for segregating active waste on the opposite side of the table. A 2000 cfm HEPA ventilation system draws air across the table through a prefilter mounted on a rear wall.

NE Technology CM7A

The CM7A is an alarming contamination meter capable of simultaneously detecting a & b/g events using a 100 cm2 gas proportional detector and pulse height discrimination. Additional features include:

- Background subtraction for the b/g channel
- High background alarm
- Excellent sensitivity
- Separate audible tones for a & b/g events
- Unit fault alarms

The CM7A uses a fixed counting time of 1 second allowing the instruments sensitivity to be calculated at a 3 cm/sec scanning speed. Typical MDA values for Cs-137 and Th-230 are provided in Fig. 3 (not provided). Problems associated with monitoring for a contamination are addressed by procedure and during training.

Table I

The high alarm and high background alarm setpoints are calculated and set based on a maximum allowable background of .1 mSv/hr. Typical background levels in the waste handling facility do not exceed .05 mSv/hr which decreases the false alarm rate to approximately one every hour. When not in use for surveys, the CM7A's function as sensitive area monitors providing an early indication of an increase in background levels. The instrument is source checked at the beginning and end of each shift with sources approximately equal in strength to the alarm setpoints of both channels. Source checks are documented and archived as QA records.

Traditional Contamination Meter (Ludlum 177)

A pancake probe is used when the larger size of the CM7A probe is impractical. For free release of materials, the user is instructed to scan the article listening for an increase in audible count rate. If an increase is detected, the probe is held stationary until the reading stabilizes. Any article with a reading greater than the minimum detectable count rate (MDCR) of the instrument for the current background is

considered contaminated. An MDCR versus background count rate chart is provided in the operating procedure and at the ventilated sorting table.

ACKNOWLEDGMENTS
The authors would like to thank the DNGS management, staff and SEG project team for their encouragement, cooperation and teamwork which has been essential to the development of the program and continues to ensure it's success.

TRACE ORGANIC REMOVAL BY PHOTOCHEMICAL OXIDATION

S.K. Sen Gupta

AECL Research
Waste Processing Technology
Chalk River Laboratories
Chalk River, Ontario, Canada K0J 1J0

ABSTRACT
Photochemical oxidation methods can be used for the destruction of dissolved organic contaminants in most process effluent streams, including those originating from the nuclear power sector. Evaporators can be used to separate organic contaminants from the aqueous phase if they are nonvolatile, but a large volume of secondary waste (concentrate) is produced, and the technology is capital-intensive.
This paper describes two different types of photochemical oxidation technologies used to destroy trace organics in wastewater containing oil and grease. The experimental results show that all of the EPA 624/625 (volatile/extractable organic) contaminants present are effectively removed. The first photochemical oxidation unit evaluated used a combination of ozone gas and ultraviolet (UV) light at the 254 nm wavelength. The effluent contained some organic acids, which are apparently not easily converted to carbon dioxide by the process. The presence of interfering carbonate ions (1,2) at concentrations of up to 1000 mg/L favoured operating the unit with water adjusted to a pH of between 6 to 8.
The other photochemical oxidation reactor investigated was a three-phase system employing a TiO_2 catalyst (with gaseous or liquid oxidant) and ultraviolet light, also at a wavelength of 254 nm. Liquid waste solutions containing oil and grease in concentrations of up to 150 mg/L were effectively treated, and there was no increase in pressure drop across the reactor. Two chemical oxidants were investigated (in addition to the dissolved oxygen in the water), including hydrogen peroxide and compressed air. It was necessary to employ hydrogen peroxide as an oxidant to achieve the method detection levels of the analytical equipment. The catalytic reactor was the more efficient based upon conversion of dissolved organic carbon to CO_2.

INTRODUCTION

Liquid waste streams at nuclear generating stations can become contaminated from a variety of different sources which include: organics released from lubricated pump seals, from hydraulic hose breaks, and organic-based liquids that get discharged into the sumps from hydraulically-operated valves and pistons. Heavy water can often become contaminated with various organic compounds, including oil and grease, and would be appropriate for treatment with the technologies described in this paper. About 2500 m^3 per year (0.66 million US gallons) of Chalk River Laboratories (CRL) waste, are volume reduced by a combination of continuous crossflow microfiltration, spiral wound reverse osmosis, and tubular reverse osmosis membrane technologies (3). The concentrate produced from the membrane systems is evaporated while simultaneously adding a bitumen emulsion in a thin-film evaporator to immobilize the radioactivity (Fig. 1). The distillate produced carries trace amounts of organics, including a variety of aromatics such as phenolics, naphthalenes, and substituted benzene derivatives.

CHEMICAL OXIDATION

Chemical oxidation is a process during which electrons are removed from a substance to increase its oxidation state. Because oxidation processes tend to be energy intensive and therefore costly, their breadth of application is limited. This is particularly the case for wastewater treatment. Because oxidation processes are fundamentally stoichiometric, proportionally greater amounts of oxidant are required for high levels of organic concentration (5).

Although the effluent quality from the evaporator meets all discharge criteria for radioactivity, there is some carryover of organics in the distillate. The source of these organics is primarily the distillation of lighter components in the emulsified bitumen from the evaporator used for immobilization of the aqueous waste concentrate (TFE-1). Chemical analyses conducted at CRL have shown that about 95% of the organics present in the condensate stream are volatilized from the bitumen, while the other 5% originating in the evaporator feed are entrained as liquid droplets with the vapor (4).

Comprehensive analyses of the distillate samples taken during the operation of the thin-film evaporator identified organics in the two phases which included an insoluble lighter phase and a dissolved soluble heavier phase (4). The insoluble phase represents the bulk of the organic present in the effluent stream. It contains greater than 96% of the total organic compounds found in the samples. The insoluble layer is composed mainly of aliphatic compounds (69%) with carbon chains ranging from 9 to 17 carbons. The remainder of the organics are aromatics.

A qualitative guide to the reactivity of selected organic compounds to oxidation is as follows (5):

High reactivity: phenols, aldehydes and aromatic amines;
Medium reactivity: alcohols, alkyl substituted aromatics, aliphatic ketones;
Low reactivity: halogenated hydrocarbons, saturated aliphatic compounds, and benzene.

EVALUATION OF TECHNOLOGIES

Previous efforts showed that charcoal absorption is effective for organic removal from the distillate. However, this technology generates a relatively large amount of secondary waste, which makes the process non-attractive from a materials handling and disposal perspective.

More recent work showed that pretreatment of the distillate stream with an oil coalescer removed greater than 96% of the oil and grease and saturated aliphatic compounds. Dissolved organics were extracted into the oil-rich lighter phase, which was periodically ejected from the coalescer using the principle of conductivity difference between the phases.

Two photochemical technologies that were investigated for organic removal downstream of the oil coalescer included: a UV-ozone reactor to oxidize soluble organics (primarily aromatics), and a titanium dioxide catalytic reactor. The UV/ozone batch reactor system was compared with the catalytic continuous reactor system, based upon the removal efficiency of trace organics (EPA 624/625 series), and percent conversion of organic carbon to carbon dioxide. Comparison between different processing conditions was made somewhat difficult due to the variability of the feed stock itself.

TITANIUM DIOXIDE CATALYTIC REACTOR

Each vessel of the reactor is comprised of an outer stainless-steel jacket, with an internal photocatalytic matrix, and a lamp that emits low-intensity ultra-violet (UV) light (at 254 nm wavelength), mounted coaxially within the jacket. Around the lamp is a sleeve of fiberglass mesh coated with TiO_2 to form the catalyst matrix. The vessels of the catalytic reactor are 1.6 m in length and 0.05 m in diameter. The reactor was set-up so that the four sets of three vessels (comprising one module-row) were in series with each other. Sample ports are located at the effluent point after each set of three vessels. The discharge pressure from the pump is set at about 585 kPa, to overcome the pressure drop across the unit. The unit occupies 1.65 m x 0.50 m x 0.80 m.

Low to intermediate-level radioactively-contaminated wastewater was passed through the reactor without any buildup of radiation field on the vessels. Based on this observation it is thought that the reactor could be used to treat organically-contaminated upgrader feed water.

The process was operated in both the single-pass and recycle modes to evaluate the effect of contact time on organics destruction efficiency. A variety of different experimental conditions were investigated including: the type and concentration of oxidant injected with the feed, pH of the feed, and the contact time. Oxidants that were tested included dissolved oxygen (already present in the water), hydrogen peroxide (at three different concentrations), compressed oxygen (at 550 kPa), and compressed air (at 550 kPa). The experiments were conducted at different pH conditions to determine if alkalinity had any significant impact on the oxidation rate.

UV/OZONE OXIDATION REACTOR

The UV/ozone reactor required distillate to be mixed with ozone in the presence of UV light (at 254 nm) in a reaction chamber. The dimensions of the reactor are about 0.97 m in height and 0.35 m in diameter. Ultraviolet lights extend into the reactor to about 0.1 m from the base. The three UV lights are immersed within the reactor at equidistant intervals along its top. There is a resident volume of about 45 L inside the reactor at all times.

The ozone generator received clean, dry production air from the air preparation unit and the feed air compressor system. This system delivered ozone gas to a maximum of 2% by weight (or 10 mg/L by concentration) in the carrier air stream. The reactor system was operated batchwise for these experiments. The feed tank was filled with about 100 L of process water, and then adjusted to the appropriate pH with mineral acid or sodium hydroxide. Water was continuously metered and removed from the reaction chamber at 22 L/min.

REMOVAL OF ORGANIC CARBON WITH CATALYTIC REACTOR

Since the application envisaged here was for treatment of wastewater produced from a variety of sources (3), there was considerable variation in the feed concentrations to the reactor. In some cases contaminants were below method detection limits (MDL) in the feed water. Hence, all figures shown in this paper have been normalised to reflect conversion efficiencies.

The pH of the wastewater feed was lowered from about 8 down to 4 to remove the carbonate and bicarbonate ions in the water (as carbon dioxide), which were both known to be present at a concentration of about 650 mg/L in the feed. The presence of bicarbonate is known to interfere in the oxidation of the organic contaminants, since there is an oxidation equilibrium with carbonate, and hence, it acts as a scavenger for the available oxidants (1). The reaction of hydroxyl ion (the active oxidant), OH, with bicarbonate to produce carbonate radical anion, (CO3-) , occurs with a rate constant of 1.5 x 107 M-1s-1 (Eq. 1). This carbonate then reacts with hydrogen peroxide via Eq. (2).

OH+ HCO3- H2O + [CO3-] (1)

[CO3-] + H2O2 HCO3- + [HO2] (2)

REMOVAL OF VOLATILE ORGANIC CARBON IN CATALYTIC REACTOR

Volatile organic carbon (VOC) refers to those organic contaminants included in the EPA 624 series. In most cases there do not exist specific discharge guidelines for these contaminants in Canada (6). However, the Ontario Provincial Water Quality Objectives (PWQOs) were used to evaluate how efficiently the water had been treated. Where there are no available PWQOs, the MDL of the analytical equipment was used to evaluate the effectiveness of the reactor.

Figure 2a,b,c,d shows the removal efficiency of the catalytic oxidation reactor for various volatile organics contaminants at a process pH of 4, and with a 3 minute contact time in the reactor. The first bar represents the feed concentration, the second bar after one module-row, the third bar after two module-rows,while the last bar represents the concentration after four module-rows. Toluene can be effectively reduced from 2 mg/L to 0.1 mg/L (which is within the PWQO), while m-xylene decreases from 10.7 mg/L to 3.38 mg/L, which is above the PWQO of 1 mg/L.

Figure 2b shows the results for an experiment in which dissolved oxygen was also used in the presence of the catalyst at a pH of 4. In comparison with the experiment in Fig. 2a, the liquid was passed from a drum into the reactor at a flowrate of 2 L/min for a period of 2 hours. The total contact time in the reactor was 18 minutes. The effluent from the reactor was recirculated back to the reactor. For each contaminant the second bar represents the fraction remaining after seven minutes of contact time in the reactor. The third bar represents the concentration left after 18 minutes in the reactor. In Fig. 2b the m-xylene can be reduced from an initial feed concentration of 5.9 mg/L to a final effluent concentration of 1.21 mg/L, representing a removal efficiency of about 80%.

Figure 2c illustrates the results of an experiment conducted with compressed air as an oxidant at a gauge pressure of 585 kPa. Each bar represents the passage of the liquid through an additional module-row. The water was continuously passed through the reactor at a flowrate of 2.7 L/min, and was not recirculated back to the feed drum. These results indicate that compressed air may be an effective oxidant for the removal of volatile organic contaminants from wastewaters.

Figure 2d shows the results of an experiment carried out with the hydrogen peroxide used as an oxidant. The flowrate of hydrogen peroxide into the reactor was

maintained at 1 L/h, and its concentration in the feedwater was 500 mg/L. The flowrate of the waste feedwater was maintained at 3 L/min, and the water was not recirculated through the reactor. Each successive bar represents the concentration after another module-row. The concentrations of toluene and m-xylene were below the method detection limits (MDL) of 0.1 mg/L, and hence the effluent quality met the existing PWQOs. Only o-xylene was above the MDL after once-through treatment with hydrogen peroxide.

Other experiments were conducted at higher hydrogen peroxide concentrations of 1 000 mg/L and 1 500 mg/L. However, these experiments showed that there was no further conversion of the organic contaminants. Hence, there was no significant advantage of using higher peroxide concentrations for the contaminant concentrations present in this feed stream. Considering that there may be several hundred mg/L of dissolved organic carbon in the feedwater, the 500 mg/L of hydrogen peroxide does not seem excessive.

REMOVAL OF EXTRACTABLE ORGANIC CARBON WITH TITANIUM DIOXIDE REACTOR

A variety of extractable organics (EPA 625 series of contaminants) were present in the distillate wastewater stream of which the most abundant included: phenol, naphthalene, 1-methyl- naphthalene, 2-methyl- naphthalene, and biphenyl. The concentration of total phenolics must be less than 20 mg/L to meet Federal Discharge criteria (6). There are no guidelines for the other contaminants. For phenol the PWQO is 1 mg/L; the PWQO is 2 mg/L for 1- and 2-methyl naphthalenes, and it is 0.2 mg/L for biphenyl.

Figure 3a,b,c,d shows the removal of EPA 625 contaminants without the benefit of any additional oxidant and the water was not recirculated. The contact time in the reactor was about 3 minutes. Each successive bar in the histogram represents the passage of the fluid after passage through another module-row. The concentrations of the contaminants are reduced marginally after treatment by the reactor, but are significantly above the PWQO guidelines. Only in the case of naphthalene is the concentration reduced to the MDL. About 50% removal of the contaminants is achieved on average in practice. The conditions employed were too mild for the effective removal of these organics.

Figure 3b shows the removal efficiency with an overall contact time of 18 minutes. For each contaminant the second bar represents the fraction remaining after seven minutes of contact time, while the third bar represents the concentration left after 18 minutes in the reactor. Destruction efficiencies in excess of 90% were observed for all contaminants. For the cases of the methyl-substituted naphthalene derivatives the final effluent value is at the MDL. For phenol, its concentration could not be reduced below 13.6 mg/L, indicating that more severe oxidizing conditions (an increase of contact time or a stronger oxidant) are required to remove this contaminant.

Figure 3c shows the removal of the extractable contaminants with the compressed air oxidant at an applied pressure of 550 kPa in a single pass through the reactor. For 'bis-phthalate', (PWQO = 0.6 mg/L), the final effluent concentration of 2.2 mg/L is only marginally above the PWQO. It is apparent that the catalytic reactor is capable of removing organic contaminants to very low values (usually to the MDL) in the presence of compressed air, even when challenged by significantly high concentrations of contaminants in the feedwater.

The removal of extractables with two minutes of contact time and hydrogen peroxide as an oxidant (at a flowrate of 1 L/h, and a concentration of 500 mg/L), is shown in Fig. 3d. The PWQOs for phenol, the methyl naphthalenes, and biphenyl can all easily be achieved. Greater than 95% of the feed concentration of the various contaminants are removed. Both naphthalene and biphenyl are oxidized to other products after the first module-row; for the other contaminants, including the methyl naphthalene derivatives, there is a gradual reduction of the contaminant across all four stages.

Evans (7) has noted that the end-product of the oxidation of naphthalene is phthalic acid, and it is improbable that further oxidation to carbon dioxide would take place. Gaul et al. (8) have found that the products of the oxidation of 1-methyl- and 2-methyl- naphthalene compounds include: 2-acetylbenzaldehyde, and (E) and (Z)-3-(2-acetylphenyl)-2-butenal, and (Z)-3-(2-acetylphenyl) propenal.

Although it was initially thought that the titanium dioxide catalyst might foul in the presence of large concentrations of oil and grease present in the feed stream, this was not observed. The catalytic reactor did not lose any throughput in spite of

oil and grease concentrations exceeding 150 mg/L, and no increase of pressure drop across the reactor was noted. This would suggest that an organics-laden waste stream containing significant concentrations of oil and grease can be treated. In all cases the oil and grease in the effluent from the reactor was reduced to less than 3 mg/L after the first module-row, which is in compliance with Federal regulations (6). The effluent from the reactor was clear, which was visual indication that the colour associated with organic material had been removed.

UV/OZONE REACTOR PERFORMANCE FOR ORGANICS REMOVAL

Although theory suggests that ozone in the presence of UV irradiation should be able to oxidize organic material to final products like carbon dioxide and water, ozone actually oxidizes an organic impurity until a refractory compound is formed that is stable with respect to ozone (9).

The evidence is overwhelming that the hydroxyl radical (OH) is the key intermediate when ozone decomposes in water. Rate constants for the reaction of OH with organic substances are commonly in the range of 109 to 1010 mol-1s-1 (1). In the course of mineralization of any organic contaminant, oxidation will logically involve a series of intermediates of progressively higher oxygen to carbon ratios on the way to carbon dioxide. Such intermediates make the conversion process multicomponent even if a single component exists in the feed. Hence, the total oxygen demand to mineralize the organics to carbon dioxide is usually in excess of stoichiometric requirements in a multicomponent system.

A significant concentration of straight chain aliphatic compounds were present in the distillate feed to the reactor. Typically the removal efficiencies of these species (from open characterization GC-MS analysis), averaged between 50 to 70% with the UV-ozone reactor. Higher carbon chains were relatively more difficult to remove from solution. It has been confirmed that the primary end-product of the batch UV-ozone oxidation are organic acids. These organic acids can be further oxidized to carbon dioxide if the pH of the liquid is maintained between 6 to 8.

Figure 4ab,c,d shows that all organic contaminants could effectively be reduced to the MDLs after a five minute contact time. It was necessary to maintain the pH below 8 to ensure that the organics were oxidized, and to minimize the scavenging of oxidants by bicarbonate (Eq. 1). For those organic contaminants having secondary and tertiary carbon-hydrogen bonds, such as straight and branched-chain hydrocarbons, the following chemical reactions are possible. Aldehydes are converted to carboxylic acids, primary and secondary alcohols to carboxylic acids and/or ketones, ethers to alcohols and esters, and hydrocarbons to alcohols and ketones (7).

REMOVAL OF EXTRACTABLE ORGANIC CONTAMINANTS WITH UV/OZONE REACTOR

Various extractable organic contaminants (EPA 625) were present in the distillate feed stream to the reactor. Figure 4b shows experimental results for which the ozone reactor was challenged with a highly organically-contaminated feed water, with an ozone inlet concentration of 10 mg/L and an initial feed pH of 6. All contaminants are reduced by at least 90% after 10 minutes of contact time with ozone. In spite of oil and grease concentrations approaching a few hundred mg/L in the feedwater, the effectiveness of the ultraviolet lights within the reactor did not deteriorate with processing time. No decrease of organic removal efficiency was observed from replicate experiments with visibly oily wastes.

Figure 4c shows the removal efficiencies of the UV/ozone reactor for various straight chain aliphatic organics ranging from tridecane (13 C atoms) to dodecane (20 C atoms). The results are presented for a pH of 6 and an ozone concentration of 10 mg/L. No discharge guidelines exist for these organic constituents but they can be effectively reduced in 5 minutes of contact time to within 20% of their initial values. After 10 minutes of contact time, less than 5% of the initial levels of these organics remain in solution, and the concentrations shown are at the MDLs.

CONCLUSIONS

The UV/ozone batch reactor, while effective in removing most priority contaminants (including phenolics to below 20 mg/L), was most effective at an operating pH of between 6 to 8. It was not as effective at removing oil and grease as the titanium catalytic reactor and the primary end-products of the oxidation were organic acids. The process was operated batchwise, which put it at a disadvantage with the catalytic reactor, which operated in a continuous fashion.

The titanium dioxide catalytic reactor was capable of reducing both EPA 624 (volatile) and EPA 625 (extractable) priority contaminants to below the method detection limits of the GC/MS analytical equipment. Phenolics were effectively

reduced to well below the Canadian Federal Discharge limit of 20 mg/L, and oil and grease was reduced to well below the 15 mg/L imposed guideline for Federal Establishments (6). Other aromatic compounds, including naphthalene and methyl-substituted naphthalene derivatives, were effectively reduced. Dissolved oxygen was sufficient to remove the colour associated with organics from the wastewater, even though not all of the organic carbon was removed. A concentration of 500 mg/L of hydrogen peroxide was found to be sufficient for the removal of the organics present in the evaporator distillate stream.

The dissolved organic carbon was not all converted to carbon dioxide in the catalytic reactor; some intermediate oxidation products were formed, which included some organic acids. Visible concentrations of oil and grease did not foul the catalyst or reduce the throughput of the system.

NITRIC-PHOSPHORIC ACID OXIDATION OF SOLID AND LIQUID ORGANIC MATERIALS

R. A. Pierce
J. R. Smith
D. C. Poprik
Savannah River Technology Center

ABSTRACT

Nitric-phosphoric acid oxidation has been developed specifically to address issues that face the Savannah River Site, other defense-related facilities, private industry, and small-volume generators such as university and medical laboratories. Initially tested to destroy and decontaminate SRS solid, Pu-contaminated job-control waste (a heterogeneous mixture of plastics, cellulose, rubber, resins, metals, etc.), the technology has also exhibited potential for remediating hazardous and mixed-hazardous waste forms. The process is unique to Savannah River and offers a valuable alternative to other oxidation processes that require extreme temperatures and/or elevated pressures.

To address the broad categories of waste, many different organic compounds which represent a cross-section of the waste that must be treated have been successfully oxidized. Materials that have been quantitatively oxidized at atmospheric pressure below 180oC include neoprene, cellulose, EDTA, tributylphosphate, and nitromethane. More stable compounds such as benzoic acid, polyethylene, oils, and resins have been completely decomposed below 200oC and 10 psig.

The process uses dilute nitric acid in a concentrated phosphoric acid media as the main oxidant for the organic compounds. Phosphoric acid allow nitric acid to be retained in solution well above its normal boiling point. The reaction forms NOx vapors which can be reoxidized and recycled using air and water. The addition of 0.001M Pd(II) reduces CO generation to near 1% of the released carbon gases. The advantages of this process are that it is straightforward, uses relatively inexpensive reagents, operates at relatively low temperature and pressure, and produces final solutions which are compatible with stainless steel equipment. For organic wastes, all carbon, hydrogen, and nitrogen are converted to gaseous products. The process catalysts are either not consumed or can be regenerated. If interfaced with an acid recovery system which converts NOx back to nitric acid, the net oxidizer would be oxygen from air.

INTRODUCTION

The purpose of this program has been to demonstrate a nitric-phosphoric acid destruction technology which can treat a heterogeneous waste stream. This technology is being developed to convert hazardous liquid and solid organics to inorganic gases and salts while simultaneously performing a surface decontamination of the noncombustible items (the decontamination effects of this process are not discussed here). Plutonium-contaminated waste is an issue because of its stringent storage, shipping and disposal requirements.

The process envisioned will be configured to handle a wide range of solid Pu-contaminated waste of which 60% is combustible. The process will oxidize the combustibles (a mixture of 14% cellulose, 3% rubber, 64% plastics, 9% absorbed oil, 4% resins and sludges, and 6% miscellaneous organics) without requiring separation from the noncombustible portion. The system is being developed to operate below 200oC at moderate pressures (0-15 psig).

OXIDATION CHEMISTRY

The technology being developed is unique to SRTC and is the subject of WSRC invention disclosures. The process identified by SRTC is a wet-chemical process for completely oxidizing organic materials at moderate temperatures and pressures using common inorganic acids, nitric and phosphoric. It differs from other comparable technologies in that it does not require the use of extreme processing conditions or RCRA-listed hazardous metals to decompose the waste.

The process uses dilute nitric acid in a concentrated phosphoric acid media as the main oxidant for the organic compounds. Phosphoric acid allows oxidation at temperatures up to 200oC and is relatively non-corrosive on 304-L stainless steel near room temperature. (1) A simple process that uses oxygen from air or another readily available cheap oxidant as the net oxidizer would be relatively inexpensive per unit of waste consumed.

A wide range of organic compounds have been completely oxidized in varying concentrations of nitric acid, including nitromethane, cellulose, tartaric acid, tributylphosphate, EDTA, neoprene, benzoic acid, polyvinlychloride, and polyethylene. Trace Pd^{+2} converts most of the CO in the released carbon gases to CO_2. (1) The oxidation is usually complete in one to three hours for most organic materials. Aliphatic compounds, because of their relative stability, oxidize slower than non-aliphatic materials.

Although oxidation of most organic compounds by nitric acid is energetically favorable, the reaction rate is slow due to the stability of the carbon-hydrogen bond. (2,3) The oxidation of organic compounds is initiated by dissolved NO_2 and NO in solution and propagated by the production of organic radicals. For many types of oxygenated organic compounds the attack by NO_2 can be first order. (1) For aliphatic compounds, higher concentrations of NO_2 and NO are needed to obtain comparable oxidation rates. The initiating reactions form organic radicals which may then readily react with nitric and nitrous acids or NO_2. (1)

Once carbon-chain substitutions begin, hydrogen-carbon bonds on carbon atoms which are also bonded to oxygen are weakened. (1) This allows much quicker hydrogen abstraction and further oxidation. As the organic molecules gain more oxygen atoms the organic molecules become increasingly soluble in the nitric-phosphoric acid solution. Once in solution, the molecules are quickly oxidized to CO_2, CO, and water. If the original organic compound contains chlorine, hydrochloric acid will also be formed.

Acid recycle will be a key part of the process. As the reaction progresses, NO and NO_2 are released from solution and nitric acid is depleted. As a result, the NO and

NO2 need to be recovered as nitric acid in order to maintain the initiation of reactions. At the same time, HCl gas from the oxidation of chlorinated compounds must be allowed to pass through to be recovered in a subsequent step. Acid recovery units for converting NOx to nitric acid are a commercially available technology.

EXPERIMENTAL SETUP

All oxidation experiments were conducted using some variation of the following. A glass reaction vessel is set up with a mixture of nitric and phosphoric acids; palladium catalyst is also added to help convert CO to CO2. The custom-made glassware uses Teflon fittings and Viton o-rings to create gas seals. Pressure was measured using a Marshalltown Manufacturing compound gauge which measures from 30"Hg - 30 psig. The system temperature is monitored using a laboratory thermometer in some cases and a Luxtron Model 750 Fluoroptic temperature probe in others. Sulfamic acid (EM Science) removed NO2 gases from the reaction vessel off-gas stream so they did not interfere with downstream carbon dioxide measurements. Downstream of the sulfamic acid is drierite (W. A. Hammond Drierite Co.) which absorbs moisture from the gas stream. Ascarite-II (Thomas Scientific) absorbs CO2 and then is weighed to determine how much carbon dioxide has been released from the reaction. Weights are taken using a calibrated Mettler AE200 balance which is accurate to 0.0001g. Polyethylene samples were taken from Nalgene bottles. Trimsol is a product of Master Chemical Company.

OXIDATION OF DIFFERENT COMPOUNDS

Early experiments demonstrated the application of nitric-phophoric oxidation for various organic materials, and the importance of adding trace Pd catalyst to reduce CO generation. (1) These tests show that in 0.05-0.1M HNO3 in H3PO4 at 120-160oC and atmospheric pressure that many types of compounds can be quantitatively destroyed. Compounds completely oxidized, within experimental error, include cellulose, EDTA, tributylphosphate (TBP), nitromethane, and neoprene. Addition of 0.001M Pd(II) reduced the percent CO of the total CO and CO2 released by a factor of 15-25. For example, cellulose released 20% CO in the absence of Pd(II) and only 0.9% when Pd(II) was present; for TBP, 43% CO evolved without palladium compared to 1.3% with Pd(II), and the percentage of CO released during nitromethane oxidation was reduced from 60% down to 2.3%. Using similar oxidation conditions, it was found that the destruction of polyethylene was slow and incomplete.

In separate tests, high density polyethylene has been quantitatively oxidized to CO2 and CO using typical microwave sample digestion conditions (150-160oC, elevated pressures) in 1M HNO3/13.9M H3PO4 (Table I). (4) Addition of 0.001M Pd(II) to solution reduces CO production by a factor of three; higher concentrations will probably reduce the CO fraction even further. Recent work has shown that the primary advantage to sealed-vessel microwave dissolutions is the ability to obtain both high temperatures and acid concentrations at the same time. The rapid oxidation of aliphatic plastics such as polyethylene and PVC depends on obtaining higher temperatures and acid concentrations. Experimental work in this area is discussed later.

As discussed earlier, oxygenated compounds are more easily decomposed than aliphatic compounds, requiring one NO2. to cleave a bond instead of three. This is clearly depicted in Fig. 1 which shows the oxidation, under different conditions, of the primary compounds in the target feed stream. Each sample of PVC, polyethylene, cellulose, and benzoic acid contained comparable levels of carbon. Cellulose oxidizes fastest because it is already partially oxygenated. The differences between PVC and polyethylene stem from different dissolution characteristics. Polyethylene dissolves faster than PVC and, therefore, experiences faster reaction rates due to the increased surface areas of its dissolved state. The nearly constant oxidation rate of PVC may be attributed to its slow dissolution.

The oxidation of benzoic acid, an aromatic compound, is relatively fast at atmospheric pressure; the high oxidation rate is not surprising because benzoic acid readily dissolves in the process liquid. Oxidation rates of ion exchange resins, a component of the target waste stream which contains styrene, are expected to be comparable to plastics and not benzoic acid. However, the benzoic acid oxidation does demonstrate that aromatic compounds will be completely oxidized once they dissolve.

PARAMETRIC STUDIES

As is evident from Fig. 1 and the fact that plastics account for about 40% of SRS solid transuranic (TRU) waste, the rate-limiting step in the process is oxidation of

plastics. Because of this, a parametric study was run with a water-soluble oil (Trimsol) to better understand the effects of temperature and acid concentration on soluble aliphatic compounds. Trimsol simulates plastics once they dissolve; it is also the same oil used in machining operations throughout the DOE Complex, particularly Rocky Flats.

Although it is known that reaction rate increases with both temperature and acid concentration, our experiments quantify those effects. Figure 2 shows the importance of temperature. Calculated oxidation rates for runs at 120, 135, 150, and 165oC, respectively, are 0.7, 1.8, 3.3, and 5.5 mL/(hr.liter of solution). It is interesting that the data suggests that the reactions at 120, 135, and 150oC probably do not go to completion, which is in general agreement with what was reported by Seminov. (2) Follow-up studies revealed the role of nitric acid concentration at 165oC. The corresponding oxidation rates for 0.1, 0.5, and 1.0M nitric acid in concentrated phosphoric acid are 1.4, 5.0, and 5.7 mL/(hr.liter of solution).

A subsequent test was run to determine which parameter plays a greater role, temperature or acid concentration. In this experiment, starting solutions were made at 155, 170, and 185oC which had the maximum soluble nitric acid concentration; solubility is a function of temperature. The respective nitric acid concentrations in concentrated phosphoric acid (determined by ion chromatography measuring the nitrate ion) were 0.148, 0.0645, and 0.0195 g/mL. The data has been plotted in Fig. 3.

The initial oxidation rate for each experiment is approximately 35 mL/(hr.liter of solution). The results were unexpected as each reaction exhibits essentially the same initial reaction rate independent of the acid concentration-temperature combination. However, the oxidation characteristics of more stable compounds is apparent as the reaction at 155oC stops before completion and the reaction at 170oC achieves complete oxidation at a much slower rate than 185oC. The slowing of the reaction at 185oC may be a function of acid depletion, but this has not been determined experimentally.

OXIDATION OF PLASTICS

The earliest experiments in the oxidation of plastics used sealed vessels and microwave heating. This approach was taken because microwave vessels offered high-pressure capabilities, and it was originally thought that microwaves might play a role in the oxidation. Making precise statements based on the early tests is difficult due to the inability to monitor temperature or pressure. Nonetheless, experiments run using microwaves and the same digestion conditions provided insight into the effects of nitric acid concentration on polyethylene dissolution (Table II). This set of data reflects quite well what was observed in comparable experiments using Trimsol. A later microwave test during a vendor demonstration suggests that the temperature for the tests represented in Table II was approximately 150-160oC and 15 psig (205.1 kPa).

The results observed with microwaves fostered tests using conventional heating to oxidize polyethylene. Runs at 175 and 190oC, 0-5 psig (101.5-136.0 kPa), and the maximum soluble concentration of nitric acid yielded the results of the bottom two curves in Fig. 4. Once again, as was observed with Trimsol in Fig. 3, the initial reaction rates are almost identical. It was also observed, consistent with Fig. 3, that the test at the higher temperature showed better oxidation of the more-stable, long-chain intermediates. The temperature effect for plastics is not as pronounced as that for the oil because the plastic is a solid and has a more limited surface area in contact with solution. Tests using the same reaction temperature and acid concentration while varying the system pressure seemed to have little effect on oxidation rates.

Because the parameter of pressure by itself had no observable impact on plastic oxidation, it was determined that the primary value of pressurized systems (as in the microwave) is that they permit both higher reaction temperatures and acid concentrations instead of forcing the selection of one or the other. The effect of having both higher temperatures and acid concentrations is clearly shown in the top curve for polyethylene in Fig. 4. Calculations using the graph yield oxidation rates at 175, 190, and 205oC of 0.036, 0.034, and 0.107 g/cm2.hr, respectively.

Based on this experiment, it is believed that optimum conditions for easily-oxidized or short- chain compounds such as cellulose involve lower temperatures and higher acid concentrations due to rapid reactions and corresponding rapid acid depletion.

Conversely, the optimum system for plastics, where the oxidation of long-chain intermediates is more important, will seek a safe way to maximize temperature and nitric acid concentration using elevated pressures. However, moderate oxidation rates can still be achieved using slightly lower temperatures and atmospheric pressure.

MATERIALS OF CONSTRUCTION

The fact that nitric-phosphoric acid attacks stable organic materials at elevated temperatures makes it likely that it will also aggressively corrode many metals. Prior corrosion data and information in the literature on the corrosivity of phosphoric acid and nitric acid provided hope that high-alloy metals would be satisfactory for construction of main processing equipment. (5) This, however, is not as substantial an issue as it first appears. Since the system will operate near atmospheric pressure, glass-lined and Teflon-lined vessels are suitable materials for the oxidation vessels. The use of glass-lined and Teflon-lined vessels helps keeps the capital cost of equipment and replacements low. All other equipment which handles lower-temperature processing can be constructed from less expensive materials such as 304L or 316L stainless steel or Hastelloy C-276.

SUMMARY

Nitric-phosphoric acid-air oxidation has been developed to address the treatment of heterogeneous solid waste. This technology aims to destroy or decontaminate Pu-contaminated job control waste, a heterogeneous mixture of plastics, cellulosics, rubber materials, and noncombustibles. Since the issue of contaminated organics is not unique to SRS Solid Waste Management, the goals of this program are also consistent with other issues at Savannah River, DOE facilities, DoD installations, commercial nuclear operations, hazardous waste generators in private industry, and small-volume generators such as university and medical laboratories. Based on current data, the technology has also exhibited potential for remediating hazardous liquids and solids.

To address this broad category of waste, many organic compounds have been quantitatively oxidized in nitric-phosphoric acid. These compounds represent a cross-section of waste that must be treated, and contain most types of chemical bonds to be encountered. Elevating the temperature to 200oC and the pressure to 15 psig significantly enhances oxidation rates, particularly for plastics, resins, and solid aromatic compounds. The use of even higher temperatures and pressures could eliminate the need to use a phosphoric acid medium, but is currently perceived as undesirable because of the impact on scale-up and safety.

The process is nearly ready for testing with larger-scale equipment (20-50 liters) using organic feeds with little or no metals. Additional developments in the areas of volatile organic compounds and mixed aqueous-organic streams, although not applicable to Solid Waste Management, could prove to be beneficial to SRS as well as other generators of hazardous or contaminated organic materials.

ABSTRACT
Heap leach of the Fernald Environmental Management Project (FEMP) uranium-contaminated soils has consistently resulted in removal efficiencies of about 85 percent in the laboratory by use of sodium-carbonate-bicarbonate leach solutions in column experiments. Preliminary optimization has been achieved by variation of leach solution concentration, carbonate-bicarbonate stoichiometric ratio, pH, and application rate. To improve hydraulic characteristics of the FEMP soils, a variety of soil preparation techniques were employed that included agglomeration with cement and/or water, and by addition of various amounts of sand. About 15 percent of the total uranium in the soil has so far not been amenable to carbonate heap leach.
In order to better understand this phenomenon and optimize efforts to increase the uranium removal efficiencies, a number of geochemical models have been investigated. The initial model suggests two distinct, and kinetically controlled, desorption processes are occurring during the leach process. The model suggests that longer carbonate-bicarbonate solution residence times in the heap results in lower leachate solution to soil ratios for equivalent uranium removal. The model does not indicate that uranium is removed from the FEMP soils by either colloidal material or by dissolution of solid uranium phases. Intimate coupling of experiments, detailed analytical characterization and modeling has provided the understanding necessary to apply results to scaled up environmental activities.
INTRODUCTION
The site of the Fernald Environmental Management Project (FEMP) is located about 18 miles northwest of Cincinnati, Ohio. The site was formerly known as the Feed Material Production Center (FMPC) and operated from 1953 to 1989 as a production site for uranium compounds for use in defense facilities. As a result of operations at the FMPC two to four million metric tons of uranium-contaminated soil at the FEMP warrant remediation.
Carbonate heap leach has been successfully employed for leach of uranium from low-grade uranium ore. (1) Heap leach of FEMP uranium-contaminated soils has consistently resulted in the removal of about 85 percent of the total uranium by use of sodium-carbonate-bicarbonate leach solutions in column experiments conducted in the laboratory. (2) The reader is referred to Turney, et al (3), for details of those experiments.
Preliminary optimization has been achieved by variation of leach solution concentration, carbonate/bicarbonate stoichiometric ratio, pH, and application rate. To improve hydraulic characteristics of the FEMP soils, a variety of soil preparation techniques were employed that included agglomeration with cement and/or water, and by addition of various amounts of sand. (4) About 15 percent of the total uranium in the soil has so far not been amenable to carbonate heap leach.
In the uranium mining and milling industry low grade uranium ore has been heaped up on impermeable pads and then leached with sodium carbonate/bicarbonate ($Na_2CO_3/NaHCO_3$) solutions. It has been proposed that uranium-contaminated soils can be heaped up and leached in the same manner with sodium carbonate/bicarbonate solutions. The experiments that were modeled for the purpose of this paper were FEMP soils contaminated with uranium as a result of air emissions at the FMPC. The soils have been characterized as having an initial total uranium concentration of about 1396 mg U per kg soil. The major uranium phases in the FEMP soil are autunite ($Ca(UO_2)_2(PO_4)_2 \cdot 8\text{-}12H_2O$ - 55 percent), uranium metaphosphate (UO_2HPO_3 - 34 percent), and uraninite (UO_2 - 5 percent). (5) Other species present in the FEMP soil likely include schoepite (UO_3H_2O) (6).
DISCUSSION OF AQUEOUS GEOCHEMICAL MODELING
Desorption Modeling
In order to better understand the leach phenomenon and optimize efforts to increase the uranium removal efficiencies, geochemical models have been defined and investigated. A desorption model developed at the Los Alamos National Laboratory (LANL) that assists in analysis of actinide geochemical systems was used to aid in the interpretation of the data collected from the FEMP soil carbonate leach tests. Use of this model calls for comparing the concentrations of the uranium in the leach solution vs. the concentration of the uranium in the soil at specific time steps. When plotting the concentration of the uranium in the effluent solution (on the

abscissa in mg U per L effluent) against the uranium concentration of the solid (on the ordinate in mg U per kg FEMP soil), two relationships emerge. Figure 1 and Fig. 2 show data from an experiment that employed a 9 cm diameter, 150 cm tall column containing 10 kg of FEMP soil that had 1 kg sand added to improve hydrological characteristics fo the leach process. Two distinct trends are readily observed in the Figs. These trends are not to be confused by the darkened data points in Fig. 1 that show the dissolution process at the beginning of the column experiment.
Fig. 1. Plot of concentration of uranium in effluent vs. FEMP soil showing first desorptive trend.
Fig. 2. Plot of concentration of uranium in effluent vs. FEMP soil showing second desorptive trend.
The first trend is shown in Fig. 1 by a line having a slope of -0.25 L effluent per kg FEMP soil (indicating a desorption phenomena) and a y-intercept of 464 mg U per kg FEMP soil. The second trend is shown on Fig. Y where the slope is -2.1 L effluent/kg FEMP soil and a y intercept of 332 mg U per kg FEMP soil. While the slopes and intercepts vary slightly from experiment to experiment, virtually all the experimental uranium leach data produces similar trends (column experiments ranged in size from 80 g to 210 kg of soil).
The first trend coincides with the time during which most of the uranium is leached from the soil near the beginning of the leach process. The slope indicates that if this trend were to predominant for the entire leach experiment that it would require 0.25 L of bicarbonate solution per kg of FEMP soil to leach the soil to a final concentration of 464 mg U per kg soil. This would account for about 67 percent of the total uranium in the FEMP soil.
The second trend occurs as uranium dissolution decreases slightly over a long period of time at the end of the leach process. The slope of this trend indicates a requirement of 2.1 L of bicarbonate solution per kg of FEMP soil to achieve a final concentration of 332 mg U per kg soil. This accounts for dissolution of 9 percent of the total uranium in the soil for a total predicted removal of 76 percent of the uranium in the soil.
The desorption model suggests that two distinct, and kinetically controlled, desorption processes are occurring during the carbonate leach process. It is not readily apparent if the two trends are occurring simultaneously, but it is presumed that if that is the case the first uranium desorption trend is masking the second trend. The model suggests that lengthened carbonate/bicarbonate solution residence times in the heap results in lower leachate solution/soil ratios for equivalent uranium removal. The model does not indicate that uranium is removed from the FEMP soils by either colloidal material or by dissolution of solid uranium phases.
Predictive Geochemical Modeling
A software package for geochemical modeling of aqueous systems, EQ3/6, has also been employed to provide understanding necessary to apply results of column experiments to scaled up environmental activities. The major components of EQ3/6 (7) include a speciation-solubility code that deals with the concepts of thermodynamic equilibrium, thermodynamic disequilibrium and reaction kinetics; a reaction path code which models water/rock interaction or fluid mixing in either a pure reaction progress mode or a time mode, a data file preprocessor, a supporting software library, and several supporting thermodynamic data files that contain both standard state and activity coefficient-related data.
The majority of the data files support the use of the Davies or B-dot equations for the activity coefficients, the other files support the use of Pitzer's equations. The code uses a hybrid Newton-Raphson technique to make thermodynamic calculations. Each data file corresponds to a general formalism for treating the activity coefficients of the aqueous species and contains the relevant activity coefficient data as well as standard state thermodynamic data. The data files used with EQ3/6 are; 1) the "com" (for composite) data file is specific to the extended DeBye-Hckel formalism and is a product of Lawrence Livermore National Laboratory, 2) the "alts" data file is based on the "com" data set but includes a data set on actinides, 3) the "sup" data file, a data base based on Johnson, Oelkers and Helgeson's (8) software package SUPCRT92, 4) the "nea" data file is based entirely on Grenthe et al (9) and a product of the Data Bank of Nuclear Energy Agency of the European Community, (5 the "hmw" data file based on Harvie, Moller and Weare (10), and (6 the Chemval ("chv") data file where Chemval is a code-comparison project involving various countries conducting nuclear waste disposal studies (11).

The results of a number of EQ3/6 runs is shown in TABLE I. Starting values of pH, uranium, sodium and carbonate/bicarbonate concentrations of the leach solution and effluent were contained in the input files. Several different data files, described above, were used to compare and validate the different output. While only one data point is examined in TABLE I, other runs indicated the same relationships between output file data.

TABLE I. EQ3/6 output for a single data point with several different data bases.

The EQ3/6 output shows that in every case more than 99 percent of the uranium in solution is in the uranyl tricarbonate complex ($UO_2(CO_3)_3^{4-}$). Except for the "chv" data file output, where uranium concentration must be input as uranyl (UO_2^{2+}) instead of $UO_2(CO_3)_3^{4-}$, the activity of UO_2^{2+} ~ 10-20 and U(IV) ~ 10-45. The activity of uranyl dicarbonate ($UO_2(CO_3)_2^{2-}$) is always two order of magnitude less than $UO_2(CO_3)_3^{4-}$.

The saturation states of a number of selected minerals (shown as log Q/K) indicate that all of the minerals shown are undersaturated by at least one order of magnitude. Autunite is undersaturated by more than 38 orders of magnitude. Schoepite is undersaturated by approximately seven orders of magnitude and uraninite by about 8 orders of magnitude.

It can be drawn from the EQ3/6 runs that the carbonate leach solution is not near close to saturation with any of the major uranium minerals that are present in the FEMP soil. It would seem that the first part of the desorptive process is not effected by kinetics, but rather by accessibility of the uranium in the soil by the carbonate leach solution. The desorptive trend shown in Fig. 1 occurs where the carbonate rich leach solution can easily access the uranium. The point of intersection between the trends shown in Figs. 1 and 2 is where the desorption process becomes kinetically controlled.

Post-leach analysis of the leached soil in the columns shows that while there is a reduction of uranium concentration at all locations within the column, there is a greater uranium concentration reduction at the top of the column rather than at the bottom of the column. Because there is not a solubility problem, i.e. precipitation of previously solubilized uranium complexes as shown by EQ3/6, it is concluded that kinetics is governing the dissolution of uranium at the bottom of the soil column.

CONCLUSIONS

Efficiency of remediation of uranium-contaminated soils by sodium-carbonate-bicarbonate leach is dependent largely on accessibility of the uranium in the soil to the leach solution, and to a lesser degree, kinetics. Modeling shows two desorptive trends occurring during the leach process; the first an uninhibited dissolution of the uranium, the second trend an indication of kinetic control of the dissolution process. A software package for geochemical modeling of aqueous systems further demonstrates that the leach solutions are not close to saturation with respect to any of the uranium minerals or complexes that are expected to be found in the uranium-contaminated soil. This further indicates sufficient leach solution is available for uranium complexation within the soil column, but during the second desorptive trend the uranium is either not physically available for complexation, and kinetics dominates the desorption process.

WASTE MINIMIZATION OPPORTUNITIES AT A LOW-LEVEL RADIOACTIVE WASTE TREATMENT FACILITY

Colleen B. Owens
Scientific Ecology Group
1470 N. Skyline Ave.
Idaho Falls, Idaho 83402

ABSTRACT

SEG is committed to reducing the generation of waste at its processing facility, at the source, to recycle and reuse as many materials as possible, and to volume reduce any material that is designated as waste. SEG's objective is to eliminate as much waste as possible going to burial whether it is commercial, DOE, or its own secondary waste streams.

INTRODUCTION

Environmental regulations in the 1970s and 1980s were promulgated to rectify the historical pollution that contaminated the air, water, and soil. These regulations were implemented at great cost to society and industry, as illustrated by the billions of dollars that have been spent on environmental restoration.
Regulatory initiatives in the 1990s, however, reflect a forward-thinking approach to prevent future corrective actions through the initial avoidance of pollution. Avoidance or minimization of pollution at the source, prior to release to the environment, is the objective of these regulations.
SEG understands the impact of its own waste generation and the importance of a sound waste minimization program. With the rising costs of using disposal sites, coupled with other compelling economic and environmental reasons to support pollution prevention, SEG has implemented a program to avoid, reduce, or reuse the waste by-products of its processing operations.
SEG realizes there are other benefits to waste reduction. There is less liability, improved worker health, potential cost savings, and a positive environmental image presented to the company employees and to the community.

WASTE MINIMIZATION ORGANIZATION

SEG understands that management commitment is the cornerstone of a successful minimization program. And that commitment helps ensure that all levels of personnel understand the impacts of waste generation. Some of the effects of needless secondary waste generation are:

- Less profit because of high disposal costs for unnecessary waste production

Problems with regulatory compliance issues.
SEG upper management has expressed its waste minimization objectives through written program directives and allocation of resources dedicated to meeting those objectives.
WASTE MINIMIZATION OBJECTIVES
To minimize all wastes and prevent pollution, the plant enforces the following objectives:
Accept only wastes that can be treated and disposed of in a timely fashion, including customer and secondary wastes
Implement waste minimization procedures to reduce the generation of waste at the source
Sort and segregate wastes to achieve the optimum volume reduction and efficiency in our treatment systems
Recycle and reuse as many materials as possible
When secondary waste generation is unavoidable, our objective is to volume reduce this material to the maximum extent possible, again reducing the economic and environmental impact to the plant. These principal operational objectives will be managed with the necessary Quality Assurance and Environmental, Safety, and Health commitment to protect the worker, the public, and the environment.
WASTE MINIMIZATION ACTIVITIES AND TECHNOLOGIES
The theory underlying waste minimization is that it is far more logical to produce less waste rather than to develop extensive treatment schemes to ensure that waste is managed in an environmentally sound manner. The following are activities and technologies implemented at the SEG facilities to help minimize waste generation.
Waste Stream Segregation
When waste is generated, proper handling and containerization is essential.
If waste is suspect then it will go through the Green Is Clean process to determine whether or not it is contaminated. SEG's Green Is Clean program uses a low-Level Waste Analysis (LLWA) System employing HPGe gamma spectroscopy to verify that wastes meet free release requirements. Only waste deemed potentially clean is accepted for processing in this program. Waste is screened by a metal detector and pre-screened for contamination. All bags passing SEG's pre-screening are placed into cardboard drums for monitoring by the LLWA system. Waste with no detectable activity is shredded as clean waste and disposed of as SEG secondary waste in an industrial landfill. Samples of the shredded waste are analyzed using SEG's laboratory HPGe system to monitor 10 CFR 61 characterization. Wastes rejected from the Green is Clean process are treated as radioactive material and processed using one of SEG's other waste processing/volume reduction methods.
An active training program is in place to help employees realize the importance of waste minimization and implementation of waste minimization incentives.
In various operations, steps have been taken to eliminate waste generation or volume reduce the waste generated during the operations. The following are the specific operations and the implementation steps for minimization:
Incineration
Before incineration, waste is sorted so that incineration will be more efficient, will protect the incinerator from materials not utilized efficiently, and meet licensing standards.
Only certifiable incinerables are accepted from generators so that all materials will be incinerated efficiently to achieve a volume reduction factor of at least 200:1.
Waste manifest is carefully checked so that SEG does not accept waste that is non-processable.
Waste acceptance criteria is strictly communicated and enforced.
Waste processing procedures are analyzed to see if production can be improved. This is done by changing the feed composition or the flow rate into the incinerator. This is especially applicable when adding oil and water to the incinerator.
SEG installed combustion chamber burners to improve carbon burnout and to reduce the volume of hearth ash waste and ensure that it is non-hazardous.
SEG now burns waste oil instead of propane in the primary and secondary incinerator chamber burners to maintain proper operating temperatures.
SEG has further volume reduced the end product by installing a vitrification unit in the end of the incineration process. Ash can either be vitrified or ash can be compacted before sending to burial.

If ash is determined not to pass TCLP, instead of storing this waste, it is solidified so that it can be sent for disposal.

Scrubber blowdown solution is evaporated, dewatered, dried, or supercompacted instead of solidified to elimate volume increases in the waste stream.

When bags of incinerator additive are empty, they are surveyed through the "green is clean" program to be certain that they are not radioactive, and then appropriately disposed of. If they are found to be radioactive, then they are compacted or incinerated. If they are found not to be radioactive, then they are sent for independent verification and sent to the sanitary landfill.

Metal Recycling

SEG segregates and feeds materials into the metal melt so that the end product will certain to be recyclable.

SEG compacts the slag coming from the metal recycling process to volume reduce the secondary waste.

Decontamination

Decontaminate materials and tools as a first approach rather than declaring them a waste.

Other types of minimization techniques

Incinerate disposable protective clothing.

Minimize the number and size of contaminated areas at SEG.

Supercompact nonhazardous bag filter, prefilters, and HEPAs.

Substitute nonhazardous materials for cleaning and degreasing as well as eliminating the potential generation of mixed waste.

All possible waste sources are identified and controls, procedures, and training are instituted to ensure that contamination control is followed by minimization of spills. Spill response kits will be kept immediately adjacent to work areas to allow rapid response to a spill. Good housekeeping techniques are maintained so there is a clean local working environment.

Good housekeeping and storage management practices are always being upgraded to be certain that uncontaminated materials do not come in contact with contaminated. Inventory control of any new hazardous materials will be rigidly controlled to not allow any mixed waste generation.

SEG carefully considers material handling to ensure the potential danger of drum damage or incidents with drums is considered in all handling operation. First, SEG engineers identify the proper equipment to be used for safe handling. For example, examination will be performed to ensure that drums are in suitable condition for lifting prior to actually making the lifts. Positive lifting means will be employed to ensure potential loss of containment. Experienced operators will be used and continually trained to minimize potential problems associated with unfamiliarity with equipment of SEG detailed written procedures.

Any spills or leaks are promptly reported and cleanup actions initiated immediately by trained personnel. Measures are taken so that, in the case of an accident, no contamination of groundwater will occur.

EDUCATION AND TRAINING

The following are activities related to educating and training individuals at SEG related to waste minimization.

A pre-job briefing or checklist is completed before entering a contaminated area to do specific work so that unnecessary tools and materials do not enter the contamination zone. Workers are trained to perform special tasks with the use of mock-ups, classroom training, or personal instruction before entering the contamination zones.

Efforts are made to ensure workers understand their assignments before entering a contamination area, making them better prepared with the proper equipment and tools for the job.

Containments are used whenever possible to prevent the spread of contamination. Containments reduce labor associated with decontamination after repairs.

Only those materials that are known not to be RCRA regulated are ordered so that the generation of mixed waste is reduced.

Intensive training is provided to each health physics technician on proper waste management techniques.

Procedures are carefully written and followed so there is little chance for a spill or contamination of materials.

Training is provided to all radiation workers on proper techniques for waste

handling, segregation, decontamination, and minimization.

Environmental regulations are updated regularly to update procedures for handling and processing of waste.

Recycling Opportunities

The following are activities implemented at SEG to recycle materials instead of designating them as waste:

Use contaminated water in the incinerator instead of fresh water. A new water system has been implemented.

Recover melt metal from the sorting process in the metal recycling operation. Decontaminate materials and reuse instead of designating them as waste.

Substitute sulfur polymer cement (a recycled product) for an organic epoxy for the microencapsulation of hazardous baghouse flyash.

Involvement of all Employees

SEG has a bonus program that controls a portion of the amount of all SEG quarterly bonuses based upon the amount of waste that is generated. These goals and allocated amounts for specific tasks are identified to the employees and each is made aware of the importance of the goal to the individual's bonus. In addition, training efforts and good procedural steps, consistent to the operating requirements, are provided for each employee to follow. In addition, each employee is trained and qualified to perform certain tasks. Only those employees who have completed necessary training, education, or experience levels will be permitted to perform such tasks.

CONCLUSION

SEG personnel are committed to finding and implementing ways to reduce waste generation. This waste minimization program is changing with the introduction of new progressive waste minimization activities that are implemented regularly at SEG.

COST-EFFECTIVENESS ANALYSIS OF THE SEAMIST MEMBRANE SYSTEM TECHNOLOGY

Anne D. Henriksen
Steven R. Booth
Los Alamos National Laboratory

ABSTRACT

SEAMIST is a new technology that consists of an airtight membrane liner that is pneumatically emplaced inside the borehole. The positive air pressure inside the liner maintains the integrity of the borehole structure. Sampling ports with attached tubing, absorbent collectors, or various in situ measuring devices can be fabricated into the liner and used for monitoring volatile organic compounds (VOCs), semivolatile organic compounds (SVOCs), pesticides, herbicides, polynuclear aromatic hydrocarbons, polychlorinated biphenyls, or radioactive substances. In addition, small instruments can be guided through the lined borehole and measurements taken inside at specified intervals.

The purpose of this study is to analyze the cost and performance effectiveness of this new technology. To do so, we constructed four hypothetical scenarios in which utilization of the SEAMIST system can address various needs of the Department of Energy's environmental remediation program. Two of the scenarios involve vertical boreholes (or vertical instrument configurations) and two involve horizontal boreholes (or horizontal instrument configurations). The four scenarios jointly address contamination by VOCs, SVOCs, various water-soluble toxic substances, and low-level radioactive waste. One of the scenarios involves towing an instrument through a borehole and taking measurements of moisture levels in the surrounding soil.

INTRODUCTION

The purpose of this report is to investigate and describe on the cost and performance effectiveness of the SEAMIST membrane and instrumentation emplacement technology by analyzing how it compares to existing methods designed to accomplish the same task or set of tasks. In this analysis, we attempt to describe SEAMIST in a sufficient number of different scenarios in order to adequately demonstrate the breadth of its capabilities. Each scenario emphasizes a different function or addresses a different need of the environmental remediation objectives of the Department of Energy. Because of the diversity of capabilities of this new technology, each scenario must use a different conventional technology as a baseline of comparison.

SEAMIST is an innovative technology with many attributes:

- SEAMIST is an innovative technology that can facilitate measurements of soil-borne contaminants in horizontal and vertical boreholes
- SEAMIST consists of an airtight membrane that is pneumatically emplaced inside the borehole along with any attached sampling or measuring equipment, e.g., sampling ports, absorbent collectors, in situ sensors
- SEAMIST can be used to facilitate characterization and monitoring for VOCs, SVOCs, pesticides, herbicides, PAHs, PCBs, radioactive substances, metals, and other soil- or water-borne contaminants
- SEAMIST can also be used as a platform from which to tow in situ instruments such as cameras, neutron logging tools, and sensors through the borehole to obtain real-time data
- SEAMIST can be installed permanently with grout, semi-permanently with sand, or on a non-permanent basis by using positive air pressure
- SEAMIST can be a substitute for conventional borehole casing, but can also perform some functions that have no simple baseline of comparison, e.g., it can be used in conjunction with absorbent wicking pads to obtain samples of pore fluid contaminants on a recurring basis
- The magnitude of the cost savings possible from using SEAMIST instead of conventional methods increases as the depth of the contamination increases and increases as the variety of contaminants at a site increases

ANALYSIS AND CAVEATS

This analysis to determine the cost effectiveness of using the innovative SEAMIST technology is performed within the context of five scenarios. Each scenario highlights a different characteristic or need for some realistic set of site conditions that the DOE may encounter. Scenario 1 consists of a deep VOC contaminant plume (about 100 ft) which must be characterized and then monitored. Scenario 2 also involves a VOC contaminant plume; however, this plume is very shallow. Scenario 3 involves contaminants which are not volatile, but which exist in the pore fluids of the soil (see bullets). Scenario 4 involves taking moisture measurements to detect leakage under a low-level radioactive land disposal pit. Finally, Scenario 5 represents a combination of the requirements of Scenarios 1 and 3; its purpose is to demonstrate that there is synergism and economies of scope possible which result in additional cost savings over and above those of the separate scenarios.

Successful use of the SEAMIST technology requires that the geology of the site be sufficiently stable so that the borehole does not collapse before the membrane is emplaced. Also, the borehole surface must not be so rocky or sharp that it will tear the membrane.

COST DRIVERS

The cost drivers for both the new and the selected baseline technologies depend on the specific scenario. For the deep VOCs of Scenario 1, the SEAMIST system consists of vapor monitoring ports fabricated into the membrane. The baseline in Scenario 1 was chosen to be vapor monitoring ports constructed in conventional PVC casing. Both systems have tubing that carries the local VOC vapors to the surface for sampling and analysis. The cost drivers for Scenario 1 are the cost of the membrane for SEAMIST and the cost of the labor to construct the port system for the baseline.

Scenario 2 deals with shallow VOC contamination. The SEAMIST technology in Scenario 2 requires horizontal boreholes, whereas the baseline in this scenario consists of shallow, implanted soil vapor probes. Again, the cost of the fabricated membrane is a major cost to the new technology; however, that cost is far exceeded by the cost to drill the required horizontal boreholes. In this scenario, the new technology is not more cost effective; it is far more economical for shallow VOC contamination to use a system of soil vapor probes. It is worth noting, however, that for situations in which the contamination is not accessible from directly above the surface (e.g., across waterways or under buildings) horizontal boreholes and SEAMIST may be the only alternative.

Scenario 3 involves obtaining pore fluid from the vadose zone to analyze for water-borne contaminants such as nonvolatile organic compounds, PCBs, PAHs, pesticides, metals, and even tritium. The SEAMIST setup consists of absorbent wicking pads attached to the side of the membrane which are in direct contact with the borehole soil. The baseline of comparison is a series of vertically stacked, analogously placed, pressure-vacuum suction lysimeters. It is important to note that in this scenario, sampling for contaminants differs between the two alternatives. The cost drivers in this scenario for the SEAMIST setup are the membrane and the

cost of drilling the boreholes. For the baseline, the principal costs are the lysimeters, the lysimeter installation, tubing, and in particular, the cost to sample the lysimeters for pore fluid.

Scenario 4 involves the use of a neutron logging tool to obtain measurements of soil moisture under a low-level radioactive land disposal pit. Four horizontal boreholes are drilled underneath the land disposal pit. A SEAMIST liner is everted in the borehole as the neutron logging tool is simultaneously towed through it while taking neutron attenuation measurements at 5-ft intervals. The baseline consists of permanently casing the boreholes with aluminum and similarly towing the logging tool using a pulley system. The cost of the conventional aluminum casing is far more than that of the SEAMIST liner.

The final scenario represents a combination of the sampling requirements of Scenarios 1 and 3. The purpose of Scenario 5 is to demonstrate the economies of scope that can be achieved with SEAMIST that are not possible with most conventional technologies. The combination of vapor sampling ports and absorbent wicking pads in one membrane produces additional savings over the sum of the two separate SEAMIST system costs. When the two sets of requirements are combined, the separate sampling systems can be combined into one membrane. Both sampling systems can not be combined for the baseline. This integration capability is by far the most advantageous cost and performance advantage of SEAMIST.

Cost Savings

The cost effectiveness of using this new technology was calculated for each scenario. The cost data used to calculate the cost effectiveness were based on actual costs or stated prices from vendors or on a combination of both. Therefore, no uncertainties were considered for these scenarios. The results are summarized in Table I. For detailed information regarding cost estimates, see Henriksen and Booth, 1993.

Overall, SEAMIST was shown to be more cost effective the deeper the contamination and the greater the variety of contaminant substances. SEAMIST can often be configured to perform tasks that require two different conventional technologies. This introduces economies of scope which can result in significant cost savings. SEAMIST is very easy to remove and to dispose of after use. This is in contrast to conventional casing, which can only be abandoned after costly procedures.

ONGOING DEVELOPMENTS

New, stronger fabric materials are continually being developed for use as SEAMIST membranes. Additional innovative uses for SEAMIST include functioning as a conduit liner or straddle packer. SEAMIST has also been used in obtaining gas permeability measurements, for fracture flow mapping, and to measure brine flow.

CONCLUSIONS

SEAMIST can save from 16% to 74% of the cost of using conventional technologies, depending on the application

SEAMIST can sometimes perform tasks for which there is no conventional analog

In contrast to expensive cased borehole abandonment procedures, discontinuing use of SEAMIST may consist of removing the sand or disconnecting the air flow and then backfilling (see Table II).

REALIZATION OF COST AVOIDANCE TECHNIQUES THROUGH THE CONTROLLED AREA TRASH SEGREGATION

Charles Menche
FERMCO
P.O. Box 538704
Cincinnati OH 45253-8704

ABSTRACT

The "Green-is-Clean" program was initiated by Waste Programs Management (WPM). This program was an effort to segregate office trash generated in the radiologically Controlled Area so that it could be disposed of as sanitary rather than as low-level radiologically contaminated waste. The controls for demonstrating "no rad added" for this waste are that the office paper that comes into the Controlled Area as clean

and is never stored or used in any area other than the office areas. The authorized offices are routinely monitored (hand held instruments and smears) by Radiological Assessment for contamination and personnel handing this paper go through the personal contamination monitors prior to leaving the Controlled Area.
This project began with a pilot program in April, 1993 in which Radiological Assessment radiologically surveyed 100% of all Controlled Area office trash collected in order to verify that the administrative controls were sufficient to demonstrate "no rad added" and allow release of this waste to a sanitary landfill. Controlled Area office personnel were not informed of the pilot program to provide a worst-case scenario. Based on the results of these surveys, a 10% random sampling plan was developed in August, 1993, as a continuing overcheck of the program. Currently, Porters collect trash generated from approved Controlled Area offices and package it in green translucent trash bags. These bags are placed next to the contaminated trash dumpsters where transportation collects them twice weekly. A Radiological Control Technician performs a visual inspection for prohibited items and surveys the outer surfaces of each trash bag prior to being released as clean to a sanitary landfill. The contents of 10% of each collection is surveyed 100% to provide confirmatory sampling results. A procedure, SOP 20-C-617, Collection and Disposal of Controlled Area Office Trash, along with a contingency plan for incidents when a contaminated item is detected has been developed. These documents provide guidance for collecting, packaging, surveying, transporting and disposing of non-contaminated Controlled Area office trash to a sanitary landfill.

INTRODUCTION

The Fernald Environmental Management Project (FEMP)is a Department of Energy (DOE) owned facility that produced high-quality uranium metals for military defense for nearly 40 years. Fernald suspended production of uranium metals in 1989 and formally ended production in 1991. The Fernald mission has changed from one of production to environmental restoration. Even though production days have ceased, the perception still exists that everything that enters the Radiologically Controlled Areas at the Fernald are automatically deemed Low Level Waste (LLW) and must be disposed of as such unless demonstrated otherwise through analysis or administrative controls. This perception has caused an enormous amount of non-contaminated waste to be disposed of as LLW at a substantial cost differential. Clean waste is prohibited from disposal at the Nevada Test Site (NTS), and its appearance within the compacted bales of contaminated trash is a potential violation of the (NVO-325) Waste Acceptance Criteria (WAC). In reviewing NTS audit results and potential cost savings, FERMCO initiated a program to segregate Controlled Area office trash from the contaminated trash waste stream.

TECHNICAL BASIS FOR FEMP UNRESTRICTED RELEASE

DOE Orders 5400.5, "Radiological Protection of the Public and Environment", and 5820.2A, "Radioactive Waste Management", establish requirements and guidelines for managing radiologically contaminated waste at DOE sites. Order 5820.2A stresses waste minimization and states "...Low Level Waste (LLW) shall be managed on a systematic basis using the most appropriate combination of waste generation, reduction, segregation, treatment and disposal practices..." Order 5400.5 establishes numerical limits and qualitative guidelines for determining the effectiveness of segregation efforts. The requirements of these orders have been incorporated into FERMCO procedures and are being used on a daily basis for the Controlled Area Trash Segregation Program to demonstrate "no rad added" through strict administrative controls. This allows for disposal or recycle of significant volumes for clean trash from FEMP Radiologically Controlled Areas.

IMPLEMENTATION OF THE CONTROLLED AREA TRASH SEGREGATION PROGRAM

The "Controlled Area Trash Segregation Program" was initiated by FERMCO in 1993. This program was developed in an effort to segregate office trash generated in the Radiologically Controlled Area in order to dispose of it as sanitary rather than as LLW. This program utilizes a combination of administrative controls and process knowledge to ensure the material meets the required release criteria prior to leaving the FEMP site. The administrative controls are threefold. First, Porter personnel responsible for collecting the Controlled Area office Wash and Radiological Control Technician personnel responsible for radiologically surveying the trash receive specific training in accordance to the approved procedure. Secondly, Radiologically Controlled Area office personnel receive informal program overviews describing the methodology used to segregate the office trash along with a

review of the list of prohibited items. Thirdly, green tinted Wash bag liners are placed in each Controlled Area office trash can to indicate to office personnel and the Porter workforce of the approved areas in the Controlled Area Trash Segregation Program.
Process knowledge is utilized to demonstrate "no rad added" for this waste. It is understood that office paper that comes into the Radiologically Controlled Area is noncontaminated and is never stored or utilized in any area other than the office areas. The authorized offices are routinely radiologically monitored (hand held instruments and smears) by Radiological Control Technician for contamination. Personnel handling this paper must pass through the personal contamination monitors prior to leaving the Controlled Area.
The "Controlled Area Trash Segregation Program" began with a pilot program in April, 1993. Radiological Control Technicians radiologically surveyed 100% of all Controlled Area office trash collected in order to verify that process knowledge and administrative controls were sufficient to demonstrate 'no tad added" and allow release of this waste to a sanitary landfill. Controlled Area office personnel were not informed of the pilot program to provide a worst-case scenario. Based on the results of these surveys, an acceptable sampling plan that meets established acceptable criteria was established.
The objective of a sampling plan is to obtain a representative sample from a population and use the results of this sample to make assumptions about the rest of the lot with a specified level of confidence. In order to identify an appropriate sampling plan, assumptions must be made. This includes determining an acceptable fraction defective and a desired probability such that a lot exceeding the acceptable fraction defective will be rejected. Statistics associated with the unrestricted release of material generally employ a 95% confidence level that a contaminated sample will be rejected. The same confidence level is used for this sampling plan.
An appropriate sample size was chosen to meet the acceptance criteria. A reasonable lot size was chosen that considers the practical aspects of lot holding times and segregation/storage requirements of the lot while awaiting sample results. The number of trash hags collected in a week is considered the lot from which the sample size is chosen. The actual number of items per bag varies considerably based on the bag's constituents. Past data has shown that this can vary anywhere from approximately 300 to 1000 items ber bag. Because of this volume, a random sample is collected and radiologically surveyed per week to ensure a minimum number is met to satisfy the 95% confidence level. The rest of the week's pickup is held until the sample population has been radiologically surveyed. If radiological contamination is detected in the sample, then the rest of the population associated with that sample is disposed of as radioactive waste. Further steps are taken to identify the cause of the finding and corrective action implemented to prevent recurrence prior to reinstating the area of origin into the program. A contingency plan was developed to address these actions.
A procedure has been issued to provide instructions to the Porter workforce, Site Transportation, and Radiological Control Technicians. The procedure includes steps for collecting, packaging, radiologically surveying, transporting and disposing of non-contaminated Controlled Area office, breakroom and restroom trash. Based on the areas collected during the pilot program, Radiological Compliance issued an approved listing of Controlled Area offices, breakrooms and restrooms. The trash cans located in these approved areas contain a green trash can liner. This administrative control provides an indication to office area occupants and Porter personnel of the approved areas in the Controlled Area Trash Segregation Program. The Porter workforce collect trash generated from these specific areas, package it in green tinted translucent trash bags and indicate the building or area of generation directly on each bag with a permanent marker. These bags are placed in specific control points identified throughout the Controlled Area. Site Transportation collects the green bags twice weekly. A Radiological Control Technician accompanies Transportation on the collections and performs a visual inspection for prohibited items, radiologically surveys the outer surfaces of each trash bag and randomly selects the number of bags to satisfy the sampling plan requirements. The contents of these bags are radiologically surveyed to provide confirmatory sampling results. If the contamination level meets the limits of DOE Order 5400.5, the lot is disposed of as sanitary waste in a sanitary landfill.

Since April 1993, the cost savings associated with this program has amounted to $140,000. The volume of trash segregated as non-radiological waste has amounted to nearly 30,000 cubic feet. By segregating the non-radiological waste, the FEMP not only establishes a firm commitment to send only LLW to the Nevada Test Site, but results in substantial cost avoidance.

A PROBABILISTIC ANALYSIS OF DECOMMISSIONING COSTS

W. John DeCooman, Jr.
U.S. Department of Energy
Michael R. Walls
Colorado School of Mines

ABSTRACT

The wide range of cost estimates associated with facility decommissioning has raised concerns among utilities, regulators, and communities regarding the financial adequacy of nuclear decommissioning trust funds. Evidence from the Nuclear Regulatory Commission and TLG Engineering cost codes suggests there is disagreement in assessing decommissioning costs. Low-level waste (LLW) disposal costs have been identified as the most important and uncertain component of the total decommissioning costs. Cost estimates from a variety of industry experts and stakeholders ware assessed to determine a reasonably accurate distribution of anticipated LLW disposal costs and associated cost drivers. This new cost estimation procedure improves the traditional point estimate methodology by providing trust fund managers and decision-makers with a distribution of total decommissioning costs. This study utilizes risk analysis and industry survey data to assess a range of decommissioning costs for a 3400 megawatt thermal pressurized water reactor. Results indicate that LLW disposal costs are highly uncertain, generating a total decommissioning cost range of $380 to $775 million (1993 US$). This cost range was generated using the new estimation procedure and can lead to a more effectively managed trust fund and safer decommissioning operations.

INTRODUCTION

Utility preparation and execution of safe and cost-effective nuclear power plant decommissioning must include sound engineering and improved cost estimating techniques. Since 1978, the Nuclear Regulatory Commission (NRC) has published several documents intended to provide utilities with guidance and requirements regarding decommissioning nuclear facilities and accruing the necessary funds for decommissioning. One such requirement is that utilities must develop and submit a decommissioning plan for the eventual shut-down of their nuclear power plants; this entails a discussion of the decommissioning cost estimate and its methodology, the decommissioning project scope, and the financial instruments and methodology for collecting decommissioning funds.

The minimal level of decommissioning funding, as outlined by NRC guidance, applies to the removal of all radioactivity contaminated material and termination of the utilities' license. Aside from the uncertainty of contaminated material removal, utilities may be faced with collecting additional funds to remove or retrofit other structures and return the site to greenfield conditions, in some instances. This has lead to varying decommissioning cost estimates and a debate regarding the impact of inadequate nuclear decommissioning trusts. The debate centers on two issues, uncertainty and inadequacy with regard to costs and trust funds.

Provided the NRC's scope of decommissioning, the primary source of uncertainty is the cost of disposing low-level radioactive waste. These costs are thought to be driven by current waste regulations, future regulatory uncertainty, disposal facility operations and capacity, and siting complications. A recent 1993 estimate states that total low-level waste disposal costs account for 20 to 50 percent of total decommissioning costs, and burial accounts for 50 to 90 percent of disposal. Table I examines other cost relationships.

Although current estimates show low-level waste disposal (composed of packaging, transportation, and burial) as the dominant cost category, changes in work scope may reveal that staff labor or spent fuel dispositioning are greeter. In either case, implications of an inadequate nuclear decommissioning trust are intergenerational inequities and potential safety concerns from financially distressed or defunct utilities.

Supplying utilities and regulators with an understanding of what drives low-level

waste costs, provides an ability to more accurately estimate nuclear decommissioning costs, thereby enhancing a utility's decisions and benefiting the rate-paying community. The objectives of this study are to develop a questionnaire that assesses future low-level waste disposal costs, assess a range of disposal costs from industry experts, modify a decommissioning cost estimating code to incorporate a reasonable range of disposal costs, and generate a distribution of total decommissioning costs for a Westinghouse designed pressurized water reactor (PWR) and facility. This methodology is applicable to all pressurized water reactors and associated facilities if site-specific data are included.

LITERATURE REVIEW

Technology, Safety, and Cost of Decommissioning a Reference Pressurized Water Reactor Power Station - NUREG/CR-0130 was the NRC's initial reevaluation policy document that focused on power plant decommissioning. This report, released in 1978, assisted the NRC and public utilities by evaluating the technical aspects of decommissioning a power reactor and describing three prescribed decommissioning strategies: Decon, Safestor, and Entomb.

NUREG/CR-0130 is particularly relevant to this report since it addresses the impact of increased shallow-land burial costs. A comparison of empirical evidence from NUREG/CR-0130 and NUREG/CR-5884, Revised Analysis of Decommissioning for the Reference Pressurized Water Reactor Power Station (1993), reveals a significant change in the weight and sensitivity of overall disposal costs and the total decommissioning cost estimate to burial costs. Since NUREG/CR-0130, the NRC and independent firms have published updated cost estimates and frameworks for estimating costs. Several of the publications attribute rising cost estimates to a lack of decommissioning experience, the multitude of reactor and facility designs, variations in labor estimates for working in radioactive areas, geographical variation, escalating burial charges, and increasing energy rates. In turn, some critics recommend higher contingencies to offset future energy, labor, and burial cost escalation.

The Atomic Industrial Forum (AIF) published Guidelines for Producing Commercial Nuclear Power Plant Decommissioning Cost Estimates (3) in 1986; this cost estimating framework is the basis of this study because of its availability and widespread acceptance among utilities. The AIF framework emphasizes breaking the complete decommissioning project into hundreds of discrete tasks under the general project elements of 1) planning and engineering, 2) site preparation, 3) decommissioning operations and license termination, and 4) site restoration. This approach allows for easy manipulation, the use of risk analysis - when used in conjunction with computerized spreadsheets, and provides readily defensible cost estimates.

With regard to trust funds, Regulatory Guide 1.159 outlines two collection methods and several financial assurance instruments associated with trust fund investments. The accrual methods, external and internal, determine how decommissioning funds are managed. The external method uses investment fund managers and bankers to manage collected funds; the internal method allows the utility to manage collected funds through infrastructure and/or market investments while exercising fiduciary responsibilities throughout. The rationale for external trusts is supported by the benefits of independent money management (i.e., investment by bankers rather than investment by utilities), greater fund growth and inspection, and creditor protection. In general, external trust fund management is expected to better serve the ratepayer's interests than internal trust management (4). Many of the documents cited throughout this paper have contributed to improving cost estimation, but have not developed quantitative methods for addressing the uncertainty and risk associated with any part or the whole decommissioning cost estimating framework. The issue of burial cost uncertainty arises ultimately from pending waste disposal release criteria since waste volumes will be a function of the release criteria. This may explain the increase in disposal costs relative to total costs by 93 percent, when comparing 1978 and 1993 NRC decommissioning cost studies. The significant increase suggests that modeling cost uncertainty, identifying the components of waste disposal costs, and applying the resulting intuition to a thorough cost estimating methodology will supply utilities and public utility commissions with an effective list of options for improved and responsive decision-making. Therefore, this report focuses on the uncertainty of future burial charges by assessing a reasonable range of low-level waste disposal fees from industry, yielding a range of decommissioning cost when input to a site-specific

costing model.
INDUSTRY QUESTIONNAIRE AND COST DRIVERS
This study examines the impact of risk, in the form of varying low-level waste costs, on a pressurized water reactor decommissioning cost estimate. Using data from a Westinghouse designed 3400 megawatt-thermal PWR, TLG's proprietary Decommissioning Cost Exposures and Radwaste code (DECCER) and an ExcelTM add-in program @RISKTM, an array of burial and final decommissioning cost estimates will be generated. This study utilizes TLG's site-specific method because of its detailed nature, adaptability, and acceptance by utilities. A questionnaire, see Fig. 1, regarding future low-level waste costs was provided to many industry experts. Wuestionnaire resonses associated with base burial costs were incorporated into building-block approach documented by Atomic Industrial Forum (1986). The TLG cost sode specifies tim cost categories related to decontamination, waste removal, waste burial, and other costs, providing a single point estimate. By incorprating a representative range of full-burdened low-level waste costs with TLG's cost code, a probabalistic reange of total decommissioning costs will be generated.
Twenty-five qualified candidates were canvassed to participate in this survey. Participants were "qualified" based on two criteria: 1) the individual is highly knowledgeable of the nuclear decommissioning dilemma and 2) the individual or their organization typically responds to Nuclear Regulatory Commission decommissioning rules and policy. The first criterion sought candidates with published papers on aspects of decommissioning and radioactive waste management, extensive industry experience, a demonstrated interest in promoting the environment, and/or accepted decommissioning guidance or policy. The second criterion sought a broad and balanced perspective of future low-level waste costs. Public records were examined to identify nuclear industry policy respondents and the following groups were solicited for survey participation: Sixteen individuals accepted the questionnaire, and seven, with varying industry backgrounds, responded. Each participant was asked to reply with a minimum, most-likely, and maximum response -providing a range of current year class A LLW disposal costs. academia, industry consultants. environmental/consumer advocate groups, LLW compact organizations, public utility commissions. government agencies pertaining to nuclear waste issues, utilities, and environmental/waste management companies (underlines indicate responding groups).
The five survey questions were divided among two cost accounting categories, base and overhead costs. The base burial charge cost, referred to as base cost, includes the following: LLW facility operation costs (regional compact fees, maintenance and closure costs), political uncertainty costs, and additional regional compact fees for unaffiliated disposers (questions 1, 3, and 4). The overhead cost includes fees for handling oversized disposal containers and municipality taxes (questions 2 and 5). Individual cost curve distributions were constructed using simulation analysis and Latin Hypercube sampling. Cost curves, from the seven constructed distributions, were interpreted by plotting simulation results and sketching a representative base and overhead curve. The aggregated or full burdened cost curve data were input to the TLG decommissioning cost code to produce the PWR decommissioning cost range. The aggregated, full burdened cost results uncover a minimum, maximum, and mean value of $197, $1230, and $702 per cubic foot. This implies that future class A low-level waste burial costs may vary between $197 and $1230 per cubic foot, in 1993 dollars. Table II summarizes the characteristics of each cost curve.
Cost Drivers
Based on questionnaire responses and sensitivity analysis of decommissioning costs, several factors tend to increase LLW costs. The first three factors relate to questionnaire base cost components such as LLW facility operating costs, political and administrative uncertainties, and compact fees. These three base cost factors represent 93 percent of the full burdened class A LLW costs. Another cost element disposers will be subjected to is a site closure fee. This fee is analogous to a mine reclamation cost and is an area likely to see increases during the next five to fifteen years. The final two factors affecting waste costs are disposal facility site availability and waste volume. Facility availability remains uncertain as evidenced by siting complications in California, Texas, and the Central Compact. Waste volumes will be driven by regulations, reactor housekeeping, and waste minimization efforts. This suggests waste volumes may or may not explicitly increase costs.
THE PWR DECOMMISSIONING COST ESTIMATE

This study examines the impact of low-level waste disposal cost uncertainty on a pressurized water reactor decommissioning cost estimate and assumes a Decon decommissioning strategy with dry spent nuclear fuel storage conditions. To include waste disposal cost uncertainty, the TLG cost code was modified to include a range, rather than waste disposal cost point estimate, equipping utilities and regulators with a complete picture of disposal and total decommissioning cost ranges.

LLW end Decommissioning Cost Estimate Ranges

To determine the risk low-level waste disposal imposes on a decommissioning cost estimate, probabilistic analysis was employed using TLG's cost code and a LLW disposal cost range based on questionnaire data. DECCER's burial cost component was supplemented by US Ecology low-level waste disposal costs, with class A, B, and C waste volumes provided by TLG. Based on the LLW volumes assessed by TLG, DECCER class A LLW disposal base, overhead, and full burdened costs were measured and substituted with questionnaire and economic data. An example of questionnaire based full burdened waste class costs is supplied in Table III.

Simulation analysis provided the following minimum, expected, and maximum low-level waste disposal values shown in Table IV. Incorporating the LLW disposal ranges with DECCER's other nine cost categories generated a range of total decommissioning costs. The expected PWR decommissioning cost range is illustrated in Table IV. The range of total decommissioning costs, $382 to $775 million, indicates future total costs are highly uncertain due to LLW disposal costs. This confirms earlier suspicions that LLW burial and disposal costs are the single most uncertain variable affecting decommissioning project costs. Figure 2 conveys the extreme variation and outcome differences among the three cost ranges, given in cumulative function form; the questionnaire based range dominates nearly all model outcomes, as expected.

SUMMARY AND CONCLUSIONS

Several decommissioning cost estimating methodologies were reviewed for their thoroughness, adaptability, and consistency with Nuclear Regulatory Commission guidance. Evidence from these reviews confirms that various cost estimating approaches taken by utilities, regulators, and contractors produce a wide range of total cost estimates. This is a concern to utilities, ratepayers, and public utility commissions because total costs are the basis for collecting adequate nuclear decommissioning trust funds. Varying estimates are the result of uncertain decontamination technologies, exposure limits, waste release criteria, and disposal costs. The one complication, or concern, common to all estimates that poses the greatest uncertainty is future low-level waste burial costs. The burial cost is driven primarily by disposal facility capacity and decommissioning waste volumes. Data reported in this study confirms this waste disposal dilemma and suggests approaches to manage the uncertainty. Most notably is the USA of risk analysis to bound and explain the cost drivers affecting future disposal cost increases. A more complete understanding of the disposal dilemma will provide improved methods to package, ship, and bury LLW and enhance present strategies for accumulating and managing nuclear decommissioning trust funds. Low-level waste burial costs account for 20 to 50 percent of the total decommissioning cost estimate, and waste disposal costs account for 50 to 90 percent of the low-level waste burial costs. Clearly, waste disposal is the primary cost component of LLW burial costs and contributes significantly to decommissioning project costs. Evidence of low-level waste's importance and sensitivity to total costs prompted this study and its objectives to define a reasonable range of future low-level waste disposal costs and strategies to counteract or decrease the disposal cost's eventual influence on total costs.

The TLG cost code, DECCER, was reviewed and determined to be best suited for this decommissioning cost study. The DECCER methodology is well documented, it can be easily adapted for risk analysis, its results are accepted by the Nuclear Regulatory Commission, and it is utilized by most utilities. To supplement the DECCER disposal cost category and provide a range of decommissioning costs, a questionnaire was developed to identify future low-level waste disposal costs. The range of LLW disposal costs was constructed using questionnaire responses from industry experts and simulation analysis. Construction of a representative cost range represents a key development for cost estimators and trust fund managers by incorporating insight from industry, government, and academia to assist with bounding the low-level radioactive waste disposal dilemma. Seven participants from academia, government, and industry provided their assessment of low-level waste disposal facility operational costs, special surcharges, compact fees imposed on out-of-compact

disposers, other costs, and municipal taxes. The sum of the five questionnaire costs ranged from a low of $83 per cubic foot, to a high of $4,838 per cubic foot, suggesting that disposal costs are highly uncertain and the cost components driving those costs are misunderstood. This span of costs was interpreted to define a reasonable and representative range of base and overhead costs; the full burdened cost range is characterized by the following parameters: minimum, $197; mean, $702; maximum, $1,230 per cubic foot.

The questionnaire cost range was supplied to the TLG cost code, DECCER, to generate a PWR decommissioning cost estimate range. Reactor equipment and inventories are modeled after a Westinghouse designed pressurized water reactor, 3400 megawatts-thermal. PWR decommissioning costs vary between $382 and $775 million if future class A LLW disposal costs varied between $197 and $1,230 par cubic foot, indicating that LLW disposal cost uncertainty greatly impacts decommissioning and should be the focal point of future resources. The range of possible decommissioning costs decreases to less than $200 million when limiting the questionnaire cost distribution to 80 percent of the total PWR cost distribution. With respect to trust funds, the impact of collecting various trust fund levels based on questionnaire LLW cost data, Fig. 3 is provided. Figure 3 relates that if one decided to collect $400 million to decommission this study's reference PWR, the chances of decommissioning costs exceeding the trust fund are 97 percent. A more conservative individual may choose to collect $600 million, this would reduce the chance of decommissioning costs exceeding trust funds levels to just 26 percent. Risk analysis assisted with establishing these decommissioning project cost limits and identifying the true magnitude of cost variability. To assist with diffusing decommissioning complications, risk analysis and decision analysis techniques can be merged with traditional cost estimating methodologies, as performed by the natural resources and manufacturing industries, to provide public utility commissions and trust fund managers with a better picture of future decommissioning costs (5), (6). Industry knowledge, use, and acceptance of risk analysis and decision analysis techniques will lead to a clearer understanding and definition of the issues, cost drivers, and relationships affecting plant operations and decommissioning. This will provide support for innovative regulatory approaches, trust fund management methods, and decommissioning strategies.

Several equitable and efficient approaches must be developed to manage the disposal dilemma and understand the application of risk analysis. Approaches such as improved forecasting tools, regulator education, and community involvement will assist with decreasing future low-level waste disposal uncertainty. Forecasting tools must incorporate historical trends, new cost developments, and facility capacity constraints and availability dates to be effective. Utilities and contractors must introduce regulators to risk analysis theory and application, and emphasize its value, benefits, and limitations. Finally, host communities and contractors may adopt the siting strategy implemented by the Appalachian States Compact and Chem-Nuclear to minimize disposal facility siting and construction delays. These approaches allow utilities to effectively plan for reactor shut down and decommissioning, rather than reacting with crisis management measures. Regulators will benefit by understanding the utilities operating, shut down, and decommissioning strategy and bases, while assuring proper management and collection of adequate nuclear decommissioning trust funds. Finally, communities will benefit from equitable energy rates, safe decommissioning, and prudent disposal operations.

WASTE MINIMIZATION MEASUREMENT AND PROGRESS REPORTING AT THE SAVANNAH RIVER SITE*

Keith A. Stone
Westinghouse Savannah River Company
P.O. Box 616
Aiken, SC 29808

ABSTRACT

Westinghouse Savannah River Company is implementing productivity improvement concepts into the Waste Minimization Program by focusing on the positive initiatives taken to reduce waste generation at the Savannah River Site. Previous performance measures, based only on waste generation rates, proved to be an ineffective metric for measuring performance and promoting continuous improvements within the Program. Impacts of mission changes and non-routine operations impeded development of baseline waste generation rates and often negated waste generation trending reports. A system was developed to quantify, document and track innovative activities that impact waste volume and radioactivity/toxicity reductions. This system coupled with Management-driven waste disposal avoidance goals is proving to be a powerful tool to promote waste minimization awareness and the implementation of waste reduction initiatives. Measurement of waste not generated, in addition to waste generated, increases the credibility of the Waste Minimization Program, improves sharing of success stories, and supports development of regulatory and management reports.

INTRODUCTION

The Savannah River Site (SRS) is a key Department of Energy (DOE) facility, focusing on national security work; environmental and waste management activities; and economic development and technology transfer initiatives. Owned by the DOE and operated under contract by the Westinghouse Savannah River Company (WSRC), the complex covers 310 square miles near Aiken, South Carolina, bordering the Savannah River.

Waste Minimization and Pollution Prevention (WMin/PP) at the Savannah River Site is a continuous improvement process. Recall the basic elements of the cyclical continuous improvement model: Baseline process; Identify and implement improvements; Define performance expectations; Measure and evaluate performance; Repeat the cycle. Obviously, the continuous improvement model breaks down if the measures and metrics chosen do not relate to performance goals. This paper addresses improvements the SRS has made in aligning measures with program WMIN/PP performance goals.

TRADITIONAL PERFORMANCE MEASURES

The performance objectives of the SRS WMin/PP program are to eliminate unnecessary waste generation and maximize the life of SRS waste storage and disposal facilities through cost-effective source reduction, recycling, and volume reduction initiatives. The traditional measure used at SRS, and across industry, to gauge WMin/PP progress is the volume of waste generated and placed in Treatment/Storage/Disposal (T/S/D) facilities. There are several reasons for the widespread use of this measure:

Convenience - The systems to track and measure waste generation were in place long before waste minimization became a focused initiative. Why develop new measures when we have one already?

Credibility - Waste volume is not a subjective measure. The reliability of waste volume data is rarely subject to dispute and cannot be manipulated.

SRS WMin/PP program planners have concluded that the total waste volume, when used exclusively as a WMin/PP measure, is a poor barometer of program effectiveness. As stated, our WMin/PP performance objective is to eliminate waste, yet our only measure is the waste we fail to eliminate. Bowling provides an analogy; the performance objective is to knock down as many pins as possible and the performance measure is the number of pins knocked down. If we approached bowling in the same manner as waste minimization, the metric would be the number of pins left standing, i.e., a measurement of failure.

There are instances where measuring the amount of waste generated can be an effective indicator of WMin/PP progress. Specifically, when baselines permit accurate predictions of waste generation. You're familiar with the widget example where waste per widget can be calculated and used as a baseline. Waste minimization success can be concluded by measuring waste per widget, before and after waste minimization initiatives. In the utility industry, waste per outage can be an effective measure. This can be further illustrated with the bowling example. Even if we measured the pins left standing, we could draw conclusions about how well our performance was because we have a fixed baseline of 300 pins per game.

NEW PERFORMANCE MEASURES NEEDED

The nature of waste generating activities at the SRS, and across the DOE Complex, is changing. Production missions have all but been replaced with environmental remediation and D&D missions. Yesterday's production facility has become today's waste. Volumes of this legacy waste, and secondary waste generated during cleanup, are predicted to spiral upwards. Budget uncertainty, land use issues, and evolving regulations make predictions of waste volumes, even on a short-term basis, extremely difficult. Utilizing total waste volume as a measure of WMin/PP effectiveness is fruitless; the measure bears little, if any, relationship to the process being measured. In the bowling analogy (last time, promise), our situation resembles a modified game where the number of pins available each frame or game changes unpredictably and we choose to measure our performance by counting pins we fail to knock down.

It should be intuitively obvious that if the objective of WMin/PP is to eliminate waste and pollution, then we should measure the amount of waste that is eliminated (WMin/PP success) versus the amount of waste generated (WMin/PP failure). In concept this is straightforward; the challenge is establishment of a data collection mechanism to support this measure. The SRS has deployed such a system to measure and quantify the impacts of WMin/PP initiatives.

IMPROVED MEASURE

A Pollution Prevention Activity Form (PPAF) (1) was developed to capture and quantify the impacts resulting from discrete WMin/PP actions. The Form is straightforward and requires little effort to complete. A copy of the PPAF, with instructions, is provided as Attachment 1 a, b, c. The intent of the PPAF is to document innovative pollution prevention activities being implemented at SRS. The PPAF helps fulfill regulatory and DOE reporting requirements for waste reduction activities, facilitates pollution prevention technology transfer, and provides a credible basis for WMin/PP cost savings calculations.

Use of the PPAF is being institutionalized at the SRS by mandating completion of the form, by the initiator of the WMin/PP action, in a Company level procedure. Instructions for Form completion are available and key personnel have been trained on proper completion. Further, the DOE has defined WSRC Cost Plus Award Fee (CPAF) goals for waste avoidance with the requirement that avoidance be documented on PPAFs. Since mid 1993, over 90 PPAFs have been submitted and verified to be accurate. Over 4770 cubic meters of solid low level radioactive waste avoidance has been documented representing a savings of $2M in waste disposal costs alone. In addition, almost 60,000 kg of hazardous and low level mixed waste was avoided due to WMin/PP actions. Use of the PPAF at SRS has been successful due to this bottom-up (procedures and training) and top-down (company Award Fee goals) approach.

To illustrate the value of collecting waste avoidance data, refer to Fig. 1 which is a measure of total SRS solid waste (sanitary, hazardous, radioactive). The reductions in waste are dramatic, however, going back to the previous discussion: are these reductions due to WMin/PP or are they simply a result of mission downturns?

Figure 2 shows the same waste generation data as Fig. 1, plus an overlay of waste avoidance data extracted from PPAFs. This improved WMin/PP program measure clearly shows the impact WMin/PP has had on reduced waste generation rates.

CONCLUSION

The traditional WMin/PP performance measure of waste volumes cannot be used as the sole measure of WMin/PP program effectiveness. Measuring waste eliminated due to WMin/PP actions is a superior performance indicator. This tool facilitates cost benefit analyses, helps justify additional investment in WMin/PP, and strengthens program credibility.

WASTE MINIMIZATION APPLICATIONS FOR CAPACITY SHORTFALL REDUCTION IN PUERTO RICO
Susan E. Boone
Nicola Bird
CDM Federal Programs Corporation
South Plainfield, New Jersey
Sin-Kie Tjho
Hazardous Waste Facilities Branch
U.S. Environmental Protection Agency
New York, NY
ABSTRACT
Section 104 (c)(9) of CERCLA requires all states to submit a Capacity Assurance Plan (CAP) projecting hazardous waste generation and management capacity for the next 20 years. Puerto Rico's CAP identified several hazardous waste management categories, such as metals recovery and incineration of sludges/solids, for which capacity shortfalls were predicted. CDM Federal to evaluate possible options for reducing the projected shortfalls. One of the mechanisms studied was waste minimization.
The results of CDM Federal's study on the appropriateness and feasibility of using waste minimization to reduce hazardous waste management capacity shortfalls in the Commonwealth of Puerto Rico is presented below. This study is unusual in that it considers hazardous waste generation and management activities for an entire island, and evaluates the overall effectiveness of implementing waste minimization programs in various key industries to reduce the capacity shortfalls, rather than concentrating on waste minimization at a single facility.
CDM Federal obtained and evaluated hazardous waste generation and management data from several sources, including the Puerto Rico Hazardous Waste Manifest Database; the Toxics Release Inventory; and the Biennial Reporting System. One of CDM Federal's most important findings was that over 95% of the hazardous waste managed in commercial HWMFs is generated by just 26 facilities in seven different industries in Puerto Rico. This finding is significant because it indicates that waste minimization efforts implemented by a small number of facilities could substantially affect waste generation patterns for the entire island. The benefits of targeting only a limited number of industries, rather than imposing an "across-the-board" requirement that all industries implement waste minimization programs, are obvious, especially when considering the limited information and technical resources available to many Puerto Rican industries and regulatory agencies.
The seven industries generating the majority of the hazardous waste in Puerto Rico include: plastics and synthetic resins; medicinal compounds and botanical products; pharmaceutical preparations; petroleum refining; plating and polishing; printed circuit boards; and surgical appliances and prosthetic devices. CDM Federal evaluated potential waste minimization techniques for these industries and calculated that the various hazardous waste streams generated by these industries could be potentially reduced by 15 to 80%, thereby significantly reducing the predicted capacity shortfalls.
The results of this study suggest that the implementation of aggressive waste minimization programs within the identified industries has significant potential to reduce the predicted capacity shortfalls in Puerto Rico. By focusing waste minimization efforts on the identified industries rather than attempting to impose them on all industries, the Puerto Rico regulatory agencies can make the most efficient use of their limited resources. In addition, with little or no capital expenditure, nearly all facilities can implement better operating procedures to reduce unnecessary waste and to improve the efficiency and economy of their manufacturing processes.
BACKGROUND
Section 104 (c)(9) of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), as amended, requires all states and territories to assure

that adequate hazardous waste management capacity for waste generated within the state will be available during the next 20 years. Capacity assurance plans (CAPs) submitted to the U.S. Environmental Protection Agency (EPA) form the basis for the assurance of capacity in any contract or cooperative agreement for remedial actions between the state and the EPA Administrator. The EPA Administrator determines whether or not the capacity assurances provided in the CAP are adequate.

The Commonwealth of Puerto Rico submitted its CAP to EPA on February 15, 1992. The CAP submission provided waste generation and management analyses for the base year 1987 and analyses for the projection years 1989, 1995, and 2009. The data in the CAP was based on the Biennial Reports and the National Treatment, Storage and Disposal Facility (TSDF) Survey. The CAP predicts that there will be capacity shortfalls at commercial facilities for several waste management categories in each of the three projection years. The major commercial capacity shortfalls (i.e., greater than 400 tons) occurring by the year 2009 are as follows (see Table I).

Capacity shortfalls are also indicated for other waste management categories, such as sludge treatment and aqueous organic/inorganic treatment. However, these shortfalls are minimal in comparison to the five categories listed above.

APPROACH

CDM Federal investigated several options for reducing these shortfalls including source reduction/waste minimization activities. Our primary focus was to identify those waste minimization activities which would have the greatest impact on reducing the projected capacity shortfalls. To do this, the waste streams whose reduction would cause the greatest reduction in the projected capacity shortfalls were first identified. For example, metals recovery is projected to have an annual capacity shortfall of 7,835 tons in the future. In order to most effectively reduce this shortfall, it was necessary to identify those waste streams that are generally treated by metals recovery. Having accomplished this, manifest databases, the Toxics Release Inventory (TRI) and the Biennial Reporting System (BRS) were used to identify the industries producing the target wastes in substantial quantities (i.e. > 1 ton/year) for off-site treatment. With the critical waste streams and industries identified, CDM Federal proceeded to evaluate appropriate waste minimization techniques.

CDM Federal determined that over 95% of the hazardous waste generated in Puerto Rico and treated off-site is generated by 20 facilities which fall into seven groups of industries as classified by Standard Industrial Classification (SIC) codes. Waste minimization potential was evaluated primarily for those seven industries (see Table II).

FINDINGS

Following are summaries of several of the waste minimization techniques identified by CDM Federal for the industries listed in Table II.

Innovative techniques for allowing reuse of scrap plastic are currently being tested by various plastics manufacturers. Foam plastics may be dissolve in a solvent, thereby reducing the volume of waste relative to the typical low density, high volume solid form of foam plastic. Even if dissolved waste plastic is not reprocessed, dissolution of solid foam plastic will reduce the total volume for disposal. Scrap plastics composed of mixtures of different materials may be depolymerized to their original monomers for potential reuse. Ideally, the dissolved solution would be suitable for subsequent reprocessing of the plastic. However, this technique has not yet been perfected.

The pharmaceutical industry is a critical one, as the majority of hazardous waste generators in Puerto Rico fall into this category. Unfortunately, this industry also has unique barriers to source reduction and waste minimization efforts. Our study discovered that there is a reduced opportunity for technology transfer, due to the proprietary nature of the industry, and the product specific processes utilized. Regulatory constraints and concern over trace impurities, prevent the implementation of activities such as solvent recovery and reuse, despite the fact that solvent use and spent solvent waste generation is very high for this industry. High costs (in time and resources) associated with obtaining approval from the U.S. Food and Drug Administration (FDA) for process changes, material substitutions, and other modifications which might impact product quality and safety represented another hurdle.

Even with these barriers, however, some waste minimization may still be achieved through the application of one or more of following methods (see Table III).

1) Minimization of laboratory and R&D wastes, by implementing formal waste collection and segregation systems, and discouraging the collection of solvents and other wastes in non reusable containers which must then be disposed as hazardous waste. 2) Process and equipment modifications when approved, that will allow more efficient utilization of raw materials, resulting in less waste generation. 3) Material substitution, when approved, such as the substitution of degradable solvents or nonhalogenated solvents for halogenated solvents, or the substitution of aqueous systems where possible. 4) On-site small scale recycling of solvents using a reflux apparatus that will produce clean solvents for reuse and distillation bottoms for disposal. 5) Segregation of wastes streams, particularly halogenated and non-halogenated solvents, to allow increased on-site treatment and/or disposal of wastes, and less need for off-site treatment or disposal. 6) Installation of solvent recovery systems (such as distillation or extraction units) if approved. If concerns about product purity are barriers to use of recovered solvents, these solvents may be appropriate to use for cleaning equipment that does not come directly into contact with products, such as storage tanks and equipment exteriors.

A large portion of solvent wastes generated is composed of solvent-contaminated water from equipment and floor washwaters. This volume may be substantially reduced through application of one or more of the following methods. 1) Minimizing spills, thereby reducing the frequency of floor washings necessary. 2) Optimizing automated equipment cleaning cycles to use the minimal amount of water necessary. 3) Using the wastewater generated from the final rinse of one cleaning cycle as the pre-rinse on the next cycle. 4) Using low volume, high efficiency cleaning (e.g., spray heads rather than hoses).

Petroleum refineries produce large quantities of sludge generated from the API separators. The volume of sludge can be significantly reduced through dewatering the sludge. The products will be soil and a heavy-oil-and water mixture. The heavy-oil-and-water mixture can be passed through a condenser and separator, with a portion of the oil returned to the facility for reuse and the water sent to the wastewater treatment plant. If the soil contains heavy metals, it may be treated through soil washing. The products of soil washing will be heavy metal-containing water and sludge. The sludge will be dewatered, resulting in soil, which may be disposed of, and wastewater. The heavy metal-containing water must be treated in a wastewater treatment plant, resulting in clean water for reuse and hazardous waste sludge containing heavy metals. The volume of this sludge will be far smaller, with a much higher concentration of heavy metals, than initially generated.

Facilities utilizing electroplating or other metal finishing processes are generally major producers of metal-containing wastewater and sludges, as well as acids and chlorinated solvents. Minimization of wastewater treatment sludges from electroplating operations can be accomplished through the application of one or more of the following methods: 1) Installation of ion exchange columns to absorb metals from the wastewater stream prior to discharge to the wastewater treatment plant. 2) Utilization of electrolysis or electrowinning for the recovery of metals from plating baths, resulting in purification of the waste stream prior to discharge or reconstitution of the plating bath for additional use. 3) More efficient use of settling agents in wastewater treatment and sludge thickening operations, since up to 85% of the F006 sludge generated in some facilities has been found to be as a result of the use of sludge settling agents such as calcium sulfate. 4) Reducing impurities which shorten the life of plating baths.

Studies have shown that up to 50% of the waste streams treated by electroplating facilities as metal-containing wastes may actually be from processes unrelated to plating. Segregation of waste streams can reduce the amount of wastewater treated unnecessarily, and thereby reduce the volume of sludges produced. As an alternative to disposal, sludges and other metal-rich wastes may be transferred to other facilities that will use the wastes as they are, or reuse them after treatment, thereby reducing the waste stream by up to 100%.

Plating or rinse bathwaters are often disposed of on a routine schedule, that may exceed required frequency and thereby produce a greater volume of metal-containing wastewater and F006 sludges than necessary. Implementation of small scale bath testing would allow operators to determine when bathwaters have reached their safe loading capacity, and eliminate unnecessary discharges.

Circuit board manufacturers also produce large quantities of F003 and F006 wastes. F003 solvent wastes may be reduced through implementation of alternative degreasing

methods such as aqueous solutions coupled with ultrasonics, and process modifications to use "clean" fabrication techniques, thereby reducing or eliminating the use of degreasing solvents.

Metal-containing wastewaters generated during electroplating processes may be treated through ion-exchange or reverse osmosis units. These treatments purify the wastewater by absorbing the metal ions until the units are saturated. When the units are saturated with metal ions, they are regenerated by washing out the ions with a regenerating solution. The resulting metal-rich regenerating solution can then be reused as a plating solution. This process reduces the volume of metal-containing wastewater discharged to the wastewater treatment plant, and consequently the volume of metal-containing sludges produced. Depending on the specific industrial processes and materials used, this method can result in a 40 to 70% reduction of metal-containing sludges.

Contaminated wastewater is produced by most industries. Depending on the specific characteristics of the wastewater, contaminants may be removed for disposal or for reuse through distillation, evaporation/condensation, ion exchange, reverse osmosis, and hyperfiltration using membranes. These methods may remove varying amounts of the contaminants from the wastewater, producing clean water for reuse or discharge, and contaminant-rich solutions or sludges which may be reused or disposed of. The percentage waste reduction possible for these methods varies extensively from method to method.

Plant management practices can have significant impact on waste reduction. Such practices include employee training programs to ensure that personnel involved in operating equipment or handling wastes are capable of detecting chemical releases, safely handling hazardous materials, and understanding regulatory requirements. Management incentives can encourage innovative ideas from knowledgeable employees which result in improved waste reduction or recycling. Closer supervision and documentation of process procedures can prevent unnecessary spills, material losses and production of out-of specification products, and will help reduce waste generation during maintenance or emergency shutdowns. Production scheduling can increase the efficiency of raw material use and minimize equipment cleaning operations.

Substantial quantities of hazardous waste are generated through the overstocking of inventory. Automated inventory control has been proven to produce significant decreases in these wastes. In addition, using materials on a first-in/first-out basis minimizes waste composed of expired chemicals. Proper storage and handling of raw materials will minimize spills and leaks.

Storage tanks and process vessels must be regularly inspected for physical integrity, and overflow alarms and secondary containment measures installed, to reduce the potential for spills and leaks. Preventive maintenance of equipment, including cleaning, making minor adjustments, lubricating, testing, measuring, and replacing minor parts can substantially reduce the volume of waste generated from equipment failure or mechanical breakdown.

Many hazardous waste streams are actually composed of two or more waste streams. Waste stream segregation, including the separation of hazardous and nonhazardous materials, chlorinated and nonchlorinated solvents, and liquid and solid waste can reduce waste volumes, simplify disposal, and facilitate recovery and recycling.

Waste exchanges involve the transfer of a waste to another company for use as is, or for reuse after treatment. Metals and solvents are the wastes that are most frequently recycled through waste exchange, due to their high recovery value. Other wastes that may be recycled through waste exchanges include inorganic chemicals, organic chemicals, and metal sludges. Since the treatment of solvent wastes and metal-containing wastewaters and sludges places a significant demand on four of the five target waste management categories, waste exchanges may provide a feasible alternative to treatment in Puerto Rico.

Taking into account the waste minimization techniques proposed the potential percentage reductions of many of the waste streams produced by the seven target industries were estimated. Due to the extremely variable and complex nature of some of the processes and materials used by some of the industries it is not possible to estimate percentage reductions for all waste streams for all industries. The percentage reductions possible are listed in Table IV, for the wastes produced by each industry.

CONCLUSIONS

The Puerto Rico CAP predicted that there would be insufficient hazardous waste management capacity over the next 20 years in metals recovery, incineration, stabilization, landfilling, and other treatment (primarily wastewater treatment). Waste minimization has significant potential to reduce the predicted capacity shortfalls in PR. CDM Federal has determined that over 95% of the hazardous waste generated in Puerto Rico is produced by just twenty facilities in seven industries. Therefore, the implementation of aggressive waste minimization programs at these facilities could significantly reduce the capacity shortfalls predicted for Puerto Rico as a whole. Spent solvents, contaminated wastewater and metal-containing sludges are the primary wastes that should be targeted for minimization. Process-related minimization techniques include installation of recovery systems for solvents and metals from wastewater; sludge reduction through dewatering, and thermal desorption; and decreased use of sludge settling agents. Non process or industry specific minimization techniques include waste-stream segregation and better operating practices. Nearly all facilities can implement better operating procedures with little or no capital expenditure, to reduce unnecessary waste and to improve the efficiency and economy of the manufacturing processes.

LOW-LEVEL WASTE DISPOSAL FACILITY SAFETY ANALYSIS EXPERIENCE: ESTABLISHING RADIONUCLIDE INVENTORIES

C. C. Fields
Westinghouse Savannah River Company

ABSTRACT

This paper describes work performed to estimate radionuclide inventories (Material at Risk) for use in developing upgraded safety documentation for the Solid Waste Management Facility (SWMF) at the Department of Energy's Savannah River Site (SRS). The general approach was to: 1) identify the best available information for the current inventory of each subfacility (or the maximum credible inventory for process-type subfacilities, such as the compactor); 2) adjust the current inventory for uncertainty allowances, biases, and projections of future additions; and 3) convert the information to a form readily usable for safety assessments. Since waste disposal began over 40 years ago and the last extended period of high-power reactor operation was in 1988, radioactive decay is significant for several important nuclides (e.g., tritium, most fission products, and most neutron activation products). Much of the available data on material deposited in the SWMF pre-dates development of current nuclear industry quality assurance requirements. Since the inventory estimates were partly based on this early data, the final inventory values were qualified for use in safety assessments by an interdisciplinary team review process, conducted in accordance with SRS procedures (in addition to the normal detailed technical peer review).

INTRODUCTION

This paper describes work performed to estimate radionuclide inventories (Material at Risk) for use in developing upgraded safety documentation for the Solid Waste Management Facility (SWMF) at the Department of Energy's Savannah River Site (SRS). The SWMF includes disposal and storage facilities for low-level radioactive waste

generated at SRS and other government-owned locations. The SWMF is primarily composed of "burial grounds," where waste has been disposed of in trenches since 1953, concrete vaults, scheduled to be used for disposal starting in 1994, and above-ground paved "pads," where transuranic (TRU) waste is stored in containers awaiting future disposal at the Waste Isolation Pilot Plant (WIPP) in New Mexico. The SWMF also includes areas for above-ground storage of contaminated used equipment, a waste compactor, tanks for storage of slightly contaminated reprocessing solvents, a facility to certify waste prior to shipment to WIPP, and buildings for storage of containerized mixed and hazardous waste.

The SRS is an approximately circular region approximately 30 km (18 miles) in diameter and approximately 800 square kilometers (300 square miles) in area. Most of the areas (or "subfacilities") making up the SWMF are located near the center of the site.

DESCRIPTION

The objective of the work was to produce radionuclide inventories (including projections for future material) that are conservatively bounding for safety assessments (but not grossly overconservative so as to artificially cause predicted accident consequences to exceed acceptance limits) without excessive effort or cost. Projecting future inventories was crucial because the inventories of waste storage/disposal facilities tend to increase; several of the areas making up the SWMF have the physical capacity to operate for several more years or can be expanded.

Inventories were needed for several different types of safety assessments. Some types of assessments need total subfacility (or subfacility-segment) inventories. Others need the inventory in the containers that can be affected by a single postulated credible event. Several different types of inventories were developed for each subfacility to meet these needs. For example, the TRU inventories included evaluation-basis inventories for single containers of several different types.

The general approach was to: 1) identify the best available information for the current inventory of each subfacility (or the maximum credible inventory for process-type subfacilities, such as the compactor); 2) adjust the current inventory for uncertainty allowances, biases, and projections of future additions; and 3) convert the information to a form readily usable for safety assessments. For most of the subfacilities, this readily-usable form consisted of lists of the radioactivity (in curie units) for 27 key radionuclides, plus two pseudonuclides, "other beta-gamma emitters" and "other alpha emitters," to cover less important nuclides not on the standard list.

Difficulties encountered included dealing with: 1) the "expandable" nature of a waste storage/disposal facility; 2) the many different areas within the SWMF and the different types of waste in each area; 3) the number of waste streams coming to the facility (which may change as the SRS mission shifts to decontamination and decommissioning); 4) lack of detail in data in the existing computer-based inventory tracking system; and 5) the need to estimate inventories for material already in the facility that was assayed, packaged, and emplaced under procedures and standards that have evolved over a 40-year period (some older procedures allowed higher single-container inventories than are allowed today).

Since waste disposal began over 40 years ago and the last extended period of high-power reactor operation was in 1988, radioactive decay is significant for several important nuclides (e.g., tritium, most fission products, and most neutron activation products). The estimates of radionuclide inventories took credit for decay where data was readily available and the decay was expected to result in significant inventory reductions.

Available data for some material does not specify its precise isotopic makeup (some enriched uranium at SRS has relatively large amounts of U-234 and U-236) and, for short-half-life material, the isotopic mix changes while the waste is stored. The estimation techniques were conservatively based on assumed isotopic mixes that maximized the calculated radiation doses from postulated releases of the material. In some instances, the assumed isotopic fractions summed to more than 100%. For example, the (14.1-year half-life) Pu-241 content of plutonium was counted as both parent (beta-emitting) Pu-241 and as daughter (alpha-emitting) Am-241 to ensure calculated doses will be bounded for material of any age.

RESULTS

The results of this work, which consist of several multi-column (and in some cases,

multi-page) tables of nuclide activity values, were documented in an Engineering Calculation prepared in accordance with SRS procedures.
Much of the available data on material deposited in the SWMF pre-dates development of current nuclear industry quality assurance requirements. Since the inventory estimates were partly based on this early data, the final inventory values were qualified for use in safety assessments by an interdisciplinary team review process, conducted in accordance with SRS procedures (in addition to the normal detailed technical peer review).
Projected future inventories are very sensitive to initial assumptions, such as the scheduled operational status of certain subfacilities, continued use of current waste packaging procedures, and continuation of restrictions on bringing specific types of waste into certain areas. These assumptions were documented in detail in the Engineering Calculation so that, in the future, they can be linked to administrative controls to protect the safety basis.
ACKNOWLEDGMENT
The work described in this paper was prepared in conjunction with work done under Contract No. DE-AC09-89R18035 with the U. S. Department of Energy.

ABSTRACT
This paper describes an original approach to providing safe disposal of Remote Handled Low Level Waste (RH-LLW) that is required to meet the Performance Assessment (PA) objectives for the Radioactive Waste Management Complex (RWMC). The system known as the RH-LLW Concrete High Density Polyethylene Vault Liner System allows a cost effective means of complying with the U.S. Department of Energy (DOE) requirements. The design approach is modular in nature, allowing additional disposal capacity to be added on a demand basis, thereby eliminating significant upfront costs associated with large facilities built on estimated needs over many years. The concept and design approach reduces the financial and technical risks associated with large construction projects. Additionally, upgrades to future installations and modifications to new disposal liners put into service based on changing regulations and technologies are possible. The versatile design of the RH-LLW Liner System offers additional benefits including potential future retrieval, a minimum 100 year design life, and continuous below ground protection from ground water intrusion and direct contact with the surrounding environment.
BACKGROUND
The RH-LLW Lined Vault design was driven by the need for disposal of high curie concentrations of Tritium (H-3) generated at the Test Reactors Area (TRA) Advanced Test Reactor (ATR) and its subsequent effect on the PA objectives for disposal of specific isotopes at the Idaho National Engineering Laboratory (INEL) RWMC. Requirements for site specific PA objectives are promulgated by DOE-HQ Order 5820.2A, and the effect of radiation disposal on the environment for future generations. To meet the criteria of DOE-HQ Order 5820.2A, PA requirements, and the management of Low Level Radioactive Waste, Chapter III, a screening process is required for all isotopes planned for disposal. Due to the significant quantities of H-3, Co-60, and Ni-63 present in past and future TRA/ATR waste streams, a screening procedure was performed to validate the significant dose contributor for the ground water pathway. To complete this, the Source Term and Hydrologic Transport Models were used in the assessment. Based on the screening assessment, it

was determined that disposal of current inventories of H-3 would exceed the committed effective dose equivalents for the all pathways analysis of 25 mrem/y criteria for the time period considered in the RWMC PA. The U.S. Department of Energy, Idaho Operations Office (DOE-ID) requires strict compliance and conformance for the disposal of Low Level Waste (LLW), and that all waste (isotope specific) is properly characterized prior to disposal. Proper disposal at the RWMC requires every "new" waste stream be evaluated to the same rigorous administrative and technical process, not only for the absence of hazardous materials, but also to determine what effect the transport of radioisotopes have on the environment and the potential uptake for the inadvertent intruder after the institutional control period. Proper collection and disposal of all LLW at the INEL, requires the operating contractor to be in verbatim compliance with all appropriate DOE, Nuclear Regulatory Commission (NRC) regulations, the Environmental Protection Agency (EPA), and 10 CFR 61.55, Tables 1 and 2, Isotope Classification Criteria. The document, Joint NRC-EPA Guidance on a Conceptual Design Approach for Nuclear Facilities, describes an acceptable facility based upon a double liner and leachate collection system with a specific design life, based on hazards. It allows generators and treatment storage and disposal facilities to develop alternative designs based upon their specific needs. These alternative designs must meet the technical and regulatory criteria as set forth by federal and state agencies, and meet the PA objectives for that facility. The RWMC considers the PA to be a Safety Analysis Report (SAR) equivalent level document and that a defensible evaluation be a prerequisite to disposal. The challenges at the INEL were based on the limited area which is available for the disposal of high radiation, short lived low level radioactive wastes and the need for cost effective solutions. The lack of double leachate collection under the designed geographic area, adequate ground water monitoring wells, ground water sampling, and individual container degradations due to soil chemistry inspections placed a greater emphasis on efficiency and challenged conventional methods of disposal. The need for the waste to be remotely handled and protection to personnel and the environment added to the design challenge. The authors have developed a design approach based on meeting the site specific challenges.

DESIGN FEATURES OF THE RH-LLW CONCRETE LINED VAULT SYSTEM

A conceptual design is provided in Fig. 1 which shows a cutaway view of the single piece unit assembly. Figure 2 shows the modular assemblies nested in a plan view "honeycomb" with side view construction. Figure 3 shows the HDPE vault liner detail and sectional view, and Fig. 4 shows the HDPE vault liner lifting and squaring device.

DESCRIPTION

The design is based on primary containment via an inner, high density polyethylene cylindrical liner which will accommodate 55 gallon containers, inserts, or unpackaged waste. This inner liner is free standing and is contained by an outer concrete liner providing structural integrity, secondary containment, and additional leachate collection. The outer concrete liners are designed in a hexagonal pattern which allows a self locking configuration and modular design. Additional vaults can be added to the honeycomb design on an as needed basis, thus lowering construction and facility operating costs. Additional benefits gained by the unique design and self locking construction, are zero subsidence between vaults, no maintenance in the future, and it provides a minimum of wasted space between vaults. This provides maximum disposal potential at the RWMC, or any disposal facility that requires segregation of waste types or lacks the necessary soil depth space for subsurface disposal. The enhanced disposal concept allows close proximity of waste types without the problems associated with migration or high radiation.

DESIGN VERSATILITY/DESIGN SPECIFIC BENEFIT

Although the existing methodology is to install this system below grade at the RWMC, the versatility of the design would allow installation on or above existing grade, or any area where below ground installation or disposal is not an option or permitted, or is inadvisable due to ground water rock formations, existing waste, or where a potential for future monitoring may be required. The design also allows for retrieval when technologies become available for reprocessing or where separation and segregation is required in the future.

MODULAR CONCRETE VAULT DESIGN

The reinforced concrete vault consists of a reinforced base, center section, top flange, and reinforced shield plug (see Fig. 1). To best utilize the available

space at the RWMC and match existing disposal packages, it was determined the project would be best served by using standard, off the shelf pipe diameters which could be manufactured locally, without the need for special tooling. The construction and design choice consists of 20 foot 54 inch inside diameter right vertical cylinder constructed in a two piece design configuration. The lower, or base section, is designed with a hexagonal six sided design which will allow for proper indexing and grid layout at placement (see Fig. 2, "Plan View"). The final disposal package would reside in the high rad center and top section, which is constructed of a male straight wall to female pipe flange, with a female upper flange that nests the shield plug (see Fig. 2, "Side View". The base and center section assemblies are grouted together with an elastomeric sealing material that is specially designed to prevent the intrusion of ground water or runoff from entering the vault disposal cavity. Prior to mating the shield plug with the vault body, the annular spaces between the vault center sections are filled with fine granular sand to lock the vault bodies in place. This also provides additional shielding between the vault shields and completes the primary boundary and support structure for the shield plug and secondary High Density Polyethylene (HDPE) inner liner. The functional and operational requirements (F&OR) for the primary concrete vault system was originally determined to be 50 years (minimum). To meet the challenge and additional requirements for this project, evaluations were required by both engineering and computer modeling to further extend the design life from 50 to 100 years minimum.

HDPE INNER LINER DESIGN AND CONSTRUCTION

The HDPE inner liner is designed as a stand alone primary containment for the waste package. The HDPE liner is constructed in three pieces; vault body, bottom plate, and macro-encapsulation lid plate (see Fig. 3). The vault body is constructed as a single piece continuously formed straight wall pipe or tube 19 feet 4 inches long with a side wall thickness of 1.625 inch minimum. The bottom plate is 1.00 inch flat that is thermo-welded to the vault body prior to installation.

The lid plate is the same construction and size as the bottom, with one exception: The lid section is equipped with a dual nichrome flat ribbon wire that is extruded in high density polyethylene. The extruded ribbon is approximately .5 inches wide by .375 inches thick with the dual nichrome flat wire evenly spaced in the center of the ribbon. This concept is a "first" in sealing and closure technology for remote handled high rad waste. The ribbons are thermally welded to the lid plate prior to placement on the vault body. The dual ribbons are equipped with 12 to 16 foot pigtails that will allow space and distance shielding for the technician performing the vault lid installation and sealing operations. Due to the remote location of the technician, and no direct contact with the loaded vault, personnel exposures to direct ionizing radiation can and will be minimized to as low as reasonable achievable (ALARA) limits. The nichrome flat ribbons are activated by a specially designed encapsulation control unit. The encapsulation control unit energizes the ribbon, thus forming a remote heat activated seal with the lid and vault body. Again, the remote activation encapsulation seal can be accomplished with zero radiation exposure to workers and provides a solid encapsulation bond between the lid plate and vault body. The encapsulation seal eliminates the possibility of material "creep" that would be common to standard sealing technologies, i.e., threaded or mechanical sealed flanges with elastomeric or chemical grouts. If future entry into the loaded vault is required, the encapsulation seals can be re-energized and the lid plate can be removed. Due to the nature of the heat seal, this would potentially ruin the integrity of the sealing surfaces which would require a new lid plate and surface preparation on the vault body (upper sealing surface).

After activation of the encapsulation seal, the control unit is disconnected and the pigtails are dropped onto the upper vault lid with the lid rigging. The design of the HDPE and concrete vault interface provides an 8 inch annular space between the bottom of the shield plug and the top of the HDPE liner thereby eliminating contact of the shield plug with the vault liner and providing a secondary storage area for rigging and encapsulation control wiring.

Please Note: The lid is equipped with a dual wire system that provides a backup to the primary system if a failure or a short circuit in the primary system were to occur. Testing was performed on the single wire system without a failure, but due to the potential of re-entry exposure contamination, it was determined that a backup system would provide an additional level of protection and safety. Activation of

the backup system is not required, but will be performed to increase the lid to vault body sealing area.
To prevent the potential health hazard of direct high ionizing radiation out the top of the vault system, and to provide a safe working platform for operations personnel and technicians at the RWMC, the RH-concrete HDPE lined vault system has been designed with a reinforced concrete shield plug approximately four foot thick. The shield plug design employs the same hexagonal shape and interlocking capability as the concrete base. The plug design also incorporates recessed coil bolt lifting eyes that can be installed to remove the plug from an empty vault and removed. It can then be plugged to prevent damage to the lifting eyes and while providing a smooth working platform for equipment and personnel. Upon completion of the loading and HDPE sealing operation, the concrete shield plug would be replaced with the spaces between the vault plugs grouted to prevent rain and snow runoff from seeping between the shield plugs. A third level of protection might employ the use of non permeable HDPE flat liners over the top of the filled vaults with a soil berm and vegetation cover to complete the closure process. Due to the uncertainty of future programs and the specific curie contents from the different INEL facilities expected to use this disposal system, it was determined that the most versatile design would incorporate a plug design and shielding equivalent to provide for the worst case scenario.
CONCLUSION
The RH-LLW concrete disposal vault offers a variety of effective and efficient design alternatives that will allow the design to be tailored to a variety of situations, needs, or specific package sizes and types and will offer an innovative solution to the management and disposal of rad and low level mixed waste. In addition to this project, efforts are in place to fabricate a prototype package overpack design that will employ a similar closure device and macroencapsulation feature that meets the definition and intent of macroencapsulation for mixed wastes per EPA and greater confinement criteria per NRC and DOE requirements.
Upgrades to the basic vault design can be accomplished with little or no impact to the facility. In addition to isotopes and highly contaminated material, the advantages of secondary and tertiary containment allows a strong management methodology. This dispels the negative public perception that the DOE and its operating contractors have a radioactive nuclear waste management mentality of "business as usual" mode and of not being proactive in their approach to the long term future management of highly radioactive wastes and the safety to the public and the environment. It is the commitment and policy of the DOE and LITCO to provide a level of confidence to the public and its shareholders that confirms our shared concern over the nuclear and waste management issues facing the United States today.
Alternative Study
Attachment 1
Cost Analysis: In determining the most cost effective alternatives, a comparison study was conducted between the following:
No Action
Upgrading the existing facility
Installing the RH-LLW Concrete High Density Polyethylene Vault Liner System.
Study on 1:
No Action.
This would allow the facility to remain "as is" with no change or upgrades.
Conclusion
DOE-ID and LITCO found the no action alternative to be inconsistent with the national policy and commitment on the environment, future public exposure, and INEL workers health and safety. Container degradation due to soil chemistry, leaks, and spread of radioactive contamination would not be known until the level of contamination spread was far beyond effective remediation. Radio isotopic spread to the Snake River Aquifer would pose and unacceptable risk to the stakeholder down gradient of the INEL. The cost of non-conformance, at a minimum, would close the RWMC due to violation of the RWMC PA, not to mention the multiple per-violation fines from State and Federal regulators. The cost of the no action alternative would far exceed the cost of alternatives 2 or 3.
Advantages: None
Disadvantages: Many
Cost of Non-conformance: Unknown at this time

Study on 2:
Upgrading the existing facility.
This would require installation of a complete monitoring well system down gradient from the proposed disposal location. To meet existing regulatory requirements, a new facility would also be required to develop a ground water sampling and analysis plan with clean-up contingency plans, and installation of a double lined leachate collection system under the disposal area.
Conclusion
DOE-ID and LITCO would have to relocate the existing facility to a new location due to the subterranean nature of disposal. Determining "need" for a new facility would require detailed solid waste projections, isotopic characterization, and long term planning. Additional costs include preparing an environmental assessment (EA), and an environmental impact statement (EIS). Costs to construct a new disposal facility, less the EA and EIS, would exceed approximately $100 million. This is a low estimate considering the changes in regulatory requirements and locating the facility potentially off the Snake River Plain Aquifer which might not be possible at the INEL. In addition, the above costs do not address waste or environmental inspections or the appropriate National Environmental Policy Act (NEPA) documentation required for a new facility. These costs would be highly speculative and would far exceed the cost of construction.
Advantages: A new facility would meet current EPA, State and Federal regulations for disposal of CH and RH waste. The facility disposal capability could be expanded if adequate leachate collection was provided in the upfront planning.
Disadvantages: Unknown costs of permitting, future regulations, and "need" present an unacceptable risk to the INEL.
Total Cost: Specifically unknown, estimated in excess of $100 million.
Study on 3:
Installing the RH-LL Concrete Vault HDPE Liner System.
This would require minor modification to the existing facility, the addition of underground power lines or remote electrical generating capability, remanufacture or retrofitting cask bearing and pads, and the purchase of slip-in liners with remote encapsulation seal control units.
Conclusion
The RWMC found Alternative 3 to provide the most benefits of the alternatives examined. Minor modification to an existing facility precludes the need for additional evaluation to the NEPA requirements and eliminate the need for the EA and EIS permitting process. Associated facility modifications and transport cask discharge systems upgrades are as follows:
Manufacture of concrete vault and HDPE vault liners
Remanufacture cask discharge systems shield plates
Design internal loading channel for cask to vault interface
Design and procurement of special manufacturing and handling equipment to build and install HDPE vault liner system
Develop Detailed Operating Procedures (DOPs) for vault loading and closure process
Purchase H-3 monitoring instrumentation and equipment trailer.
COST BREAKDOWN AND SETUP COSTS FOR SIXTEEN
HDPE VAULT LINER UNITS:
HDPE vault body blank 19 feet 4 inches long x 52.5 inches
in diameter. Unit cost 6.5K each x 16 units needed. 104.0K
HDPE lid and bottom blank 1 inch x 52.5 inch diameter.
Unit cost (set) 1.2K per vault x 16 sets needed.
19.2K
HDPE encapsulation control unit. Single time purchase.
Unit cost 8.5K x 2 units (primary and backup) needed. 17.0K
Inset seal groove cutter with centering device (single time purchase) 9.5K
HDPE vault liner welding fixture for bottom plate installation (single time purchase).
6.5K
HDPE vault liner squaring fixture to maintain vault body roundness
during welding operations (single time purchase). 3.5K
HDPE lid blank inset seal groove lid preparation with encapsulation
seal installation. 1.4K each x 16 units needed.
22.4K

HDPE bottom plate installation with spark integrity test.
Per unit cost 1.4K x 16 units needed. 22.4K
HDPE vault liner installation in RH-LLW concrete vaults. 40.0K
Per unit cost 2.5K x 16 unit installations. TOTAL 244.5K
Minus single time purchases and set up costs.
-36.5K
208.0K

NOTE: The RWMC currently has 100 each RH-LLW concrete vaults installed with outyear projections of 400 total vaults identified (1998 projections). The costs associated with design, procurement and installation are approximately 20.0K per unit, or 100 units installed is equal to 2.0M total. We feel the per unit costs will be significantly reduced on outyear procurements due to the elimination of the upfront design and analysis costs associated with the start up of this project.

ADVANTAGES

Meets all existing disposal and packaging regulations without building a new facility. Provides container corrosion protection, remote, modular design, multiple boundary protection, and meets the DOE/LITCO ALARA goal of no exposure to personnel. Additional vaults may be added to the system as the need arises.

DISADVANTAGES

Only one prototype has been purchased for the RWMC. This will only provide disposal for four TRA/ATR inserts of RH-Low Level canal waste. Additional vaults can be added but would require the validation process be successfully completed. Manufacturing and setup costs are extremely high for single unit purchases.

ABSTRACT

SOURCETERM is a comprehensive computer program that combines an interactive low-level radioactive waste (LLRW) database with waste accumulation and radioactive decay algorithms, enabling planners to forecast the quantities and characteristics of LLRW requiring management and disposal. The tabular results from SOURCETERM are direct inputs to disposal facility siting, design, and long term Performance Assessment efforts. Although a variety of independent software programs have been available in the past to manage source term data, project waste generation, and evaluate radioactive decay, SOURCETERM is unique in its combination of these functions into a single comprehensive planning tool.

SOURCETERM provides LLRW planners with the following database management and modeling capabilities:

Managing the LLRW source term database, including the characteristics, generation rates, and accumulation of LLRW expected during the operational life of a LLRW disposal facility. Specific functions include browsing, adding, editing, deleting, sorting, and displaying the data. SOURCETERM currently allows the user to manage the following waste characteristics for each waste stream in the database: waste stream, waste class, generator, total volume (m3 or ft3), total activity (Ci), radionuclide inventory, solidification agent (if applicable), physical/chemical characteristics, container type, container volume (m3 or ft3), container weight (kg or lb), container on-contact radiation levels, number of containers, waste volume (m3 or ft3), waste weight (kg or lb), waste density (kg/m3 or lb/ft3), packaging efficiency, annual generation rate, and applicable deposition years.

Modeling the accumulation of waste in a disposal facility according to user-defined scenarios. A waste generation scenario includes selected waste streams (characterized in the database), generation rates, starting points, and ending points over time. The model incorporates both accumulation functions and the effects

of radionuclide decay on the radionuclide inventory (and in-growth of daughter products) over any user-specified period of time.

Producing a range of user-selected reports that include 1) listings of the source term input database, including waste characteristics and generation rates, 2) volume and activity projections for any user-specified period of time, 3) radionuclide inventories for any user-specified period of time, and 4) cross-tabulations of waste characteristics with waste quantities, including both volumes and radionuclide activities.

SourceTerm was developed specifically for the Microsoft Windows operating system using the C++ programming language. All data and modeling results can be viewed on-screen, and the information can be exported in tabular form to other programs, such as spreadsheets, databases, and word processors.

INTRODUCTION

SOURCETERM is a comprehensive computer program that combines an interactive low-level radioactive waste (LLRW) database with waste accumulation and radioactive decay algorithms, enabling planners to forecast the quantities and characteristics of LLRW requiring management and disposal. The tabular results from SOURCETERM are direct inputs to disposal facility siting, design, and long term Performance Assessment efforts. This paper presents an overview of the software, it's capabilities, and sample results for a typical LLRW disposal facility.

DATABASE MANAGEMENT

There are two databases used by SOURCETERM to model a LLRW disposal facility: a database of waste stream characterizations and a database of radionuclide decay information (half-lives, daughter products, etc.). The database management functions used to enter and maintain both of these databases are typical and cover both working with files and the individual records that they contain. Although the native, binary file formats used by the program are unique to SOURCETERM, the data can be imported from and exported to dBase compatible files.

The primary data entity for SOURCETERM is the waste stream. A waste stream characterization includes both qualitative and quantitative information and is stored in a single file. This characterization includes a waste category, an identification of the generator of the waste, the waste class (A, B, or C), the annual volume and activity generated, a range of applicable years, multipliers for minimum, expected, and maximum cases, and a breakdown of activity by radionuclide. Also, there can be multiple container types for each waste stream. These containers are characterized by the container type (B-25 box, 55-gallon drum, etc.), volume, weight, packaging efficiency, number of containers generated, and the physical/chemical properties of the contents of the container. For each container type (and for each waste stream), there can be multiple on-contact radiation levels, expressed as a fraction of the containers at some radiation level.

WASTE ACCUMULATION ALGORITHM

The waste accumulation algorithm is relatively simple: it implements behavior much like that of an interest bearing savings account. Waste is deposited at regular intervals (one year, end of period) and radionuclide decay is calculated on the remaining balance. The complexity of the waste accumulation function lies in managing the waste quantities (total volume, total activity, and activity by radionuclide) for each of the waste characteristics of interest (waste class, waste category, waste generator, waste stream, and radiation levels by waste class and container type).

The user creates a waste accumulation "scenario" by specifying a scenario title, a beginning year, and an ending year. When the scenario is generated, the accumulation function models the total waste inventory in the disposal facility over the range of years specified in the scenario. For each year in the scenario, the existing radionuclide inventory is decayed for one year, and then the entire database of waste stream characterizations is scanned to identify those waste streams that apply to that year. The contents of each applicable waste stream is added to the accumulating inventory. With respect to radionuclide decay, the waste is placed in the disposal facility at the end of the year, so that there is no decay calculated for the waste stream on the year that it is deposited.

For each scenario, the following information is accumulated:

The user-specified title of the scenario (e.g. "60-Year Scenario"),

the user-specified beginning year (e.g. "1995"), the user-specified ending year (e.g. "2054"),

the total volume of waste accumulated for each case, where a "case" is defined as the minimum, expected, and maximum amount anticipated,
the total decayed activity accumulated for each case,
a list of decayed activity totals by radionuclide for each case,
a list of undecayed activity totals by radionuclide for each case,
a list of waste quantities by waste class (e.g. Class A, B, or C) for each case, where a waste quantity
includes total volume, total decayed activity, and
a list of decayed activity totals by radionuclide,
a list of waste quantities by waste category (e.g. boiling water reactor, etc.) for each case, a list of waste quantities by waste generator (e.g. utility, medical institution, etc.) for each case
a list of waste quantities by waste stream (e.g. resins, irradiated reactor components, etc.) for each case,
a list of annual inventory totals (total volume, total decayed activity, and decayed activity by radionuclide) for each case, and
a list of radiation levels (waste volume at that level) by waste class and container type for each case.

A similar waste accumulation function can be utilized for a single waste stream. In this case, the total volume, total decayed activity, and total decayed activity by radionuclide for each case (minimum, expected, maximum) is accumulated over a specified range of years for the selected waste stream. This function can be used to assess the incremental impact of a single waste stream over the life of the disposal facility.

RADIONUCLIDE DECAY ALGORITHM

The radionuclide decay algorithm is necessarily complex, given the nature of radioactive decay. A common occurrence in radioactive decay is a parent radionuclide decaying to a daughter that is also radioactive. Also, it is not uncommon for a parent radionuclide to have two possible daughter products, each of which may themselves be radioactive. Consequently, it is possible to set up a radioactive decay chain where each node can have zero, one, or two daughter nodes, depending on the characteristics of the radionuclides involved.

The source of these radionuclide decay characteristics is a database of radionuclides, their half-lives, daughter products, and branching probabilities. This information is in the public domain and is available from a number of sources. One prominent source is the RADIOACTIVE DECAY DATA TABLES by David C. Kocher, DOE/TIC-11026, available through NTIS. The radionuclide decay database distributed with SOURCETERM (the file "nuclide. dk") is the same as that used to generate Kocher's decay data tables, published in 1981.

A generalized form of the radioactive decay equation is required to calculate the activity remaining after an elapsed time for the parent radionuclide and any daughter products. Although the Bateman equation is a generalized decay equation commonly used for straight decay chains, it does not incorporate the effects of multiple daughter products from a single parent radionuclide. It was therefore necessary to derive a similar equation that would account for multiple branching daughter products. The resulting generalized radioactive decay equation used in SOURCETERM is:

Equation A

As an example, for the third radionuclide in a branching decay chain (the parent is the first radionuclide) the above expression evaluates to:

Equation B

This decay algorithm is used heavily by the waste accumulation functions to determine the impact of radionuclide decay on the accumulating inventory. It is not uncommon for a typical 60-year scenario to require millions of decay calculations. Consequently, for waste accumulation purposes, an activity of less than one pico-curie is considered to be zero. This greatly reduces the number of radionuclide decay calculations required (almost a 50% reduction) and improves the processing performance without affecting the numerical significance of the radionuclide inventories.

A single radionuclide can be decayed by selecting a radionuclide from the decay database and specifying an initial activity and elapsed time. The default values are one curie and one half-life. This function can be used both for validating and verifying the operation of the decay algorithm and as a general radionuclide decay

calculator.

MODELING RESULTS

SOURCETERM enables planners to forecast the quantities and characteristics of LLRW requiring management and disposal. The modeling results include:

an annual waste inventory comprised of total volume, total activity, and activity by radionuclide for each of the minimum, expected, and maximum cases;

a total waste inventory by waste characteristic (class, category, generator, and stream);

a total radionuclide inventory, including a comparison of the decayed activity with an undecayed activity for each radionuclide to show the effect of incorporating radioactive decay into the model; and

the volume of waste within a specified surface radiation level range for each waste class and each container type in the disposal facility.

These results are direct inputs to disposal facility siring, design, and long term Performance Assessment efforts. They can be exported in tabular form for use in other programs, such as spreadsheets, databases, and word processors. Results can be saved on disk in either ASCII text or dBase file formats, and they can be copied and pasted into other Windows applications through the Windows Clipboard.

A few results for a typical 60-year scenario are presented in the following figures. The impact of radioactive decay on the accumulating inventory is apparent in Fig. 1, which illustrates the total activity over time. Prominent events are identified in the scenario, such as when nuclear power plants begin decommissioning. Figure 2 shows a breakdown of the prominent radionuclides at the point of closure of the facility. Figure 3 shows a distribution of the accumulated inventory at closure by waste class, both on a volume basis and an activity basis. As expected, the Class C waste contains the most radioactivity in the smallest volume. Figure 4 shows the distribution of waste, both on a volume basis and an activity basis, at closure by waste category. The general categories used include non-utility waste streams, utility routine waste streams, and utility decommissioning waste streams.

ABSTRACT

The Multimedia Environmental Pollutant Assessment System (MEPAS) is a computer program which evaluates exposure pathways for chemical and radioactive releases according to their potential human health impacts. MEPAS simulates the exposure pathways through standard source-to-receptor transport principles using a multimedia approach (air, groundwater, overland flow, soil, surface water) in conjunction with specific chemical exposure considerations. This model was originally developed by Pacific Northwest Laboratory (PNL) to prioritize environmental concerns at potentially contaminated U.S. Department of Energy (DOE) sites. Currently MEPAS is being used to evaluate a range of environmental problems which are not restricted to DOE sites. A partnership was developed between PNL and Mesa State College during 1991. This partnership involves the use of undergraduate students, faculty, and PNL personnel to complete enhancements to MEPAS. This has led to major refinements to

the original MEPAS shell for DOE in a very cost-effective manner. PNL was awarded a 1993 Federal Laboratory Consortium Award and Mesa State College was awarded an Environmental Restoration and Waste Management Distinguished Faculty Award from DOE in 1993 as a result of this collaboration. The college has benefited through the use of MEPAS within laboratories and through the applied experience gained by the students. Development of this partnership will be presented with the goal of allowing other DOE facilities to replicate this program. It is specifically recommended that DOE establish funded programs which support this type of a relationship on an on-going basis. Additionally, specific enhancements to MEPAS will be presented through computer display of the program.

INTRODUCTION

Multimedia Pollutant Assessment System Computer Program

The Multimedia Environmental Pollutant Assessment System (MEPAS) is a human health risk computational model (Multimedia in this context refers to multiple environmental transport and exposure media.) (1,2) MEPAS takes the nontraditional approach of integrating all major exposure pathways into a single public health computational tool. MEPAS employs an integrated, physics-based approach that couples source, contaminant release, migration and fate for environmental media (groundwater, surface water, air), with exposure routes (inhalation, ingestion, dermal contact, external dose) and risk/health consequences for radiological and non-radiological carcinogens and non-carcinogens (Fig. 1).

Throughout MEPAS' development and subsequent application, PNL has subjected the methodology to thorough external evaluation. Extensive review by the scientific community has fostered and confirmed the validity and usability of MEPAS. (3) Some of the evaluations and applications of MEPAS are:

Table I

MEPAS' versatility and sound technical basis make it applicable for a wide variety of risk estimation applications, which has resulted in its extensive use by PNL, DOE, universities, state governments and private firms for a variety of risk estimation problems.

Mesa State College

Mesa State College (MSC), located within the western slope of Colorado, provides liberal arts and sciences undergraduate education to approximately 4500 students annually. An Associate of Applied Science degree entitled Environmental Restoration Engineering Technology (ERET) was implemented the fall of 1990. This program was intended to address the immediate need of creating technologists who could efficiently resolve the complicated environmental problems which our industrialized nation has created. The ERET degree was initiated by strong interest from the Grand Junction Projects Department of Energy (GJPO DOE) Office and its prime contractor, RUST Geotech.

It was recognized during the development and implementation of the A.A.S. degree that there was an equally critical need for a baccalaureate degree in this general area of study. A Bachelor of Science degree in Environmental Restoration and Waste Management (ERWM) was initiated for the 1993-94 academic year. The ERWM program is an interdisciplinary based degree which fosters an understanding of natural science, mathematics, and communication skills coupled with environmental courses which integrate the support courses in an applied manner. The enrollments within the two degrees were approximately 130 students the fall of 1994.

This relationship with the GJPO DOE office facilitated establishment of several other industry and governmental partnerships. The result has been a quality educational program which is responsive to work-force needs.

EDUCATIONAL PARTNERSHIP ADDRESSES SPECIFIC DOE NEEDS

PNL/MSC Addressing Cooperative Objectives

MEPAS 1.0 was created to estimate risk at DOE site to enable DOE to prioritize the cleanup problems. The tool's most important feature is that it was to apply to many installations and many different sites. The approach chosen by the MEPAS team was unique in the sense that they started with the data that was commonly available at the installation and then created the models to use the data. To make the models general enough for wide spread use semi-analytical approaches were chosen over finite element, this is because the data required for a finite element model is very site specific. The structure of the package was designed (Fig. 1) and experts in specific fields were used to write the actual models.

The MEPAS 2.3 user interface was written to ease the burden of entering data into

text files that are read by the MEPAS models directly. (12) MEPAS 2.3 UI was written in Clipper for dBase III. This interface did ease the burden of data entry but had many drawbacks. Specifically the interface was limited to the MS-DOS operating system and the database structure was spread across many files making sharing of MEPAS data and input difficult if not impossible.

In 1990 MSC began working on enhancements of environmental software to be used for educational purposes on equipment donated from NCR/AT&T. Coincidently Dr. Karl Topper, an environmental professor at MSC, had worked with Dr. Gene Whelan during their doctorate studies. Dr. Whelan was one of the primary developers of the RAPS/MEPAS methodology. This relationship led to an agreement whereby students at MSC would work on programming enhancements of MEPAS and use of MEPAS for educational purposes while PNL would have the rights to the newly developed software. Initially the college funded several students to begin this work. However, this arrangement was unsatisfactory due to limited funds. PNL arranged for summer appointments through the DOE Student Research Associate Program administered by the Northwest College and University Association for Science (NORCUS: This program is now administered by the Associated Western Universities (AWU)). Further funding augmentation was obtained through a DOE Environmental Restoration and Waste Management Distinguished Faculty Award presented to Dr. Topper in 1993. Unfortunately, this two-year award was shortened to one year due to elimination of this valuable program by DOE.

Specific MEPAS Enhancements

Since the MEPAS models were developed as stand-alone models not all of the MEPAS package needed to be modified, only the user interface. During the summer of 1992 PNL assigned five MSC students to tackle the task of the MEPAS UI conversion. At the beginning of the appointment, the students spent a week with the staff at PNL designing a new MEPAS user interface. The remainder of the work was completed at MSC under the direction of Dr. Topper and in coordination with PNL personnel. The new interface used pull-down menus and dialog box methods which reflected commonly available computer software. In addition the design optimized the data handling so that all of the user input would be in one file, making it trivial to share data with other MEPAS users. The new and improved MEPAS UI made converting the units of input values easier for the software developers as well. The new MEPAS package was completed during the summer and was named MEPAS 3.0.

In 1993 Oak Ridge used MEPAS 3.0 to do a risk analysis of the Savannah River Site and validated the usefulness of this undergraduate student product. As a result of this collaboration PNL received a more user-friendly (Fig. 2), more flexible software package and decided to employ one of the students as a staff member. For this joint effort, the MEPAS team received a Federal Laboratory Consortium award for Technology Transfer in 1993.

The new data handling for MEPAS 3.0 made many new products possible. One task that is often difficult for environmental models is a sensitivity or uncertainty analysis of the models. (13) Both require the user to change multiple parameters many times to see the effect of the input changes. The sensitivity analyses allows the modeler to evaluate the degree of accuracy required within the input parameters. MEPAS 3.0's new data handling facilitated development of the sensitivity/uncertainty analysis routine because all that need be modified is the one input file generated by the new MEPAS 3.0.

Four MSC students were selected to start work on developing a MEPAS sensitivity shell during the summer of 1993. The result of this work has been a stand-alone package that can do sensitivity/ uncertainty analysis on the MEPAS models as well as on other models which conform to the data format that MEPAS 3.0 uses. This package used some of the same parts as the MEPAS 3.0 interface so that a user feels like they are running one application.

The MEPAS Sensitivity/Uncertainty Analysis Module is now maintained by PNL staff with the aid of the original MSC developers. It has been used to compute the uncertainty in the Hanford Remedial Action Environmental Impact Statement as well as a poster session on ecological risk estimates, which used a model other than the MEPAS models.

Computational models often produce and analyze large amounts of numerical data which makes it difficult to visualize. This problem, along with the need to produce useful results to decision makers, has now focused the attention of the MSC and PNL partnership on the process of producing report ready charts and tables from MEPAS

3.0 results. This task required the designers to understand MEPAS and be able to work with the same tools that have been used in the past. Once again this task of design and implementation of a Graphics Display user interface for MEPAS was passed to MSC.

During the spring of 1994 three MSC students began working on the Graphics Display for MEPAS. This is the most ambitious task that has been taken on by MSC because it requires the students to develop parts of a much larger application. The MEPAS Graphics Display is not entirely completed yet but significant accomplishments have been realized. MEPAS is no longer a single program of models, it is a collection of tools that allow the user to do a thorough job of estimating risk for contaminants from waste sites. MEPAS allows the user to calculate, graph and assigned a probability distribution to all parts of the calculation (Fig. 3). The majority of the tools in the toolbox have been produced by the MSC and PNL partnership in a very cost-effective manner.

LESSONS LEARNED AND PROJECT BENEFITS

This relationship between PNL and MSC has resulted in a truly symbiotic partnership in which each organization has realized significant benefits. We hope that other DOE facilities and contractors will seek similar partnerships. There are many reasons why there may be some initial reluctance to initiate such activities, but the benefits have far outweighed any inconveniences. The following highlight a few of these benefits:

Efficient, effective development of enhancements to MEPAS which has resulted in greatly improved usability and flexibility.

Using the undergraduate students with faculty and PNL supervision has allowed development and implementation of ideas which might never otherwise be accomplished because of the enthusiastic expertise the students bring to the project along with the extremely low cost of this approach.

Enhancement of the technology transfer mission of DOE through MEPAS improvements and educational use.

Enhancement of the undergraduate student experience through working on a "real" project.

National recognition for the on-going benefits of this project.

This project has also had some constraints which had to be addressed. However, each one of these constraints were readily overcome with sufficient attention. The first touchy issue was protection of rights to the software developed within the project. Yes, the lawyers on both sides had to become involved to help produce a legally acceptable document. The next major issue has been project funding. This has been addressed through the use of student research appointments within the AWU infrastructure and by the DOE research faculty award. Using this approach requires careful attention to deadlines in terms of submitted paperwork. Given that the AWU funding only addresses direct student wages, other means of funding must be sought for this to be a sustainable project. We have signed an MOU which administratively supports the idea that MSC and PNL may seek joint proposals to help seek such augmentation funds in a more stable manner. This is an area which we will be actively seeking as the efficiency of this program is unmatched within the DOE system.

Another point in terms of "lessons learned" is that there needs to be a strong commitment and responsive communication between the partners. We have used a combination of computer communi cations (Internet) to send computer files/messages and telephone conferences for group discussions. However, there is a need to directly fund the supervising staff so that they have the dedicated time to be responsive as needs arise. This leads back to the previously discussed need for on-going funding which is dedicated to this type of program. Thus, it is our recommendation that DOE and its contractors re-evaluate some of their funding priorities to include development of similar partnerships. There needs to be competitive programs which specifically target undergraduate colleges to develop similar projects. The costs are extremely insignificant relative to the benefits.

ESTABLISHMENT OF THE ENVIRONMENTAL APPROVAL COUNCIL AT THE WIPP IN AN EFFORT TO MAXIMIZE WASTE MINIMIZATION
Karen M. Cargnel
Cindi C. Wright
Westinghouse Electric Company
Waste Isolation Pilot Plant
P.O. Box 2078, MS-170
Carlsbad, NM 88220
ABSTRACT
The Waste Isolation Pilot Plant (WIPP) is a research and development facility located in Southeastern New Mexico, designed to demonstrate the safe disposal of defense-related transuranic (TRU) waste in bedded salt 655 meters (2,150 feet) underground. Even though the main purpose of the WIPP is to act as a disposal facility, there are still hazardous wastes being generated on site. To keep site generated waste at an absolute minimum, the Westinghouse Waste Isolation Division (WID) established the Environmental Approval Council.
The Environmental Approval Council at the WIPP is comprised of individuals having knowledge of the different types of waste generated on site and the various regulations. Examples of the areas represented on the board include Resource Conservation and Recovery Act, transportation, waste minimization, operations,

safety, fire protection and property management. The intent of the council is to have all applicable organizations present that can identify alternative methods to decrease waste generation.
The board reviews all site documents that are associated with waste generation activities. When a waste generating activity is identified, a Waste Stream Approval Form is initiated. The board meets twice a week to review waste streams and determine the ultimate fate of the waste. The packaging, characterization, substitutions, recycling possibilities, and the disposal facility are determined before the waste generating activity begins. Also, the Waste Stream Approval Form will be used as a record to document every waste stream on site.
This process enables the WIPP to reduce waste generation, increase recycling activities, and maintain control over waste streams at the site. Due to the establishment of the Environmental Approval Council and its processes, the decrease in cost associated with waste disposal is significant.
This paper describes the benefits of a waste management system and the process for establishing such a system. It highlights the cost avoidances that can occur and the increased site control over generated waste.

INTRODUCTION

The Department of Energy (DOE) Waste Isolation Pilot Plant is a mined geologic repository, located in Southeastern New Mexico, designed to demonstrate the safe disposal of defense related transuranic (TRU) waste in bedded salt 2,150 feet underground.
Even though the disposal stage has not started yet, there is still hazardous waste being generated on site. The Environmental Approval Council (EAC) was established to address the need of documenting and managing the waste streams on site. This need was met by incorporating the EAC approval into the review process already in place. Through this incorporation, the EAC approval only extended the original process; therefore, an additional burden was not put on the customer. Improving customer satisfaction and soliciting pertinent information for managing waste streams were the drivers for establishing the council.
The council met some resistance in the beginning stages but gained support based on the idea that it would not only facilitate the approval process but also eliminate the confusion over the required sign-offs. The need to eliminate this confusion was accomplished even though the underlying focus continued to be awareness and control over waste generation. In the end, this approval process has proven to be a useful tool in documenting waste streams and maximizing waste minimization.

BACKGROUND

The need for more control over waste-generating activities arose when the hazardous waste being shipped for disposal was examined. It was apparent that the organizations on site generating the waste were not conscious of the process of waste disposal and associated costs. A system of examining waste before generation was needed.
Every activity that was performed on site, whether it was routine maintenance or a major construction project, was approved by definite areas of expertise within the Environment, Safety, Health and Regulatory Compliance (ESH&RC) Department. It was often difficult for customers of ESH&RC to obtain all required signatures in one trip to the department. In addition to this problem, the ESH&RC representatives approving each process were not sharing information with each other, creating the duplication of effort in some instances. Also, minor projects were required to obtain the same levels of approval as large projects, therefore, creating long turnaround time. This system obviously needed to be refined.
The EAC was established to meet the needs of the customer and incorporate the needs of the department. This council meets twice a week to review all work being done on site to approve and document the waste streams being generated. This allows the waste generation information to be collected early in the process, therefore, giving more time to characterize, sample, or identify recycling/reuse opportunities. The establishment of the EAC provided a focal point for other departments needing waste stream approval and allowed the council members to meet and discuss the various issues of each activity. This eliminated the duplication of effort by the individuals approving each process.

PROCESS

The Environmental Approval Council is managed by the Council Facilitator (CF) and the Deputy Facilitator (DF). Each project that is to begin on site is routed through

the CF, usually in the form of Engineering Change Orders (ECOs) or Plant Work Requests (PWRs). At this time, the CF initiates the Waste Stream Approval Form. This form documents the different areas that will be affected and the waste streams that will be generated. The CF logs the project onto the tracking database and completes as much of the Waste Stream Approval Form as possible. At this time, each project is rated according to size and importance and is split into one of the following categories: 1 - minor, every day activity; 2 - emergency situation; 3 - large, substantial activity.

For minor activities (1), the waste stream is documented and the Waste Stream Approval Form is routed to obtain the correct signature approval in a timely manner. Each activity is documented so that if the same project is encountered again, it will have instant approval because of the record of approval from the prior activity.

Emergency situations (2) are similar to minor activities. Since there is not enough time to hold up the approval process for concurrence at the bi-weekly meeting, the activity is documented and approval is obtained quickly. These projects are still reviewed for waste characterization and waste minimization opportunities, but source reduction cannot be evaluated because of the quick turnaround required.

Large, substantial projects (3) are logged into the database and the Waste Stream Approval Form is started. These forms are collected by the DF and summarized in a listing that is distributed the day before each of the bi-weekly meetings. This allows the council members adequate time to review the upcoming projects prior to the actual meeting to examine past problems or new methods to reduce the amount of waste generated. If the council member(s) does not have any problems with the project, an approval can be granted prior to the meeting thereby eliminating the need for that council member to attend.

The EAC meetings are held on Wednesday and Friday mornings. At the EAC meeting the proposed project is presented and discussed. If there are any concerns from the involved parties, they are discussed in the meeting. The person cognizant of the waste generation activity is in attendance to answer any questions that arise. If there are changes to the process that are decided in the EAC meeting, they will be documented. The EAC has the authority to block an activity until the process has been approved by the council. The approval signatures are documented, and the work order is released at that time. The maximum turnaround time for large, substantial projects is 2 1/2 working days.

BENEFITS

The establishment of the EAC at the WIPP has given the ESH&RC Department better control over waste streams. The EAC allows better management of waste being generated on site by reviewing processes prior to generation to incorporate source reduction techniques. It also allows advance notice to effectively characterize, sample, or recycle/reuse the waste streams generated. By documenting the activities in a database, the ESH&RC Department has up-to-date information to facilitate the process for preparing various environmental reports that must be submitted regarding waste generation amounts.

Another benefit from the EAC is being able to provide the site with a more thorough and timely ESH&RC review. The EAC has also increased awareness of the role of ESH&RC and of waste disposal at WIPP.

CONCLUSION

By incorporating the needs of the department and our customers, the EAC has brought about the necessary control on waste streams, while enhancing the departmental review process that was previously in place. The marriage between the need of the customer and the need of the department eased the incorporation of the waste stream approval process. This program has proven to be a creative and effective tool in managing the waste streams at the WIPP site.

7-31

WASTE MANAGEMENT AUTHORITY AND THE WASTE STREAM APPROVAL PROCESS

Kent L. Miller
Lockheed Idaho Technologies Company

ABSTRACT

Early in the spring of 1993 a program was developed at the Idaho National Engineering Laboratory to promote excellence in the area of waste management. The intent of the program was to formalize the idea of prohibiting waste generation

without sufficient preplanning and approval. In support of this program, a Waste Management Authority (WMA) was initiated at the DOE's Idaho Chemical Processing Plant (ICPP). Development of the WMA has provided an effective method of implementing waste management technologies and techniques to improve waste management operations.

The WMA is comprised of technical representatives from various organizations and disciplines at the ICPP. Together as a team, the WMA has a wide variety of responsibilities in the area of waste management, including minimizing waste, identifying new regulatory issues, ensuring that appropriate treatment technology development/requirements are addressed, reducing waste management cost through planning, communicating lessons learned, improved reporting accuracy, and enhancing communication between facility operations, waste management, and environmental personnel.

The purpose of the WMA is to review and approve/disapprove mixed, hazardous, radioactive, and liquid industrial waste streams prior to their generation. It's primary focus is to ensure that wastes are identified, treated, stored, and disposed in compliance with all applicable regulations. The program is also designed to ensure that waste streams are eliminated/minimized, or recycled/reused when possible.

Prior to waste generation, generators are required to complete a waste profile which identifies the waste generating activity; planned waste composition, pollution prevention/waste minimization activities, sample and analysis data, sampling requirements, and treatment, storage, and disposal options. This information is then submitted to the WMA and a interactive review meeting is conducted with the waste generators. This gives everyone involved an opportunity discuss any issues and resolve comments.

Once a waste stream is approved, the waste profile information is entered into a waste management database. Much of the data gathered is used to support various other reporting databases. Additionally , information in the database is used to evaluate any newly proposed waste streams. This enables the WMA to identify previously approved technologies and techniques, thus eliminating any redundancies in sampling, treatment, etc.

The WMA concept and the waste stream approval process can be used at any facility and was piloted at the ICPP with the intent of being used at other sites in the DOE complex.

BACKGROUND

Industry, in general terms, is a generator of numerous waste types which require proper handling and subsequent disposal. Wastes must be generated in many instances to carry out company objectives. Strategically linked to this waste generation process, however, are company waste minimization objectives, process efficiency goals, cost savings objectives, waste predictions/tracking, safety concerns, planning, compliance and reporting requirements for various environmental agencies. All facets of these activities require integration and coordination to successfully accomplish them while maintaining cost effective compliance.

Traditional environmental organizations at generator facilities manage waste handling, disposal and compliance. However, these organizations are not necessarily responsible for waste minimization or cost savings of process related functions. Although conceptually not a new or unique way to account for waste, environmental organizations can provide these and other beneficial functions through planning, forethought and a matrix to evaluate and maintain data. Such is the case with the WMA.

Lockheed Idaho Technologies Company (LITCO) recently refined the basic concepts behind such an organization and developed a multi-departmental Waste Management Authority (WMA). Development of the WMA formalized a long-standing policy of prohibiting waste generation without sufficient preplanning and approval. In support of this policy and to improve its effective implementation, the WMA program was developed with the vision of establishing a more comprehensive approach to waste management.

The WMA is based on benchmarked information from NASA and a number of Government Owned/Contractor Operated (GOCO) sites, with the underlying theory that anything that comes into an industrial site must be disposed of, or be discharged in one form or another as a product, solid or hazardous waste, or emission. In the case at the Idaho Chemical Processing Plant (ICPP) and other GOCOs, this also includes

radioactive and mixed waste. Therefore, the final form, regardless of its destiny, should be qualified and quantified to the extent possible during the planning stages to make certain that company objectives are met while ensuring compliance throughout the material life cycle. Of course this is not always possible, for example, in the case of remediation waste, but can be accommodated within any planning forum.

WMA IMPLEMENTATION

In the spring of 1993, work began on the pilot program that resulted in the development of a team of topical experts from throughout the ICPP entitled the Waste Management Authority. This multi-departmental team is comprised of technical experts representing research & development analytical chemistry environmental compliance, facility operations, and waste management organizations. The first six months of the program was devoted to the development of company procedures and forms and establishing a six month implementation schedule. Because of the number and complexity of specific waste streams at the ICPP, it was determined that a "phased in" approach would be necessary to start the review process. Initially, the WMA evaluated mixed waste followed by hazardous, radioactive, and liquid industrial waste streams that were currently being generated. Then they began looking at newly proposed waste streams prior to their generation. The complete process from the development of procedures to full implementation of the WMA took approximately twelve months. During that time, the WMA reviewed and approved 150 individual waste streams. Subsequently, annual reviews and approvals are performed for all of the waste streams.

WMA ELEMENTS

The overall philosophy of the WMA is that waste generators provide information about their waste stream prior to generation so that a critical review can be made as to the appropriateness of generating the waste. The primary function of the WMA is to ensure that these waste streams are controlled, minimized, and handled in compliance with applicable laws, rules and regulations. In order to accomplish this function a comprehensive review by the WMA is performed on various information provided by the generator. A waste profile of the generation process is submitted that includes the following fundamental elements: 1) Waste generating process description, 2) waste minimization activity or pollution prevention opportunity assessment, 3) hazardous materials used in the process, 4) physical and chemical characteristics, 5) anticipated volume, 6) hazardous and/or radioactive characteristics, 7) waste characterization information including analytical data or process knowledge, 8) waste disposal destination, 9) waste handling and packaging information, and 10) applicable treatment capability. By providing detailed information in the planning stages of a waste generation activity, the WMA is able to assess all of the options available and make recommendations that LITCO's environmental objectives are met.

LESSONS LEARNED

Since implementation of the WMA, communication between generators and the environmental/ waste management infrastructure has improved significantly. The information required for various reports, i.e. Idaho Hazardous Waste Quarterly Report, Radioactive Waste Management Information System, Federal Facilitities Compliance Act, etc., has greatly improved because the identification and quantification of current and future waste streams is gathered and reviewed in a consistent manner. Operational safety has improved in the area of chemical compatibility of waste treated at the ICPP or sent off-site for treatment and disposal. Through the waste stream approval process new waste streams have been identified that require additional treatment technologies and these waste streams have been presented to management in a more timely manner as a result of the WMA. Enhancements to technology transfer for waste minimization,
process development, and various other critical aspects to waste management have all been centralized in a database for consistent reporting to EPA, State, DOE and other regulatory agencies that inspect the ICPP.

THE FUTURE

Goals of any environmental program such as the WMA follow the obvious; to track waste, maintain on-site compliance, ensure off-site approvals are in place for disposal, maintain accurate records for required reporting and many more regulatory aspects. But many of the varied waste streams that exist in the DOE complex make achieving these goals very difficult. In addition there is a growing trend at the state and federal levels toward increased regulations of solid and hazardous waste. As such, LITCO's pilot program, the WMA, has demonstrated that it is an excellent

vehicle for keeping up with the constant changes in world of waste management. By establishing the WMA, LITCO has developed a unique approach to managing waste that keeps pace with their vision of environmental leadership. The success of the WMA pilot program has led LITCO to expand the program to other facilities at the Idaho National Engineering Laboratory (INEL) under the direction of LITCO and to share the concept with other GOCOs within the DOE complex.

Argonne National Laboratory
Argonne, Illinois

ABSTRACT

A computational framework and integrated PC-based database have been developed by Argonne National Laboratory (ANL) to assess atmospheric releases from facility accidents in support of the U.S. Department of Energy Environmental Management Programmatic Environmental Impact Statement (EM PEIS). One objective of the EM PEIS project is to provide an automated capability for performing the large number of calculations required in the accident analysis. These calculations are required for evaluating the relative risk of the many combinations of process technologies, facility selections, and site consolidation strategies in the EM PEIS alternatives for each waste type.

The computational framework developed accesses several relational databases that contain information used to determine the risk-dominant accidents for each waste stream on the basis of throughput volume, radionuclide characteristics, treatment process, and other data needed to calculate releases. This paper describes the computer framework and supportive database used to conduct accident analyses and assess potential atmospheric releases that may affect on-site workers and off-site members of the public.

INTRODUCTION

A PC-based computer code was used to develop source terms for operational accidents and for externally initiated accidents such as airplane impacts or natural phenomena. Both radiological and chemical source terms can be evaluated; however, the following description pertains only to calculation of radiological source terms. A radiological source term is defined as the amount (in curies) of each radionuclide released during an accident, where release is assumed to be instantaneous. The code uses unit-risk factors, defined to be the consequence associated with a unit release of a radionuclide from a given facility and site, obtained from Oak Ridge National Laboratory (ORNL) to screen accident sequences for risk dominance. It allows risk-based comparisons of EM PEIS strategies for consolidating the retrieval, storage, and treatment of wastes at DOE sites throughout the country. The database incorporated into the code includes a radionuclide inventory, waste generation rate, physical and chemical characteristics of the waste streams, associated treatment process throughput, amount of waste at various components of the treatment facility that can be affected in an accident, accident frequencies, and other pertinent parameters needed to calculate chemical and radiological releases (1,2). This paper describes the computational framework and supportive database used to conduct accident analyses and assess potential atmospheric releases that may affect on-site workers and off-site members of the public.

METHODOLOGY AND COMPUTATIONAL IMPLEMENTATION

Methodology and Modules Description

This section describes the methodology and computational framework for the facility accident analysis for the EM PEIS. Figure 1 provides an overview of the accident analysis system and its interaction with other portions of the EM PEIS project. As shown in Fig. 1, the accident analysis system performs three major tasks: 1) prescreening for risk-dominant sites, facilities, and process options; 2) development and frequency estimation of accident sequences; and 3) development of

radiological source term information for accident sequences. Implementation of this analysis included selection and development of the risk-dominant accident sequences (determined by considering both the likelihood and severity of plausible accidents) and generation of the source term output.

The radiological source term associated with each accident is the product of five factors that vary for each radionuclide within the inventory affected by the accident.

Source Term = MAR DF ARF RF LPF (1)

where

MAR = material at risk,
DF = damage fraction,
ARF = airborne release fraction,
RF = respirable fraction, and
LPF = leak path factor.

MAR is the total inventory of waste in a facility with the potential of being impacted, and the DF is that portion of MAR involved in a particular accident sequence. MAR and DF are functions of the process, the facility, and the accident initiator. The variable ARF refers to the fraction of the potentially available radionuclide inventory rendered airborne as a result of the accident. ARF is a function of the original composition of the waste, the physical properties of the radionuclides, and the accident mechanisms. The respirable fraction of the airborne release is RF. The product of ARF and RF, referred to as the respirable airborne release fraction or RARF, therefore, represents that portion of the radionuclide inventory that is released and respirable. The leak path factor (LPF) is the fraction of the airborne inventory that passes through the containment barriers and filters to escape into the atmosphere. The LPF is a function of the physical form of the nuclide being released and the integrity of the containment systems. The source terms were then combined with site-specific unit-risk factors developed by ORNL and the frequency of occurrence estimates for the accident sequences to establish the reference risk-dominant accidents for more rigorous evaluation. Overall accident health effects will be calculated by ORNL.

Several integrated modules have been developed to determine the risk-dominant accidents for each waste stream on the basis of throughput volumes and radionuclide characteristics. Three classes of accidents are considered in the accident analysis for each waste type: 1) general handling accidents, 2) accidents at storage facilities, and 3) accidents involving treatment processes and facilities. The calculation of MAR depends on the class of accident; the MAR for a general handling accident is given by (assuming that the waste is contained in a 55-gal drum with a volume of 0.2 m3) the following equation:

MARgeneral handling = CONCi 0.2 (2)

where

CONCi = concentration of radionuclide "i" in treatment stream (Ci/m3).

The calculation for a treatment facility took the following form:

MARtreatment facility = TR CONCi TAO (3)

where

TR = treatment throughput rate (m3/yr), and
TAO = average residence time of MAR in treatment facility (yr).

The treatment throughput rate and radionuclide concentration were calculated by the WASTE_MGMT computational model (1) and are a function of DOE site, treatment technology, and alternative siting configuration. The values of TAO were developed as a function of treatment technology (where incineration is an example of a treatment technology) from available safety documentation. The calculation of MAR for a storage facility was estimated by the following equation:

MARstorage facility = CONCi SC (4)

where

SC = generic storage facility size (m3), which was generally taken to be 2,000 m3 (equivalent to about 10,000 drums).

An event-tree approach was used to calculate the probability associated with particular accident initiators and event sequences for each site. Generic event trees were used for the analysis, although the model includes an option allowing the user to specify an alternative tree to reflect more precise site-specific data.

All the main components of the accident analysis methodology have been programmed into a menu-driven FoxPro 2.5 database system capable of processing any of five

waste streams (HLLW, TRUW, LLW, LLMW, and environmental restoration [ER]) under the various alternatives. The programming challenge was to develop a user-friendly, PC-based system capable of processing large amounts of data with the flexibility to accommodate various alternatives, waste streams, and site-specific information. To make the data more manageable, tasks were divided among several different modules. The accident analysis modules are as follows:

Event Tree develops accident tree and assigns probability to each event sequence.

Material at Risk calculates MAR from waste management output and is a function of waste stream, physical form, treatability category, radionuclide inventory, and treatment throughput.

Risk Calculation links MAR, damage rate, and accident probability information with atmospheric release and unit-risk factors to obtain consequences for screening risk-dominant accidents.

Risk-Dominant Sequences identifies the highest risk accident initiators and event sequence for each site.

Source Term Output automatically creates source term files for ORNL based on site risk-dominant sequences.

Figure 2 shows the databases and data flow for the accident analysis methodology. The output from the WASTE_MGMT computational model was used as the accident analysis input. To predict the volumes and radionuclide concentrations of the MAR for the various cases, a data preprocessing methodology was applied. The methodology outlined in the previous section is generally applicable to all radiologically contaminated waste streams analyzed within the EM PEIS: HLW, TRUW, LLW, and LLMW. The MAR is then linked with the appropriate unit-risk conversion factor, which is a function of site, radionuclide, and type of receptor.

A spectrum of accident scenarios that could occur during treatment, storage, or handling activities with the chosen waste stream were developed on the basis of the waste's physical characteristics and type of activity. The product of the MAR and the unit dose conversion factor was then combined with the ARF, RF, and LPF, which are a function of release class, accident category, and radionuclide. Preliminary health effects estimates of the accident consequence were derived by including the DF for the various accident sequences. The conditional probabilities of the individual accident sequences were combined with the initiator probability to become the annual sequence probability. The risk for each accident sequence and site was simply calculated from the consequence and annual sequence probability. Determination of the risk-dominant sequence resulted in the source term generation for the associated releases. These source terms were transmitted to ORNL for the final health effects calculations.

Input Files

The accident analysis model requires a number of databases to analyze a case: the MAR file, a file containing the accident initiator frequencies, an accident scenario file, and a series of databases containing information on radionuclide, release, and dispersion characteristics. Figure 3 shows abbreviated layouts of the various database files. The shaded areas in Fig. 3 indicate key fields that, when combined, would be unique to each record and are used to link or retrieve associated data in the other files.

Fig. 3

SAMPLE ACCIDENT ANALYSIS CALCULATION

To demonstrate the interaction of the modules, a sample calculation (Table I and Table II) is presented below along with a chart of the data flows (Fig. 2). The example shown involves a general handling accident involving one 55-gal drum containing ER-generated LLW. General handling accidents are expected to dominate the radiological and chemical risk to the work force because of the close proximity of the workers to any release. This class of accidents includes drops and spill of a container or punctures by a forklift. Tables I and II provide example output files generated for a LLW case that includes ER-generated waste. Table I is part of a data file that presents the calculation of the product of MAR, ARF, LPF, and the unit-risk conversion factor; estimation of the consequence would require the further multiplication of this product with the DF. Determination of the sequence probabilities for the different accident scenarios is shown in Table II as a function of waste- processing activity and accident release class. The risk for a given accident sequence is the product of the consequence and the annual sequence

probability.
FUTURE DEVELOPMENT
Although much has been accomplished in terms of automating the accident the analysis, additional work is ongoing in optimizing the computational routine and automating graphics capabilities to further facilitate the evaluation of waste management alternatives across waste streams.

7-35
DEVELOPMENT OF A DECISION SOFTWARE PROGRAM FOR RADIOLOGICAL EVALUATION DECISION INPUT (REDI)
T. Shane Bush
Agnes R. Gentillon
Lockheed Idaho Technologies Company
ABSTRACT
In December 1992, the Department of Energy (DOE) implemented the DOE Radiological Control Manual (1) (RCM). Westinghouse Idaho Nuclear Company, Inc. (WINCO) submitted an implementation plan showing how compliance with the manual would be achieved. This implementation plan was approved by DOE in November 1992. Although WINCO had already been working under a similar Westinghouse RCM, the DOE RCM (1) brought some new and challenging requirements. One such requirement was that of having procedure writers and job planners create the radiological input in work control procedures. Until this time, that information was being provided by radiological engineering or a radiation safety representative. As a result of this requirement, The Idaho National Engineering Laboratory developed the Radiological Evaluation Decision Input (REDI) program.
INTRODUCTION
During a March 1993 Defense Nuclear Facility Safety Board (DNFSB) visit to the Idaho Chemical Processing Plant (ICPP), WINCO was questioned about how the expertise of other Westinghouse organizations was being utilized in the development of programs required by the DOE RCM (1). Although some examples were given, WINCO felt that more involvement on a corporate-wide level could provide great savings throughout the Westinghouse organization. Soon after that visit, a corporate-wide committee was organized to develop a program for the development of Radiological Work Packages.
WesTIP Team
Because the DNFSB had questioned the use of Westinghouse expertise from other sites in RCM (1) implementation, WINCO officials began to review items which were to be implemented in the near future for the possibility of corporate involvement. The Radiological Work Package process was a very good possibility, and was eventually chosen for corporate committee review.
WINCO sponsored the committee known as the Westinghouse Technologies to Improve Processes (WesTIP) Combined Team Review. The goal of the committee was to reduce the costs and time associated with development of Radiological Work Packages while improving quality and consistency. WINCO, West Valley Nuclear Services (WVNS), Westinghouse Savannah River Company (WSRC), and Westinghouse Hanford Company (WHC) chose to participate in the project, and selected members with appropriate expertise for the team. This committee then met in Pittsburgh, Pennsylvania to begin learning the WesTIP Process and begin applying it to the creation of radiological work packages.
The first step in the WesTIP Process was to define the current process being used. To do this, the committee members outlined the process being used by their

individual facilities and then the processes were combined to get an overview of the basic process being used within the Westinghouse Complex. Problems associated with each step were discussed, and those which were deemed to be significant were then listed on the flow chart model of the process.

Once the overview was completed, each step in the process was reviewed to see how much time it took and how much it cost to complete. Costs for individual steps ranged from $25 to $1,625 and time spent ranged from 0.1 day to 5 days per step. Those steps which cost the most or took the most time were then highlighted on the flow chart and reviewed to see where reductions could be made.

Findings revealed that it was taking an average of 37 days and costing an average of $6,875 to complete one radiological work package. Using the WesTIP technique, the committee developed a plan which would allow a radiological work package to be completed in 7 days and cost $2,480. This established a time reduction of 30 days and a cost savings of $4,395 per work package (Fig. 1). Because of the number of work packages created in a year, the committee determined that significant yearly savings would be realized through the use of the program they proposed. A key point to implementation of the new program was the need for a risk-based decision tree process for creating and completing radiological work packages.

The committee discovered that gathering data from various resources was the largest consumer of both time and money. Much of the data gathered was standard information which was recreated every time a radiological work package was needed. This collection of information was spread over several different steps in the original process.

With the decision made that the goal of the group would be to reduce time and costs associated with gathering information and writing work packages, the work of improving the process could begin. Several changes to the process were proposed, including creating "points of contact" who would function as area experts and creating a decision tree program which would eliminate recreation of information for every work package.

The committee decided that approximately 80 percent of the information recreated every time a radiological work package was developed could be placed into a decision tree software, thus eliminating the need for recreation of that information. This information included Radiological Control Manual (1) requirements, Federal Regulations, common work standards and policies, and local procedural requirements.

Development of REDI

Once the WINCO representatives returned from Pittsburgh, they began to explore hardware/software resources and availability. They made the determination that DClass, a commercially available software, would be used to develop their decision tree. This determination was based upon applicability, adaptability, and cost. Because DClass was already being used by WINCO personnel who would be doing the programming, a significant cost savings was realized.

The first step in development of the REDI program was to produce a risk-based decision tree which could be input into DClass. To accomplish this, a number of radiological packages were reviewed to determine the questions that must be answered in order to create a valid work package. The answers to these questions were not the same in all cases, and were dependent upon the specifics of the work to be completed. With this in mind, multiple choices were designed to cover all probable answers to a question. These choices correspond with precise output devised to be used for final work package details.

Prior to the development of the REDI program, planners and procedure writers would normally solicit information from a number of resources. With the use of the REDI program, the information could be automatically compiled by simply answering area-specific questions. By answering such questions, the requirements could be narrowed for the specific job to be performed. The program was to be designed to automatically create radiological input containing the appropriate guidelines. This input would then be available for use in creating radiological work package portions of procedures.

The REDI program asks the user multiple choice questions. Based upon the answers to those questions, appropriate information is placed into a radiological input package (Fig. 2).

Features of REDI

One of the main features of the REDI program is the capability it offers for electronic review and approval of radiological work packages. REDI is installed on a

network with access by all individuals in the review and approval process. When the package is ready for review, it is electronically transferred. When the appropriate personnel have reviewed the package, they enter a password which allows the package to be sent back to the originator with comments or approval. If changes are made to the package, prior approvals are voided and the package is retransmitted for approvals. Any forms associated with the work evolution such as radiological work permits can also be attached and forwarded electronically.
The approved package is returned to the document originator who then places the package in the work control procedure for use in the field. The REDI cycle is not yet complete; however. Post-job critique information is
entered as "lessons learned" before the work package can be closed out and considered complete.
All packages are stored electronically. Each package has its own unique file name which allows retrieval for review or modification at any time. For future referencing, packages can be retrieved using the file name assigned to the package. The information contained in this package can be used for future work packages, either in its entirety or by removing pertinent sections. "Lessons learned" will be of great value when planning for future work. Users can refer to previously developed radiological work packages to retrieve pertinent information for the development of the current work package.
CONCLUSION
Development of REDI is an ongoing process. It is currently being used at WINCO, and will be released to other Westinghouse GOCOs when the initial testing phase is complete. It will be customized for each facility, and will likely be released for other DOE facilities shortly after delivery to Westinghouse.
Effective October 1, 1994, WINCO is no longer a contractor at the ICPP. Lockheed Idaho Technologies Company (LITCO) has assumed the contract for the entire Idaho National Engineering Laboratory (INEL), including the ICPP. All future development of the REDI program will be under the auspices of LITCO.

INCINERATION OF LOW LEVEL RADIOACTIVE VEGETATION FOR WASTE VOLUME REDUCTION
Narinder P. S. Malik
Gregory G. Rucker
Marshall G. Looper
Westinghouse Savannah River Company
P.O. Box 616
Aiken, SC 29802
ABSTRACT
The purpose behind DOE's changing mission at the Savannah River Site (SRS) includes increasing activities for Waste Management and Environmental Restoration. At SRS there are a number of Comprehensive Environmental Response, Compensation and Liability Act (CERCLA) locations that are contaminated with radioactive materials, support dense vegetation, and are targeted for remediation. Two such locations have been studied for non-time critical removal actions under the National Contingency Plan (NCP). Both of these sites support about 23 plant species. Surveys of the vegetation show that radiation emanates mainly from vines, shrubs, and trees and range from 20,000-200,000 disintegration / minute (d/m) beta gamma.
Planning for the removal and disposal of low-level radioactive vegetation was done with two principal goals: to process contaminated vegetation for optimum volume reduction and waste minimization; and for the protection of human health and environment. Four alternatives were identified as candidates for vegetation removal and disposal; chipping the vegetation and packing in carbon steel boxes (lined with synthetic commercial liners) and disposal at the Solid Waste Disposal Facility at SRS, composting the vegetation, burning the vegetation in the field, and incinerating the vegetation. One alternative, incineration, was considered a viable choice for waste volume reduction, safe handling, and the protection of the environment and human health. Advantages and disadvantages of all four alternatives have been evaluated.
For waste volume reduction and the ultimate disposal of radioactive vegetation, incineration is the preferred method. Advantages of incineration are that volume

reduction is achieved and low-level radioactive waste is stabilized. For incineration and final disposal, vegetation will be chipped and packed in cardboard boxes and discharged to the rotary kiln of the incinerator. The slow rotation and long resident time in the kiln will ensure complete combustion of the vegetative material. The ash from the incinerator will be solidified with cement and rendered immobile. Solidified ash will control the potential contaminant pathways for the protection of human health and environment.

INTRODUCTION

At the Savannah River Site (SRS) there are a number of sites that have been contaminated with radioactive materials. Two such sites have been placed in the Resource Conservation and Recovery Act (RCRA) Facility Investigations/CERCLA Remedial Investigations (RFI/RI) Program. These sites are to be closed. The first part of closure implementation is to remove radioactive vegetation from the project sites.

The objective of this study was to develop planning strategies for radioactive vegetation removal, environmentally safe disposal, and to achieve maximum waste volume reduction. Three alternatives for vegetation removal and four options for vegetation processing were considered during the study. For this study, an analysis was performed on the type and volume of vegetation to be removed, level of radioactivity present in the vegetation, and options for vegetation removal and disposal.

LEVEL OF RADIOACTIVITY IN VEGETATION

The Health Protection Department (HP) at SRS has been periodically recording the rates and concentration of radioactivity in vegetation since the 1970's.1 The range recorded by HP is contained in Table I. A probe survey conducted on vegetation showed that the radiation levels ranged from 20,000-40,000 d/m beta/gamma and came mainly from vines and shrubs. Radiological survey observations made of a sweet gum tree showed a radiation level of 200,000 d/m beta/gamma, the trunk of a tree showed a radiation level of 40-60 mR/hr at 5 cm above the ground. The tree under observation was about 12-13 cm in diameter, and broken limbs from the tree showed a radiation level of 5 mR/hr.

TYPE OF VEGETATION

Both project sites support dense vegetation. About 23 types of trees, shrubs, and grasses were observed growing within the boundaries of the project sites.2 Trees are of mixed heights and girth; many appear to have reached a height of about 12 m with a breast-height diameter of about 30-36 cm. Additionally, there are a number of young trees that have attained breast height The majority of shrubs are in the range of about 1-2 m in height.

VOLUME OF VEGETATION

The volume of fresh vegetation to be removed is presented in Table II. This table shows that the estimated vegetation to be ranges from 375-495 m3.2

VEGETATION REMOVAL ACTIONS

According to the Federal Facility Agreement (FFA)3, the two project sites under study must be assessed and remediated. Removal alternatives for these sites should be consistent with nine CERCLA remedial evaluation criteria.4 Closure options for these sites are to be environmentally sound. To establish a range of potential consequences and funding requirements for the chosen removal alternative of these two sites, the following three alternatives were examined for vegetation removal:

- no action (no removal of vegetation)
- cutting of vegetation and no removal
- cutting of all vegetation and removal

Alternative 1 - No Action

For this alternative, the vegetation at the project sites would not be cut or removed. The vegetation would continue to grow and multiply, and presumably continue to absorb radionuclides from the soil. Radioactive substances would continue to migrate along contaminant pathways to potential receptors. The potential impact to human health and the environment would continue unabated with the possible exposure of wildlife and the surrounding ecosystem from contaminated vegetation.

Exposure of radioactive vegetation to the public's health could occur as a result of transportation via several pathways. The potential contaminant pathways of concern are atmospheric, groundwater, surface water, and fugitive dry vegetative material. The potential contaminant exposure routes are ingestion, inhalation, and dermal contact. As a result of this alternative, the contaminant pathways and exposure

routes would remain active and continue to cause adverse impacts on the environment.
Alternative 2 - Cutting of Vegetation and No Removal
This alternative involves cutting down the vegetation and leaving it on the ground. As a result, there will be no removal of the contaminated vegetation. This action will continue to impact the human health, the environment, and wildlife. Long-term remedial actions (close the site and construct a cap system) could be hindered because of interference from the large volume of dead vegetation lying on the ground. Contaminant pathways will remain active and unobstructed and that would cause the possible migration of radioactive substances off the site.
Dead vegetation lying at the ground, within the project boundaries, would biodegrade. As a result, biodegraded vegetation would reintroduce the radionuclides to the environment, either through wind erosion of vegetative materials or with surface water run-off (until the site is closed and a cover system installed). This could have a significant detrimental impact on the ecology of water bodies located in the near vicinity of the project sites.
The integrity and performance of the closure cap/cover system installed without removing vegetation could suffer adversely. Over a period of time, unremoved vegetation would undergo volume reduction due to biodegradation and could cause a serious threat to the performance of the cover system including localized subsidence, settlements, or complete failure of the cover system. Failure of the closure cover system would eventually reintroduce contamination to the environment.
Alternative 3 - Cutting of All Vegetation and Removal
This alternative processes the vegetation and removes it entirely from the project sites. This alternative will reduce and limit the likelihood of human and wildlife exposure to radioactive substances, as the contaminated medium would be physically removed, and alter and control the potential contaminated pathways. Removing the vegetation should also make the implementation of long-term remedial actions, cap construction, feasible.
PLANNING FOR VEGETATION REMOVAL, WASTE REDUCTION, AND DISPOSAL
The design analysis required consideration of each of the following removal and vegetation processing management practices; burying the removed vegetation at the Solid Waste Disposal Facility, open burning of vegetation, composting of vegetative mass, and incineration of vegetation.
Handling of Removed Radioactive Vegetation
Large trees, shrubs, small saplings, and other ground cover removed with the aid of mechanical equipment must be chipped and placed in 0.54 m cubed (21 inches cubed) cardboard boxes for incineration, and/or lined carbon steel boxes (2.8 m3 volume [96 cu ft.]), for storage at the Solid Waste Disposal Facility. This practice will ensure safe storage and efficient handling of removed radioactive vegetation until its final destination for disposal is established.
Vegetation Processing for Waste Reduction and Disposal
The following four options were considered for processing radioactive contaminated vegetation for final disposal:
Disposal at the Solid Waste Disposal Facility: Remove all chipped vegetation from the project sites in lined- carbon steel boxes (approximately 130170 boxes) and transport them to the Solid Waste Disposal Facility at SRS. The disadvantage of this option is that considerable space will be required at the Solid Waste Disposal Facility for the storage of about 130170 boxes. Additionally, the vegetative mass over the period of time will decompose and reduce in volume, thus creating additional void space in boxes.
Composting the Vegetation: Composting the vegetation from the project sites could be done under controlled conditions. However, the composted vegetation would not be suitable for soil amelioration as it will still be contaminated with radioactive substances, and subsequently contribute contamination to the environment. Therefore, composting at SRS is not recommended because of its foreseeable detrimental impacts to the environment.
Open Burning of the Vegetation: Burning of radiological contaminated vegetation is unacceptable due to the high potential for an uncontrolled release of radioactive substances to the environment. Because of environmental consequences, this option for vegetation processing is not recommended.
Incineration of Vegetation: Based on a cost analysis, it is still to be decided whether incineration of vegetation is done either at a commercially licensed incinerator or at the Consolidated Incineration Facility (CIF) at SRS. The CIF,

located at SRS, is currently under construction with operations scheduled in February 1996. The facility is designed to treat mixed wastes containing both hazardous and radioactive contaminants. The actual waste streams designated for treatment using CIF are currently being evaluated under the National Environmental Policy Act (NEPA).5 If the CIF is selected as the acceptable option for treatment of non-hazardous, low-level combustible waste, then the CIF can be used to treat radioactive vegetation. The advantages of incineration are a substantial reduction of vegetation volume, and better control of contaminant pathways leading to the environment.

Incineration Process: The chipped vegetation from the project area will be packed in 0.54 m cubed (21 inches cubed) disposal cardboard boxes. These boxes are discharged into the rotary kiln incinerator by a ram-feeder assembly. The kiln operating temperature ranges from 760-870oC. The slow rotation of the kiln promotes thorough combustion of the waste material. Ash drops from the discharge end of the kiln into a water-filled ash collection tank. This ash is scooped from the collection tank by a backhoe and dumped into a 55 gallons (208 l) drum until it is partially filled. Cement is then added and mixed with the ash to form a stabilized waste matrix to meet RCRA's Land Disposal Restriction (LDR) treatment standards.6 Solidified ash drums (cured drums) are placed in onsite-concrete vaults for final disposal.

CONCLUSION

Three vegetation removal alternatives for these project sites were analyzed. The only feasible alternative for vegetation management was to remove all the vegetative growth from the project sites. The benefits of this alternative are that the contaminant pathways will be controlled and threats to human health and environment would be significantly reduced. Additionally, the implementation of this alternative will create conditions that are conducive to long-term integrity of the closure cap system as part of the final remedial action.

Four options for vegetation disposal processing from these two project sites were considered. Two options, open burning and composing were not recommended because they can pose serious risks to human health and the environment, and these two options will continue to contribute to the contaminant pathways. Analysis performed for volume reduction and controlling the contaminant pathways indicate that incineration of radioactive vegetation would be the best management option for waste volume reduction and safety of the public and environment. This option would control the potential contaminant pathways and protect human health and the environment. Additionally the final disposal of solidified ashes will require less space for burial as compared to disposal of chipped vegetation at the Solid Waste Disposal Facility. However, if the incinerator is not permitted to burn radioactive vegetation, then the second best option for vegetation disposal would be to place chipped vegetation in carbon-steel boxes and bury them at the Solid Waste Disposal Facility at SRS.

ACKNOWLEDGMENT

The authors wish to express their gratitude to Bob Harley and Dan Dixon of U.S. Forest Services, at SRS for their valuable contribution in assessing the volume of the vegetation at the project site.

ABSTRACT
A magnetic swing adsorption (MSA) process is proposed, which utilizes a column of magnetic adsorbent surrounded by a magnetic field to effect separation of certain metal species from solution. In this process, an electromagnet is simply energized for adsorption and shut-off for elution. During the adsorption mode, an effluent stream is produced that is depleted of certain metal species, whereas during the elution mode, an effluent stream is produced that is enriched in these same metal species. Both the magnetic field strength and relative flow rates during adsorption and elution control the degree of enrichment of the metal species. Magnetic adsorbents in various physical forms can be used in this MSA process for the removal of a variety of metal ions from waste water. A synergistic effect between a magnetic adsorbent material and an external magnetic field is thought to be responsible for the enhanced removal of metals from waste water. Results presented for the removal of plutonium and americium using a magnetic resin clearly demonstrate this synergy. These results also point the way for the development of a variety of new external field-enhanced separation processes.
INTRODUCTION
Adsorption swing processes have utilized a variety of physical properties, such as pressure, temperature, concentration, and electric potential to effect separation between various species in fluid streams. Pressure and temperature, as swing variables, have received the most attention in recent scientific literature; and both pressure swing adsorption (PSA) and thermal swing adsorption (TSA) have been commercialized to perform a variety of gas separations and purifications (1-3). Moreover, hybrid processes utilizing, e.g., both pressure and temperature (4) or concentration and temperature (5), are also being developed, as are processes utilizing potential swing adsorption (6,7). However, to our knowledge, the coupling of magnetic properties with adsorption properties has not been utilized to effect separation. To fill this gap we propose a magnetic swing adsorption (MSA) process. The closest technology to MSA of which we are aware is based on suspending adsorbent particles in a magnetically stabilized fluidized bed (8-10). This fixed-bed configuration has allowed for the development of a two-dimensional, cross flow chromatograph (8); the focusing of biochemicals under an imposed pH gradient (9); and easy processing of viscous and particulate containing feeds (10). However, none of these studies have considered exploiting the effects of the magnetic field on the adsorptive properties of the adsorbent. This paper presents a demonstration of MSA, using a magnetic adsorbent material in a fixed-bed (column) mode surrounded by an electromagnet, for the removal of certain metal ions from waste water. Experimental results are presented for the removal of actinides (plutonium and americium) from waste water using this resin and MSA. Also demonstrated is a synergistic effect between the magnetic resin and the external magnetic field, manifested as a significantly enhanced adsorption capacity. Further, a comparison between conventional ferrite-based processes (where no magnetic field is applied) and this ferrite-based MSA process is also presented, along with a description of a conceptual MSA process. Overall, the results presented in this paper illustrate the potential of MSA processes, and they point the way for the development of a variety of new, field-enhanced separation processes.
BACKGROUND
Magnetic Separation Processes
Magnetic separation and high gradient magnetic separation (HGMS) processes are used extensively in the processing of minerals (11,12), and more recently for water treatment and environmental remediation (13-15). We would like to emphasize, however, that this new MSA process differs significantly from these common magnetic

separation and HGMS processes. Conventional processes use, for example, a fine stainless steel wool to form a magnetic matrix within a flow field of a solution containing mineral particles to be separated. Ferromagnetic or paramagnetic particles in this solution move in the direction of an increasing magnetic gradient, and are attracted to and stick to this energized stainless steel mesh. Diamagnetic materials, on the other hand, move in the direction of a decreasing magnetic gradient, and are essentially repelled from the mesh. This phenomenon has resulted in the development and commercialization of numerous magnetic separation and HGMS processes, which have the ability to remove particles from solution. Therefore, in order for these processes to remove soluble metal species from solution, they must utilize precipitating or flocculating agents to first effect formation of the particles. In contrast, our MSA process has the ability to remove soluble metal species directly from solution as well as colloidal and particulate matter.

Our MSA process is unique because the highly porous adsorbent material not only acts as a magnetic matrix, but also contributes an adsorptive component to the system. We believe that this adsorptive component allows for the removal of soluble metal species from solution, and that the coupling between the magnetic field and the magnetic adsorbent material accounts for the enhanced adsorption capacity observed in our experiments (see below). As a result, precipitating or flocculating agents are not needed in MSA processes. This allows for the direct treatment of a variety of aqueous streams containing soluble metal species, and for the subsequent recovery of the soluble metal species from a concentrated eluent solution. Moreover, because of the highly porous nature of some magnetic adsorbent materials, high magnetic field strengths may not be necessary to significantly enhance the adsorption capacity of a magnetic adsorbent material, as demonstrated below.

Magnetic Adsorbent Materials

Recently there has been increasing interest in developing new magnetic adsorbent materials (10,16). This interest stems from their use in magnetically stabilized fluidized beds (8-10), or in their recovery from a batch adsorption process (10,16). In both situations, however, the adsorption component was not coupled with the magnetic component. This is also true of traditional magnetic materials, which have been used simply as adsorbents to separate a wide range of substances, such as dissolved metal species, particulate matter, and organic and biological materials; however, they have been used almost exclusively for treating metal-laden waste waters (17-20). For the most part, these magnetic materials have utilized the well-known adsorptive properties of iron-based materials for various metal species. For example, ferrites, even in the absence of an external magnetic field, make excellent adsorbents for the separation of hazardous metals (cadmium, lead, mercury, etc.) and actinide elements (americium, plutonium and uranium) from waste water (17-21).

Ferrites are a class of mixed valence iron oxide compounds having the crystal structure of spinal, $MgAl_2O_4$. Iron atoms in iron ferrite ($FeOFe_2O_3$), or magnetite, can be replaced by many other metal ions without seriously altering the spinal structure. They are also ferromagnetic crystalline materials which are soluble only in strong acid. Ferrites can be applied to the treatment of waste water in various physical forms. Natural magnetite needs activation to have the same capacity as freshly prepared ferrite. Kochen and Navratil (22) have found that magnetite ore can be effectively activated to increase the surface area and adsorptive characteristics of the material; they have also discovered a synergistic effect in using supported ferrites, in a fixed-bed (column) mode with an external magnetic field, for removal and subsequent concentration of plutonium and americium from waste water.

EXPERIMENTAL

Resin Preparation

MPE resin beads were synthesized with activated ferrite particles attached to the outer bead surfaces (23,24). This was performed using a two-step procedure and reagent-grade materials (22). MPE resin synthesized according to this procedure contained 28 wt. % magnetite (i.e., 280 mg of magnetite per gram of dry resin). In the supported resin form, the magnetite freely adsorbed actinide ions of interest, while the interstices between the beads promoted good flow-through properties in the fixed-bed mode. Note that non-magnetic, polyamine-epichlorohydrin resin (PE) was also synthesized following this same procedure. However, in this case, magnetite was not used in the resin synthesis. This report contains results based on both types of resins, MPE and PE.

Column Preparation and Operation

The upper portion of a glass, chromatographic column (19 mm id. x 25 cm) was packed with a small plug of glass wool and a 10 cm plug of No. 431 stainless steel wool and placed (with the bottom portion of the stainless steel wool) between the pole faces of an electromagnet. The bottom and top of the column were fitted with a stop-cock and rubber stopper with exit tube, respectively. Tygon tubing was attached to both ends of the column.

Next, the MPE resin was activated and pumped (up-flow at 10 mL/min via a peristaltic pump) into the glass column while a field strength of 0.5 Tesla (5000 Gauss) was applied to the electromagnet; the resin was retained in the column by the stainless steel and glass wool plugs. The column was then ready for use.

For a typical experiment with simulated waste water (de-ionized water spiked with americium and/or plutonium ions, and prepared fresh before each experiment), the magnet was energized, which created a magnetic field strength of approximately 0.3 Tesla (3000 Gauss). The solution containing the actinide ions was then pumped through the column (up-flow at a specified flow rate, see below), and the effluent was radiometrically monitored by alpha (Pu) and gamma (Am) counting effluent fractions (22); the results were plotted as a function of time (plotted in this work as the volume of effluent that was passed through the column) until the actinide ions began to break through the column. For an experiment to demonstrate MSA, while passing solution containing plutonium ions through the column, the electromagnet was energized for a short period of time (to allow a few liters of effluent to emerge from the column) and then de-energized for a short period of time (again, to allow a few liters of effluent to emerge from the column). Further experimental details are described elsewhere (22), and the results of these experiments are given below.

RESULTS AND DISCUSSION

Breakthrough Experiments with MPE and PE Resin

Twenty grams of MPE resin (particle size range of 0.063 to 0.125 mm) were evaluated for actinide removal from water at pH 12.0 (column mode). The breakthrough curves for plutonium and americium are shown in Fig. 1. A total of 341 L of actinide solution (1.28x10-4 g/L plutonium-239 and 3.57x10-7 g/L americium-241) were processed through the MPE resin bed (up-flow) at 3.5 mL/min/cm2. The results showed that 325 L of actinide solution were lowered to 2.77x10-8 g/L plutonium and 7.17x10-10 g/L americium before the plutonium activity in the effluent started to increase. This translates to 4.16x10-2 grams of plutonium and 1.16x10-4 grams of americium that were sorbed from 325 L of water. Thus, 8550 L of actinide contaminated water could be treated with one liter of MPE resin.

For comparative purposes, the PE resin (no magnetite) was also evaluated for actinide removal from water at pH 12.0 (column mode). Breakthrough curves for both the PE and MPE resins are shown in Fig. 2. Note that the PE and MPE columns were prepared and operated in an identical fashion. Three liters of actinide solution (9.42x10-5 g/L plutonium) were pumped (up-flow) through 20 grams of the resin (particle size range of 0.063 to 0.125 mm) at 3.5 mL/min/cm2. The results showed that 2.75 L of actinide solution were lowered to 5.16x10-8 g/L plutonium before the activity in the column effluent started to increase. Although the minimum concentration observed for plutonium was comparable to the MPE resin, breakthrough occurred two orders of magnitude sooner. This represents treating only 72 L of contaminated water with one liter of PE resin, a significantly reduced capacity compared to the MPE resin. These results showed that the non-magnetic PE resin and the stainless steel wool contributed very little to the significant adsorption capacity exhibited by the MPE resin. The results also allude to the synergistic effect that apparently occurs between a magnetic field and a porous, magnetic adsorbent material.

A comparison can also be made with conventional, non-magnetic batch processes. Traditionally, ferrites have been used effectively for actinide removal, but usually in a batch mode in the absence of a magnetic field. For example, two grams of magnetite (when used in a batch operation with no magnetic field) are required to treat one liter of waste water and lower the plutonium concentration from 10-4 to 10-8 g/L (20). Scaling these results to our current work indicated that 650 grams of magnetite would be required to lower plutonium from 10-4 to 10-8 g/L in 325 L of water. However, in a magnetic field, only 20 grams of the MPE resin (containing 28 wt. % magnetite) were required to achieve similar results. Clearly, water decontamination can be improved significantly using magnetic adsorbents in the

presence of a magnetic field, as compared with traditional batch decontamination methods employing ordinary ferrites with no external magnetic field. This marked improvement is also illustrated below with the demonstration of the proposed MSA process.

Effect of Magnetic Field

To show the effect of the magnetic field on plutonium removal using the MPE resin, the electromagnet was energized for a short period of time and then de-energized for a short period of time, while passing a few liters of plutonium solution through the column. The conditions for this experiment were similar to those used previously with the MPE resin. Samples of the column effluent were also filtered through Whatman No. 41 (20 to 25 m) filter paper and analyzed to check the complete removal of the resin particles. The effluent profile is displayed in Fig. 3. Clearly, the external magnetic field, coupled with the magnetic MPE resin, resulted in an apparent synergistic effect that was responsible for high efficiency removal of actinide ions from waste water. While the magnet was energized, the plutonium concentration in the effluent decreased rapidly by two and one half orders of magnitude during the time 3.5 L of solution were passed through the column. When the magnetic field was turned off, the plutonium concentration began to increase rapidly during the time 1.5 L of solution were passed through the column, generating a nearly symmetric profile about the time when the field was turned off. In fact, the desorption kinetics appeared to be faster than the adsorption kinetics, possibly indicating the enrichment effect even at identical feed and elution flow rates and in the same flow direction (see below). Overall, this experiment demonstrated the cyclic, reversible nature of magnetic field-enhanced adsorption processes, and the possibility of achieving fairly rapid adsorption and desorption kinetics (mass transfer) with MSA processes.

In qualitative terms and based on simple magnetic (25) and adsorption (26) theory, we suggest an explanation of the apparent synergistic effect between a magnetic field and a magnetic adsorbent material, manifested as a marked increase in adsorption capacity for certain paramagnetic metal ions. The magnetic susceptibility of a paramagnetic substance generally decreases with increasing temperature. Furthermore, at room temperature, the atoms of most substances are in a state of thermal agitation. This thermal agitation, in the form of random fluctuations in the atoms, opposes alignment of the atomic moments in a magnetic field. This is, in fact, why most paramagnetic substances are influenced only weakly by a magnetic field. However, when an atom, e.g., a paramagnetic metal ion in solution, approaches a solid surface and becomes adsorbed (temporarily or not), energy is released (adsorption is a spontaneous, exothermic process). Some of this energy should be manifested as a reduction in the thermal agitation of the adsorbed species. Further a decrease in thermal agitation due to adsorption should have an effect that is similar to a decrease in temperature. As a result, the magnetic susceptibility of a substance should increase in the presence of a magnetic field and a magnetic adsorbent material, giving rise to a synergistic effect on the adsorption capacity. If this is indeed the case, it can be anticipated that the effect of the magnetic field would be greater for more strongly adsorbed substances. Experimental and theoretical research is ongoing to find quantitative evidence to support this supposition.

Magnetic Swing Adsorption (MSA) Process

A conceptual, two-bed MSA process, designed to continuously remove and recover metals from solution, is illustrated in Fig. 4. This figure shows the magnetic field and associated column step sequences, and the bed loading profiles during adsorption and elution. It is worth noting that there are many similarities between a MSA process designed for the simultaneous removal and recovery of metals from solution, and a simple PSA process designed for the simultaneous removal and recovery of solvent vapors from air (27). With this in mind, a MSA process could be operated as follows.

Two identical beds (Columns I and II) would operate in tandem in a cyclic fashion. While one bed is magnetically energized and in the adsorption mode, the other bed would be de-energized and in the desorption or elution mode. During the elution mode, the void spaces within the column would be flushed by directing a certain fraction of the raffinate from the energized bed through the de-energized bed as purge; this purge flow necessarily being counter current to the feed flow. Ideally, a decrease in the counter current purge flow rate relative to the feed should

generate an extract having a higher metals concentration relative to the feed. There would also be no particular reason to saturate the entire column during adsorption or to completely regenerate the column during elution, as is typically done in conventional waste water treatment processes. In this way, the beds would approach cyclic steady-state operation (similar to PSA systems); and the bed loading profiles would cycle in time, as indicated in Fig. 4. At cyclic steady-state, two streams would be produced continuously: raffinate depleted of the unwanted metals and extract enriched with these metals. Assuming no breakthrough, 100% recovery of the metals would be achieved. Moreover, the certain fraction of the bed that would not be utilized specifically for adsorption would be used to contain the mass transfer zone and act as a guard against breakthrough (refer to the bed loading profiles in Fig. 4). This would ensure a low concentration of metals in the raffinate during the adsorption step; yet enough of the bed would be used to provide sufficient capacity to temporarily contain the metals and subsequently produce a concentrated extract during the counter current elution step. The degree of
enrichment of the metal species could be controlled both by the magnetic field strength and by the purge to feed ratio, i.e., the relative flow rates during elution and adsorption, respectively.

CONCLUSIONS

We have demonstrated an apparent synergistic effect between a polymeric adsorbent containing activated magnetite and an external magnetic field. This synergistic effect yielded an enhanced adsorption capacity for actinide removal from water, as compared to using conventional ferrite-based processes. Based on the well known metal adsorptive properties of various ferrites, these kinds of magnetic adsorbent materials can be used to remove a wide variety of heavy metals (Pb, Hg, Cd, etc.) and actinides (Th, U, Pu, Am, etc.) from a wide variety of aqueous waste solutions, but with a significantly enhanced adsorption capacity as explained above. Furthermore, a variety of inexpensive supports, such as sand, glass, etc., could be utilized in place of the polymer resin (22).

In addition, we have shown that magnetic adsorbents can be regenerated simply by turning the magnetic field off. This provides a mechanism not only for reuse of the magnetic adsorbent material, but also for recovery of the heavy metals and actinides from a concentrated stream. This is accomplished using a proposed magnetic swing adsorption process, where an electromagnet can be energized for adsorption and shut-off for elution. The degree of enrichment of the metal species can be controlled both by the magnetic field strength and by the relative flow rates during adsorption and elution.

Overall, we feel that MSA processes have the potential to make a significant impact on the development of new technologies for the removal of soluble metal species from aqueous solutions. We are presently exploring other applications of MSA, including the removal of certain heavy metals from waste water; and we are developing new magnetic adsorbent materials. Clearly, the results from this study and from our future studies are pointing the way for the development of a variety of new, field-enhanced separation processes.

HOME RADON MONITOR MODELED AFTER THE COMMON SMOKE DETECTOR

R. D. Bolton
J. P. Johnson

G. J. Arnone
Los Alamos National Laboratory

ABSTRACT

The Environmental Protection Agency (EPA) has declared that five million or so of the nation's 80 million homes may have indoor radon levels that pose an unacceptably high risk of lung cancer to occupants. They estimate that four times as many people die from radon-induced lung cancers as from fires in the home. Therefore the EPA has recommended that all homes be tested and that action be taken to reduce the radon concentration in homes that test above the 4 pCi/L level. The push to have homeowners voluntarily test for elevated radon levels has been only marginally successful. A reliable, inexpensive, and accurate in-home radon monitor designed along the same general lines as a home smoke detector might overcome much of the public reluctance to test homes for radon. Such a Home Radon Monitor (HRM) is under development at Los Alamos National Laboratory. To be acceptable to the public, HRMs should have the following characteristics in common with smoke detectors: low cost, small size, ease of installation and use, low maintenance, and high performance. Recent advances in Long-Range Alpha Detection technology are being used in the design of an HRM that should meet or exceed all these characteristics. A proof-of-principle HRM detector prototype has been constructed and results from tests of this prototype will be presented.

INTRODUCTION

The Surgeon General has warned that radon is the second leading cause of lung cancer (1). Radon is estimated to cause between 7,000 and 30,000 lung cancer deaths in the United States each year. Between 1,000 and 4,500 of these deaths could be avoided if the five million homes with elevated radon levels could be identified and mitigated to levels below the 4 pCi/L action level recommended by the Environmental Protection Agency (EPA) (2). For example, in New Mexico, it is estimated that about 8 to 10% of the state's 632,000 homes have been tested, with about 25% showing radon levels above the 4 pCi/L level. The average cost for short-term testing (2 to 90 days) is about $150 and for long-term testing (longer than 90 days) the average is about $35 per home (3). Long-term tests generally provide a better measurement of the year-round radon exposure from living in a particular house and represent the best measurement method on which to base remediation decisions, especially for homes with radon concentrations near the action level. The average cost per home to mitigate high radon levels is estimated to be about $1,200 so the total remediation cost to US homeowners and landlords could reach as high as $6 billion. With such large expenditures on the part of the home-owning public being recommended by the EPA, it is important that the decision to mitigate be based on the most reliable and accurate measurements available.

A reliable, inexpensive, and accurate in-home radon monitor designed along the same general lines as a home smoke detector might overcome much of the public reluctance to testing for high radon levels. This detector, the Home Radon Monitor (HRM), would measure radon concentration levels at intervals of one hour or less. These measurements would be stored in onboard nonvolatile memory so that the integrated long-term radon exposure could be extracted, compared to a threshold exposure level, and an alarm activated if the threshold was exceeded. The radon concentration history would be maintained for at least one year and could be read through a communications port for detailed analysis of exposure patterns. To be acceptable to the public, such a detector would need to have the following characteristics in common with smoke detectors:

a. Low cost HRMs should retail for less than $50 each.
b. Small size HRMs should be no bigger than a wall clock.
c. Ease of installation HRMs should hang on the wall like smoke detectors.
d. Low maintenance HRMs should require, at most, a yearly battery replacement.
e. Ease of use HRMs should have a high-radon alert light or audible alarm.
f. High performance HRMs need high accuracy and stability to preclude false alarms.

Recent advances in Long-Range Alpha Detection (LRAD) technology (4), under development at Los Alamos National Laboratory, are being used in the design of an HRM prototype that should meet or exceed all the requirements listed above. A

proof-of-principle HRM prototype has been built to addresses the size, maintenance, and performance objectives. To provide a significant improvement over existing radon measurement devices, this proof-of-principle prototype should have an operating range of at least 0.1 to 100 pCi/L and a 1-hr measurement accuracy of 0.1 pCi/L at the remediation action level of 4 pCi/L recommended by the EPA.

LONG-RANGE ALPHA DETECTION TECHNOLOGY

Monitors based on LRAD technology measure alpha contamination by detecting the ionization that alpha particles create in air (5). The energy lost by an alpha particle in ionizing an air molecule is approximately 35 eV, so a typical 5.5-MeV alpha decay from 222Rn will produce approximately 157,000 ions. Each ionized electron will quickly attach to another air molecule creating an ion pair consisting of two charged molecules. These ion pairs can be transported to an electrode where the current produced can be measured. Airflow LRADs use air currents to transport ions to the collection electrode. Detectors of this type are useful for monitoring irregularly shaped or metal objects (6). Electrostatic LRADs use an electric field to attract ions onto the electrode. Detectors of this type have been successfully used for monitoring flat surfaces such as concrete walls and floors or for soil surface contamination measurements (7). Alpha decay rates can be measured in two distinct modes. If the alpha decay rate is low enough to preclude pileup, current pulses produced by individual alpha decays can be counted. This is called the "single event" measurement mode. If the alpha decay rate is too high to resolve individual current pulses, the integrated current at the ion collection electrode is measured. This is called the "integrated current" mode. LRADs are unique in that the ionization produced from alpha decays in air is measured directly, without the gas gain, special gases, thin windows or other characteristics typical of ionization detectors.

To measure radon gas, air samples are drawn into a detection volume through electrostatic and particulate filters via fans or through diffusion. The electrostatic filter prevents the 107 ions/cm3 that are generally present in air from entering the detection volume. The particulate filter insures that radon progeny attached to airborne particles do not enter into and decay in the detection volume, creating ions that would bias the measurement. Ions produced and collected within a detection volume can be attributed to one of the following sources.

Material Contamination: The material from which an LRAD is constructed will contain some alpha contamination. When contamination located on the inside surface of the detection volume decays, ions will be produced and the measured current will increase. The background signal that can be attributed to material contamination is typically less than 0.02 femtoamperes (fA) of integrated currenta or 0.05 counts/minute per liter of detector volume.

Penetrating Radiation: External sources of penetrating radiation, such as cosmic rays, will produce ionization that will add to the overall current measured. However, a minimum ionizing cosmic ray will only produce approximately 1000 ion pairs per liter of detection volume. Therefore, the integrated current due to cosmic rays is less than 0.1 fA per liter of detector volume. Penetrating radiation will not produce large enough current pulses to contribute to the single-event count rate.

Radon Gas: Because radon is a noble gas, it is unaffected by particulate or electrostatic filtering and will enter into the detection volume. Some radon will decay and produce ionization in this volume. The ionization produced by these decays is proportional to the concentration of radon. A radon concentration of 1 pCi/L will produce from 1 to 2 fA of integrated current, depending on detector design and geometry, and 2.2 counts/minute per liter of detector volume.

Radon Progeny: Radon progeny from radon decays inside the detector can plate out on inside surfaces or be swept out of the detector by the airflow. In airflow LRADs most of the progeny are swept out of the detector, while in electrostatic LRADs most of the progeny become attached to the inside walls. In-growth from 222Rn daughters reaches equilibrium in about three hours. Because radon daughters 218Po and 214Po are also alpha emitters, electrostatic LRADs at equilibrium will see three alphas for each 222Rn atom that decays within the detection volume.

HOME RADON MONITOR PROTOTYPE

An HRM prototype detector has been constructed from a set of nesting stainless steel camping pans. The simplicity of design and construction inherent in LRAD-technology-based detectors is readily seen in the HRM schematic diagram and

photograph shown in Fig. 1. Sample air enters the 1.5-L detection volume via diffusion through an electrostatic/particulate filterb attached to the lid. Filtering is required to prevent radon progeny attached to particulates, such as dust motes, cigarette smoke, or automobile exhaust, from entering into and possibly decaying in the detection volume. The HV pin is held at high-voltage (typically 300 VDC) relative to the outer pan. The Teflon standoffs are designed to minimize leakage currents between the inner and outer pans and between the inner pan and the high-voltage pin. A current path exists from the inner pan to the outer pan through the signal BNC connector and an electrometer. An electrostatic field of about 40 V/cm exists within the detection volume. Radon gas decaying within this volume will produce ions which are attracted to the HV pin, the lid, and the inner pan. The charge that collects on the inner pan is grounded to the outer pan through the electrometer. The current pulses produced by collecting the ions from individual alpha decays can be counted or the total integrated current measured.

The current generated in an LRAD-technology-based detector from the ionization produced by 1 pCi of radon gas is less than 1 fA. Measurement of such small currents requires a very sensitive electrometer coupled to a detector designed and constructed to eliminate leakage currents. Figure 2 shows a block diagram of an electrometer specifically designed for LRADs. The current to voltage input stage, A1, of this electrometer uses an ultra-low-input-current operational amplifier in the standard current to voltage configuration. This amplifier maintains the "-" input at the same potential as the "+" input by means of the closed loop feedback action. Because the "+" input is tied to ground or zero voltage, the "-" input is forced to this same potential and functions as a virtual ground. The current flowing into this stage, Iin, flows through the feedback resistor, Rf, which produces an output voltage, Eout, equal to -(Iin.Rf), therefore for an input current of 1 fA, and an Rf of 100 GW, Eout would be -100 V. The input conversion gain is selectable providing -100 V out for either a 1 fA or 10 fA input current. The current to voltage input stage, A1, is followed by a gain stage, A2. This stage provides a buffered output and has a selectable gain of 1 or 10. A1 also drives A3, which provides an integrated version of the signal. The time constant of this integrator is selectable for either 5 or 10 seconds. The electrometer includes a gain potentiometer for calibration and an offset potentiometer for nulling the circuit. The circuit uses very little power and can operate for several years on a set of batteries.

The conversion of femtoampere currents seems relatively straightforward, but several effects can cause errors in the measurement. First, leakage currents at the critical node, the "-" amplifier input, must be kept extremely low if one is trying to resolve femtoampere currents. Also the amplifier's bias current, i.e., the current that flows into the amplifier's inputs, must be very low. Although bias current errors can be canceled out by providing an offset adjustment, bias currents vary with temperature. There are other errors, such as the temperature coefficient of resistance and the voltage coefficient of resistance, which cause the conversion gain to change as a function of temperature or voltage. Cancellation techniques have been incorporated in the design of this electrometer to minimize these effects.

The HRM prototype detector was tested using sources of 222Rn and 220Rn gas constructed by enclosing naturally occurring uranium and thorium ores in bottles. Gas from these bottles was injected into the HRM prototype detector to study speed of response, radon daughter in-growth, and single event pileup. Data acquisition and analysis were done using a personal computera. Electrometer outputs were acquired at 3 to 5 readings/second, and the results were displayed on the computer screen as a strip chart and recorded to disk. The raw data were averaged into 1-minute bins and, along with the single event count, the results were displayed and recorded to disk for later analysis.

RESULTS

The current output of the HRM prototype detector operating in a 1 pCi/L radon environment over a typical 1-minute time interval is shown in Fig. 3. The current pulses at 20 and 40 seconds are due to ions from individual alpha decays. The average integrated charge per single event from the 5.5-MeV decays of 222Rn in the HRM prototype detector is about 2.4 x 10-14 Coulombs. This value corresponds to an ion collection efficiency of 95%. In a 40-V/cm electrostatic field, all the ions from a single alpha decay are collected within a 3-second time interval. These single event current pulses can be easily distinguished from the background current

if the frequency of decays is low enough to preclude significant pile-up. For the HRM prototype detector, single event pile-up starts to significantly affect the precision of radon-level measurement at about the 15 pCi/L level.
Several LRAD prototype detectors have been calibrated in the Radon/Radon Daughter Environmental Chamber operated by RUST Geotech at the DOE's Grand Junction Projects Office in Colorado (8). These detectors were operated in the integrated current mode in a variety of configurations. Figure 4 shows detector response to radon concentrations ranging from 0.06 to 825 pCi/L. For each detector at each point, a 1-hr data set was taken after radioactive equilibrium was reached. The arithmetic means of these 1-hr data sets, minus a constant background due to leakage currents and cosmic rays, are plotted against the mean radon concentration as determined by RUST Geotech personnel. As can be seen from this plot, LRADs operating in integrated current mode respond linearly, with R2s of 0.999 or better, over the entire 4-decade radon concentration test range.
By combining the single event counting mode with the integrated current mode, the HRM prototype detector spans an operating range from zero to 800 pCi/L or higher. At the low end, precision is limited by single event counting statistics. For the 1.5-L HRM prototype detector, this leads to a 1-hour measurement precision of 0.1 pCi/L at a radon concentration of 4 pCi/L, assuming material contamination of 0.05 counts/minute and that half of the 218Po and 214Po radon daughters will decay into the detection volume instead of into the detector walls. A larger detection volume would improve measurement precision at the expense of lowering the changeover point from the single event counting mode to the integrated current mode.
Long-term stability of an LRAD-technology-based HRM operating in single event mode is assured due to the digital nature of the measurement. Calibration in the single event mode is similarly simplified. There is a large detection region, from about 1 to 15 pCi/L, where the single event and integrated current measurement modes overlap. Calibration of the detector in the integrated current mode can be tied to readings obtained from the single event mode while operating in this overlap region. Because LRADs collect the air ionization from alpha decays directly without relying on gas amplification of the total charge, a major source of long-term drifts in the calibration of the detector in integrated current mode is removed.

ABSTRACT
Shoe covers and waste bags made of polyvinylchloride (PVC) are used at the Savannah River Site (SRS). Plans are to incinerate shoe covers and disposal bags in the Consolidated Incineration Facility (CIF) after its scheduled start-up in the first quarter of 1996. The exhaust gas from the incineration of PVC must be processed through a hydroxide scrubber to remove the chlorides. This liquid scrubber waste stream is referred to as the CIF blowdown. The blowdown volume from processing the chlorides will be disposed of in a cement matrix in either the SRS E-Area Vaults (EAV) or in a proposed Hazardous Waste/Mixed Waste Disposal Facility (HW/MW DF) vault at a significant cost.
We have completed an investigation of alternative materials for PVC shoe covers and waste disposal bags to minimize disposal costs. Savings of about $2.89 millions a year in vault disposal costs are expected from replacing PVC shoe covers and standard-sized bags with non-PVC products, through a reduction in the volume of CIF blow-down generated. Recommended acceptable substitutes will cost about $450,000 a year more than the current PVC products. SRS plans are to implement PVC replacement starting June 1995, commensurate with the current CIF start-up schedule, to take advantage of the $2.45 million per year in net cost savings.
SHOE COVERS (1)
Manufactures' Information
Information from twelve (12) different shoe cover manufacturers were collected on seventeen (17) shoe cover samples and recorded on a spreadsheet for comparison. Specific information include the following: style, material(s), cost, size availability, tensile strength, puncture resistance, tear resistance, thickness, length, height, weight, carton weight, wear resistance, elongation percentage and miscellaneous information that appeared relevant. Some of the information was not available from a few of the Manufacturers.
The list of rnanufacturers is as follows:
- FRHAM Safety Products, Inc.
- Island Poly
- G/O Supply Company
- JSM Protective, Inc.
- Mar-Mac Manufacturing Co., Inc.
- Designs by Norvell, Inc.
- Associated Bag Company
- Euclid Garment Manufacturing
- Lancs Industries, Inc.
- RAD-SAFE
- FAB-Ohio
- Rich Industries

Acceptance Criteria
To be accepted, a replacement alternative had to meet certain requirements. It had to be waterproof, disposable versus re-usable, incinerable (but non-PVC), durable, cost effective and highly ranked within a "figure of merit" scale. A number of simple tests were conducted to quantify the acceptability of replacement products, as described below.
Puncture Resistance Tests
Using a force meter and two different puncture bits, each shoe cover sample was pressed separately on both bits (Fig. 1). The force meter measured the strength required to puncture the shoe covers. One bit was pointed and the other was wedge-shaped (Fig. 2). The diameter of the pointed bit was 250 mil, with an angle measure of 60. The diameter of the wedge-shaped bit was also 250 mil, with an angle measure of 60. The ridge on top was .013 mil wide.
To rank the samples, the two puncture bit readings were averaged. The highest average was found to be 56.72. Each shoe cover result was then divided by 56.72 and multiplied by 100 to calculate the percentage. The puncture resistance rankings, rounded to the nearest whole number, ranged from 1 to 100.
Coefficient of Friction Tats
Using a force meter, an 18.5 pound stainless steel brick, and kraft paper, the coefficient of friction between the shoe cover and the kraft paper was measured. Kraft paper is used extensively as a floor covering material to prepare for waste

removal, D&D and other activities in radiologically contaminated areas. Each shoe cover sample was fitted over the brick. The force meter was used to push the brick and shoe cover sample across the kraft paper. The force required to push the brick was measured (Fig. 3).

To tabulate the coefficient of friction, the formula of F/N was used. F is the force measured by the force meter and N is the normal pressure which is the weight of the brick. The highest coefficient of friction reading was 0.76. For ranking purposes, each shoe cover's coefficient of friction reading was divided by 0.76 and then multiplied by 100 to get the percentage. The coefficient of friction rankings, rounded to the nearest whole number, ranged from 28 to 100.

Durability Walking Tests

Two colleagues, each weighing around 200 pounds, walked in leather shoes wearing the shoe cover samples. They walked 1.5 miles over a trail constructed of "fines" gravel, which is smaller than "pea" gravel. The trail is shown in Fig. 4 and a close-up of the "fines" gravel is shown in Fig. 5.

After each walk, the description of each shoe cover was recorded in a journal. The shoe covers were rated on a scale from 1 to 17, with 1 being the least durable and 17 being the most durable.

Test Results

Of the 17 shoe covers evaluated, one brand of polyethylene shoe covers was found to be most satisfactory and was recommended to replace PVC shoe covers currently in use at SRS. These polyethylene shoe covers are both disposable and incinerable. They have a relatively high coefficient of friction and puncture resistance.

WASTE DISPOSAL BAGS (2)

Evaluation of waste disposal bags was conducted in two phases. In the first phase, bags made of poly-ethylene, PVC and polyurethane were evaluated. In phase two, only polyurethane bags of different thicknesses were evaluated, along with the PVC bags currently in use.

Manufacturers' Information

Information from four (4) different waste disposal bag manufacturers were collected on nine (9) waste disposal bag samples and recorded on a spreadsheet for comparison. Specific information include the following: description (material and dimensions), cost, tensile strength, puncture resistance, cutting resistance, and wear resistance.

The list of manufacturers and waste bag samples is as follows:

- JSM Protective, Inc. (6-mil, 8-mil polyethylene)
- Associated Bag Company (3-mil, 4-mil, 6-mil polyethylene)
- Rich Industries (12-mil PVC (2),12-mil polyurethane)
- Nuclear Power Outfitters (4-mil polyethylene)

Acceptance Criteria

To be accepted, a replacement alternative had to be non-PVC, yellow-tinted, capable of being incinerated without producing regulated emissions, cost effective and comparable in strength to the PVC bags being replaced. A number of simple tests were conducted to quantify the acceptability of replacement products. The tests and results are described below.

Puncture Resistance Tests

Using a force meter and two different puncture bits, as described above for testing shoe covers, each bag sample was pressed separately on both tips.

Polyurethane tested more resistant to puncture from the point bit (14.4 lb) and the wedge bit (25 lb) than any other material tested, including the PVC currently in use. The overall puncture resistance measurements ranged from 1.0 to 14.4 lb for the point bit and 1.2 to 25 lb for the wedge bit tests.

Cutting Tests

Each bag was cut with scissors connected to a force meter. The force meter determined the force required to cut each bag. The cutting force is thus also a function of the sharpness of the scissors.

The highest force required to cut the bags was 6.7 lb, which was observed for the polyurethane bags and the PVC bags currently in use. The cutting measurements ranged from 4.9 to 6.7 lb.

Wear Resistance Tests

The polyurethane and PVC bags were tested for wear resistance. The six polyethylene bag samples were deemed unacceptable, based on the puncture and cutting resistance test results, and were thus not tested for wear resistance. To conduct the wear

resistance test, the polyurethane and PVC bags were filled with atomic wipes and dragged across pavement in 50 ft intervals. After each interval the bag was inspected for any noticeable holes. When found, the hole was marked and the drag distance recorded. Distances were avenged for a number of tests. The average for polyurethane was found to be 1550 ft and for PVC bags, 1750 ft. This wear resistance test produced wide scatter of data. Phase two evaluation tests used a modified wear resistance test.

Phase Two Tests

Polyurethane bags of 12 mil, 10 mil, 8 mil and 6 mil thicknesses were requested from Rich Industries for additional testing. Thicker samples of polyethylene samples were considered, but they were not ordered for further evaluation because the thicker material would have made handling by area operators in protective gloves too difficult. Again, three tests were conducted: puncture resistance, cutting and (modified) wear resistance.

Modified Wear Resistance Test

The modified wear resistance test involved testing two different samples at the same time with a glass bead sprayer. Two 3" x 3" samples of the materials to be tested were clamped between two plates of carbon steel. Each samples was exposed through a " hole in the front plate. The holes had been filed smooth to prevent any burs in the metal from tearing the samples.

The test apparatus was placed in a bead tester (a glovebox used to clean or smooth machined parts). The blaster contains a pneumatically operated spray gun inside a glove box chamber. The gun sprays glass beads at high speeds against a sample set in the chamber that is to be cleaned or smoothed. The test apparatus was leaned against the back of the chamber at a 45 angle. The samples were blasted for varying lengths of time at a 45 angle with respect to the plane of the sample. Pictures were taken of the resulting worn patch using a scanning electron microscope. Relative information on the degree of resistance to the wearing effects of the pellets was recorded.

The phase two test results are summarized in Tables la and lb.

Summary of Test Results

A 10-mil polyurethane waste bag is recommended as a replacement for 12-mil PVC bags currently in use. 12-mil polyurethane waste disposal bags tested stronger than the 12-mil PVC in puncture tests and as strong as PVC in cutting tests. Polyurethane bags, however, cost more than PVC bags of the same thickness. 12-mil, 10-mil, 8-mil and 6-mil polyurethane bags were then tested. Results indicated that 10-rail polyurethane is as strong as the 12-mil PVC currently in use. 8-mil polyurethane is not as strong as 12-mil PVC. Substituting 10-mil polyurethane is expected to result in a cost savings over 12-mil polyurethane while still retaining the strength of the current PVC

COST-BENEFIT ANALYSIS(3)

SRS PVC Usage

Table II shows the breakdown of PVC operating materials use at SRS into shoe covers, two types of standard-sized bags (large and small), non-standard-sized bags and miscellaneous items, as surveyed in 1993(1,2). Shoe covers represent the majority of PVC used at SRS, about 60% by weight. The two standard-sized bag together make up 33% of the PVC used at SRS (28.5% large 42" x 50" bags and 4.5% small 22" x 36" bags). Together, shoe covers and standard-sized large and small waste bags comprise 93% of the PVC expected to be incinerated in the CIF.

Cost of PVC Replacements

Ten-mil polyurethane bags cost about twice as much per bag as 12-mil PVC bags currently in use (Table III). Based on the cost data from the recommended manufacturer, it is estimated that to replace both sizes of standard large and small sized PVC bags with 10-mil polyurethane bags will cost an additional $227,000 per year over current procurement costs.

Based on cost data from the recommended manu-factur, polyethylene shoe covers are expected to cost about twice as much as PVC shoe covers ($0.31/pr vs $0.15/pr). It is thus estimated that to replace PVC shoe covers with polyethylene shoecovers will cost an additional $222,000 per year over current procurement costs.

Disposal Fault Cost

SRS vault space costs have been estimated at $49/ft3 for the EAV and at $374/ft3 for the proposed HW/MW DF vaults.(4) These costs include both total project cost and operating cost

In a recent CIF Blowdown study(5), it is estimated that the yearly amount of waste generated from CIF blow-down is 185,000 gal/yr. With replacement of both shoe covers and standard-sized bags, the CIF blowdown waste is estimated to be 50,000 gal/yr, which represents a 73% reduction in volume. Thus PVC replacement will result in a 93% reduction in PVC usage and a 73% reduction in CIF blowdown volume. SRS stabilization studies have shown that 28 gallons of blowdown solution may be cement-stabilized in a 55-gallon drum. The cement-stabilized blowdown is planned to be disposed of in either the EAV or the HW/MW DF Vaults, depending on whether the stabilized waste qualifies as low level waste or as mixed waste.

Cost Savings

For the purpose of this cost-benefit analysis, it is assumed that 90% of the stabilized blowdown volume will be disposed of in the EAV and 10% disposed of in the HW/MW DF vaults. The reduction of 265,200 gal/yr in stabilized CIF blowdown volume thus equates to vault space savings of about 31,900 ft3/yr of EAV and 3,550 ft3/yr of HW/MW DF vaults.(4)

PVC repalcement of both shoe covers and standard sized bags thus will result in $1.563 million of savings in EAV space and in $1.328 million in HW/MW DF vault space. The total savings in vault space is $2.89 millions. Recommended acceptable substitutes will cost about $450,000 a year more than the current PVC products. SRS plans are to implement PVC replacement starting June 1995, commensurate with the current CIF start-up schedule, to take advantage of the $2.45 million per year in net cost savings.

Notes:

1. Reduced volumetric processing of CIF blowdown is also expected to result in reduced CIF operational costs associated with stabilization material and operating labor, increased life of the offgas processing equipment and easier compliance with proposed CIF air emission standards.

These savings have not been quantified and credit was not taken in this analysis.

2. It is also recognized that both SRS usage of PVC operating materials and costs of bags and shoe covers have changed since the completion of these studies. The actual savings may have changed, but the general conclusion is expected to remain the same.

Through this paper we hope to convey our strong belief in the need to quantify the "quality" of replacement products to avoid the griefs of "you get what you pay for". To that end, this paper has offered some simple tests that may be easily utilized by many organizations.

ABSTRACT
An innovative method of placing soil barriers to contain vertical flow is being prepared for demonstration by the Fernald Environmental Restoration Management Corporation (FERMCO), working in conjunction with the Department of Energy Office of Technology Development (DOE/OTD) and two principle subcontractors. The method employs proven directional drilling techniques, jet grouting technology and unique placement tooling to form horizontal soil barriers in situ. This is done without disturbance to existing land disposed wastes.
This paper is a summary report on the current state of that demonstration, including: a discussion of the construction methods, the results of the initial tool tests, an overview of the Fernald site conditions and, the resulting path of tooling development for the second phase of tool testing.
INTRODUCTION
Temporary or long term containment of mobile contaminants from existing land disposal waste site requires effective surrounding barriers. Current technologies typically require removal and repackaging/reprocessing of waste from its existing location or rely on existing impermeable soil layers beneath the waste. In situ constructed vertical barriers, or cut-off walls for the restriction of horizontal flow, have been used extensively and are relatively well understood. However, a full containment is difficult to achieve unless these walls can be tied into existing impermeable layers (clays). Those layers may be very deep or missing entirely. In either case, the containment then depends on the integrity of the existing geology. This is often difficult to assure.
The use of in situ constructed horizontal containment to restrict vertical flow is not highly developed. When dealing with existing sites, it is a problem to place containment without disturbing the waste. The excavation to or through the waste can create unacceptable health risks and/or regulatory problems.
At several DOE sites natural barriers to vertical migration do not exist at usable depths beneath existing sources of contamination. Examples are both Hanford and Savannah River sites (although their basic geology varies greatly). Like situations exist at government and commercial industrial, chemical and petroleum storage sites. Attempts to produce barriers to vertical flow have generally relied on permeation grouting, using large amounts of material, to form a floor beneath the source. The uncertain nature of these processes and the difficulty of conclusive inspection at depth raises regulatory concerns.
This paper describes a demonstration/innovative adaptation of jet grouting techniques to form a soil barrier in situ, the results of initial tooling tests and, the plan to bring the technology demonstration at Fernald to successful completion.
TECHNOLOGY/PROCESS DESCRIPTION
This innovative process for placing in situ barriers is a self verifying technique that actually moves a solid tool completely beneath existing sources of contamination, leaving a continuous soil and grout (soil-cement) mix behind, in the tool's wake, to form a containment. Multiple passes of the tool can be used to form a barrier of significant size.
The typical jet grouting process uses a cement grout pumped at very high pressure (up to 10k PSI) to a set of nozzles arranged in a single line on a pipe tool. When the grout exits the nozzles of the tool, the pressure is converted to velocity. If the tool is in contact with a soil formation, the high velocity grout transfers its kinetic energy to the soil, erodes the formation and mixes with the spoil. This forms a soil-cement. Both the soil and the grout and their respective ratios determine the properties of the resulting mix. Portland cement in a 1:1 ratio with water is a common grout mix. Bentonite, pozzolans and other additives are often used to modify properties and control costs.
A rod shaped jet-grouting tool (with a single line of jets down its length) may be placed vertically into the soil (by drilling or driving) and used to form a soil-cement cylinder, column or pier by rotating the tool and slowly withdrawing it leaving soil-cement behind. Conceptually, if the same vertically placed tool is

moved perpendicular to its axis and along the line of flow of the jets, it will cut the soil and leave a soil-cement "wall" in its wake. This action is the key to placing continuous horizontal barriers.

The equipment set necessary to perform successful jet grouting includes dry grout bulk storage bins or tanks, efficient mixing systems, effective grout cleaning equipment (screens), high pressure pumps (10k PSI) and power systems to support the production equipment. All parts of this supporting suit must deliver sufficient reliable capacity to ensure a steady flow of clean grout to the tooling. In addition, the horizontal barrier formation process requires powerful pulling equipment and directional drilling equipment.

The process of forming a horizontal grout barrier begins by placing two generally parallel directionally drilled holes from the near side (clean) surface, passing completely beneath the source of contamination and emerging again at the (clean) surface on the far side. The drilling stems remain in the holes and are attached to a draw bar and a pulling device at one end. The stems' other ends are attached to the front of a jet grouting tool. A grout feed line and a trailing drill stem are attached to the rear of the jet grouting bar, forming a capital "H"-shaped arrangement with the jet grouting tool as the crossbar of the "H" when viewed from above (see Fig. 1). A tractor, winch or pipe puller then pulls on the draw bar attached to the stems forming the top of the "H" and moves the jet grouting tool through the soil along a path between the directionally drilled holes.

Fig. 1. Solid bar tool ready for testing.

The jet grouting tool is an injector-mixer which leaves a soil-cement (grout and native soil) slab in its wake as it is pulled through the soil and beneath the source of contamination. It emplaces the soil-cement slab by employing grout delivered at high pressure, up to 10k PSI, to develop high velocity through use of jet nozzles. The high velocity grout streams emerging from the tool's jets cut soil formations by transferring their kinetic energy (through impact of the grout) to the formation around the tool. The high amount of energy involved and the abrasive nature of the grout currently in use gives a strong cutting action (which can be augmented by mechanical cutting). The remainder of the grout's energy is dissipated in a turbulent mixing action that forms the soil-cement. The formed barrier slab is continuous back along its path to the surface and remains fluid. Therefore, there is no significant build up of grouting pressure. A flow of excess grout and some spoils to the surface keeps the formation open and is expected to avoid pressure build up and issues of significant slab jacking or extensive fracturing of the soil formation.

Joined slabs, necessary to form an extensive bottom, are to be formed continuously and sequentially by using the previously mentioned trailing drill stem from the last slab and an additional, generally parallel, directionally drilled-in stem to make each additional slab. (see Fig. 2) The use of the trailing pipe ensures that each slab overlaps the previous one and that a continuous bottom is formed. Continuous forming and the grout formulation ensures wet joints with commingling along seams to enhance the integrity of the final barrier. This process is repeated until a bottom of the required width is formed.

This process produces grout overflow, drilling spoil, excess soil-cement and washout water, as secondary waste. Because the path of the directional drills and the barrier does not have to contact the waste, these secondary wastes may not be problematic.

Conceptually, the technique is simple to use. It relies on two proven technologies: grout high pressure pumping techniques and DOE/OTD demonstrated directional drilling methods. The difficulties of operating in rocky soil, cobbles, till and other challenging conditions remain to be determined and are challenging areas for additional work.

The horizontal barrier is potentially applicable to containment of a wide range of existing land disposal sites, underground storage tanks, spills and ruptures. The types of grout that may be placed are extensive, the jet grouting tool may be expected to place materials that can be fed to it as a liquid at the required volumes and pressures (grout tolerance to shear and impact may be issues). It should also be noted that this "horizontal barrier" can vary from the horizontal plane through the vertical for special applications, simply by varying the arrangement of the directionally drilled holes.

THE FERNALD DEMONSTRATION PROJECT

The objective of this work is to place a joined, four pass, demonstration horizontal barrier on a radiologically "clean" site at the Fernald Environmental Management Project (FEMP) site in southwest Ohio. The demonstration will build various tooling combinations and test them at a separate location prior to mobilizing to FEMP with at least the two tools thought best suited to the local conditions. Placement techniques, surface support systems operations and longitudinal joining integrity (seaming) are of primary interest in the work. A simple portland cement-based grout will be employed to control costs.

The FEMP site is a 600' x 200', area clear of surface and below grade obstructions. The site is accessible from plant roadways for trucks and heavy equipment. The completed demonstration barrier will cover approximately 100' x 40' of the test area and will begin near the surface and drop to a nominal placement depth of 12', rising to the surface at the far end. Soils at the site were classified as Pleistocene (6,000 - 10,000 year) glacial till to a depth of 30'. Well developed, historically cultivated A and B loam horizons are located to a depth of approximately 18". As a homogeneous, semi consolidated unit, the unweathered tills generally consist of approximately 75% mixed brown and gray clays, with 25% silt and fine sand in approximately equal proportion. Organic concentration below the cultivation level is less than 5% and moisture content varies from 3 - 10%. Lenses of moist to saturated sand, 1' to 3' thick, exist at random through the body of the till. Exploratory excavations revealed that the predominantly brown clays are underlain by a discontinuous rocky layer containing both limestone slabs and glacially transported granite schist, at a 12' depth below grade. The gray clays below that depth were distinctly less sandy and silty, and more plastic.

The existence of the rocky layer and strata change at 12' depth on the FEMP site is a concern for both tooling and testing and will impact the final operating depth for the demonstration.

The FEMP demonstration barrier will be placed, allowed to cure and then excavated for testing by an independent academic agency. The testing will include: surveying the site, measuring displacements and tilts during placement, physically sectioning and characterizing the barrier and conducting applicable strength and permeability tests to evaluate the uniformity and integrity of the barrier across seams. Key to the test effort is the issue of determining if adjacent barrier panels, formed on sequential passes of the tooling, can be joined in a reliable and reproducible manner to form a uniform and competent barrier.

PROGRESS/STATUS

The work involved in this project covers more than two years of effort directly aimed at establishing a viable capability to place in situ soil barriers to vertical flow. Two separate series of tool tests have been conducted and the knowledge gained from those tests was incorporated into the design of a third generation of tooling for up-coming field testing. For all testing completed and planned, the directional drilling was/will be simulated by trenching in the drill pipe, backfilling and compacting the overburden. Directional drilling is considered a DOE proven "enabling technology" at this point. The cost savings to place the drill pipe by trenching, rather than by drilling, were significant to the project.

The initial field work, begun in 1992, involved simple proof of concept work to answer the issues of "can this be done at all." Two basic types of tool were successfully tested in sandy soil and soft sandstone formations in Oklahoma.

The first tool was a solid bar with a line of forward-pointing jets for distributing grout forward, in the direction of travel, in streams like the teeth on a pocket comb. Also developed was a prototype rotary tool shaped like an automotive camshaft with angled, cross cutting jets distributing grout from the circumference of the lobes. The rotary tool was driven directly by a down hole hydraulic motor with fluid lines to the surface. Each tool was approximately 10' wide.

The solid bar tool produced the strongest cutting action, as its 61 jets were all aimed forward, concentrating the available kinetic energy on the formation directly ahead, shattering the soil and liquefying the path of travel. The solid bar was also relatively efficient in the use of grout since the cutting action all took place forward of the path of travel. Panels could be formed at the rate of 20 to 100 square feet/minute. Several shortcomings were apparent: the barrier formed was thin, barely exceeding the width of the bar; the barrier was irregular, due to the non-homogeneity of the formation and the fixed direction of the jets and; the solid bar was very susceptible to failures from the blockage of one or more jets. These

drawbacks to the solid bar led to increased soil resistance and bent or broken tools. While the simplicity of the tool was a plus, improvements were deemed necessary.
The prototype rotary tool produced a thicker and more uniform barrier slab, one that was 10' wide, 12" thick and literally looked like an underground highway when a section of it was excavated. Because the same available energy (as the solid bar) was spread over a greater surface area, the rotary tool formed a panel more slowly; about 10 to 30 square feet/ min. The rotary tool also experienced jet blockage, but it could compensate to a degree as the rotation of the tool brought other jets into play at the cutting face. Nevertheless, the tool exhibited what was considered to be excessive grout use and back flow through the slab, as only the jets at the face aided forward progress. In addition, the size of the down hole motor caused excessive resistance. The use of a down hole hydraulic motor had a second negative: in the event of a mechanical failure, the hydraulic fluid (a RCRA material) could escape into the soil. A combination of drag from the motor case and blocked jets ultimately resulted in the structural failure of the prototype rotary tool during testing. It had to be dug out with a back hoe and was destroyed in the process.
The first round of testing showed that barriers could be formed in situ using the horizontal grout barrier technique. The project goals were redefined to gain increased effectiveness in terms of barrier thickness, surface uniformity, cutting effectiveness and grout use.
The second round of tooling design, fabrication and evaluation concluded in mid 1994 with testing at a more challenging area of the Oklahoma test site. Three second generation tools were produced with the specific objective of optimizing against the new goals. The new tooling items were also about 10' wide but were widely different in design from the first generation and from each other:
The solid bar tool #1 was retained to gain a performance baseline for other tooling.
A second solid bar tool, #2, used a 54-jet array placed in a crosscutting arrangement in two horizontal rows.
A mechanical head tool (shuttle tool), the most complex new tool, consisted of a drive mechanism with a reciprocating mobile cutting head consisting of a steel box with two sets of 12 jets arranged in two rows of six (total 24 jets) at each end of the box. This device was approximately the size and shape of a baby grand piano with a shoe box on the keyboard. As the main tool body was moved forward (with the keyboard leading) the shoe box-shaped cutting head shuttled across the keys. The intent was to reduce grout usage through reducing the number of jets (24 vs 61) and to maintain the tool's cutting effectiveness by concentrating the remaining jets close together on the shuttle. The mechanical complexity of this tool, the cable linkage to the shuttle head, and its related surface support equipment with the long flexible drive shaft necessary to reciprocate the shuttle head was recognized as a negative at the inception. The potential for reduction of grout waste and backflow of spoils through the barrier was considered significant enough to warrant testing the concept.
A catenary (flex) tool was the most innovative of the second generation tools. This tool consisted of two separate cutting heads (subs) attached to a curved structural steel member. This assembly was, in turn, connected to the drill stems by two flexible spring steel straps. The design was to allow the tool to reciprocate across the face of the cut like a cable saw cutting wood, propelled by alternately pulling and playing out alternating drill stems in a coordinated back and forth stroking action. Each sub was equipped with 10 jets in two rows of five. The resulting total of 20 jets was expected to reduce grout waste and retain cutting effectiveness.
The supporting equipment for the second test was a custom flatbed mixing plant with mechanical drive equipment for the shuttle and flex tools, a 1,500 gal. grout surge tank and a tracked power unit to advance (pull) the unit and tool through the length of the barrier. The mixer capacity was 300 - 400 gal./min. with direct transfer to the grout surge tank. High pressure pumping was provided through a 1000 horsepower twin positive displacement pumping unit.
The grout formulation was cement kiln dust and water mixed to an original density of 12.6 lbs./gal. Grout density was later lowered to 11.4 lbs./gal. to increase cutting power. Lignosuphonate was added to act as a retarder. This mix was chosen for reasons of low cost and low hydration shrinkage.
The second round of testing did not produce the same successes as the first. A combination of more challenging soils, mistaken design assumptions and, support

equipment shortcomings resulted in multiple failures to form a satisfactory barrier. The original solid bar tool #1 with 61 jets was tested at both 3,300 PSI and 5,000 PSI. The bar appeared to improve in cutting performance at the higher pressure. In both cases the bar moved forward about 25' and stopped due to exhausting the grout supply in the 1,500 gal. surge tank and exceeding the 300 - 400 gal./min. grout make up capacity. The forward progress of the bar could not be resumed in either test after halting to replenish the grout supply because of plugged jets at the center of the bar.

Solid bar tool #2 with 54 jets was tested at 5,700 PSI on a single twin pump (1,000 horsepower). The tool traveled 15' - 20' into the soil and the tracks on the advancing mechanism began to slip. The grout flow began to drop and the test was halted. The bar was excavated and 25% - 30% of the jets were plugged with kiln dust from the grout mix and the bar was bowed up from horizontal. After cleaning and straightening the bar, the test was repeated with essentially the same result: 15' of travel, 10% of jets plugged and the bar bowed.

The shuttle tool functioned as designed during surface check out, and then was positioned at the face of the cut. When the tool was moved forward into the cut, the shuttle appeared to bind and the cable drive mechanism stretched. This reduced the travel of the shuttle to less than the full width of the tool body. The shuttle, therefore, could not clear a path for the tool, and progress halted at the face of the cut. The stretched cable could not be expediently corrected and the test was ended.

The flex tool was tested at 5,000 PSI and it was unable to construct a barrier. The system could stroke or reciprocate smoothly, pulling the tool through a 180 degree arc on the surface. When the tool was moved into the face of the cut however, it was able to complete only half a stroke. Upon attempting to recover from that stroke, the tool stuck in the face of the cut and the 40,000 lb. pull of the support system hydraulics could not move it. The main body of the tool was damaged when it was extracted from the cut.

LESSONS LEARNED

It is now clear that barrier formation is more difficult than the initial tests indicated. The second generation tooling did not create any satisfactory panels in the more challenging soils at the Oklahoma test site. Operational problems with the tools included jet plugging on solid bar tools #1 and #2, stretching of the drive cable and possible binding of the shuttle on the shuttle tool, and inability of the stroking mechanism to reciprocate the flex tool across the face of the cut.

A new understanding has been developed of the criticality of the surface support equipment. The grout required for successful employment of jetting methods must be much cleaner than grouts used for other soil amendment. It is necessary to use a high quality screening system to avoid jet plugging. Grout mixing must be more complete, and equipment must be maintained thoroughly clean and free from trash that can plug the grouting jets. The grout mixing, holding and delivery capacity must be sized to ensure no interruption in supply or pressure in order to maintain progress through a complete pass of the barrier. A halt invites failure due to jet plugging. The skin friction of the emplaced drill stems and the pulling angles for the flex tool may dictate considerably more hydraulic power requirements and/or consideration of scale factors when this type tooling is applied. The belief is that the geometry of a much larger catenary arc with a greater number of jet subs and much more bearing area in the cut would be a better design.

The excess grout flow that is produced with the use of a rotary tool may be a cost of enjoying less impact from the plugging of a few jets. In addition, the backflow of excess grout through to the surface may clear spoils and mix them better to help in barrier formation.

The use of solid bars with fixed jet patterns can cut formations effectively, but, the barriers produced are thin and the tools are highly susceptible to failure through plugging of a small percentage of jets.

NEXT STEPS

The success of the prototype rotary tool and the realization that the backflow of grout through the barrier slab to the surface may be acceptable factors have prompted the development of two third generation rotary tools. The first, rotary #1, is driven mechanically through a drive shaft from a surface support power unit. The cutting and mixing action come from the kinetic energy of the grout jetting through the tool. The second, rotary #2, will employ the same mechanical drive system to

drive mechanical cutting teeth mounted on the circumference of the lobes of the tool. Grout jets will be used to assist the teeth and to generate the turbulent mixing required to form a uniform slab.
The initial failure of the flex tool pointed up the importance of scale in the design of this tool. A wider tool has been developed and is expected to cut less sharply into the face of a soil formation on each stroke, and ,therefore operate at more "gentle" angles, reducing the tendency to bind in the cut.
The third field testing session will evaluate these tools in progressively more difficult situations beginning with open air testing with water and progressing through shallow cuts through loose material with water, deeper cuts, cuts into unexcavated strata with water and finally cuts into unexcavated strata using grout at full operating pressures. The two most successful tools will then be taken to Fernald for a full scale demonstration on the prepared site.
The Fernald demonstration is to take place in the summer of 1995 with the full report being completed in winter of 1996.

DESIGN OF A FULLY MOBILE SUPERCOMPACTION SYSTEM

Paul B. Woollam
Nuclear Electric plc
John Sims
WasteChem Limited

ABSTRACT

A design review was undertaken on the feasibility of a solid low level radioactive waste supercompaction system, requiring only a concrete hard standing. The prime aim of such a system was to be totally independent of any reactor site services, except for the disposal of any liquids arising from the supercompaction process.

THE SUPERCOMPACTOR

Although a number of proven high force compactors were investigated in this study, the unit shown in Fig. 1 most closely met the reviewed specification, i.e.:

- Adequate compaction force of 1600 kN,
- Light weight, suitable for transportable use,
- Compact dimensions, particularly the overall height,
- Relatively easily enclosed with primary containment,
- Automated drum feed and puck delivery systems,
- Programmable electrical and hydraulic control systems.

Basically, the main body of the compactor (1) is a circular forged structure, the top section of which forms the hydraulic, high pressure cylinder, while the bottom section is partially removed to permit the drum being compacted to pass through the structure. The hoop stresses produced by the compaction process are absorbed by the bolster (5) and the longitudinal forces are accepted by the remaining material of the structure. The bolster is designed to be 'parked' inside the cylinder when the high preecontamination.
Bottom and top platens (10 &11) are made convex to produce a concave form of pellet, which relaxes to a virtually flat form on cessation of the compaction force. Wear has been reviewed by the original designers of this high force compactor and as a result, it is possible to change the bolster liner, the top and bottom platens and the hydraulic seals in the cylinder.
The overall sizes of this high force compactor are 1.53 meters width x 1.53 meters length and 3.3 meters height. The weight is 22,000 Kg.

THE TRANSPORTABLE SUPERCOMPACTOR

In considering supercompactor concept was, therefore, assumed to meet the following:

- that nothing short of total contamination control would be acceptable - the

compactor operation, together with the drum feeding and the puck discharge would be completedly enclosed within a primary containment envelope.
  the containment envelope would be provided, if possible, with a ventilation system designed to capture radioactive particulate released from the compacted drums.
  a means to be found to ease the difficulty of transferring contaminated pucks from the primary containment, without spreading airborne particulate to the exterior environment.
  suitable drainage system to be provided in the likely event that some drums will contain radioactive liquors.
The Primary Containment is arranged in the classical manner with the minimum of equipment installed inside the envelope and the maximum on the outside to reduce the problems of maintenance. It should be fabricated from stainless steel, polished on the interior surfaces for ease of decontamination.
The entry of drums into the Containment is via the Air Lock system and the exit of the compacted pucks is achieved using a double lid and overpack drum technique or the more traditional, cost effective bagging transfer. There is space around the Transfer Port to park 6 pucks, the height of each puck having been recorded by the Control System, to aid optimum filling of overpack drum or bag.
Roller conveyors, with their drive motors installed outside the Primary Containment, have been employed to provide the horizontal movement of the drums. Prior to entering the Compactor, the drum is pierced in 4 places, close to the bottom rim. The number and position of these holes has been carefully chosen to get optimum draining of any liquors in the drum and to prevent the drum bursting under the compaction load. The liquors draining from the drums are collected in a large capacity Sump, which is an integral part of the Containment and is emptied by a system of pump and centrifuge, to separate any oil from water.
Although the controller of the Supercompactor can see a limited degree of the operations through a small window, all of the processes within the Primary Containment can be viewed by means of a series of CCTV cameras relaying pictures to the Control Room monitor. The control of the High Force Compactor is an automatic function of the programmable system, all other operations being the responsibility of the controller. The control supervisor can override the automatic programme in an emergency, if required.
The various process steps in the Transportable Supercompactor system, and the extent of the Primary Containment envelope are indicated in Fig. 2.
The Hydraulic Power Pack for the compaction process and the filters and fans of the Active Ventilation system are all mounted at the rear of the Trailer in sound proofed enclosures. Suitable openings in the Trailer exterior weather covering enable the circular coarse and HEPA filters to be changed employing the traditional bagging technique. There is also a HEPA filter fitted to the inlet to the Ventilation system to prevent any back diffusion of radioactive particulate escaping from the Containment when the HFC is closed down overnight. All filters, being of circular form, can be disposed of in standard 200 liter drums, suitable for compaction in this Transportable Supercompactor.
The estimated overall weight of trailer and equipment was 38,000 Kg and using a standard 3 axle trailer configuration, pulled by a 3 axle tractor unit, it has been calculated that the trailer axle loadings would all be within European traffic regulations, as were the overall dimensions of the finished trailer.
An illustration of the Transportable Supercompactor arrangement is provided in Fig. 3

FULLY MOBILE SUPERCOMPACTION SYSTEM

The Transportable Supercompactor briefly described above was always going to need some support services from the sites being visited. The prime aim of investigating a Fully Mobile System was to review the possibility of transporting all of the services and equipment with the TSC and, if so, the complications of a totally self supporting unit.
Before commencing the investigation, it was necessary to establish a number of important factors, as shown below:

Number of reactor sites needing compaction services	:	10
Number of sites to be visited (Note 1)	:	5
Average number of 200 liter drums per site visited	:	573
Assumed throughput of compactor per hour	:	10
Average number of pucks per bag	:	4

Time required to pack 4 pucks per bag in minutes : 24
Bag production rate per hour : 2.5
Average number of pucks per 1/2 ISO container (Note 2) : 148
Average number of 1/2 ISO containers required per site visited : 4
Average time to fill 1/2 ISO container in hours : 14.8
Note 1 - It was assumed that it would be more cost effective to set up the Supercompaction service on a reactor site where there was a second site in close proximity, the second site transporting drummed waste to the set-up site. . The subsequent financing calculations took into account the cost of transporting the drums between sites.
Note 2 - The Low Level radioactive waste disposal regulations in the UK stipulate the use of 1/2 height ISO freight containers for the emplacement of compacted material in the Drigg repository. These containers are specially designed to be stacked when full of waste and cement grout, the grouting being undertaken at Drigg through dedicated holes provided in the container lid. The number of pucks assumed to be placed in the container is derived from having 4 rows of bags (4 pucks per bag) with 9 bags per row plus some 4 single bagged pucks filling the odd spaces, making 148 bagged pucks (drums) per 1/2 height ISO containers.
The first requirement of a self supporting system was a Building in which to carry out the compaction service. There are available on the market a number of portable buildings which are easily erected in a short time scale, with a minimum of manpower or auxiliary equipment requirements. Generally, these consist of a series of quickly erected portal frames covered with a reinforced pvc covering.
It was decided to use two different buildings, based upon manageable erection size, one to act as a Drum Buffer Store and the other as the 1/2 height ISO container Loading Building. The Buffer Store had a floor area of 47m2 with a ridge height of 4.4 m. The Loading Building had a floor area of 81m2 and a ridge height of 5.25 m. Both Buildings would be used side by side and in direct contact with each other through a curtain door.
It has been demonstrated that portable buildings of this size could be erected on a prepared hard standing by an experienced team of 4 people in under than two days. It is proposed that one side of the reinforced pvc covering of these Buildings are provided with openings which coincide with the service openings in the Transportable Supercompactor trailer. On the arrival of the TSC, the openings in the Building covering will be attached to the trailer by means of Velcro fastenings, making the complete assembly water and wind proof.
Another important requirement for a self supporting system is a radiological Change Room, particularly as the chosen location for the TSC might not be convenient to a site change room. For the same reason, a Messing Cabin was also provided. The Change Room provided would be in the form of a towable cabin, equipped with monitoring instruments, toilets, washbasins and shower. The toilets should be of the pumped/macerator type, the products of which would be automatically transferred into a dedicated, portable Bowser.
The potentially contaminated water arising from operator washing or showering would also be automatically pumped into a second dedicated, radioactive Bowser, which would also receive active water from the Sump below the High Force Compactor.
As the Drum Buffer Store and the container Loading Building would be classed as Secondary Containment, a classification which would be particularly necessary if, for example, a bag of pucks was accidently dropped and punctured, thus releasing some contamination into that Building, a small emergency type ventilation system is connected to the two portable Buildings and the Change Room. This portable, wheeled Air Mover is fitted with a fan and circular HEPA filter which can be changed using the bagging technique.
To permit the heavy 1/2 height ISO freight containers to enter the Loading Building, rails are installed inside and outside the Building. A portable, dedicated Crane is also assembled and placed on its own rails, straddling the container rails. As the utility being visited has a little used side loading truck, specifically designed to handle ISO freight containers, there was no call for this type of equipment to be included. The dedicated Crane could, if required, be modified to undertake the off-loading of 1/2 height ISO containers.
Once the container has been positioned on the external rails, it can be rolled into the Loading Building through the curtain door provided until it is located under the Crane, which, combined with a Tilting Lifting Frame, can be used to remove the

container lid and park it in the Lid Stillage provided. With the Roller Conveyor placed under the TSC puck Transfer Port and an empty bag sealed to the Port, the only item requiring connecting and starting is the diesel Generator to provide electrical energy to power the complete system.
The estimated convoy of vehicles likely to be required to transport the Fully Mobile Supercompaction System from site to site, would be:

Unit 1 - the Transportable Supercompactor
Unit 2 - a flat bed Truck towing the Change Room and carrying:
- 2 Portable Building Structures and pvc covering, accessories,etc.
- 1 Power Generator, cables and fuel
- 2 Bagging Stillages and Bags
- 1 Liquids Bowser
- 2 Roller Systems for 1/2 height ISO container

Unit 3 - a flat bed Truck towing the Messing Cabin and carrying:
- 1 Liquids Bowser
- 1 Electric Fork with Drum Grab
- 1 Crane rail, A frame, hoist unit and tracks
- 1 Container cover Lift and Tilt Frame
- 1 Working Platform (for erecting buildings)
- 1 Portable Air Mover

METHOD OF OPERATION
The operating team of four people would erect the complete system, as shown in Fig. 4, over a two day period, using the portable Crane, Fork Lift and Working Platform. The Transportable Supercompactor would be planned to arrive at the end of the second day and would be connected and tested before the compaction process commenced on day three. The same four personnel would also be responsible for operating the plant to compact drums and load bagged pucks into the ISO container. At the end of the campaign, the team would also dismantle the complete system.
To spread the radiation dose uptake, it is recommended that the operators regularly change stations to share the work load. The 4 work stations are:
1. Unload drums of solid LLW from the site transporter into the Buffer Store Building and the loading of drums on to the Supercompactor feed conveyor, all by means of the small Fork Lift provided.
2. Control room supervision, logging drum information into data bank and generally controlling the process via window and tv monitors, mimic diagram, etc
3. Bagging out of pucks in contamination free manner to a point on the output conveyor where they are ready for lifting into container.
4. Loading of bagged pucks, each of which can weigh up to 1 tonne, from the end of the conveyor to the ultimate position in the 1/2 height ISO container. The operator at this station, together with operator No 3 will also be responsible for changing the filled ISO container for an empty unit.
It has been estimated that the average dose uptake for each of the operators would amount to some 3.4 mSv per year, based upon compacting 3000 drums of typical waste in that year. This calculation indicates that a higher utilisation factor for the TSC of, say 8000 drums per year, would still allow the same team of 4 to operate the unit without exceeding the recommended target radiation dose uptake Fig. recommended by ICRP.
The safety review undertaken during this design study investigated, among a wide variety of subjects, the problems of decontaminating the System for transport on public roads. The Primary Containment meets the transport regulatory authorities requirements of preventing any radioactive material being released into the transport vehicle. It was, however, recommended that other precautions were observed to ensure radiological safety, i.e., that the Sump was completely evacuated of any liquids, by swabbing if necessary, until the surfaces were dry; any loose waste in the puck posting area was removed and transferred out in the final bag; a security hinged cover be fitted externally over the puck Transfer Port; and all suspect surfaces to be monitored and swabbed clean, if necessary, rather than washed down. After all those precautions had been observed and the site health physicist satisfied that the TSC was clean enough to issue the clearance certification, the unit should be free to leave the reactor site.
The complete layout of the Fully Mobile Supercompaction System is show in Fig. 4
COST
A careful analysis was used to establish the likely capital equipment costs involved

in building the Fully Mobile Supercompaction System.
The authors have then calculated the actual compaction cost per drum, based on depreciating the complete Mobile Supercompaction System over a 10 year period, compacting only 3000 drums per year and that 5 sites were visited and including in that calculation all operating costs of UK staff, consumable, transport from site to site, etc. With all of those factors taken into account, the actual cost for compacting Low Level Waste is in the order of 100 ($150) per drum. With better utilization of the System, a lower cost per drum would result. For example, if the throughput was raised to 5000 drums per year, the cost for the compaction operation reduces to around 77 ($116) per drum, even with the increased operating cost.

CONCLUSIONS

It is possible to design a Fully Mobile Supercompaction System which can be transported from site to site on two flat bed Trucks and the High Force Compactor Trailer. It also proved possible to assemble the System and have it operating in 3 days. The disassembly and radiological checking required to release the vehicle from a licensed site should also consume no more than three days.
It also proved feasible to be totally independent of any site services apart from a concrete hardstanding of 630 m2 with a capacity to accept axle loads of up to 10,000 Kg.

REBAR CORROSION DUE TO CARBONATION IN STRUCTURAL REINFORCED CONCRETES FOR NEAR-SURFACE LLW REPOSITORIES - A CRITICAL FAILURE MECHANISM

J. Torok
AECL Research
Chalk River Laboratories, Chalk River, Ontario, Canada.

ABSTRACT

The concrete roof of a near-surface radioactive waste repository is the principle protection against water infiltration and intrusion. The following potential roof failure mechanism is examined: Carbon dioxide generated by the biodegradation of organic materials in the repository initiates corrosion of reinforcing steel embedded in the concrete roof. Because the bottom surface of the roof is mostly under tension, it is susceptible to cracking. The migration path for carbon dioxide is through cracks in the concrete between the bottom of the roof and the reinforcing bars. Carbonate corrosion of the reinforcing bars may result in concrete spalling, more extensive rebar corrosion and ultimately structural failure. Attention is brought to this failure mechanism, because it has generally been overlooked in repository performance assessment.
Literature relevant to the above failure is reviewed. Prerequisites for rebar corrosion are the presence of carbon dioxide and oxygen in the repository gas, high relative humidity and through cracks in the concrete. High carbon dioxide concentrations and relative humidity are expected in the repository. The oxygen concentration in the repository is expected to be very low, and that is expected to minimize rebar corrosion rates. Cracks are likely to form in locations with high tensile stresses. Healing of the cracks could be a mitigating factor, but based on our analysis, it can not be relied on. To minimize the potential of this failure mechanism for the Intrusion Resistant Underground Structure (IRUS), Canada's proposed near-surface repository, the carbon dioxide will be absorbed from the repository gas by reactive, porous concrete placed between the waste and the roof.

INTRODUCTION

Reinforced concrete is the principle structural material of construction for most radioactive waste repositories sited in the vadose zone. A concrete roof acts both as an intrusion barrier and as an infiltration barrier. The natural degradation of this barrier material will ultimately lead to a loss of integrity and the infiltration of water into the repository.

The assessment of degradation processes of reinforced concrete has been the subject of significant R&D, with the objective to design durable structures and estimate the rate of degradation. Radioactive wastes placed in near-surface repositories require 300 to 500 years of isolation from the environment. During that time period the radionuclides such as 137Cs, 90Sr, and 3H, with half lives 30a decay to insignificant concentration levels.

The carbon steel reinforcing bars can be one of the weak links in the long-term stability of the concrete structure. As long as the steel is encapsulated in the concrete, the steel is in its passive state and hence its corrosion rate is very low. However, the ingress of corrosive agents, by diffusion through the concrete or through cracks, will result in accelerated corrosion of the reinforcing bars and the ultimate failure of the structure. The most important chemicals responsible for accelerated corrosion are chlorides and carbon dioxide. Carbon dioxide is generated in the repository by the biodegradation of organic waste material. Carbon dioxide reacts with the alkaline (mostly calcium hydroxide) components of concrete shifting the pH of the concrete pore water from the alkaline towards neutral, where carbon steel is in the active corrosion range.

Requirements for the retrievability of waste from near-surface repositories vary with jurisdiction. Where retrievability is not a requirement, the space between the waste packages is generally backfilled with porous concrete. The concrete backfill is reactive with the carbon dioxide and thus the repository pore gas is not expected to contain carbon dioxide. Where retrievability is a requirement, usually only small quantities of materials are present that are capable of absorbing the carbon dioxide generated by the decomposition of organic material. In those repositories, a high concentration of carbon dioxide can be present in the repository gas, and hence structural failure initiated by carbonate-induced rebar corrosion is a possibility. In this paper we examine the potential mechanisms that can lead to an early failure of the repository structure, review the literature, and its relevance to the expected environment, and suggest an approach for the removal of the carbon dioxide generated in that repository to reduce the potential of rebar failure.

POSTULATED MECHANISM FOR REBAR FAILURE

The prerequisites for rebar corrosion are the migration of chloride and/or carbonate to the rebar, the migration of oxygen to the rebar and the presence of moisture on the rebar surface. Papadakis et. al. (1) examined the parameters that determine the rate of carbonation of concrete. They found that the rate of carbonation is highly dependent on the relative humidity (RH) of the environment the concrete is placed in. Carbon dioxide can migrate to the concrete through the gas phase, or as carbonate through the liquid phase. In dry environments, most of the pores in the concrete are filled with air. Since the rate of the gas phase diffusion is about four orders of magnitude higher than liquid phase diffusion, the carbonation reaction proceeds fastest in low RH environments. Experimental results (1) indicate that the carbonation rates are asymptotic to zero at 100% relative humidity. The RH of repositories placed in humid climates is expected to be very close to, or equal to 100%. In such an environment the migration rate of the carbonate front to the rebar is negligibly slow, and the repository concrete structure is not expected to absorb a significant portion of the carbon dioxide generated in the vault. In arid climates the carbonation of the concrete is of no concern for rebar corrosion, since the rebar is expected to be dry, and hence corrosion rates will be negligible.

Another, but more important route for carbon dioxide penetration to the rebar is by gas-phase diffusion through the fractures in the concrete, when the fractures are dry or only partially filled with water. Fracturing of the concrete takes place in regions where the structure is under tension. When the concrete structure is subjected to design loads, mostly micro cracks are formed. Through cracks, that lead from the surface, through the concrete cover, to the rebar, can also develop in the structure. They can be conduits for carbon dioxide and oxygen diffusion from the repository or the outside soil pore gas to the rebar. There are two factors that can mitigate rebar corrosion: the expected low oxygen concentration in repository pore gas, and the potential for the healing of the cracks in concrete. The examination of both of these factors follow.

The oxygen concentration in soil pore gas, outside the repository, is not much lower than in air. This gas can penetrate the repository mostly by atmospheric pumping, driven by atmospheric pressure changes. While most of this will take place through the bottom of the repository, such as the drain line leading to the sump, some may

occur at joints in the concrete. In the repository, oxygen is scavenged by steel corrosion and the aerobic degradation of organic matter. However, the presence of oxygen inside the repository in regions where air ingress takes place can not be ruled out.

The healing of fractured concrete has been widely observed, and has been the subject of several investigations. Guppy (2) noted that only a limited amount of experimental and archival work is available on crack healing. The mechanism of crack healing is not well understood, but the most likely process responsible is calcite formation under wet or high humidity conditions. Investigators found no evidence of amorphous material, such as CSH gel formation in the cracks. The following components are required for crack healing:

- flooded or high humidity;
- supply of carbonate or carbon dioxide;
- and a supply of portlandite.

Portlandite ($Ca(OH)_2$) in cement is produced by the hydration of Ordinary Portland Cement (OPC). In the newer, blended cements generally used for repository construction, a portion of the OPC is replaced by Blast Furnace Slag (BFS) and/or Pulverized Fly Ash (PFA), resulting in reduced portlandite production that is partly due to the reduced OPC content, and partly due to the pozzolanic reaction between portlandite and BFS/PFA. We were unable to locate literature on the crack-healing properties of these advanced cement compositions.

The carbon dioxide concentration in air is approximately 0.03 vol%. Most of the experience in crack healing is with air containing ambient carbon dioxide concentrations, or water in equilibrium with ambient air. The carbon dioxide concentration in the repository gas is expected to be at least several percent, which is two to three orders of magnitude higher than ambient.

For crack healing to take place, calcite must form within the crack. For this, the carbon dioxide (or carbonate) supply to the crack controls the reaction rate. Under those circumstances, there is ample supply of portlandite in the concrete pore water adjacent to the crack. When there is a large concentration of carbonate ion in the pore, and limited portlandite supply, calcite formation in the cement matrix, rather than in the crack is favored. The carbonation front advances into the concrete structure. This does not lead to crack healing. Brodersen et al. (3) assessed crack healing in flooded conditions, and advanced a similar argument to explain why cracks only heal for a short time after their formation. Thus the concrete used for repository construction and the repository environment are different in at least two aspects from those associated with in current field experience, and both differences disfavor crack healing. There is a need for research in crack healing, where both the repository-concrete and repository-environment are simulated.

LOCATION AND CONSEQUENCES OF REBAR FAILURE

The physical integrity of the repository concrete roof is essential for both infiltration and intrusion prevention. The function of the walls are less critical, their primary role is to provide a stable support to the roof. Only extensive deterioration of the walls will compromise the integrity of the roof. Tensile stresses are expected to be highest in the roof, since it has to carry its own weight, the weight of the water sheading layers and the soil cover. Thus premature roof failure has been the focus of our analysis for the IRUS (Intrusion Resistant Underground Structure) planned for the Chalk River Site. While we expect to have significant quantities of chloride ions present in the repository pore water, the chloride initiated corrosion of the rebars in the roof is not considered to be an issue. The repository roof will be supported by the walls, but it will be poured over repository contents covered by sand and porous concrete. With time the contents of the repository are expected to subside, creating an empty space between the waste and the roof, that will form a diffusion barrier for the salts leached from the waste. Our concern with carbonate induced rebar corrosion is due to the following factors:

The formation of cracks in the roof and the ingress of carbon dioxide into the cracks can start soon after the repository roof is poured.

Once corrosion is initiated, the deterioration of the structure is a progressive process. As corrosion proceeds, the expansion of the corrosion film can apply pressure on the concrete surrounding it, resulting in the widening of the fracture, and the eventual spalling of the concrete cover (4). This process than exposes more rebar surface area to the corrosive environment.

PREVENTATIVE MEASURES.

While the projected low oxygen concentrations in the repository provide some assurance of low corrosion rates of rebars exposed to a high carbonate environment, an additional preventative design feature was deemed desirable. A layer of porous concrete with a high surface area will be placed between the waste and the repository roof. The portlandite and other basic components of the porous concrete will react with and hence remove the carbon dioxide generated in the waste, and thus minimize the carbon dioxide concentration at the inner surface of the roof. The composition of the porous concrete has not been finalized yet, but it will have sufficient capacity to remove carbon dioxide generated during the first 500 years following repository closure.

SAFETY EVALUATION FOR THE CS-137 ILW IN REPOSITORY OF ABADIA DE GOIS, BRAZIL

Barbara Oliveira dos Santos
Erivaldo Mario dos Passos
Antnio Srgio De Martin Alves
NUCLEN - Engenharia e Servios S/A

ABSTRACT

A shallow ground intermediate level waste repository is being designed for the final disposal of the radioactive wastes which resulted from the Goinia accident. Its site has already been selected and approved by the regulatory authorities. It lies in Abadia de Gois in the outskirts of the city of Goinia. A brief description of the repository is given and a simple but otherwise conservative safety analysis is presented. This analysis consisted in the evaluation of the effective dose arising from the use of water from a hypothetic well located at various distances from the edge of the repository building along the direction of the groundwater flow. The source term has been evaluated on the basis of a sudden disruption of the building right after construction assuming that all the activity present at that time reaches without delay the water table. The dose limit of 0.25 mSv/y set by the authorities is reached if the well is located 5.5 m away from the building edge at a time equal 768 years after the repository disruption.

INTRODUCTION

In September 1987 a shielded strongly radioactive Cs-137 source was removed from its protective housing, in a teletherapy machine in an abandoned clinic in Goinia, in the Brazilian state of Gois. The source capsule was subsequently ruptured, and the remnants of the source assembly were sold as scrap to a junkyard owner, who noticed that it glowed blue in the dark. Over a period of days friends and relatives came to see the fascinating phenomenon. Small fragments of the source ended up in the homes of several families and some were dispersed to places throughout the city. By the time the accident was discovered and counter-measures were initiated, many people had incurred doses of radiation and many residences and public places were contaminated. Four persons ultimately died and 28 people suffered severe radiation burns. The decontamination and clean up activities resulted in a total of 3500 cubic meters of radioactive wastes which were accommodated in over 5000 packages of various types and activity concentrations. These packages have been temporarily stored in the open on concrete platforms built for this purpose at a site near the village of Abadia de Gois, about 23 Km from the center of Goinia (1).
Subsequently the Brazilian authorities, namely, Comisso Nacional de Energia Nuclear (CNEN), determined the site-selection procedures for the final disposal of the radioactive wastes from Goinia. In all 189 preliminary areas within the state of

Gois were identified and evaluated and from these, three candidate sites were chosen and presented to the state government for the final site selection. It was then jointly decided with CNEN to start the environmental impact assessment in the area nearest the temporary storage site. The selected site will house two different repositories. The first one will receive the packages whose activity concentration is lower than 87 Bq/g, which is the exemption limit, and the other one which will receive the 1078 packages with activity concentrations higher than that value and which will be dealt with in this paper.
A brief description of the repository is given and then a simple but otherwise conservative safety evaluation is presented.

DESIGN FEATURES

The repository design, for the final disposal of low- and intermediate-level radioactive waste makes use of a multiple barrier concept, in which the release of radioactive material to the environment is avoided by a succession of barriers, called engineered barriers. It consists of a reinforced concrete structure which is to be constructed in an excavation in the unsaturated soil and covered with seven different layers. The concrete building has external dimensions of 65.20m x 20.50m x 5.85m, and is situated in the center of a 300m x 300m terrain. The concrete structure is partitioned in three blocks each one with a different height. Within the concrete building 1078 packages will be deposited totaling a volume of 3200 m3 (2). The spaces inbetween packages and between the packages and the concrete building will be filled with a buffer material, reducing the voids to a minimum. The compacted buffer material (of low hydraulic conductivity) is composed of sand plus a minimum of 5% clay.
The external top layers are constituted by different materials with main function of impermeabilization (avoid and reduce a water infiltration), drainage and filtration, as indicated in Fig.1. The minimum distance between the top of the repository and the soil surface is 1.60 m. The inclination of the top layers will permit the runoff of the water in direction of the side region beyond the structure, conducting this water to the aquifer.
The engineered barriers like the steel/concrete barrels, the concrete containers, the buffer material and the repository concrete structure will retard the migration of activity for a long period of time when its level can be considered relatively high.
A fence around the repository, permanently inspected in order to guarantee its integrity by the local security service, has the purpose of avoiding intrusion.
The design and construction of the repository, including the transportation and the handling of the radioactive wastes, are conceived to be performed so that the Cs-137 release is of negligible level. The main planned measures to minimization of leakage possibility, during the transportation and handling of the packages are: maximum shortening of transportation route of the packages; utilization of safe equipments and vehicles; special conditions of protection during package handling, if necessary utilization of impermeable plastic cover; and operation supervision under safety and radiologic control, in strict accordance with a Radioprotection Plan.

SAFETY ANALYSIS

Preliminary safety analyses have indicated that the most important dose pathway to members of the public would be the use, for whatever purpose, of contaminated groundwater around the repository site. Thus the following scenario was selected for the safety evaluation: groundwater contamination, transport of radioactivity to a well along the direction of the groundwater flow and use of the well water for various purposes. The concentration of Cs-137 in repository, soil and biosphere is estimated by analytical methods, with help of parameters and input data resulting from laboratory measurements and field tests.

Source Term

It has been deterministically assumed that the groundwater below the repository building got contaminated in such a way that its activity concentration became equal to that, that would result from the dilution of the whole amount of caesium chloride (total activity 4.580E+13 Bq) present in the repository in a volume of water corresponding to the void volume of all the waste packages. This conservative assumption neglects the retention of caesium in the waste material, by the packages structure, by the repository itself and in the unsaturated soil layer above the water table.

Transport of Activity

The Darcy's Law for porous medium was employed, which allows determination of the average velocity of the groundwater. The representative parameters of groundwater movement (velocity, flow rate and direction) were determined based in properties of the local soil/aquifer and water table variations. The fundamental flow parameter (average pore water velocity or seepage velocity) was evaluated according to (3). The radionuclide migration velocity will be significantly lower than that of the groundwater, due to the sorption phenomena that takes place in the soil. It must be remarked that along the aquifer path, only a fraction of the radionuclide amount that leaked from repository will be present in the water, while the remaining part will be absorbed by the soil. This retardation mechanism prevents that a high concentration of activity can reach the water of an hypothetical well. The average velocity of a Cs-137 ion through a porous medium can be connected with the movement of ground water by the following equation:
See Eq. 1
where: Vr = average velocity of Cs-137 radionuclide; Va = average velocity (average pore water velocity) of the groundwater, whose value is 6.0 m/year for the terrain. The retardation factor, F, is a term that condensates the several retardation mechanisms of physical-chemical nature, expressed by:
$$Fr = (1 + r.e.Kd) \qquad (2)$$
where: e = number of porosity = (1-f)/f (4) and (5); r = density of the solid phase = 1.715 g/cm3; Kd = distribution coefficient. All the parameters contained in the retardation factor resulted from measurements and are characteristic of specific repository site. The distribution coefficient, Kd, is the most important parameter that constitutes the retardation term. The distribution coefficient represents the ratio of the concentration of the radionuclide sorbed on the soil and the concentration of the same radionuclide in the ground water (4,5). The employed value of the distribution coefficient was obtained from measurements performed by the "Instituto de Radioproteo e Dosimetria (IRD)" for a total of 32 samples of the soil of the local of the repository. The recomended value for the Kd is of 430 cm3/g (average value).
The radionuclide concentration along the aquifer path (distance X), neglecting the effects of convection and diffusion, can be determined by following equation (5):
See Eq. 3
where, C = Cs-137 concentration along the X-axis; C0 = 1.434E+08 Bq/l = Cs-137 concentration at t=X=0; l = 0.0231 year-1 = constant of radioactive decay of the Cs-137. The time necessary for the Cs-137 radioisotope to move through a distance X from a release point, called migration time, t,can be determinated by the following equation:
See Eq. 4
The calculation results are presented in Table I (columns 2 and 3), that contain the calculated activity concentration of Cs-137 in groundwater and the migration time, for various distances along the groundwater flow direction from the repository building edge.
Dose Evaluation
The analysis is based on the evaluation of the dose due to the use of water from a well hypothetically situated at the site of the repository. The radiation dose rate was estimated for a person that would belong to the critical group, considering the following dose pathways:
1) drinking water;
2) milk (water - cow - milk - man (ingestion));
3) meat (water - cattle - meat - man (ingestion));
4) milk (water - pasture - cow - milk - man (ingestion));
5) meat (water - pasture - cattle - meat - man (ingestion));
6) vegetables (water - soil - vegetable - man (ingestion)).
The ingestion dose rate, D, can be determined by the following equation:
See Eq. 5
where, Fc = 1.4E-08 Sv/Bq = Dose factor for internal exposure via ingestion of Cs-137; Ai = Activity of Cs-137 incorporated annually, Bq/y, and the index i, varying from 1 to 6, represents each one of the previously cited dose pathways. The activity incorporated annually, Ai, was estimated by using the equations and parameters recommended by (6).
Calculated values of dose rate (Sv/year) for several migration distances from the repository site, are presented in Fig. 2.

CONCLUSIONS

With help of the Table I and Fig.2, it is possible to estimate the annual dose due to the use of the water of a well in the repository terrain, as function of the distance repository-well. It must be pointed out here that the minimum distance from repository edge to fence is about 150 m.

In Table II one can find the main results in a condensed form. It can be observed that the Maximum Permissible Dose Rate established by the Brazilian regulatory authorities (0.25 mSv/y) (7,8), is reached when the Cs-137 concentration in the well water corresponds to 2.8E+03 Bq/m3. In this case, the migration time is 768 years and the well is situated at a distance of 5.5 meters from the repository structure edge.

It can be concluded that the resulting effective dose will be lower than the legal limit established by the Brazilian regulatory authorities, if the well is located more than 5.5m away from the repository edge in the direction of the ground water flow

This simplified, but conservative model used in this analysis gives a good indication of the minimum distance around the repository where the use of local ground water will not lead to the incurrence of doses above the established limit (7).

The resulting time span, as presented in Table II, is long for all practical purposes to be used as the period of institutional control. A more precise evaluation of the period of institutional control requires the use of a more realistic model, that considers the migration through several engineered barries, taking in account others processes (leaching, dissolution, diffusion, etc).

Work is been developed presently in Brazil for detailed modeling of the processes of Cs-137 migration in repository and adjacent soil, by considering saturated and unsaturated flow.

NATIONAL EXPERIENCE IN COLLECTION AND STORAGE OF UNCONDITIONED RADIOACTIVE WASTE IN GHANA

H.O. Boadu
E.O. Darko
I.K. Wilson
National Nuclear Research Institute
Ghana Atomic Energy Commission
P.O. Box 80, Legon, Accra.

ABSTRACT

Radoiactive materials have been used in Ghana for more than three decades. The areas of application include agriculture, hydrology, medicine, research, industry and environmental studies. They also find applications in well logging, thickness gauging, radiography, radiotherapy and as well as calibration standards. From all these uses, radioactive wastes produced that must be managed safely and efficiently. Presently the waste management program in the country is handled

by the Radiation Protection Unit. Liquid, solid and mixed radioactive wastes are collected separately. Ghana has no treatment and conditioning facilities at the moment, however, there are plans to acquire the necessary facilities to immobilize the sealed sources in concrete matrix using 200l drums.

INTRODUCTION

The management of radioactive waste in Ghana is the responsibility of the Ghana Atomic Energy Commission. The Commission operates the National Nuclear Research Institute, NNRI, which through its Radiation Protection Unit, RPU, keeps records of all radioactive sources in the country. The Commission was established by an Act of Parliament in 1963 but the necessary legislative instrument which would enable the Commission perform its regulatory functions was not passed until January 5, 1993.

The law has not been published in the official gazette but it is known that it establishes a Radiation Protection Board under the Atomic Energy Commission. The Board is the licensing authority in Ghana for the issuance of licenses required for the purpose of radiation protection. A waste management committee, set up at NNRI, has now acquired the legal support to carry out its duties. Current waste management practices have been confined mainly to collection and storage of waste in a temporary facility controlled by the RPU.

Sources of Radioactive Waste in Ghana

The main producers of radioactive waste in Ghana are NNRI, the universities, the nuclear medicine unit and to a smaller extent the industry. At the NNRI, the main type of waste is that which arise from beta-scintillation counting; they are organic liquid waste. The waste from research activities in the universities is basically of the same type.

The activity concentrations range from few bequerels to hundreds of mega-bequerels or more. The composition of the wastes range from contaminated items such as paper, vials, filters, plastics, gloves and glassware to liquid effluents, carcasses and sealed sources. The radionuclides composition include C-14, Cs-137, Am-241, H-3, S-35, P-32, I-125, Tc-99m, etc. Another source of potential waste is the use of some gas chromatographs with electron capture detectors. One such chromatograph recently received in the Chemistry Department at NNRI employs 10mCi of Ni-63 as the source of electrons from the detector system; nickel-63 is a 100-year half-life beta emitter.

The NNRI, together with the University of Ghana, operates a Nuclear Medicine Unit at the teaching hospital. From this unit there arise two main types of wastes, i.e. solid and liquid wastes. The solid waste is the aggregate of expired technetium-99m generators. These are imported into the country at the rate of one a month and upon expiration are stored at the storage facility at NNRI. Eventually we plan to dismember the generators and remove the lead housing and thereby reduce the volume of waste significantly. The other type of waste generated from the Unit is that from radioimmunoassay, RIA, procedures. These are liquid wastes containing very low activities of iodine-125. RIA procedures are also conducted at the rate of about once a month.

There is a 30kW research reactor in the Department of Nuclear Engineering of Chinese design and a Co-60 source (7.5kCi, 1975) for food irradiation research. The operation of the research reactor will result in the generation of the following waste: spent ion exchange resins from water purification (cation and anion, volume of resins in columns is about 50l), compatible solid waste from mechanical filters, non-compatible solid waste such as ion-exchange resins and liquid waste aqueous and organic. It is anticipated that about two 55 gallons waste drums will be needed per year for the research reactor.

There is a reduced utilization of radioactive sources in industry compared to NNRI. Their sources are either sealed beta-sources used to measure thicknesses of materials, or those which have been imported into the country by oil companies for exploration. The latter are returned to the places of origin when the exploration work is over and the RPU keeps a record of all such sources. Another feature of our documentation process is the cooperation of RPU with the Customs Excise and Preventive Services, CEPS. In this regard the CEPS instructs all importers to obtain clearance from the Commission prior to actual importation. In this way the RPU knows

which sources are imported into the country and who is responsible for them. There is a radiotherapy unit at the School for Medical Sciences in Kumasi which uses Ra-226 needles in brachytherapy. The radiation safety aspect of its operation is under the Radiation Protection Unit of NNRI.

WASTE PROCESSING AND STORAGE TECHNIQUES

There is no treatment of radioactive waste in Ghana apart from storage for decay.

Collection and Storage of Liquid Wastes

Liquid wastes which are mainly produced from the hospitals and research centers are made up of mainly liquid effluents containing scintillation materials used to measure
C-14, H-3, I-131, Tc-99m and I-125 from nuclear medicine. For volumes of waste below exemption level, discharge into the sewage system is recommended after decay and dilution with sufficiently large volume of water and with the approval of the Radiation Protection Board. For volumes of liquid wastes which are not suitable for discharge into the sewage system, plastic or glass bottles are used. These are provided with appropriate labels bearing the name of the person or institute, type of radionuclide(s), activity, date of storage and source identity. They are then kept in a store room meant for radioactive wastes for subsequent disposal. Glass bottles are used for the organic wastes which contain mostly scintillation materials and plastic bottles for inorganic wastes. For relatively high activity wastes, the glass or plastic bottles are kept in lead or concrete shielding.

Establishments which find it difficult to manage their wastes are advised to send them to the NNRI after preparing the wastes in accordance with requirements. In this case, the person or establishment generating the waste notify the NNRI. The necessary transport arrangements to collect the wastes from the premises are made. The transportation is usually provided by the sender, but where necessary the institute finds its own means of transport.

Collection and Storage of Solid Waste

In order to facilitate subsequent handling and storage, the waste producers are advised to segregate the combustible wastes from the non-combustible wastes. The combustible wastes are made up of mainly contaminated vials, tissues, paper, filters,
plastics and carcasses from animals used for experiments. The non-combustible wastes compose of sealed sources, glassware and contaminated metallic scraps.

For wastes which can be handled by the individual, advice is sought from the NNRI. Wastes with half lives less than one year are advised to be stored for at least five half lives to reduce the activity below exemption. All sealed sources are however asked to be sent to NNRI. Wastes below the exemption level are advised to be disposed off onto the landfill. The combustible wastes below exemption can be incinerated in an incinerator meant for domestic wastes and the ashes treated as solid wastes which can be dumped onto the landfill. In the hospitals, the wastes are incinerated with other toxic chemicals after decay. For wastes which cannot be handled by the individual, it is recommended that they should be sent to the suppliers if there exist a contract agreement between the two parties (in the case of sealed sources). If there is no such an agreement the NNRI is notified, and the necessary arrangements made to collect the wastes. The combustible wastes are normally packaged in plastic bags and the sealed sources in lead containers.All types of sealed sources are exempted from ordinary disposal.

At the NNRI, treatment and conditioning facilities are not available at the moment apart from interim storage. there are however, plans to acquire the necessary facilities to immobilize the sealed sources in concrete matrix 200l drums.

STORAGE FACILITIES

The storage room currently in use consists of a concrete building with room size 5mX3m. This is located about 30 meters from the Chemistry department building. It is provided with a lock and a radiation warning sign.

A second storage facility was constructed in the early sixties for the storage of spent fuel and interim storage of other wastes from an anticipated 2Mw research reactor which was never built. The facility is presently not in use. This facility will require rehabilitation and safety and performance assessment. When completed, it can be used as a disposal site for spent sources and wastes from the 30Kw research reactor which has just been commissioned.

RADIATION SOURCES REGISTRY

The unit has developed a computerized database package to identify, monitor and

control of spent radiation source in Ghana. The database allows on-line queries by source name, characteristic, activity and location etc., and supplies status reports on any source in the country. The package creates, updates, sorts and organizes data and generates various reports.

CONCLUSION

In conclusion, one can say that the radioactive waste management is in its infancy in Ghana. With the promulgation of the Radiation Protection Law we are ready to carry out our duties to safeguard and protect people and the environment from the possible dangers associated with the use of radioactivity.

TREATMENT OF IODINE-125 EFFLUENTS BY COLUMN METHOD USING MALAYSIAN LATERITE SOIL

Syed Hakimi Sakuma
Malaysian Institute for Nuclear Technology Research (MINT)
Bangi, 43000 Kajang, Malaysia

ABSTRACT

Soil column experiments were conducted to treat effluent wastes containing 125I by using four different samples of laterite clay materials commonly found in the local environment. XRD and XRF analyses showed that kaolinite, illites, aluminum hydroxides and iron oxide (geothite, a-FeOOH) were the major components of the soils. Iron oxide content was high and responsible for the yellowish-brown or reddish color of the laterite clays. Batch experiments using kaolin were conducted from pH 3.0 to 9 using spiked solution of 125I to determine the optimum pH condition for treatment. pH range from 4.5 to 5.0 were the determined values for removal of the 125I in the effluent where kaolin exhibited net positive charge and attracted the 125I anions. Soil column experiments using effluent wastes from hospitals, adjusted to pH 4.5 showed that about 87 % of 125I radioactivity was removed after treatment. At the moderately acid soil condition, pH between 4.5 to 6.5, positive charges predominated on the kaolinite, geothite and aluminum hydroxides. The negative 125I anions were electrostatically held by the positive charges on the mineral components of the laterite clay materials. Environmental parameters, C.O.D and pH values were within the local environmental quality criteria's values required. The treated effluents released to the environment will undergo further dilution, decay and will not harm the environment. This work shows treatment process by soil column provides another alternative for present and future producers of 125I effluent wastes to treat their wastes at their premises.

INTRODUCTION

Iodine-125 radioisotope is routinely used in clinics, hospitals and research institutes for blood cell screening of hospital patients and blood donors. Radioactive effluent wastes if not managed properly have the potential to contaminate the local environment. Even though the 125I radioactivity content is not high, it can pose negative effects on the environment. The radionuclide has toxic properties and a half-life of 59.7 days (1).

Choice of Soil Samples

Many soil do not exhibit significant ion-exchange absorption of iodine (2-4). Soil material samples in the presence of kaolinite, gibbsite and geothite with low net negative charge gives low positive charges between 2 - 5 cmol/kg depending on the soil pH (5). For soil with pH value between 4.0 and 6.5, the net overall charge for the soil is positive (5). The formation of the positive charges enables the negative anion 125I from effluent wastes to be attracted to the soil. The process lowered the aqueous effluent radioactivity. The charge characteristics of selected soil colloids are shown in Table I (5).

Laterite soil samples collected from four different locations in Malaysia were used in the experiments. Laterite is a residual ferruginous material in the soil and frequently exists in the form of lateritic pellets or nodules; locally it has developed into true laterite. The samples have different colors and composition contents of clay minerals and minerals. The minerals have a pH dependent charge characteristic. The reddish brown and yellowish color of laterite soil samples shows high composition content of iron oxide. In the literature, it was reported that the soils have texture and composition that vary. Normally a matrix of finely granular gibbsite containing different proportions of limonite, hematite, chamosite, and kaolinite that forms the actual ores (6). There are also soils which have low-grade iron-rich bauxite (or aluminum laterite) (6). Specific adsorption of anions and

cations by iron oxides at different pH equilibrium solution was reported in the literature (7). Literature reviews on the sorption of iodine radioisotopes by various minerals can be obtained from (8-9)
The choice of the soil material are due to its acidity where the soil samples were collected, presence of kaolinite clay minerals, aluminum hydroxides and high content of iron oxides. The minerals have variable (pH - dependent) negative charges and exhibits modest positive charges at low pH values and produced overall net positive charge. The positive charges can attract the anions of 125I from the effluent and eventually being released to the environment satisfying the local environment regulations. The laterite soil is easily available in Malaysia and its characteristic properties can lead to an effective effluent treatment by the column method.

Objective of Experiment

The objective of this study is to treat aqueous effluent wastes containing 125I by using soil column techniques using laterite soils. This can provide another alternative to treat effluent wastes containing 125I radioisotope. The wastes are currently generated from clinics, hospitals and research institutes in Malaysia. This was accomplished by : (1) Batch experiment using kaolin clay minerals to determine the optimum pH values suitable for optimum removal of the 125I radioisotope. This is to identify the required optimum pH values that are suitable for the conditioning of the laterite soil columns (2) Proper preparation and conditioning of the soil columns at the required experimental conditions (3) Four different soil column treatment experiments conducted simultaneously with the same experimental conditions and duration.

EXPERIMENTAL PROCEDURES

In the soil column experiments, aqueous effluent wastes containing 125I radioisotope was directly obtained from a local hospital. In the batch experiment, 125I in the form of NaI in sodium solution from Amersham International was used. High Resolution Hyper Pure Germanium Coaxial Detector was used to resolve gamma ray of 35.5 keV energy emitted from the 125I radioisotopes (1). High spiked 125I effluent activity was used in the batch experiments while in column experiments the effluent wastes activity was slightly higher than the wastes normally received from users. The aim is to produce 125I spectrum peak with the gamma spectroscopy method.
The batch experiment was conducted using kaolin clay minerals obtained from Source Clay Minerals Repository, Geological Science Department, University of Missouri-Columbia.(10). Ten stock solutions of 100 ml spiked with 125I were prepared between pH 3 to pH 9. Dilute NaOH or HCl was used to adjust the stock solution pH. The kaolin clay minerals were weighed precisely 1.00.001 gm. Twenty ml of each stock solution were added into a 50 ml polycarbonate centrifuge tube and equilibrated for 14 days at room temperature. The tubes were then centrifuged at 4000 R.P.M. for one hour and the final pH values of the solutions were measured. Two ml from each solution were collected with a 0.2 mm disposable filter, acidified by adding 10 ml of concentrated hydrochloric acid or nitric acid (6M or 12M) and then analyzed for 125I gamma. The solid materials were removed from each tube by filtering through a 0.2 mm filter, then allowed to dry. The solid materials were transferred to counting tubes for gamma analysis.
In the column experiment, laterite soils with different composition contents were used which were collected from 4 locations in Malaysia. Each soil type was send for XRD and XRF analyses to identify the types of clay and mineral present. The soils were air dried, filtered by filters (size 0.250-0.350 mm) and then mixed with sand (0.250 mm) with ratio of 3 to 1, respectively. The sand was used to enable the column to be porous in order to allow the aqueous effluent to pass through the soil column. Each mixture soil was packed every 2 cm thick into a polyethylene tube (5.0 cm diameter, 12.0 cm height) and then compacted uniformly. The tube was filled up to 90 % full. The four laterite soil columns were prepared with the same method and dimensions. Prior to the actual experiment, preequilibrated distilled water of pH 4.5 was run into the carefully saturated packed columns for 3 days. The conditioning of the soil column will enable the soil at the required pH 4.5 and maximum contact between solution and the soil. The experimental schematic diagram is shown in Fig. 1.

Fig. 1. Experimental schematic of diagram of soil column.

Twenty-five liters of untreated aqueous effluent wastes was stirred for 24 hours after being conditioned to pH 4.5. For each column experiment, three liters of the

wastes were used and poured into a holding container and allowed to pass through the saturated soil column at a constant rate for 4 days. The four experiments were conducted simultaneously but using different apparatus. The treated effluents were collected at few hours intervals by using a fractional collector at the bottom of the column into ten ml test tubes. The 10 ml treated samples were transferred to 20 ml counting vials, acidified by adding 10 ml of concentrated hydrochloric acid and then analyzed for 125I gamma. Handling of treated samples were carefully performed to prevent contamination in order to minimize error.

Counting Procedures and Data Processing

Prior to counting of samples, aliquots of a standard 125I solutions were counted. Samples' activities (corrected for background) were calculated from the 125I standard count rate and activity. In batch experiments, solid sample's activities were calculated from count rate and activity of standard solution mixed uniformly with the same solid material. All the standard 125I aliquots, solution and solid samples were collected at the bottom of the counting vials of the same geometry. In the column experiments, solution samples were only analyzed for 125I gamma before and after treatment in 20 ml counting vials. Counting was conducted the same day to minimize error due to decay of the 125I. Therefore, no correction for radioactive decay of the 125I radionuclide was included.

Decontamination factor value was calculated by:

$$\text{Decontamination Factor (DF)} = \frac{\text{Counts in Effluent before Treatment (cps)}}{\text{Counts in Effluent after Treatment (cps)}} \quad (1)$$

where, cps = counts per second

Decontamination factor was determined at each time collection of the treated samples. The average DF value for each column experiment was used as index comparison of the efficiency of treatment of each laterite soil used in the treatment.

The distribution coefficient Kd was calculated by :

$$Kd = \frac{\text{Activity of solid samples (KBq/gm)}}{\text{Activity of effluent samples (KBq/ml)}} \quad (2)$$

RESULTS AND DISCUSSION

Batch experiment

Table II summarizes the results of the batch experiments. Figure 2 shows a plotted comparison graphs effluent activity versus initial and final effluent pH before and after equilibrium, respectively. The initial effluent pH at low pH and high pH, increased and decreased, respectively, after the equilibration period. At low effluent pH values between 3.37 to 5.60, the effluent activity values were smaller than effluent activity values at high pH between 5.77 to 6.45. Figure 3 shows a plotted graph of distribution coefficient Kd versus final effluent pH. Between pH 4.5 to 5, the distribution coefficient Kd values are larger than at pH between 6.18 to 6.45. When the soils become more acidic, protonation-the attachment of H+ ions to the surface OH groups take's place. The reaction for kaolin clay mineral can be shown simply as:

Eq. (3)

At moderate acid soil conditions pH 4.5 to 5.0, the kaolin clay minerals exhibited positive charges. This caused the 125I anions to be attracted to the kaolin clay minerals, causing high Kd values.

Column Experiment

Figure 4 shows a plotted graph comparison effluent counts of 125 after treatment by the four laterite soils. From XRD and XRF analyses' results, the four laterite soils showed presence of kaolinite and illite clay minerals; and high percentage of iron oxide minerals such as geothite. From (5, 7, 11), kaolinite is one of the most widespread clay minerals in soils and is abundant in soils of warm moist climates in the equatorial belts such as conditions in Malaysia.

Table III shows the results obtained from the four column experiments conducted. Initial counts for untreated effluent were between 0.46 cps to 0.64 cps. The pH values of the untreated effluent wastes were 4.3. The average decontamination factor values were 90, 98, 33, 99 for samples A, B, C and D, respectively. Sample A, B and D showed to have the highest average DF values, where the treated effluent average counts have decreased to between 0.07 cps and 0.09 cps after 100 hour's treatment. Data showed that removal of 125I from effluent wastes by samples A, B, D was 88 %,

86 % and 86%, respectively. From Fig. 4, efficiency treatments were very effective before the 10 hour's treatment period, however as the treatment period increases, the counts of the treated samples became constant at about 0.13 cps. There were no large differences in the counts from treated effluent collected between 10.00 hours to 100 hours treatment period. The three liter effluent wastes were completely treated after about 100 hour's period and the treated effluent count were maintained at about 0.13 cps for the four columns. For treated effluent collected, the pH values have varied to 5.5, 6.2, 6.4, 6.3 for samples A, B, C, and D, respectively. Table IV shows the comparison of environmental quality criteria values for domestic effluent and the treated effluent environmental quality parameters after treatment by the four laterite columns. The pH treated effluent 6.2, 6.4, 6.3 by sample B, C and D were according to the requirements of the local environmental regulations. Determined C.O.D. values by column A, B, and D produce 36, 32 and 48, respectively, also attained local environmental regulations. However, the total solid values after treatment by the four columns were slightly above the regulation value of 1500 mg/l. The removal of the 125I was mainly due to the presence of the kaolinite, ferrous oxide and aluminum hydrous oxides that exhibited positive charges at pH 4.5. 125I anions were attracted to the positive particles when the effluent wastes passed through the column. The surface charge of ferrous oxide is created by an adsorption or desorption of H+ or a desorption or adsorption of OH-, respectively, in the potential-determining layer consisting of surface O, OH, and OH2 groups. The results were comparable to the model proposed by Parks and de Bruyn (7) shown as follows:
Eq (4)
The pH-dependent charges ferrous oxide (positive surface charge) was balanced by an equivalent amount of 125I anions that were electrostatically held in the outer diffuse electric double layer. The study showed high efficiency treatment about 87 % removal of 125I from effluent wastes were produced by A, B and D column. Environmental parameters C.O.D and pH values were within the requirements of the local environmental quality criteria. The low counts of 125I indicated that the laterite soils were suitable and able to treat effluent wastes containing 125I. Treated effluents release to the environment will undergo further dilution and decay and will not harm the environment.

CONCLUSION

From the study conducted, several conclusions can be drawn:
In the batch experiments using kaolin clay minerals, it was found that the optimum removal of 125I was at pH 4.5 to 5. In laterite soil, there was presence of high content of ferrous oxide, aluminum oxides and kaolinite clay minerals that can exhibit positive charges, formed at the optimum pH condition. This resulted in the 125I anions to be electrostatically held on the minerals. High average decontamination factor values were obtained using laterite A, B, and D where about 87 % removal of the 125I radioisotopes from the effluent wastes. Environmental parameters C.O.D and pH values were within the requirements of the local environmental quality criteria's values. The treated effluents released to the environment will undergo further dilution and decay and will not harm the environment. Treatment process by the soil column method was suitable, easy to handle and this would enable present and future producers of 125I effluent wastes to treat their wastes at their premises. Study is currently continuing to treat larger volume of effluent wastes consisting of other radioisotopes by using the laterite soils.

INVESTIGATION OF ISOTOPE MIGRATION RATE IN CONCRETE USED AS BACKFILL MATERIAL IN SHALLOW LAND DISPOSAL FACILITY FOR LOW- AND INTERMEDIATE-LEVEL RADIOACTIVE WASTE

Vilmos Friedrich
Institute of Isotopes of the Hungarian Academy of Sciences
Budapest, Hungary,
Kroly Brci
EROTERV Power Station and Network Eng. Co.
Budapest, Hungary

ABSTRACT

Shallow land burial is being considered in Hungary as an option for the disposal of low- and intermediate-level radioactive waste from NPP. According to the conceptual plan the waste packages containing solid wastes and liquid concentrates immobilized by cementation will be placed in vaults constructed of reinforced concrete. Voids between the waste packages will then be filled with cement solution, thus forming a concrete monolith. This monolith structure improves the mechanical strength of the repository and represents a part of the engineered barrier system delaying the dispersion of radionuclides in case of water penetration.

The retention capability of the backfill concrete has been investigated by determining the migration rate of some radioisotopes which are typical in low- and intermediate-level NPP-wastes. Sorption coefficients (Kd) for 125I, 137Cs, 60Co and 85Sr isotopes (in their ionic form) were determined in static sorption experiments. Mass conductivity coefficients (D*) were determined in laboratory-scale migration experiments using cylindrical concrete probes of various moisture content and eliminating water movement and evaporation.

The results of the static sorption experiments showed that the sorption effect was the weakest for 125I and the strongest for 60Co, in order of 125I < 137Cs < 85Sr < 60Co. This order was also observable in the migration experiments. The mass conductivity coefficients were found in the range of 10-11 - 10-12 m2s-1, being higher at the beginning of the migration process and decreasing about one order of magnitude afterwards. Average linear migration rates were also calculated from the concentration distribution along the axis of the probes.

INTRODUCTION

In the course of selecting proper sites for the disposal of low- and intermediate-level radioactive waste from NPP the shallow land burial option has also been considered. A conceptual plan has been developed for establishing a system of engineered barriers to improve the isolation of the radioactive waste from the environment. This system consists of the waste packages containing solid wastes and liquid concentrates immobilized by cementation, the vaults constructed of reinforced concrete in which the packages are to be placed and the concrete filling in the voids between the packages. When assessing the performance of the system each barrier can be characterized by describing the rate of the process leading to the dispersion of radioisotopes from the waste packages. Such processes are the corrosion of the steel drums, the leaching of the radioisotopes from the solid

matrix and the migration of radioisotopes through the surrounding material, in this case through the backfill concrete.
Since concrete may be described as a porous solid with water-filled pores, a mass transfer by diffusion in the pores can be expected to be the dominating transport mechanism (assuming a very low or zero water flow rate). Diffusion due to a concentration gradient can in general be described by the Fick-law, which, in case of one-dimensional diffusion, is formulated as (1)
Eq. (1)
where
c = concentration in the liquid phase (mol m-3)
t = time (s)
D = diffusion coefficient (m2 s-1)
x = length (m)
In case of sorption on the solid due to reversible reactions (such as adsorption and ion exchange) apparent mass transfer rate will be decreased. Concrete may be expected to act as ion-exchanger and the sorption process can be regarded as linear as long as the concentration of the interacting ion is low (less than 5-10% of the total ion exchange capacity) (2). In this case the sorption process can be described by a linear isotherm equation
Eq. (2)
where
q = concentration in the solid phase (mol kg-1)
Kd = sorption coefficient (m3 kg-1)
Assuming that Kd is independent of concentration the apparent diffusion rate will be described by the following equation:
Eq. (3)
where
r = density of solid (kg m-3)
Inserting (2) into (3) gives
Eq. (4)
Equation 4 describes mass transfer rate when diffusion and sorption are the rate determining processes. The mass conductivity coefficient (D*) is defined as
Eq. (5)
Thus, D* can be calculated using experimental data for D (from diffusion measurements in pure aqueous phase) and Kd (from static sorption experiments), if the structure of the solid phase (porosity, apparent density) is accurately known. It is, however, expedient that mass conductivity coefficient (D*) data be obtained from direct migration experiments using representative samples of the given solid matrix (3). Such experiments have been carried out and reported here.
EXPERIMENTAL
The type of cement selected for preparing the backfill concrete was 350 PPC-10, the water/cement ratio was 0.49, the gravel/cement ratio was 4.76, gravel fractions of particle sizes less than 2 mm were used only. The concrete after one week was crushed and a size fraction of 0.045 - 0.063 mm was collected by sieving for the static sorption measurements. The mass ratio of the concrete sample and the solution in these experiments was 1:10. The solution of 125I, 137Cs, 60Co and 85Sr radioisotopes (each of 5 MBq cm-3) was prepared by dissolving the salts of the radioisotopes in natural ground water sample. The time period of 48 h needed for reaching the equilibrium distribution of the isotopes between the solid and liquid phase was determined in preliminary experiments.
The migration experiments were carried out by using cylindrical concrete probes of a diameter of 46 mm and length of 200 mm. The cement mixture for a 10 mm thick layer at half length of the cylinder was prepared with the solution containing the radioisotopes while for the rest of the probe pure water was used. Thus, a one dimensional isotope distribution along the longitudinal axis of the cylinder could be expected, which was symmetrical to the half length. The probes were sliced up after different time periods and the activity of the radioisotopes in each slice was measured as a function of distance from the half length of the probe.
RESULTS AND DISCUSSION
The results of the static sorption experiments were calculated by the following equation:
Eq. (6)
where

Ao = initial radioisotope concentration in the liquid phase
Ae = equilibrium radioisotope concentration in the liquid phase
V = volume of the liquid
m = mass of the solid
Kd = sorption coefficient

The sorption coefficients obtained from static sorption experiments are shown in TABLE I.

The Kd obtained for 125I was just comparable with the experimental error, the sorption of iodide was negligible compared to that of the other three isotopes.

When evaluating the results of the migration experiments the concentrations of the radioisotopes in each slice as the function of distance from the central layer were plotted first. As an example, the distribution of 60Co isotopes (in percentage of the maximum concentration) after different migration times is shown in Fig. 1.

Mass transfer coefficients (D*) were obtained by fitting the appropriate solutions of Eq. 4 to the experimental distribution curves4. When choosing the appropriate solution care was taken that in case of the curves measured after 112, 238, 378 and 643 days the migration was not limited by the length of the probe while in case of longer migration times increasing isotope concentration was observed in both outermost slices (see Fig. 1). Mass transfer coefficients obtained from experimental results are summarized in TABLE II.

It is seen from TABLE II. that the mass transfer coefficients in most cases decrease about one order of magnitude with increasing migration time. This effect can be caused by some moisture transport during the preparation of the probes and solidification of the concrete, or by diffusion on the surfaces.

The average migration rate of the radioisotopes could also be calculated from the shifting of the concentration profiles. These migration rates relating to 1% of the maximum concentration (calculated from the distance between the 1 % points of two concentration profiles and the respective time period between the two measurements) are shown in TABLE III.

Similarly to mass transfer coefficients, the average migration rates relating to shorter migration periods are also higher, decrease after longer migration and tend stabilizing around 10-3 cm day-1. In this case, beyond the above possible reasons, the decreasing concentration gradient is an additional explanation.

The influence of moisture content of the probes up to 30 % (by weight) was also investigated. Increasing moisture content resulted in increasing migration rates but this increase was less than one order of magnitude and could be observed for the short migration periods only. However, numerical evaluation of these results was not possible due to the relatively high experimental errors caused by deficiencies of the long term sealing of the probes.

CONCLUSION

The retention capability of the backfill concrete has been investigated by determining the migration rate of some radioisotopes which are typical in low- and intermediate-level NPP-wastes. Sorption coefficients (Kd) for 125I, 137Cs, 60Co and 85Sr isotopes (in their ionic form) were determined in static sorption experiments. Mass conductivity coefficients (D*) and average migration rates were determined in long-term laboratory-scale migration experiments. The obtained values can be used as input data when modelling the performance of this part of the engineered barrier system.

ABSTRACT
The Office of Environmental Management of the U.S. Department of Energy is currently preparing a Programmatic Environmental Impact Statement that evaluates the risks associated with managing five types of radiological and chemical wastes. The release source terms for potential facility accidents are evaluated for storage operations (current and projected waste storage and post-treatment storage) and for waste treatment facilities. This paper summarizes the facility accident analysis that was performed for low-level (radioactive) waste. A set of dominant accident scenarios and a set of dominant facilities and waste treatment processes were selected for analysis by means of a screening process. A subset of results (release source terms) from this analysis for storage and treatment facilities is presented, including storage of waste management and environmental restoration wastes and treatment of alpha and non-alpha contaminated low-level wastes.
INTRODUCTION
The risk to human health of potential radiological releases resulting from facility accidents constitutes an important consideration in the U.S. Department of Energy (DOE) waste management program. The DOE Office of Environmental Management (EM) is currently preparing a Programmatic Environmental Impact Statement (PEIS) that evaluates the risks associated with managing five types of radiological and chemical wastes in the DOE complex. Several alternatives for managing each of the five waste types are defined and compared in the EM PEIS. The alternatives cover a variety of options for storing, treating, and disposing of the wastes. Several treatment methods and operation locations are evaluated as part of the alternatives. The risk induced by potential facility accidents is evaluated for storage operations (current and projected waste storage and post-treatment storage) and for waste treatment facilities. For some of the five waste types considered, facility accidents cover both radiological and chemical releases. This paper summarizes the facility accident analysis that was performed for low-level (radioactive) waste (LLW). As defined in the EM PEIS, LLW includes all radioactive waste not classified as high-level, transuranic, or spent nuclear fuel. LLW that is also contaminated with chemically hazardous components is treated separately as low-level mixed waste (LLMW). LLW with radionuclide concentrations exceeding thresholds specified in Title 10, Part 61.55 of the Code of Federal Regulations is also treated separately as greater-than-class C waste.
LLW results from a variety of DOE operations at more than 30 different sites and ranges from low-activity waste that can be disposed of without further treatment to higher activity waste that requires treatment and disposal techniques involving greater confinement. LLW is also generated by environmental restoration (ER) activities of DOE sites. Operations LLW can include a wide variety of items such as contaminated equipment, dry solids, clothing, solidified sludge, spent ion exchange resins, and contaminated water and oils. ER waste can also contain contaminated metal and equipment and possibly soils.
Treatment technologies considered in the EM PEIS alternatives are based on the physical characteristics of the waste and the final form acceptable for disposal. Because of the nature of LLW, low radioactivity levels are frequently contained in large volumes. To minimize land disposal requirements, all DOE sites must minimize the quantities of LLW generated and emphasize volume reduction. Thus, in the EM PEIS treatment stage for LLW, processes are sometimes limited to volume reduction methods; these methods can include incineration of combustible waste. Other treatment processes considered are solidification and stabilization, which are intended for liquid wastes, incineration by-products, and higher activity waste.
The LLW accident analysis covers storage and treatment facilities for the various EM PEIS alternatives defined for LLW. The facility accident analysis, in accordance with DOE guidelines, addresses a spectrum of accidents ranging from internal events (initiated within operations carried out at a facility) to external events either man-made or initiated by natural phenomena. The following section briefly describes the accident analysis approach and is followed by the results for storage and treatment facilities. The facility accident analysis was also conducted for one EM PEIS alternative that includes management of ER waste. The results of including ER waste in the analysis are discussed.
OVERVIEW OF FACILITY ACCIDENT ANALYSIS

The purpose of the DOE EM PEIS is to evaluate a number of alternatives for dealing with the different types of waste in the DOE complex. The four major groups of alternatives can be summarized as 1) no action, in which existing sites will store and treat their own waste streams, 2) decentralization, 3) regionalization, and 4) centralization, depending on the degree of consolidation and the number of sites involved in waste treatment and disposal. The comparison of alternatives involves a variety of criteria, including economic aspects and the estimated environmental and health impact risks. To assess the environmental and health risks, routine and accidental release source terms from waste transportation and waste management facilities were developed at Argonne National Laboratory (ANL); health effects calculations were performed by Oak Ridge National Laboratory (ORNL).

Each EM PEIS alternative siting option involves existing, planned, and new facilities; the alternatives also evaluate a number of treatment technologies currently in different stages of development. Given the number of alternatives, sites, and treatment options, the variety of facilities existing and nonexisting involved in the EM PEIS, and the limited information about waste characterization and specific facility designs, a generic framework for generating facility accident source term estimates was needed. A generic accident analysis methodology and a uniform accident source term computational framework were developed for the facility accident analysis for all alternatives and waste types. The method consists of selecting a set of initiating accidents and developing a set of accident progression and radioactive release models sufficiently generic to permit adaptation to the peculiarities of the different waste and facility characteristics. A more extensive description of the generic methodology has been published previously (1).

LLW FACILITY ACCIDENT ANALYSIS

To facilitate analyzing and comparing numerous facilities and alternatives, risk-dominant scenarios were selected. These were selected on the basis of (1) risk-significant initiating events and accident progression scenarios and (2) risk-significant sites and facilities.

The facility accidents selected for analysis must provide an adequate basis for comparing alternatives and must be representative of the significant sources of risk expected at the types of facilities and operations involved. The initiating events selected range from high-frequency operational events to low-frequency, high-consequence events induced by natural phenomena. The representative accident progression scenarios expected to dominate the risk are those involving potential dispersion sources, such as fires or explosions, particularly when the material affected has a high specific activity, for example, after volume reduction processes.

Representative accidents were selected in accordance with the type of facility in use and the waste management operation being performed. This approach required a second screening that resulted in the selection of facilities and processes expected to be risk-dominant among those involved in the different LLW EM PEIS alternatives. The facility and treatment technology screening process was based on consideration of waste volumes, waste characterization, and waste physical and chemical form. Liquid and combustible wastes are more susceptible to accidents that would result in material dispersion. Similarly, dispersion of waste with higher specific activities is expected to dominate the consequences. On the other hand, processes limited to packaging, stabilizing, or compacting non-combustible solid LLW are not expected to be involved in accidents among the risk-dominant scenarios.

After determining the representative accidents and the risk-dominant facilities and processes, the LLW alternatives were more closely examined to reduce the number of cases to a manageable size. If the difference between two alternatives was limited to operations that were screened out as non-risk-dominant, only the risk-dominant alternative was explicitly included in the analysis. For each of the facilities and accidents selected, an accident sequence scenario was constructed that includes the conditional probabilities of different effects that could influence the material dispersion (fires, explosions), damage ratios (the fraction of the total amount of waste in the facility that is affected by the accident), and release fractions (the airborne fraction of the material involved in the accident). Because the storage facilities and the treatment facilities are significantly different, a slightly different analytical approach and set of assumptions were required for the accident sequences. The following sections describe the accident analysis methodology for the two types of facilities.

LLW Storage Facility Accident Analysis

In the EM PEIS, two types of storage are involved in LLW management: pre-treatment (often referred to as current) and post-treatment. The purposes of treatment are volume reduction and waste stabilization so that the waste can be converted into a form suitable for disposal. Because of the additional stability, treated LLW is in a physical form that is not readily dispersable; consequently, post-treatment storage is considered a much smaller risk than pre-treatment storage. For these reasons, pre-treatment (current and projected) storage was the focus of the accident analysis. The waste characterization, including waste form and radionuclide profile, for the different alternatives and sites, was obtained from the waste characterization database developed at ANL for the EM PEIS (2). The database indicates that, with very few exceptions, the LLW inventories in storage are mostly in solid form. Pre-treatment storage of solid LLW usually takes place in drums or containers located in storage pads or buildings with a low structural design. Uncertainties in the initial and maximum storage volume and uncertainties in the storage capacity fluctuations over the period covered by the EM PEIS led to the selection of a single facility capacity for all storage facilities analyzed, that is, those at the major LLW-generating sites. A generic facility design was selected in which storage takes place in containers that are unprotected from outside forces and are located on concrete pads. Ten major storage sites, as provided by the waste characterization database, were selected for accident analysis. The accident analysis for these 10 storage sites applies to all EM PEIS alternatives since the EM PEIS assumes that pre-treatment storage occurs at the generation site as opposed to the treatment site.

The representative accidents analyzed include operational accidents (representative of container drops, punctures, and overpressurization), facility fires, and external events, including seismic events to represent natural phenomena and aircraft impacts to represent man-made external events. The operational or handling events were assumed to involve a single container of waste, and the initiating event frequency was assumed to be dominated by the estimated frequency of incidents in container handling (container loading, stacking, etc). Thus, the operational event frequency is proportional to the number of handling operations to be performed at the facilities. For the facility fire and external events, a fraction of the entire contents of the facility, depending on the accident severity, was assumed to be involved in the event. The frequency of fire initiators was assumed to be site-independent, but the fraction of material involved in the accident progression is a function of the facility contents, in particular, of the fraction of combustibles in storage. Aircraft accident frequencies are site-dependent and were obtained from aviation statistics and the locations of DOE sites with respect to major airports and aviation routes. The frequency of damaging natural phenomena events was evaluated from DOE site natural hazard data (3,4) by selecting the expected annual frequency of the hazard whose magnitude exceeds a threshold estimated to cause damage to the stored containers (i.e., hazard magnitude at which containers can be thrown from their stacking position). The source terms for the radiological releases were estimated as functions of the waste amount and characterization involved in the accident.

Treatment Facility Accident Analysis

The waste volumes to be treated, the waste stream characterization, the characteristics of the treatment methodologies, and the physical form of the waste resulted in selecting incineration as the technology treatment with the potential for dominating the risk. Incineration facilities present opportunities for fires and pressurized releases that can heighten the dispersion of radioactive material. Furthermore, if the material affected consists of incineration by-products, there is a potential for more significant amounts of radioactive material being dispersed. Therefore, incineration was selected as the risk-dominant treatment for several alternatives. Because of the potential difference in the source term composition, a distinction was made between incineration of alpha-bearing LLW and incineration of LLW without alpha-activity.

The range of accidents analyzed was the same as that for storage facilities from operational events (i.e., an overpressurization or explosion in the incinerator chamber) to facility fires to external events (i.e., seismic events and airplane crashes). In all these accidents, the material at risk would consist of the ashes resulting from the incineration process since they contain the radioactivity

concentrated in a reduced volume and are readily dispersable. Following this consideration, the facility fire selected was a fire in the baghouse that affects accumulated ashes. The representative natural phenomenon analyzed was a seismic event because of its potential to affect the entire facility; aircraft impacts were also analyzed as potential man-made external events. The accident frequency for seismic events was estimated on the basis of the performance goal for an incineration facility, that is, a moderate hazard facility, as defined in DOE guidelines, and the aircraft impact event frequency was estimated as for storage facilities. The event frequency is site-dependent for aircraft accidents but not for seismic events. The accident sequences that were dominant in terms of releases were those involving large fires. The source terms are a function of the amount of waste at the facility (proportional to the annual throughput) and the waste characterization (radiological composition) (2).

RESULTS AND DISCUSSION

The results of the accident analysis were obtained in the form of a detailed source term and an associated estimated annual frequency. The source term includes the amount of each radionuclide released to the atmosphere during the accident and corrected for the respirable fraction (1). The accidents have been grouped into four categories on the basis of their estimated frequency: the categories range from anticipated (frequency higher than 10-2 per year) to extremely unlikely (frequency less than 10-6 per year) events.

Sample results are provided in Tables I and II for storage and incineration, respectively. The tables provide some important parameters, such as the waste volume in the facility, the damage fraction, and the total amount of activity released (without the breakdown by nuclide). Because of space restrictions, only the storage analysis results for four of the largest LLW-generating sites (Hanford, Idaho National Engineering Laboratory [INEL], ORNL, and Savannah River Site [SRS]) are included in Table I. Similarly, only one EM PEIS alternative, number 18, which involves treatment at the same 4 storage sites displayed in Table I, is shown for incineration in Table II.

The possibility of including Environmental Restoration (ER) waste in the LLW accident analysis was also addressed. Because it is anticipated that the bulk of ER waste will only undergo benign treatment, probably limited to size reduction and packaging, the radiological risk impact of ER waste in LLW treatment is expected to be low. Therefore, only ER waste storage was addressed. The analysis was performed under the same assumptions that were applicable to operations LLW, that is, a site-independent facility size (storage pad) and a site-dependent waste composition. The results of the ER waste storage accident analysis are also shown in Table I for the same four sites displayed for operations waste.

The results in the tables suggest that, in general, the risk of releases from LLW waste management facilities due to accidental causes would be low. Preliminary screening estimates for the maximally exposed individual confirmed that the risks to human health involved in LLW management would be relatively low. Generally, releases of large activities are associated with a very low estimated frequency, while frequent events potentially result in small released activities. The releases associated with LLW incineration are, in general, very small, in part a result of the small LLW throughput at the facility.

The accident source terms in Table I also indicate that the risk associated with generic storage of ER LLW in similar amounts and facilities as operations LLW Waste Management (WM) LLW can be slightly higher or lower than the risk of the same accidents for WM LLW. The increase or decrease in the estimated amount of radioactivity released depends on the physical characteristics of the ER waste and its radiological profile, both of which are site-dependent. Because of the physical form of ER waste (contaminated metal, debris, and soils with a lower fraction of combustible material), the dominant accident sequences are slightly changed; an earthquake followed by a spill is more risk-dominant (in terms of radioactivity released) than a seismic event followed by a fire. For the same reasons, the relative importance of a facility fire (normalized to the total activity in storage) is lower for ER waste. In general, the release estimates are the same order of magnitude as those for WM LLW, and, therefore, suggest a low risk impact.

The results of alpha-incineration for Alternative 18 (4-site treatment) are also shown in Table II for comparison of the relative releases. The amounts released in the scenarios analyzed are considerably lower than those of non-alpha LLW, a

function of the waste throughput and, more significantly, of its radiological profile. Although the dose conversion factors for alpha-emitters are considerably higher than for other nuclides, the doses are not expected to exceed those of the non-alpha LLW. These results are not unexpected since only waste with very low levels of alpha-activity can qualify as LLW. With the projected inventories and waste characteristics available, including alpha-LLW in LLW incineration operations does not appear to alter the releases due to facility accidents.

EXPERIMENTAL CHEMICAL MILLING PROCESS TO DECONTAMINATE AND DISPOSITION REACTOR FUEL AT THE SAVANNAH RIVER SITE

Jack R. Davis
Rahn H. Ross
Westinghouse SRS

ABSTRACT

This paper presents the results of a scoping test to determine if a large scale chemical etching process would be effective at extraction of radionuclide and other hazardous contaminants from manufactured fuel tubes and assemblies. A review of the effectiveness of this process against other similar solid materials is considered. Because contaminants in contact with these types of materials tend to become electrostatically bonded to the substrate material, successful removal requires a chemical reaction to break these bonds. The process proposed is effective at bond deactivation and maintains an advantage over other decontamination alternatives due to its highly effective extraction of subsurface as well as surface contaminants. The large scale repeatability of the process makes it applicable to many areas of DOE decontamination and dismantlement (D&D) activities complex wide.

INTRODUCTION

The Savannah River Site (SRS) has operated since the early 1950s producing nuclear materials for the U.S. Government. The reactor materials production mission of the site has declined in recent years, and the facility is currently in a DOE-mandated decontamination and de-inventory mode (1). All building inventory of HEU is being melted and recast into solid cylindrical U-Al alloy ingots for shipment and storage at the Oak Ridge Y-12 Plant.

It has recently been proposed to return fuel assemblies from the SRS reactors to the Fuel Fabrication Facility to decontaminate, disassemble, melt, and recast this material as well. Because the fuel assemblies were contaminated by contact with reactor coolant, the Fuel Fabrication Facility's Tube Cleaning Process was proposed to decontaminate the assemblies sufficiently such that the disassembly, tube handling, and casting operations can be safely performed using the existing facilities. Since it is not certain that this process can effectively decontaminate the assemblies and because the process will introduce new, solid and liquid wastes containing radioisotopes which are not present in the facilities existing waste streams, a scoping test to demonstrate the effectiveness of the proposed activity was initiated.

BACKGROUND

Over time, contaminants have migrated into the substrate of the assemblies through the pores in the material. This migration has occurred naturally with the assemblies in contact with the contaminated moderator. The depth to which this migration has occurred is dependent upon many factors, including the porosity of the cladding, the mobility and solubility of the contaminants, and the existence of other drivers. To preclude personnel contamination during the casting operations, this surface and subsurface contamination must be eliminated.

The proposed tube cleaning technology is a sequential process, which prepares and then removes the outer layers of the selected material. The process was preferred over other decontamination alternatives because of its high likelihood of effective extraction of the subsurface as well as surface contaminants. This is important since total destruction and recasting of the material in a virgin metal casting environment would vaporize and release most of the radioactive materials present. Because the chemical treatment facility remains operational in the Fuel Fabrication Facility area, it would be more economical than other decontamination methods. The chemical formulations of this process are nonflammable and nonexplosive, and the process does not pose additional health risks for facility operators.

Since the assemblies would be shipped in aluminum cans, a special receiving area would not be required. Minor modifications to the Tube Cleaning Area would be needed to control contamination as the assemblies are removed from the transport cans and cleaned. A breathing air system and exhaust gas tritium monitors would likely be required during the initial handling steps.

EXPERIMENTAL PROCEDURE

To demonstrate a process for decontaminating the fuel assemblies, one contaminated inner target tube was returned from the SRS Reactors to the Metallurgical Laboratory. Prior to the transfer, surface contamination levels had been reduced by flushing the target tube. This was necessary since the Metallurgical Laboratory was not designed to process high contamination products, especially tritium. Post-rinse analysis indicated acceptable transferable contamination up to ~400 dpm g, ~200 dpm a; and ~90,000 dpm tritium. Although the surface radioactive contaminants were present in low quantities, the detection system was precise enough to measure the alpha emissions and allowed a decontamination factor (DF) to be calculated for the beta emitting tritium.

The tube was cut into 12" long sections and processed in ~8 liter solutions of caustic (NaOH), nitric acid (HNO3), and hot and cold water rinses to simulate the full-scale cleaning process. The samples were first submersed in a caustic solution to remove oxidation and etch the aluminum. The chemical representation of this action is given below.

$$Al2O3\ (s) + 6NaOH\ (aq) \rightarrow 2Na3AlO3\ (aq) + 3H3O\ (1) \qquad (1)$$

The action causes a sticky sludge to develop on the sample surface which is removed by submersing the specimen in a nitric acid rinse followed by hot and cold water rinses:

$$Contaminant\ (C) + HNO3\ (aq) \rightarrow Cx(NO3)y\ (aq) + NOz(aq) + H2O\ (1) \qquad (2)$$

The specimens were then allowed to air dry before making post-cleaning measurements. The complete laboratory experiment was carried out in a ventilated enclosure and monitors were in place to evaluate the air emissions.

The effectiveness of the cleaning process was determined by standard radiological smear tests before and after the chemical etching process. Each of the smears were evaluated by liquid scintillation spectroscopy. The processing time per cycle was maintained at 75 seconds, but multiple cycles were evaluated to determine the depth to which the contamination had migrated. The chemical bath temperature (150F), the caustic molarity (1.45M), and nitric normality (~5N) were all set to normal operating values expected in the full-scale operation, and were not varied. The hot water rinse was maintained at ~100F.

RESULTS

Test results show that the process proposed is very effective at removing radioactive surface contamination bound in the oxide layers of the sample material. Results after the first cycle showed an average increase in tritium levels of ~3 over original activity levels in 9 out of 15 samples analyzed as the subsurface was exposed. Individual samples ranged from 1.4 to 5.2 times higher. Six of the samples analyzed actually decreased in activity levels after the first cycle. Reduction in activity levels ranged from 1.1 to ~5 times lower. Three samples were run through

multiple cycles for a total process time of ~5 minutes. The retesting showed only a slight amount of residual beta activity from tritium contamination with no other activity present. Calculated decontamination factors of greater than 102 were demonstrated following repeat cycles.
A review of Fig. 1 demonstrates that tritium had permeated into the cladding to a maximum depth of ~3.5 mils. Unaltered surface contamination indicated a much lower value until the subsurface was exposed. The average depth of maximum activity within the substrate was around 1.4 mils. The tritium activity levels per cycle as measured are given in Table I. Based on the limited experience with this sectioned target tube, no airborne tritium contamination was detected external to the ventilated enclosure.

CONCLUSIONS

The test results show that the process proposed is very effective at removing radioactive surface and subsurface contamination from fuel tubes. The entire process can be repeated several times to achieve the desired levels of decontamination. Sampling is easily performed at the end of each cycle to determine remaining contaminant levels. Since chemical etching to a depth of 3.5 mils appears to completely decontaminate the surface of the tube which maintains a 30 mil thick cladding, no exposure of the fissile core material is expected during the full-scale operation.
Since the scoping test utilized a sectioned, flushed, target tube, there is uncertainty that the surfaces of concentrically nested tubes making up an assembly can be satisfactorily decontaminated using this process, especially at the contact locations between tubes. However, air sparging which is present in the full-scale operation may be able to effectively assist with the decontamination process in these reduced flow areas. The calculated decontamination factor was limited by the low contamination present on and within the tube sections evaluated. A much greater decontamination factor would be expected with non-flushed tubes.
Based on these preliminary results, it is planned to obtain additional contaminated subassemblies to further test and evaluate this process. A mechanical agitation apparatus will be used to simulate operational air sparging. Further research and tests are being performed to improve the process and broaden the applications into other areas of decontamination and dismantlement (D&D) activities complex wide.

WASTE MANAGEMENT BUSINESS MODELING

J. H. Fiore
C. S. Jonson
Professional Analysis, Inc.
1050 East Flamingo Road
Las Vegas, NV 89109
702-794-0290

ABSTRACT

The U. S. Department of Energy, Nevada Operations Office, has been analyzing its hazardous, low-level, and mixed-waste management operations with an eye toward improving productivity and efficiency using business modeling, a graphical systems engineering analytical technique. The low-level waste management operations on the Nevada Test Site were analyzed, along with mixed-waste operations as presently configured. Results provided a basis for making process improvements and minimization of noncompliance with federal and state regulations.
Professional Analysis, Inc., is using Computer-Assisted Software Engineering (CASE) software to develop the business models. The software has the capability of extracting and exporting information from the model, which can then be imported into a variety of databases. Business models already completed (Hazardous Waste Management, LLW/MW Management) are being used to reengineer operations in order to minimize noncompliance and increase productivity and efficiency.

INTRODUCTION

The U. S. Department of Energy, Nevada Operations Office, (DOE/NV) has taken the first step in the application of systems engineering to improve its routine waste manage-ment activities. Managers have developed baseline graphical representations

of their waste management activities and have begun to engineer new and improved methods. Their goal is to ensure a world-class operation into the future -- a cost-effective, safe operation that is continually improving. The DOE/NV Waste Management Division has been analyzing its hazardous, low-level, and mixed-waste management operations with an eye toward improving productivity and efficiency. Business modeling was proposed for operations at the Nevada Test Site (NTS) where noncompliance with federal and state regulations could result in action by a regulatory agency. The business modeling used is an application of systems engineering methods for analyzing and graphically displaying activities performed to accomplish a business function or operation. The graphical output from the business modeling effort provides a tool that can be used as a basis of communication between interested parties. It serves as a means of documenting activities necessary for carrying out a business function.

BUSINESS MODELING DESCRIPTION

A business model is extremely useful in developing a view of how activities are related to one another across organizational and functional boundaries. It is not uncommon for managers responsible for a facility or single operation to attempt to optimize that function without clear understanding of the role their function has in the larger system. Focus on only one part of the system typically produces improvements only in that function that may be detrimental to the overall system operation. By using a business model focused on the total system, each operation and activity can be viewed as a contributing part, regardless of organization or functional boundary. Note that this type of model is intended to represent system structure only, not behavioral structure.

A business model is also means of identifying the actual activities performed, i.e., defining what steps the specialists are really doing, not just what the procedures say they should be doing. Unlike process flow models, along with determining actual activities, these models are used to identify the actual information and documentation used between activities. The models are particularly useful for processes that have been evolving over many years. They are equally useful in engineering new functions that have not yet been performed. An example is future activities associated with disposal of mixed waste under the to-be-approved RCRA Part B permit at the NTS.

Because it documents the way things are really done, a business model is a powerful tool for managers to develop better ways of performing and organizing tasks. Reviewing current practices allows a manager the opportunity to identify redundancies, question why certain activities are being performed, question the validity of the sequence of activities, evaluate whether activities may be outdated, and to prepare a new model of proposed improvements. Since the modeling uses graphical computer tools, it permits instant changes and many iterations to obtain the best mix of activities for achieving the desired end product. It is an effective management tool that can be applied to re-engineer an operation.

Business models can also serve as a means of verifying procedures by validating actual practice to the procedural requirements. This permits managers the opportunity to modify procedures to reflect actual practice or to modify actual practice to match procedural requirements, or to modify both to improve productivity.

Models can be designed to identify all known standards and requirements imposed on individual activities within a process. This can be very useful in identifying specific regulatory standards or requirements to individual work activities, rather than arbitrarily imposing these controls throughout an operation on all activities. Additionally, because standards and requirements can be identified to individual activities, the communication of applied standards to external regulatory reviewers is facilitated.

The diagram in Fig. 1 provides information on the activity (in the box), inputs and outputs to and from each activity, and controls and mechanisms needed to accomplish the task(s). Activities are arranged in the order they are performed. All activities are evaluated to determine whether they should be "decomposed" into more detailed steps in order to study the process more thoroughly. The major summary of activities is the "A0 (A Zero)" level. The number of activities displayed on an 8-1/2 x 11" page is generally restricted to six and no less than three. For every activity, inputs and outputs are defined, and procedural, regulatory, standard, and code controls are identified. Mechanisms can include the type of specialized personnel,

equipment, or databases needed to perform the activity.
Figure 2 shows how the decomposition works. Each decomposition is on its own page. The Tree Structure of the model provides an outline and guide to the flow of decompositions. An example of a portion of the Tree Structure for Low-Level and Mixed Waste (LLW/MW) is shown in Fig. 3.

MODELING METHODOLOGY
Professional Analysis, Inc. is using Computer-Assisted Software Engineering (CASE) software to develop the business models. The software has the capability of extracting and exporting information from the model, which can then be imported into a variety of data bases. Business models already completed (Hazardous Waste Management, LLW/MW Management) are being used to reengineer operations in order to minimize noncompliance and increase productivity and efficiency.
To initiate the process, modelers interview personnel involved in the day-to-day operations and prepare a graphical representation of how all elements of the work process are actually being performed, ensuring that the operations personnel are involved in the iterative steps needed to understand the process.
During preparation of the baseline model (i.e., representation of how things are really done), the many suggestions for improvements from knowledgeable managers and staff are brought together with observations from the modelers and are combined into an initial proposed model. The output is a combination work process model and a graphical baseline record of how work is really done. Actual activities are compared with how the work is described in procedures as part of the proposed model; any differences between actual and procedural are defined and presented to the contractor for resolution.
A proposed model is then developed as a first step in re-engineering the process for improvement. It is essentially a place to start for managers and staff to consider how the overall system in the model might improve the process. For example, the proposed model may represent an "ideal" method of executing a process such as implementation of new or improved automated tools.
Both the baseline and proposed models can be used as a basis for understanding the total, obtainable direct cost savings by comparing the actual cost for each activity in the baseline model with the anticipated costs from the proposed model. The proposed model can thus be used for preparing process-change cost justifications.
Since all users of the model may not be familiar with reading and interpreting the graphical output of the model, a report describing both the baseline and proposed models is prepared. As part of this improvement analysis, the modelers observations and recommendations are recorded for possible action by senior management.
The model can represent the process from the perspective of DOE management or from the contractor management perspective. The LLW/MW and hazardous waste models were done from the DOE/NV management perspective.
A review of the standards and requirements controlling the activities associated with the LLW/MW model was also performed. A separate listing was developed supplementing the original model. This listing, recorded in simple, straightforward relational database tables, provides the details associated with each identified control. It also permits easy identification of activities affected by changes to regulations.
A static modeling paradigm was applied to represent the LLW/MW system structure, as opposed to using a dynamic modeling paradigm that represents behavior over time. The initial intent was to use the modeling to develop procedural and physical-barrier mechanisms to minimize noncompliance. However, not only was the business model valuable for modifying the operational processes to minimize noncompliance, it was also found to be valuable for improving the process overall. Examples are updating or correcting procedures, improving database capabilities, eliminating redundant steps, consolidating activities, clarifying responsibilities that cross organizational lines, reducing the amount of paperwork currently used, and providing a cross-procedural view as a communication tool.
APPLICATIONS
A hazardous waste management system model from the DOE/NV perspective was the first prepared. Immediate productivity increases were realized. Short- and long-term savings may more than offset the investment in the business model. While preparing the hazardous waste management model, the value of business modeling became apparent

as a tool for implementation of the Defense Nuclear Facility Safety Board Recommendation 90-2 (that DOE redefine all operating standards and requirements) because controls are identified on the model for each discrete activity. The DOE/NV 90-2 Implementation Plan requires that baseline process models be developed for each facility subject to 90-2 Recommendation requirements. In order to maximize benefit from the process models, they must be developed and analyzed from both the DOE management perspective and from facility operator viewpoints. The facility-specific standards and requirements identified during both processes can then be compared and evaluated to ensure that applicable requirements have been identified, are adequate for the work being performed, and are implemented by the contractor.
Because the regulations cited in facility operating procedures are applied to each specific activity in the business model, 90-2 Implementation functional area experts, peer reviewers, or facility experts who review the required regulations will use the business model as a "map" of functions related to specific regulations and standards for each discrete activity, as well as using models as a valuable communications tool.
Business modeling can also be used as a tool to engineer a business process prior to inception, resulting in a baseline process model. The process identifies resources necessary to perform each activity (mechanisms), so initial resource loading can be determined by skill or specialty required to perform the tasks. In addition, a work breakdown structure can be prepared based on the model because the process and products are already mapped out. A baseline model can be used to monitor and record a management system's evolution. For example, to facilitate development of a management system for implementing 90-2 Recommendation at DOE/NV, the process was modeled. This model facilitated understanding of the complex process and provided the mechanisms and sequence of steps needed to successfully complete the Generic and Facility-specific Standards/Requirements Identification Documents required by the 90-2 Recommendation.

REACTOR FACILITIES ALTERNATIVE USE SCOPING STUDIES
Mr. Brian Getson
Westinghouse Savannah River Company
Mr. Craig McMullin
Raytheon Engineers & Constructors
ABSTRACT
The purpose of the Reactor Facilities Alternative Use Scoping Studies (1) was to determine if excess Savannah River Site (SRS) reactor facilities were suitable for interim alternative uses and to determine if such uses were preferable to immediate Decontamination and Decommissioning (D&D).
Westinghouse Savannah River Company (WSRC) and Raytheon Engineers & Constructors considered over 50 potential alternative uses for the excess reactor facilities. Study priorities were determined with the help of a matrix of potential alternative uses that evaluated each alternative against 14 pre-selected criteria including immediate need, cost to implement, involvement of private industry, benefit to the Department of Energy (DOE) complex, etc.
Scoping studies for 20 of these alternative uses have been completed to date. Each study evaluated the viability, suitability, and economic value of the alternative, listed its advantages and disadvantages, and made recommendations based on its conclusions. Due to the nuclear nature of the facilities, most alternative uses involved radioactive material and, therefore, were generally under the cognizance of the DOE Office of Environmental Restoration and Waste Management. Some of the proposed uses (e.g., transuranic waste treatment and storage, and lead decontamination) can take advantage of the unique design, radiation control, and security features available at the reactor areas.
The results of these alternative use studies have led to the conclusion that DOE, as well as commercial and private operators, could benefit by using the excess SRS facilities. Outside industry may also benefit by employing their own surplus facilities for alternative uses. Utilizing an excess facility for other than its original function could eliminate the need to build costly new structures, and could be a valuable means for forming profitable business relationships in the local communities.
A separate comprehensive document entitled Alternative Uses for Reactor Facilities

(2), often referred to as the main report, incorporated the completed alternative uses studies as well as other site and facility information into a single-source document that could be used by other departments, DOE sites, or private industries. The main report describes the physical layout, support services, and status of the excess facilities, and includes a database of facility configuration information useful for determining the ability and practicality of using the facilities for other purposes. The main report was written to be understood by those unfamiliar with SRS facilities.

The completed main report is being reviewed by WSRC and the Department of Energy-Savannah River (DOE-SR). Direction to implement some of the more promising alternative uses is expected to be forthcoming.

WSRC has many assets available to other DOE sites and to private industry. These assets include:

Substantial experience in the beneficial reuse of excess facilities and resources.

Numerous excess facilities that could be made available for alternative government and private sector projects or other business endeavors. Available services and utilities are typically more than adequate to allow a wide range of operations to be performed.

Technical support provided by the Savannah River Technology Center (SRTC). SRTC can provide research, testing, development, and analytical services in the areas of robotics, metallurgy, thermodynamics, isotope development, radiology, and computer science.

WSRC is available to perform alternative use studies for facilities at other SRS locations, at other DOE sites, or at commercial nuclear operations.

BACKGROUND

In the 1950s, five nuclear reactor facilities were built on the SRS in South Carolina to produce Special Nuclear Materials for the nation's defense programs and special isotopes for non-defense applications. Four of the reactors are now considered "excess" by the DOE and are being evaluated as to their disposition. D&D, the ultimate disposition for all of the facilities by entombment or dismantlement, could be initiated immediately or delayed to allow short-lived, high-energy radioisotopes to decay.

If D&D is delayed, the facilities may be used for alternative functions or allowed to lie dormant. Both options require continued financial support for surveillance and maintenance to assure public health and safety. Unless an interim alternative use is identified that would be economically and/or environmentally preferable, these facilities will either be entombed (buried in place) or completely dismantled and removed. Using these excess facilities for other than their original purpose is potentially the most cost effective alternative to storage or immediate D&D.

ALTERNATIVE USE EVALUATION

The initial potential alternative uses for the reactor facilities were identified by senior reactor division personnel participating in brainstorming sessions. These personnel were familiar with the reactor facilities and the unique nuclear-related challenges and concerns of the DOE defense organization. A weighted value was assigned to each of 14 evaluation criteria:

1. Impact on worker safety
2. Impact on environmental safety
3. Impact on public safety
4. Benefit to waste reduction
5. SRS short-term need
6. Impact on public perception
7. SRS employment opportunities
8. Estimated capital cost to implement
9. SRS long-term need
10. Political impact
11. Benefit to other DOE sites
12. Net Operating & Management costs
13. Value as a national asset
14. Benefit to outside industry

These criteria were arranged from the most significant (impact on worker safety) to the least significant (benefit to outside industry). Each potential alternative use was then evaluated against each criterion and given a rating from +5 to -5 based on the relative benefit or liability, respectively, incurred by implementing the

alternative. Some alternative uses were determined to be impractical due to radiological, environmental, or public perception considerations. Other alternative use studies were deferred due to budget constraints or higher priorities. The remaining alternative uses were researched, analyzed, and documented for presentation in stand-alone reports. To date, the project team has evaluated the following alternative uses:

- Lead Decontamination
- Decontamination Technology Center
- Plutonium Vitrification and Storage
- Transuranic Waste Storage
- Transuranic Waste Treatment
- R-Reactor Transuranic Waste Storage
- Basin Aquaculture
- Engineered Trenches for Low-Level Radioactive Waste Disposal
- Engineered Trenches for Monitored Retrievable Storage
- Suspect Soil Treatment/Disposal
- Waste Volume Reduction
- UO3 Ultimate Disposition
- Stainless Steel Recycling
- Hydraulic Test Facility
- Museum/Visitor Information Center

Additional studies were requested and funded by departments other than WSRC Reactor Engineering Division based on their specific priorities. These studies were not necessarily subjected to this selection process.

Where applicable, environmental permitting considerations were discussed in the individual scoping studies. Most studies concluded that alternative use of SRS reactor facilities would not only be cost beneficial, but would also provide solutions to several SRS and DOE complex concerns.

FACILITIES DATABASE

As the first alternative use studies were being developed, it became apparent that current and accurate data on certain plant attributes were universally required to properly evaluate the facilities for the proposed alternatives. Among other things, this information included:

- Physical building attributes (floor loading, door sizes, room locations and volumes, etc.),
- Support equipment (location and condition of fans, cranes, pumps, etc.), and
- Utilities and services (location and capacity of electric, telephone, steam, sewage, and water systems).

A dedicated research and documentation effort was performed by a team of engineers whose purpose was to gather data for the alternative use teams. Numerous documents were examined including Reactor Safety Analysis Reports (SARs); site historical documents; and Cold Shutdown, Lay-up, and Transfer Packages.

Walkdowns were performed to determine the existing condition of each facility and to confirm and supplement information obtained from research documentation. Valuable information from the walkdowns and research was compiled and sorted in a computerized database. The database consisted of four forms (Area, Building, Elevation, and Room) which were provided as an appendix to the main report. A database search of needed facility requirements can be performed to determine what available facilities meet or exceed the specified criteria.

The General Facility Descriptions section of the main report includes a general description of the reactor areas, a tabular record of differences between the areas, and the status of services and structures in each. Specific details of the reactor areas are contained in the Specific Reactor Facility Information section, also in tabular form. These tables provide for a quick comparison of areas and are good references, but they were not Intended to present the level of detail available in the appendices. The reactor facility information sections discuss the following services and features:

- Communications
- Radiation Monitoring Equipment
- Contamination Control
- Security
- Water Systems
- Steam Supply

Electrical Service
Ventilation
Fire Detection/Protection
Water
Gas Systems
General Conditions
Licenses

SCOPING STUDIES

To date, there have been 20 scoping studies performed to evaluate the potential use of excess SRS reactor facilities for alternative uses. A brief description of the major Alternative Use Scoping Studies are given below.

Lead Decontamination

This study evaluated various lead decontamination methods, the feasibility of using excess reactor buildings for the interim storage of lead, and the feasibility of using these same facilities for housing a lead decontamination operation and its secondary waste treatment operations.

The best decontamination method for lead was found to be a two-step process consisting of abrasive or CO2 blasting to remove coatings and paint from the lead, followed by chemical immersion to remove remaining contaminants. It was concluded that using SRS reactor buildings for the interim storage of lead, and the further use of one of these buildings for a Lead Decontamination Facility (LDF) would be both feasible and desirable.

It was recommended that more analyses be performed concerning specific modifications and costs required for using reactor facilities for the interim storage of lead, performing abrasive blasting and chemical immersion decontamination operations, and performing appropriate secondary waste treatment for these methods. The additional analyses should also consider the possibility and feasibility of decontaminating lead from other SRS facilities as well as other DOE sites and private industry.

Decontamination Technology Center

A major objective of the DOE's decontamination plans is to reuse and recycle as much material from the D&D process as is practical, both to conserve valuable raw materials and to minimize the amount of waste requiring disposal. Existing technologies are inadequate to solve many problems, including how to cost-effectively decontaminate structures and equipment, what to do with materials and wastes that are generated, and how to adequately protect workers and the environment. New and improved technologies resulting from research and development at a Decontamination Technology Center could increase decontamination efficiency and cost-effectiveness.

The SRS must manage radioactively contaminated materials that are generated as a result of past operations and as an unavoidable consequence of current cleanup efforts. This study evaluated the possibility of using excess reactor buildings to house a decontamination research facility and its associated laboratories. The Decontamination Technology Center would also include operating decontamination processes for demonstrating decontamination technologies.

Based on this initial assessment, the establishment of a Decontamination Technology Center would be a feasible and desirable alternative use for the SRS reactor buildings. It was recommended that a detailed analysis be performed concerning the specific modifications and costs required for using the reactor facilities for decontamination research and development, and for demonstrating decontamination processes.

Plutonium Vitrification and Storage

This study examined the feasibility of converting an existing SRS facility for the vitrification and storage of plutonium. The Defense Waste Processing Facility, F-Area facilities, and reactor facilities were evaluated. This initial assessment led to the conclusion that plutoninm would best be vitrified at an F-Area facility and stored at a reactor facility. The F-Area facilities were designed to handle plutonium and have much of the required process equipment already in place. The reactor facilities have large amounts of storage space and would need only minor modifications to upgrade necessary equipment.

Consideration should be given to the possible public perception and political impact regarding the storage of vitrified plutonium from commercial facilities and/or other DOE facilities. If plutonium is to be shipped from other facilities, then consideration should also be given to the public concern and the political impact

related to transportation on public roads.

Transuranic Waste Storage

This study examined the possible use of one or more of the four excess reactor facilities for storage of transuranic (TRU) waste. The findings of this study support the use of R Reactor for non-mixed TRU waste storage and P Reactor for mixed TRU waste storage. Mixed and non-mixed TRU waste should be handled separately for optimum management of resources.

Several factors contribute to the need for additional storage space for TRU and other solid waste. Waste containers that have been stored for twenty years may be compromised or may already be leaking into the environment. Treatment requirements, the condition of storage containers, more stringent environmental protection requirements, and fund limitations are important concerns to examine when addressing optimum use of resources available for TRU waste storage.

Storage of non-mixed TRU waste in the R-Reactor facilities is of immediate interest since the present storage accommodations may be saturated before the end of fiscal year 1995. The use of the R-Reactor facility to store the present inventory of TRU waste would alleviate the shortage of space in less time than may be required to build new facilities.

Transuranic Waste Treatment

A large majority of the TRU waste generated through the 1980s contains hazardous materials and is therefore categorized as mixed-TRU waste. The current plan is to ship the TRU waste to Carlsbad, New Mexico for final disposal at the Waste Isolation Pilot Plant (WIPP), when it becomes operational. However, the facility will reject waste that has not been certified to be in compliance with the WIPP Waste Acceptance Criteria (WIPP/WAC).

Prior to shipment, the SRS-generated TRU waste will need to be assayed to verify that the waste does not contain:

- Hazardous materials that are not co-contaminants
- Excessive free liquids
- Explosives, pyrophorics, PCBs, or asbestos
- Unidentified waste materials

Uncertifiable TRU waste must be processed to remove, stabilize, and dispose of the unwanted hazardous constituents.

With modifications and upgrades, C-, L-, or P-Reactor facilities contain the necessary support systems and floor space to be used as a TRU waste treatment facility. When compared to the estimated $200 million dollar design and construction cost of a new treatment facility, the reactor reuse option may be economically preferable.

R-Reactor Transuranic Waste Storage Evaluation

This report evaluated the feasibility of converting vacant space in the R-Reactor building, the largest of the four excess SRS reactor buildings, for TRU waste storage.

There is an immediate need for additional interim storage space for TRU waste at the SRS. The waste is presently stored on outdoor concrete pads in E Area. The majority of these pads are permitted for storing "mixed" waste, which contains both hazardous and radioactive constituents. Some pads contain non-mixed TRU waste, consuming valuable space that could be used for storing more problematic mixed waste. Since a storage permit is not required for non-mixed waste, this waste can be relocated to other areas to make permitted space available for mixed waste.

R Reactor has been out-of-service since 1964 and has been extensively cannibalized, with equipment and components salvaged for use at other reactors. Structural modifications would be needed to allow storage of the large TRU waste containers that will not fit through existing entrances. The estimated cost for this work totaled $750,000 and included activities such as equipment removal, wall demolition, and floor decontamination.

Federal and State environmental permitting for interim storage of mixed-TRU waste in R-Reactor building would be difficult and time consuming due to the large number of radioactively contaminated areas and the potential for water intrusion into the lower elevations of the main building. However, the use of 0' elevation floor space for the storage of non-mixed TRU is achievable. It is estimated that the use of R Reactor for non-mixed TRU waste interim storage would clear two existing, permitted E-Area pads for continued mixed-TRU waste interim storage. This scenario, when compared to the cost of $1.0 to $1.5 million to design, construct, and permit

additional E-Area storage pads or building a new storage facility, is feasible and cost beneficial.

Basin Aquaculture

This study evaluated the feasibility of using the SRS C-, L-, P-, and R-Reactor 186 cooling water basins and 904 retention basins for aquacultural purposes. Proposed options included growing plant life, aquacultural research, and raising various aquatic life. The earthen 904 Basins were found unsuitable for fish production, and several of the proposed options were excluded due to time restrictions and/or a low probability of success. The study ultimately focused on using the 186 Basins for raising fish, crayfish, shrimp, or prawns for food.

Of the species that could grow in the basins, the hybrid striped bass was found to be superior in marketability, growth rate, disease resistance, temperature tolerance, and general compatibility with existing facility design. A hybrid striped bass operation could also have a large profit potential. The basins would not, however, support shrimp or prawn production, but could be used to profitably raise Australian crayfish.

The initial assessment shows that raising hybrid striped bass and Australian crayfish would be a feasible and potentially profitable alternative use for the SRS 186 Basins. It was recommended that a detailed analysis be performed and a pilot program run to test the feasibility of using the basins for crayfish or food-fish production.

Engineered Trenches for Low-Level Radioactive Waste Disposal

This alternative use study evaluated the economic feasibility of using spaces within the C-, L-, P-, and R-Reactor Areas for the permanent disposal of Low-Level Radioactive Waste (LLRW). Results show that the reactor cooling water basins (186 Basins), the disassembly basins, and the P- and R-Reactor pipe pit areas offer impressive disposal capacity which could be converted into LLRW disposal sites. Structural modifications would be required to ensure the 100+ year service life requirement for a LLRW disposal facility.

Calculations show that up to 300,000 cubic meters of LLRW could be disposed in the 186 Basins. Compared to the planned construction of new disposal vaults, the converted basins could replace up to six vaults. Assuming a construction cost of $23 million per vault, minus the estimated $40.8 million for facility improvements, the total SRS disposal cost savings could approach $97 million.

Engineered Trenches for Monitored Retrievable Storage

SRS solid wastes that require treatment are being stored onsite until the DOE and SRS long-term waste treatment and disposal plans are finalized. Once approved, these plans could take several years to implement. In the interim, one or more Monitored Retrievable Storage (MRS) facilities will be needed to store the future inventory of solid waste generated from environmental restoration and D&D projects.

This study examined the technical feasibility and cost associated with converting the C-, L-, P-, and R-Reactor 186 cooling water basins and the P- and R-Reactor pipe pit areas into usable MRS facilities.

Results of this study revealed that adequate storage capacity already exists through fiscal year 1998. After this date, existing TRU waste storage capacity will be exhausted. Similar indicators exist for mixed and hazardous waste in fiscal year 2000 and fiscal year 2001, respectively. Unless additional mixed waste storage space is permitted by the South Carolina Department of Health and Environmental Control (SCDHEC), or unless effective site waste reduction methods are implemented over the next one to two years, the site will exhaust its permitted storage capacity.

The conversion of the 186 Basins or pipe pit areas into suitable MRS facilities is feasible. Based on current SRS solid waste generation rates, the storage capacity gained from the MRS conversion of one 186 Basin would add approximately 25 years of non-LLRW storage capacity. The estimated MRS conversion cost is between $3.28 and $8.4 million per basin, which includes the cost of facility enhancements and the installation of a roof (choice of two types) for protection from the weather. The P- and R-Reactor pipe pit areas also offer considerable storage capacity but will require removal of the heat exchanger inlet and discharge piping.

Suspect Soil

This study investigated past and present methods for disposing of contaminated and potentially contaminated SRS soil, and evaluated soil treatment and disposal plans that could utilize reactor facilities. The reactor areas were considered for contaminated soil treatment applications. The 904 and 186 Basins, in particular,

were considered for interim soil storage and remediation operations.
A Soil Treatment Facility in a reactor area would provide many benefits. The volume of soil disposed of as contaminated waste could be reduced to as little as one percent of the current volume using remediation techniques that have been proven or investigated by the Savannah River Technology Center (SRTC). More actual waste could be disposed of in existing burial space, and new or expanded soil burial facilities may not be needed. Finally, hazardous and radioactively contaminated soil from most onsite locations would not have to be moved across public roads, thereby reducing regulatory requirements.
It was recommended that a Soil Treatment Facility be planned for one or more of the reactor areas. The new Soil Treatment Facility would process hazardous and radioactively contaminated soil. The existing petroleum-contaminated soil remediation facility in D Area and new bioremediation facilities to be built at T Area would process soil contaminated with non-hazardous and non-radioactive materials (e.g., kerosene and diesel fuel). These facilities would initially be used to meet site needs but could be expanded to process offsite soil contaminated with hazardous materials.
Waste Volume Reduction
This study examined the need for, and feasibility of, establishing a Waste Volume Reduction Facility at the SRS. Wastes to be handled by the facility would include transuranic waste, mixed waste, low-level radioactive waste, and hazardous waste, but would exclude high-level waste. The function of the Waste Volume Reduction Facility would be to assay, characterize, and physically reduce the size of accepted wastes. Emphasis was placed on using existing equipment and excess reactor facilities for this purpose.
It was concluded that although a Waste Volume Reduction Facility is not immediately needed, the expected increase in waste from planned D&D operations will likely exceed existing volume reduction capabilities. Since plans have been made for much of the site to undergo D&D at some point, it is recommended that a centralized Waste Volume Reduction Facility be established.
The existing reactor facilities appear suitable for a Waste Volume Reduction Facility. While some of the needed equipment can be obtained onsite, a fair amount must be purchased. The Waste Volume Reduction Facility would initially accommodate site needs but could be expanded to serve other DOE sites and commercial generators. Additional studies need to be performed to address the specific waste types and generation rates, desired level of volume reduction, specific equipment to be used, and modification requirements for site facilities that are proposed for volume reduction operations.
UO3 Ultimate Disposition
Uranium trioxide (UO3) is one of the by-products of past DOE nuclear production operations. Thousands of drums of UO3 are now stored in the reactor facilities and other areas at SRS. The purpose of this study was to identify beneficial uses for the UO3 that may be employed as an ultimate disposition and alternative to storage. This study investigated the possibility of mixing UO3 with cement to act as a shield in concrete used in waste disposal vaults or engineered trenches. Disposal of the UO3 as a LLRW may also be possible; however, final disposal would likely require a special license due to the high uranium content of UO3 (toxicity concerns). This option is considered undesirable due to its complexity and cost.
R was concluded that no obvious beneficial uses currently exist for UO3. If neither of the above options are exercised, continued storage may be the most desirable option until a viable alternative use is found.
It was recommended that the regulatory limits associated with mixing UO3 in concrete be further investigated and that tests be performed on concrete-UO3 mixes to determine structural adequacy and leachability characteristics. Proposals have recently been made to perform a concrete-UO3 demonstration project.
Stainless Steel Recycling: Final Report
This study evaluated the potential alternative use of excess SRS reactor facilities for recycling slightly contaminated stainless steel (SS). Using one of the reactor facilities for recycling contaminated SS would have two benefits: one, it would prevent burial of the SS and two, it would delay D&D of the facilities selected for the recycling tasks.
The proposed SS recycling program would convert contaminated SS scrap into two types of LLRW containers: 2.8-cubic-meter boxes and 208-liter drums. The cost benefit of

the SS recycling program was studied in four phases: decontamination, sizing, melting, and fabrication.
A Final Report integrated the cost results of the four phases and recommended locations, onsite or offsite, for performing the phase activities. lf onsite performance was recommended, a specific reactor facility was suggested. The lowest cost combination of phase activities and locations was estimated to result in costs of $202 per SS drum and $1192 per SS box compared to new drum and box prices of $370 and $1240, respectively. For the recycled containers, the least expensive container capacity is provided by boxes at $0.47 per liter compared to drums at $0.97 per liter.
A $51.3 million dollar savings could be realized by using recycled SS containers for waste disposal instead of purchasing new containers. This savings includes both the difference in container costs (cost to manufacture waste containers from recycled SS venus cost to purchase new waste containers--$37.1 million) and the savings from not having to dispose of the contaminated SS as a separate waste ($14.2 million).
Locations within C-, L-, and P-Reactor buildings appear feasible for all SS recycling activities except rolling sheet metal from cast slabs; the rolling mill requirements for space and floor loading cannot be accommodated.
Hydraulic Test Facility
This study evaluated the potential for using an excess SRS reactor facility as a Hydraulic Test Facility. Emphasis was placed on using the cooling water system pumps and/or the K-Reactor cooling tower recirculation pumps to provide the motive force for the hydraulic testing. Four hydraulic testing alternatives were investigated:
- Flow-testing large mechanical equipment
- Testing civil-hydraulic structures
- Dynamically testing boat hull designs or other water-borne devices
- Cooling tower research and testing using the K-Reactor cooling tower

Alternative uses found to have promise and warrant additional consideration are a permanent testing station for medium to large pumps and use of the cooling water basin(s) for short-term research projects.
Museum/Visitor Information Center
This alternative use scoping study evaluated the possibility of using reactor facilities for a museum and visitor information center. Part of the Museum/Visitor Information Center would include exhibits and displays that describe the history of the SRS, its mission in the DOE complex, and its many operations. Actual reactor system equipment could be viewed as individual pieces in a museum-like display and/or in a reactor building in their original setting.
The Museum/Visitor Information Center could also include exhibits, displays, and demonstrations associated with environmental restoration and management, energy production and use, nuclear weapons, nuclear medicine, and other related subjects. The capabilities and expertise available at the SRTC could also be highlighted. SRTC has produced many patents and is involved in high technology projects such as the NASA space program. The center could provide research, testing, development, and analytical services in the areas of robotics, metallurgy, thermodynamics, isotope development, radiology, and computer science. An extensive technical library at SRTC has recently opened to the public.
A basic Museum/Visitor Information Center that uses existing reactor facilities is expected to cost approximately $1.9 million. Costs would increase proportionately with the number and complexity of exhibits.
Based on the results of this initial evaluation, it was recommended that a Museum/Visitor Information Center be planned for C-, L-, or P-Reactor Area. A site Museum/Visitor Information Center could be an educational and public relations asset for the DOE, SRS, and surrounding communities.
CONCLUSION
The results of the Reactor Facilities Alternative Use Scoping Studies generally reinforced the idea that the excess SRS facilities are valuable assets and should be used for alternative purposes versus immediate D&D. Implementing recommended alternative uses generally provides the following benefits:
- Economically beneficial reuse of existing structures
- Cooperative and mutually advantageous relationships with private and commercial industries Preclusion or delay of D&D of valuable assets
- Stimulation of local economy
- Solution to several DOE and site facility needs

Reconciliation of many environmental concerns

Other alternative use studies have shown comparable advantages. It is likely, therefore, that further studies of other excess facilities (DOE and commercial) would see similar results. The completed Reactor Facilities Alternative Uses Study comprehensive report is now being reviewed by WSRC and DOE, and direction to implement promising alternative uses is expected to be forthcoming.

It is apparent that full advantage should be taken of surplus facilities whenever possible. Many facility operators (including DOE, commercial, and private owners) could very likely benefit from using the excess facilities available at SRS, or from using their own surplus facilities for alternative purposes. Reusing excess facilities for other than their original functions could eliminate the need for building costly new structures, and could be a valuable means for forming profitable business relationships in local communities--possibly through the use of Cooperative Research and Development Agreements (CRADAs).

WSRC has many assets available to other DOE sites and to private industry. These assets include:

Substantial experience in the investigation of beneficial reuse of excess facilities and resources.

Numerous excess facilities that could be made available for alternative government and private sector projects or other business endeavors. Available services and utilities are typically more than adequate to allow a wide range of operations to be performed.

Technical support provided by the Savannah River Technology Center (SRTC). SRTC has an impressive amount of expertise in the areas of robotics, metallurgy, thermodynamics, isotope development, radiology, and computer science. Research, testing, development, and analytical services are now being offered to other DOE sites and to outside industries. Work can be performed in-house or at the client's facilities.

The facilities now available for alternative uses are four excess reactor buildings and their support buildings, each consisting of several office-type structures, two 115kV substations, and a 31,000 cubic meter water basin supplied from the Savannah River. Each 291,000- to 303,000-square-meter reactor area is cleared and level, has road and railroad access, and is surrounded by a security fence.

Electric service is supplied by a 13.8kV electrical distribution system, with 240 and 480VAC power available throughout the facility. Low-pressure steam, potable water, telephone, sewage, and fire protection systems are also available in each area. The reactor buildings are constructed of reinforced concrete with total volumes of approximately 255,000 to 340,000 cubic meters and between 37,200 and 46,500 square meters of floor space. These structures are ideal for applications ranging from office space to heavy industrial use.

WSRC is available to perform alternative use studies for excess facilities at other SRS locations, other DOE sites, or commercial nuclear operations.

For more information concerning the resources, capabilities, and availability of SRS facilities, services, and technical support contact Mr. Brian Getson, Westinghouse Savannah River Company, Building 707-C, Rm. 349, Aiken, SC 29802, telephone number (803) 557-9765.

ABSTRACT

Currently in Korea, there are 12 Pressurized Water Reactors (PWR) either operating or under construction. These units encompass several different designs for

radioactive waste processing systems. However, the different designs may be separated into three(3) basic groups based upon waste processing technology. This paper will describe the design concepts and operating experiences for the each waste processing group.
Based upon design and operating experience from these 12 units, KOPEC implemented to improve waste processing systems by simplification (i.e. elimination of unnecessary equipment) and employing current technology. This paper will also describe some of the features and benefits of upgrading the waste processing systems.
Table I
INTRODUCTION
Since the first nuclear power plant went commercial in 1978, Korea has fully developed 3 sites for Pressurized Water Reactors (PWR), with eight (8) operating PWRs. There are an additional four (4) more PWRs under construction at these sites, scheduled to begin operation through out 1995-1998. Thus there are 12 PWRs either operating or under construction. These units encompass several different designs for waste processing systems. However, the different designs may be separated into three (3) basic groups of waste processing technologies. This paper will describe the design concepts and operating experiences for each waste processing group. It will also describe some of the features and benefits of upgrading the waste processing systems based upon design and operating experience from these 12 units.
DESIGN CONCEPTS AND OPERATING EXPERIENCE OF THE EXISTING WASTE PROCESSING SYSTEMS
Group 1 Waste Processing System
Group 1, which is an older design, has no waste recycle capability. However, the concept of Unit Operations were considered in the system design for liquid, solid and gaseous wastes. The two (2) nuclear plants, Kori-1 and Kori-2 constitute Group 1.
Liquid Radwaste System
Liquid wastes generated in the plant are collected in three (3) tanks depending upon the processing required: the laundry & hot shower tank, the floor drain tank and the waste holdup tank. The laundry & hot shower tank wastes are filtered only and the floor drain tank wastes are filtered and demineralized. But, the waste holdup tank wastes are processed in an evaporator, and the evaporator distillate is normally demineralized. All processed liquid are collected in the monitor tanks for holdup prior to discharge.
The system capacity may be less than input flow during the abnormal operation since the capacity is based upon normal operation inputs. Since an evaporator, which has no redundancy, is incorporated into the system, an out-of-service evaporator may also cause an increase of radioactive material release to the environment. As a result of operation, however, the actual releases of radionuclides in the liquid effluent has been about 0.11 Ci/yr/unit.
Gaseous Radwaste System
The Gaseous Radwaste System (GRS) is a closed loop comprised of two waste gas compressors and several gas decay tanks to collect fission product gases. Gas decay tank capacity permits at least 45 days for decay before discharge. Prior to releasing waste gas to the environment, it is sampled and analyzed to determine the activity.
The pressurized-tank gaseous radwaste system has several limitations of operation, for example waste gas leaks due to high operating pressure and pressure transients in the waste gas input sources. Another unfavorable design of this system is that the required tank volumes are large and the system operation is more complicate than other operating plants.
The actual release of radionuclides in the gaseous effluent has been about 183 Ci/yr/unit.
Solid Radwaste System
Spent resin is collected from the plant demineralizers, stored in the spent resin storage tank to permit decay of short lived fission products, and then transferred to the drumming room for dewatering and packaging. Concentrates from the waste evaporator are also transferred to the drumming room. These concentrates are blended with cement and chemicals in a mixer, and injected into a drum. Spent filter cartridges are transferred to filter cartridge drums and stored for later disposition. Miscellaneous solid wastes are compressed into drums and also stored for later disposition.
Since system operation is performed manually, occupational radiation exposure(ORE)

to workers is relatively high in comparison with other operating plants.
Solid waste volumes shipped to offsite is about 600 drum/yr/unit, with 55 gallon drum.

Group 2 Waste Processing System

Group 2 has a similar configuration as Group 1, but Group 2 has a larger waste processing capability and increased redundancy to improve the waste processing system availability. Six (6) nuclear plants, Kori-3&4, Yonggwang-1&2 and Ulchin-1&2, constitute Group 2.

Liquid Radwaste System

Input into the Liquid Radwaste System(LRS) is divided into three (3) process trains based on the processing required : high total dissolves solids (TDS) waste, low TDS wastes, and chemical wastes. Decontamination wastes are directed to the chemical waste train which normally filters wastes prior to discharge. Low TDS wastes are routed to the low TDS train which usually filters and demineralizes the waste. High TDS wastes are collected and then processed in the evaporator, which has a capacity of 30 gpm, the evaporator distillate is normally demineralized. All processed liquid is collected in the LRS monitor tanks for holdup prior to discharge or recycling. Discharge from the monitor tanks is usually directed to the condensate storage tanks for reuse, but may be discharged offsite.
To improve system operability, the storage capacity has been increased based on anticipated operational occurrences, and system reliability has increased by providing two(2) evaporators. However some troubles have been at the group 2, such as frequent replacement of filters, degradation of ion exchangers and evaporator loss due to the waste oil and the suspended solid in the liquid wastes.
The actual release of radionuclides in the liquid effluent has been about 0.02 Ci/yr/unit.

Gaseous Radwaste System

The GRS has been designed to utilize the technology of ambient temperature (104 F) charcoal adsorption to reduce the radioactivity in a gas stream by delay and decay of the radionuclides. The system consists of a surge tank, a header drain tank, two (2) parallel 100% dehumidification trains, four (4) charcoal delay beds and a HEPA filter to process gaseous wastes generated in the plant during normal operation. The system provides at least 45 days holdup for Xenon gases during normal operation. Design flowrate of the system is 2 scfm.
System operation is relatively simple and the area for the equipment is small. In addition, off-site dose has been reduced and the actual releases of radionuclides in the gaseous effluent has been about 150 Ci/yr/unit.

Solid Radwaste System

The SRS consists of the Radwaste Solidification Subsystem(RSS), the Resin Transfer Subsystem(RTS), the Filter Handling Subsystem and the Dry Active Waste Subsystem. The RSS which is In-Line Mixing Process operates remotely on a batch process basis to solidify radioactive spent resins, liquid, evaporator bottoms, and to immobilize filters and other miscellaneous contaminated objects in the 55-gallon drums for shipment offsite. The system uses portland cement mixed with lime as the solidification agent. The RTS provides for removing and storing radioactive spent resins from the plant, and consists of a spent resin tank, for storage of resins to permit decay, a resin sluice pump, valves, and piping. Following decay, resin is removed from the spent resin tank and sent to the RSS for solidification. The Filter Handling Subsystem provides the capability to replace normally radioactive filters with a minimum of personnel exposure. The Dry Active Waste (DAW) Subsystem is used to reduce the volume of compressible, slightly radioactive dry wastes. Wastes are compacted into 55-gallon drums for eventual shipment offsite.
Since the system is operated remotely, ORE to workers has been reduced, compared to Group 1 systems. In-line mixing RSS has also, however, several troubles, such as cement setup in the components, poor drum capping operation, undesirable drum surface decontamination capability and unoperable level sensors. These are reasons to increase the ORE to worker in the system operation.
Solid waste volumes shipped offsite are about 500 drum/yr/unit.

Group 3 Waste Processing System

Group 3's main design improvements were the addition of waste tank sludge removal and oily waste removal processes for the Liquid Radwaste System. Adding these features improves operability by permitting the processing of additional types of waste without shutting down the system. However, with additional features, system

complexity is also added. The system now requires more work from the operating staff, and the possibility of component failures and maintenance is expected to increase. The four(4) nuclear units Yonggwang-3&4, Ulchin-3&4 constitute Group 3.

Liquid Radwaste System

The LRS has been designed to operate in the maximum reuse mode (Zero Release Concept) with releases as required to maintain the plant water balance and to control tritium concentrations in the primary and secondary systems.

Segregation of wastes are the same as Group 2's system. All liquid wastes are processed by filtration, oil removal, evaporation, and ion exchange methods by processing required for recycling or discharge. Prior to processing, settled sludge and waste oil in the waste holdup tank are separated from liquid wastes to improve processing efficiency. Another features of this Group 3 is that all processing paths consists of batch operation concepts, so that many feed tanks are installed in the system.

Gaseous Radwaste System

The GRS has the same configuration as Group 2, because it is one of the most improved technologies to process the gaseous wastes.

Solid Radwaste System

A subsystem, Sludge Waste Subsystem, is added to the configuration of the Group 2' SRS which are necessary to meet the interface requirements of the LRS, and to satisfy the waste conditioning requirements. The Sludge Waste Subsystem provides the means to receive and store sludge wastes from the LRS holdup tanks for radioactive decay prior to transferring to the RSS.

To eliminate the limitations of Group 2 RSS, In-Drum Mixing Solidification System is used in Group 3.

UPGRADING PLAN OF WASTE PROCESSING SYSTEM

General

Based upon design and operating experience from these 12 units, the following design goals were developed to be incorporated into future nuclear power plants.

a. Reduce the release of radioactive material to the environment
b. Reduce the radwaste volume shipped to disposal sites
c. Reduce the occupational radiation exposure (ORE) to plant personnel
d. Increase the waste processing system reliability using proven technology

KOPEC implemented aggressive feasibility studies for the improvement of waste processing systems at future nuclear power plants and conducted evaluations of available technologies related to waste processing from all over the world (1).

As a result of these studies, the conceptual design for upgrading PWR waste processing systems for the future plants were modified by using the following features to meet the basic design goals;

a. Reduction of Activity Release
- Use an effective liquid-solid separation system, such as a centrifuge system
- Use a selective ion exchange media for liquid waste processing
- Prolong Xe delay time (45 days) for gaseous waste processing

b. Reduction of Waste Volume Shipped to Disposal Site
- Eliminate evaporators to eliminate evaporator bottoms
- Volume reduction of Dry Active Waste
- Volume reduction of spent resin

c. Reduction of Occupational Radiation Exposure
- Eliminate troublesome equipment
- Incorporate ALARA goals into equipment layout
- Establish long term storage of high activity spent resin prior to processing.

d. Improved System Reliability
- Use duplex components and processing trains
- Use mobile processing equipment

Description of the Waste Processing System

Liquid Radwaste System

To remove radioactive materials from the radioactive and potentially radioactive liquid wastes generated in the plant, all liquid wastes are divided into three (3) process trains according to the processing required: high radioactive liquid waste train, low radioactive liquid waste train, and decontamination liquid waste train. High radioactive liquid wastes are processed by centrifuge and then ion exchangers. Low radioactive liquid wastes and decontamination liquid wastes are processed by centrifuge only. After the liquid wastes are processed through each train, it is

transferred to the monitor tank for sampling and analysis to determine if it should be released to the environment or recycled to the feed tanks. The monitor tank is the only tank in the LRS from which processed waste can be released to the environment.

Gaseous Radwaste System

The GRS collects and processes the radioactive waste gas. The gaseous wastes are delayed in a low pressure, ambient temperature, charcoal delay bed. The GRS is sized to provide the capability of delaying Xenon for at least 45 days. The GRS limits the release of gaseous activity so that personnel exposure and activity releases in the environment are meet ALARA goals.

Solid Radwaste System

The SRS is designed to collect, process, and package solid radwaste in a suitable manner for storage until the material is shipped offsite for disposal. The SRS consists of the Resin Handling Subsystem, the Dry Active Waste sorting and Segregation Subsystem, and the Filter Handling Subsystem

a. Resin Handling Subsystem

The spent resin beads used in the plant are transferred to the Spent Resin Dewatering Equipment or to the Spent Resin Long Term Storage Tank, depending upon the resin activity. Low activity resins are transferred to the spent resin dewatering equipment, where they are dewatered and capped in the container in preparation for disposal. High activity resins are stored for approximately 10 years prior to processing to permit radioactive decay in the long term storage tanks. After storage, the high activity resin will be processed in the same manner as the low activity spent resin.

b. Dry Active Waste sorting and Segregation Subsystem

For DAW minimization and volume reduction, the system allows for waste processing to be classified into three (3) separate operations, such as the sorting and shredding operation, the pre-compacting operation, and the supercompacting operation.

To perform above operations the system consists of the various equipment, such as a sorting table, a shredder, a bag monitor, three waste compactors, a screw compactor for polyethylene waste (mobile equipment), and a supercompactor (mobile equipment).

c. Filter Handling Subsystem

This subsystem provides for removal of expended filters from filter housings with a minimum of personnel exposure. Removed filters are transferred to the filter capping area and securely stored in a special drum.

Expected Release Activity and Waste Volume

The estimated release rates for radionuclides using the PWR-GALE computer program is 0.62 Ci/yr/unit for liquid waste and 2,300 Ci/yr/unit for gaseous wastes. These estimates are based upon the improved radwaste system design.

Solid radwaste volumes shipped to disposal site are expected to be approximately 250 drums/year/unit with 55 gallon drum.

SUMMARY

Sufficient operating and design experiences on PWR waste processing systems has enabled us to upgrade waste processing systems. Plant operational experience has proven to be an important source of information allowing KOPEC to achieve an improved waste processing system design.

Using the improved conceptual design, KOPEC is currently performing the design work for the next nuclear power plants, Yonggwang Unit 5&6, which is in the early design stage.

KOPEC will make an effort continuously to improve the waste processing systems incorporate with advanced processing technologies.

Department of Energy, Headquarters
ABSTRACT
Restoration of the Fernald Environmental Management Project is now moving from the environmental investigation stage to real, tangible remediation progress. Using a variety of programmatic innovations, DOE and FERMCO continue to strengthen an effective partnership that supports a mutually-developed mission of safe, least-cost, earliest final remediation of the Fernald Site while complying with all applicable DOE Orders, regulatory requirements and commitments and addressing the concerns of the many stakeholders who have an interest in how remediation at Fernald progresses. The progress that is occurring at Fernald is testimony to a productive DOE/FERMCO partnership that will continue to be an essential part of the difficult environmental restoration task at this site.
DOE/FERMCO PARTNERSHIP KEY TO SUCCESS
The U. S. Department of Energy (DOE) and the Fernald Environmental Restoration Management Corporation (FERMCO) have developed an effective partnership that has resulted in real, tangible progress in the environmental restoration of the DOE's Fernald Environmental Management Project near Cincinnati, Ohio.
FERMCO, which is managing the remediation under a performance-based contract with DOE, assumed responsibility for the Fernald Site in December 1992. FERMCO was the first DOE Environmental Restoration Management Contractor (ERMC) in the DOE complex. Together, DOE and FERMCO established the Fernald mission as the safe, least-cost, earliest final remediation of the site. The mission also commits Fernald to compliance with all applicable DOE Orders, meeting all regulatory requirements and commitments, and -- most importantly --addressing the concerns of the many stakeholders who have an interest in what happens at Fernald.
In July 1994, DOE and FERMCO successfully negotiated the first performance-based contract in support of DOE's new contract reform initiatives. The new contract includes more specific (and objective) criteria by which FERMCO's performance is assessed and fee is earned. The contract demonstrates the mutual trust and cooperation between DOE and FERMCO in planning and executing the environmental restoration effort at Fernald.
Since 1986, DOE has entered into several agreements with the U. S. Environmental Protection Agency (EPA) and the Ohio Environmental Protection Agency (OEPA) that guide the environmental restoration effort at the Fernald Site. These agreements require DOE to conduct the remediation in compliance with a variety of environmental regulations, including the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) and the Resource Conservation and Recovery Act (RCRA). CERCLA regulations, in particular, require exhaustive environmental studies and development of remediation alternatives before final field remediation can begin. Today, much of that work has been completed. The Fernald skyline is changing as buildings are dismantled and new facilities are constructed in preparation for the final remediation work.
Originally called the Feed Materials Production Center (FMPC), the Fernald Site began producing highly-purified uranium metal products used as feed materials in U. S. defense programs in 1953. All production was suspended in July 1989 to allow concentration of resources on environmental restoration activities.
This paper discusses how DOE and FERMCO have used innovative approaches to make safe, least-cost, earliest remediation at Fernald a reality.
ENVIRONMENTAL RESTORATION REQUIRES CAREFUL PLANNING
Much of the initial remediation effort at Fernald centered on CERCLA requirements for exhaustive environmental sampling and analysis of soil, water, and other media to determine the nature and extent of contamination at the site. Based on results of this Remedial Investigation (RI) work, a Feasibility Study (FS) carefully evaluated various alternatives for removing or containing the contamination. The RI/FS supported generation of Proposed Plans (PPs) for final remediation of the site. The CERCLA agreement established five Operable Units based on their location or the potential for similar response actions. This concept allows final remediation design to begin for each Operable Unit as soon as its individual RI/FS-PP phase is completed and a Record of Decision (ROD) is approved by the EPA.
During the course of the RI/FS process, DOE and FERMCO have built solid

relationships with regulatory agencies overseeing the Fernald remediation. Fernald management recognized the need to partner with regulators during the development of environmental restoration plans to promote early resolution of issues and common understanding of approaches for remediation. Fernald worked with regulators to effectively integrate RCRA and CERCLA requirements, thereby reducing costs and eliminating duplicate requirements. This was done through technical exchanges to update OEPA on the status on the closure of various Hazardous Waste Management Units. Similar technical exchanges with EPA have resulted in steady progress toward reaching final remediation decisions.

Fernald management and the regulators have jointly developed innovative approaches that will speed the remediation effort significantly. For example, EPA has approved an Interim ROD for Operable Unit 3 -- the first of its kind in the DOE complex -- that will allow accelerated decommissioning and dismantling of some 125 production buildings and other structures located in the former uranium processing area. Thus, while the final ROD addressing treatment and disposition of soil and wastes from Operable Unit 3 is not scheduled until early 1997, work has already begun on the dismantling of the former uranium production facilities. In fact, the Interim ROD for Operable Unit 3 is expected to allow dismantling of the former production areas some 3-4 years ahead of schedule and at a savings of about $300 million from the original cost estimates.

Perhaps the most visible evidence that full-scale remediation at Fernald has begun was the dismantling of Plant 7, the tallest building on the site and the first former production building to be removed. That dismantling effort included implosion of the building's steel superstructure in September 1994. The Plant 7 project was completed well ahead of schedule and at a cost of about $11 million, compared with the $33 million estimated in the FY 1993 budget baseline.

As old production structures at Fernald are being dismantled, new facilities are under construction to handle final remediation work. The recent EPA approval of a ROD for Operable Unit 4 calls for radium-bearing waste in two concrete silos and production waste from a third silo to be removed and vitrified (converted to a s glass form) prior to its shipment off site for disposal. A vitrification pilot plant is under construction to house that operation. Fernald also has constructed an advanced waste water treatment facility to help reduce the uranium content of wastewater discharged from the site as the remediation work accelerates. The became operational in late January.

FINAL REMEDIATION DECISIONS NEAR

Fernald has received conditional EPA approval for Proposed Plans for two other Operable Units. DOE is currently reviewing a draft ROD for Operable Unit 1 that calls for the excavation and treatment of material stored in six waste pits at Fernald prior to its shipment off site for final disposition. Nearing completion is a draft ROD for Operable Unit 2 that proposes disposal of fly ash, lime sludge, slightly contaminated soil, and other material in an engineered cell on site. Work also is well under way toward a final Record of Decision for Operable Unit 5, which includes soil, water, and all other environmental media on and around the Fernald Site.

Concurrent with the detailed investigation and planning associated with the RI/FS process, Fernald is making steady progress on several interim risk reduction projects called Removal Actions. Removal Actions are initiated when there is a need to accelerate removal or containment of hazardous substances posing a significant potential threat to the environment or to the human population. Removal Actions are coordinated with both Ohio and U. S. EPA to ensure that they are consistent with the long-term remedial actions expected as a result of Records of Decision.

One of the more significant ongoing Removal Actions is the extraction of uranium-contaminated groundwater from an area south of the Fernald Site known as the South Plume. The years of production operations at Fernald and stormwater runoff from the site have contaminated the aquifer which underlies the area. Fernald also has completed a number of projects aimed at preventing any further introduction of contamination to the aquifer, including installing stormwater runoff controls and upgrading and sealing concrete pads where drummed wastes are stored.

Another continuing Removal Action is the off-site disposition of low-level radioactive and mixed wastes, including both residues from past production and construction rubble from remedial activities. In FY 1994 alone, Fernald shipped more than 577,000 cubic feet of low-level waste and more than 3,500 cubic feet of mixed

waste off site for disposal.
STAKEHOLDERS KEY TO DECISION-MAKING PROCESS
Fernald's success in moving from the environmental restoration planning process to actual field remediation is due in large part to an innovative public involvement program that emphasizes person-to-person communication and early stakeholder involvement in the decision-making process.
A key public involvement activity at Fernald was the formation of the Fernald Citizens Task Force. The Task Force, the first Site Specific Advisory Board established as part of the DOE Environmental Management program, is an independent panel comprised of representatives from virtually all of the major stakeholder interests, including local government and the Fernald Residents for Environmental Safety and Health (FRESH). DOE commissioned the Task Force to develop a public consensus on specific aspects of the Fernald remediation, including potential future uses of the site, appropriate maximum risk levels, final disposition of waste, and development of environmental restoration priorities. The Task Force meetings are open to the public, thereby offering still another avenue for community involvement in the decision-making process at Fernald. The Task Force delivered its interim report on risk levels and general future land use decisions on November 30, 1994. The final report, scheduled for July 1995, will contain recommendations on waste disposition, environmental restoration priorities, and specific future land uses.
CERCLA regulations include requirements for holding meetings and providing information to help the public understand the environmental restoration process and to provide input into the selection of remedial action alternatives. While public comment periods are an integral part of the CERCLA community involvement requirements, complying with the letter of the law limits the public involvement aspect of the remediation planning to essentially one-way communication. Traditionally, public involvement has consisted of publishing newsletters and fact sheets and holding public hearings. These hearings too often focused on providing information and asking for public comment on what has already been done, rather than genuinely soliciting public input on what should be done.
Fernald recognized that a significant stakeholder audience remained unaware of or uninterested in the decision-making process. To reach those groups, Fernald developed an Envoy Program. Some 75 DOE and FERMCO employees have volunteered to serve as envoys to various governmental bodies, civic groups, service clubs, and other organizations. Envoys establish face-to-face contact with these groups by attending their meetings and listening to any ideas and opinions their members may have to offer. This input is relayed directly to Fernald management for consideration in the ongoing decision-making process.
Fernald also recognized that stakeholder involvement will be necessary well beyond the RI/FS stage of the remediation effort. To ensure that established relationships continue, Fernald is revising and updating its Public Involvement Program to maintain a high level of stakeholder participation throughout the Remedial Design/Remedial Action phase of the environmental restoration.
An important element of Fernald's stakeholder involvement is reaching out to stakeholders of those facilities planning to receive remediation wastes from the Fernald clean-upthe Nevada Test Site (NTS) and Envirocare's facility at Clive, Utah. For over two years, Fernald has built and maintained open relationships with DOE's Nevada Operations Office, the NTS Community Advisory Board since its inception, and state regulators in Nevada and Utah. These relationships are based on candor, full disclosure of information and proposed plans, and a sincere desire to understand the needs and concerns of stakeholders at these sites of crucial importance to Fernald. This non-traditional outreach effort has been very successful.
STRENGTHENING THE SAFETY CULTURE
While external stakeholder involvement is an extremely important element of the environmental restoration effort at Fernald, management has placed an equally high priority on the involvement of internal stakeholders -- the Fernald work force -- in strengthening the safety culture at the site and improving productivity. In another first for DOE sites, a broad-based Safety First Team formed in early 1994 has developed several initiatives to encourage Fernald workers to find safer and more effective work practices. A pilot work group concept successfully demonstrated that teams of employees can effectively identify potential safety hazards and develop work methods that both reduce those hazards and increase productivity. The success of this pilot program has led to the establishment of similar work groups throughout

the Fernald organizations, with both DOE and FERMCO management playing an active role in nurturing the program.
Because the environmental restoration effort at Fernald is a complex program requiring careful balancing of regulatory requirements with available funding and other resources, Fernald management has placed strong emphasis on the area of project controls. FERMCO was the first DOE contractor to produce a project baseline containing thousands of schedule activities and hundreds of thousands of cost elements that serves as a yardstick for planning and measuring remediation progress. In March 1994, a DOE-HQ Cost Quality Management Assessment commended Fernald for putting a fully-integrated cost/scheduling system in place.
Fernald has established a formal, structured cost savings/cost avoidance procedure in support of cost savings goals established by DOE Headquarters. The procedure establishes criteria for measuring cost savings that require initiatives to be innovative, go beyond simply good business practices, and reduce the Fernald Performance Measurement Baseline.
During the second half of FY 1994, FERMCO achieved $17,880,154 in cost savings. Major contributing components for those cost savings included: streamlining and accelerating certain Operable Unit 1 studies and expediting the remediation of Waste Pit No. 6 (a savings of $1.5 million); acceleration of Remedial Action decommissioning and dismantling design packages in Operable Unit 3 ($8.2 million savings); and changes in scope for a Removal Action for improved storage of soils and debris ($2.4 million savings).
The Cost Savings Program is closely allied with the DOE-wide productivity improvement initiative, and Fernald management regularly shares productivity improvement ideas with other sites. Fernald also is developing a team to provide the additional productivity improvement focus required by the current climate of tightened federal budgets.

TECHNOLOGY DEVELOPMENT PRODUCES EFFICIENCIES

DOE and FERMCO also place heavy emphasis on developing new technologies and adapting existing technologies for use at Fernald. The introduction of safer and faster technologies will produce efficiencies in both cost and schedule for the remediation work.
For example, Fernald has used a Solid Block Modeling technology -- developed by FERMCO's parent company Fluor Daniel for use in the mining industry -- to aid in the difficult process of site characterization. Solid Block Modeling uses three-dimensional computer images to show the location, types, and amounts of contamination in waste pits and other areas. The process has been particularly helpful in identifying "gaps" in existing characterization data at Fernald and in guiding subsequent sampling efforts.
Other technologies have also been adapted for use at Fernald. Micro-Purging, a groundwater sample collection method that eliminates the need for excessive well-water purging, both increases the accuracy of sampling by reducing water dilution effects and reduces the amount of contaminated water requiring disposal. Rotasonic (spoil-less) Drilling, a method which captures almost all of a soil sample within the core barrel, eliminates sample loss or cross contamination and reduces drill cuttings by 95-100 percent. Using this technology, a sample at 130 feet below the surface can be obtained in two days, as opposed to two-three weeks using other methods.
Fernald is hosting the DOE Office of Technology Development's Uranium in Soils Integrated Demonstrations (USID). The USID program continues to evaluate various technologies for the removal of uranium from soil using chemical and physical separation methods, as well as Real Time Characterization, Cone Penetrometer probes, and related technologies. Fernald also has applied innovative robotics in the management of wastes and the remediation operations.
Finally, Fernald pioneered Minimum Additive Waste Stabilization (MAWS), a process which converts optimum mixtures of waste to a much safer glass form using specially-designed furnaces. The MAWS developments led directly to the construction of a vitrification plant now under way at Fernald to remediate wastes from the K-65 silos.

REMEDIATION NOW A REALITY

The environmental restoration effort at Fernald has, by necessity, required an enormous investment in preliminary activities related to characterization, analysis, and planning. It also continues to require significant effort in the development of

stakeholder consensus on the appropriate level of restoration and the most desirable remediation alternatives. Fernald is demonstrating that it is among the leaders in the DOE environmental restoration effort and is achieving tangible success in the environmental restoration that all who have an interest in the site have been anticipating. Together, DOE and FERMCO have developed an effective partnership that is successfully melding the interests . . . and the ideas . . . of both internal and external stakeholders in the common goal of environmental restoration at Fernald. See Fig. 1

FERMCO

ABSTRACT

The Fernald site is rapidly transitioning from an Remedial Investigation/ Feasibility Study (RI/FS) site to one where design and construction of the remedies dominates. Fernald is one of the first sites in the Department of Energy (DOE) complex to accomplish this task and real physical progress is being made in moving the five operable units through the CERCLA process. Two of the required Records of Decision (ROD) are in hand and all five operable units will have received their RODs (IROD for OU3) by the end of 1995. Pre-design investigations, design work or construction are now in progress on the operable units.

The lessons learned from the work done to date include implementing innovations in the RI and FS process as well as effective use of Removal Actions to begin the actual site remediation. Also, forging close working relationships with the Federal and State Regulators, citizens action groups and the Fernald Citizens Task Force has helped move the program forward. The Fernald successes have been achieved by close coordination and cooperation among all groups working on the projects and by application of innovative technologies within the decision making process.

INTRODUCTION

The Fernald site is located approximately 20 miles northwest of Cincinnati and has been managed by Fernald Environmental Restoration Management Corporation (FERMCO) since December, 1992. For more than 37 years, the facility manufactured uranium metal products for use at other DOE sites to satisfy Defense Program demands. Production operations were suspended on July 10, 1989 due to a sharp reduction in the demand for uranium metal products by user sites and continuing problems in achieving full regulatory compliance. Following necessary Congressional notifications, the facility was formally shut down on June 19, 1991 when its mission became environmental restoration.

The primary law regulating cleanup of the Fernald site is the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) as amended by the Superfund Amendments and Reauthorization Act (SARA) in 1986. Another major regulation, the Resource Conservation and Recovery Act of 1976 (RCRA), governs the generation, transportation, treatment, and disposal of the hazardous waste at the site. A Consent Decree was signed by the State of Ohio and the DOE in December, 1988, establishing milestones to bring the FEMP into full compliance with RCRA and other regulatory requirements. Amendments establishing additional milestones regarding the management of hazardous waste were later proposed to the Consent Decree, and in January 1993, the amendments were approved, resulting in the Consent Decree and its Stipulated Amendments (SACD).

In July 1990, the United States Environmental Protection Agency (USEPA) and the DOE entered into a Consent Agreement establishing milestone schedules for the completion of necessary studies to support the CERCLA clean-up process. The agreement established schedules for implementing near term clean-up actions (Removal Actions) while final clean-up solutions were being evaluated and selected. In September 1991, the DOE and USEPA jointly signed the Amended Consent Agreement establishing revised milestones for the completion of the required studies and identifying a series of

additional near-term actions for implementation by the DOE.
Here are some background notes of significance:
Production
Production initiated in 1952
Operations placed on hot standby in July, 1989
Formal plant closing - August, 1990
Total Uranium Production (1952 to 1989) - 462 million pounds U delivered product
Average Waste Generation Rate - 2.2 lbs waste per pound U product
Total Waste Product (37 year product history) - 1 billion pounds
Maximum Annual U Production - 10 metric tons (1960)
Environmental Issues
Plant designed to spray calcine raffinate, with pit usage exclusive to lower volume off specification material
1958 economic confrontation with Weldon Spring led to decision to abandon spray calcining process and build raffinate pits
All process residues sent to pits/silos from startup to August, 1984
August, 1984 began drumming all raffinates
80,000 drum waste inventory created by end of 1987
Pits ceased to be used in April, 1987
Plant estimates 400,000 lbs U discharged to atmosphere over 37 year production history
The Fernald site is broken down into five operable units. The following paragraphs discuss the scope and current status of each, along with a description of the remedy and discussion of some of the innovations employed on each and the lessons learned. Figure 1 provides an overall schedule for the five OUs.
OPERABLE UNIT 1 - WASTE PITS
Scope
Waste Pits 1 through 6
Clearwell
Burnpit
Berms, Liners and Soils Within the OU Boundary
Status
RI and FS/PP Reports submitted and approved
Final ROD submitted January 26, 1995
ROD signature expected February 1995
Pre-Design investigation in process
Description of Remedy
The Proposed Plan for the remediation of OU1 involves the excavation of an estimated 710,000 cubic yards of waste materials from six waste pits and two ancillary contaminated areas, the drying of this waste to meet waste acceptance criteria and its disposal in a permitted commercial disposal facility.
Highlights
In order to facilitate obtaining the Record of Decision for OU1, a successful strategy for informing the stakeholders of the Proposed Plan for Operable Unit 1 was employed. One of the greatest concerns to the public is the safety and integrity of transshipment by rail of waste materials along the spur connecting the FEMP with the main rail line to the west. In anticipation of the issues that the stakeholders would raise at the CERCLA public meeting scheduled for August 23, 1994 where formal comments from the public would be received on the Proposed Plan, OU1 held a series of public meetings prior to the official meeting to assure a thorough airing of the issues. A Rail Transportation Workshop was held on August 9, 1994 where a complete disclosure of DOE's plans for rail transport was laid out. A followup availability Session was held a week later on August 16, 1994 with CSX, the rail carrier along the spur line and the carrier for the waste freight from the FEMP to East St. Louis, Illinois. DOE's unit train concept and sealed gondola plans, Emergency Response activities, potential use of adjacent rail facilities were described and discussed with the objective of determining the public's overall reaction to the DOE Transportation plans. These reactions were then addressed and incorporated into the presentations which were made to the public at the formal public meeting held on August 23.
Ohio EPA's Office of Federal Facilities Oversight held an availability session with members of the public during the public comment period and prior to the public hearing for the OU1 Proposed Plan. Availability sessions are held by Ohio EPA during

the public comment period for each operable unit's Proposed Plan. The meetings provide an informal atmosphere for the citizens to ask questions and share concerns one on one with the agency. In addition, Ohio EPA is able to inform the public and address some issues that would otherwise have to arise through the formal public comment process.
As a result the public meeting was a very smooth, non-confrontational exchange of ideas about which USEPA's remedial project manager stated that "this was the best public meeting that he had attended."
It is estimated that $300-400 M could be saved if OU1 were allowed to ship waste in bulk to a commercial disposal facility such as the Envirocare facility currently in operation at Clive, Utah instead of sending the waste materials to the Nevada Test Site (NTS). These estimated savings derive both from the packaging requirements associated with NTS disposal and from the intermodal transfer required to dispose at NTS since NTS does not currently have any direct rail service to its disposal areas.
Working closely with DOE HQ, OU1 sought and successfully obtained an exemption from the portion of the DOE order 5820.2A which requires the DOE to dispose of low level radioactive waste at a DOE facility. The exemption, which is specific to OU1 at Fernald, allows OU1 to dispose of Low Level Waste materials at a permitted commercial disposal facility.
In order to optimize the excavation of the waste, a program entitled the Dewatering, Excavation Evaluation Program (DEEP) project was launched in 1994. DEEP consists of a 4 phase project; geotechnical testing, wet excavation, dewatering, and dry excavation for waste pits 1, 2, and 3. Waste pits 1, 2, and 3 were selected because these pits represent over 80% of the total waste OU1 plans to dry excavate during remediation.
Geotechnical testing will be utilized to evaluate the characteristics and geotechnical properties of the waste before, during, and after dewatering tests have been conducted. Wet excavations consisting of pre-dewatering back hoe excavations and waste reslurrying and pump tests will be performed after initial geotechnical testing. The feasibility of dewatering will be established by comparatively testing alternative well configuration and well types and through the testing of electro-osmosis and vacuum assist enhancements to determine the optimal method to employ during final remediation. Dry excavations, to include dry trench excavation and ramp excavation, will be performed to determine the efficiency of the dewatering techniques, amenability of the waste to excavation and handling, and the ability of the waste to support heavy equipment. To date, the initial geotechnical testing has been completed in the waste pits. Wet excavations are scheduled to begin in mid-January, followed by dewatering, and dry excavation.
OPERABLE UNIT 2 - OTHER WASTE UNITS
Scope
Fly Ash Piles
Lime Sludge Ponds
Solid Waste Landfill
Other South Field Disposal Areas
Berms, Liners and Soils Within the OU Boundary
Status
RI and FS/PP Reports submitted and approved
Draft ROD submittal scheduled February 1995
ROD signature expected June 1995
Pre-Design investigations in process
Description of Remedy
Excavation of materials and disposal in an on-site disposal cell. Shipment of any hot spots off-site.
Figure 2 shows the preliminary size and location of the on-site cell.
Highlights
Three Dimensional Modeling
Throughout the Operable Unit 2 remedial investigation process, soil and groundwater sampling results were fed into a modeling process that accounted for spatial variations in the data and created an estimate in 3D of the extent of contamination. The resulting graphics provided images that were easy to understand and easy to remember. Those images simplified interaction between the DOE and the EPAs and provided an important tool for informing the public about the operable unit.
Reduced Time Frame & Cost for Laboratory Services

The new FEMP program for preapproval of chemical analysis laboratories resulted in shorter procurement periods and reduced overall costs during recent Operable Unit 2 groundwater monitoring and the second phase of the disposal facility predesign investigation.

Cone Penetrometer Testing

Cone penetrometer tests (CPTs) are being used in the proposed disposal facility predesign investigation. The objective of this preliminary work is to better define the lithology in the potential facility location. The CPTs have proven to be five to ten times faster than routine drilling and to have associated cost savings. While CPTs do not provide samples for ex situ testing, they do provide full classification over the depth of the borehole.

The information learned from the CPTs also allows better placement of future wells and borings.

Meetings for Citizen Involvement on the Proposed Disposal Facility

DOE organized three opportunities for the public to discuss the proposed on-site disposal facility. Two public workshops were held, on June 28 and October 25, 1994, to discuss the Operable Unit 2 Feasibility Study/Proposed Plan and details of the preferred remedial alternative. A public meeting took place on November 8, 1994. During this meeting, DOE answered questions and accepted formal public comments on the Operable Unit 2 Proposed Plan and preferred remedial alternative. In addition to the DOE workshops and meeting, OEPA sponsored two availability sessions, in September and November, to discuss the Operable Unit 2 Proposed Plan and preferred remedial alternative. DOE also made presentations to smaller groups of local elected officials at their request. A priority has been placed on public outreach for this remedial action because of the sensitivity and strong public opinions associated with leaving waste on-site in an engineered disposal facility. Important perspective and useful input on this set of issues resulted from deliberations by the Fernald Citizens' Task Force. Indeed, Task Force input was instrumental in determination of the proposed remedy for OU2.

OPERABLE UNIT 3 - FORMER PRODUCTION AREA

Scope

All Man-Made Structures and Facilities at the Fernald Site, Above and Below Ground.

Status

Interim ROD issued July 1994, which allows D&D of all OU3 facilities

A D&D contract has been placed to take down the Plant 4 complex.

RI/FS/PP Report submittal scheduled to EPA September 11, 1995.

Draft Final ROD (disposition of waste material) submittal scheduled July 25, 1996.

Description of Remedy

Dismantlement of structures, excavation of materials and disposal in an on-site storage cell. Some items and material may be disposed offsite. Considerable emphasis on recycling.

Highlights

The Record of Decision for the Interim Remedial Action, signed by EPA on July 22, 1994, represents the first Operable Unit Record of Decision for the Fernald Site. This landmark decision allows remediation of the site buildings and structures to proceed, resulting in significant cost savings and schedule acceleration.

Plant 7 represents the first Fernald Facility to undergo the D&D process. As Fernald's tallest structure, the Plant 7 takedown became a symbolic gateway to future work at the site. (See Fig. 3) The task was difficult and frustrating at times, and the successful takedown was the result of diligent planning, hard work, and perseverance by all involved. The project, in spite of the building's resistance to our planned efforts, was completed significantly ahead of schedule and below cost.

The CRU3 RI/FS Field Investigations Program initiated the field sampling activity in late September 1993 and completed it on August 4, 1994. The program was completed 6 weeks ahead of schedule and under budget. During this time 1000 construction samples were collected. The samples were of excellent quality, resulting in a zero resample rate. Also, an impressive record of zero down time in the field and no lost time injuries are testimony to the good planning and enthusiasm of the program's personnel.

Other significant highlights

Plant 1 Ore Silos - completed demolition

Fire training facility - completed demolition

Plant 1 Pad - expanded/upgraded capability to stage and process remediation waste streams.
Awarded contract to recycle 700 tons of structural steel.
Completed demolition of Plant 7.
Established a prioritization and sequencing schedule and associated cost estimate for decommissioning of all Fernald facilities consistent with site wide remediation goals.

OPERABLE UNIT 4 - SILOS

Scope

Silos 1 and 2 (K-65 Silos)
Silo 3 - Metal Oxides
Silo 4 - Empty
Decant Sump System
Soils and any Buried Concrete
Berm Surrounding Silos 1 and 2
Perched Water (encountered During Remediation)

Status

RI and FS/PP Reports submitted and approved
ROD signed December 1994
Pilot Plant under construction, glass making to begin in July 1995, with radioactive glass scheduled for late 1995.

Description of Remedy

Remove silo contents by hydraulic excavation, vitrify the waste, ship to Nevada Test Site for final burial.

Highlights

Operable Unit 4 was the first operable unit to incorporate NEPA requirements into the CERCLA process at Fernald. This had a dramatic effect on the time and cost for responding to the requirements of each law, taking some extra time to begin with, but reducing the overall requirements by elimination of duplicate efforts. This was done through a Notice of Intent which integrated the process and documentation packages into a Feasibility Study/Proposed Plan-Environmental Impact Statement (FS/PP-EIS). The first final ROD for the Fernald site was also OU4's and was signed on December 7, 1994. This started the clock under the CERCLA process for remediation to commence within 15 months.

Several technical innovations are part of the OU4 project and revolve around the need to handle the silo material with care. The K65 silos are the largest radon concentration source in the United States (and maybe the world). Gas headspace in silo 2 is approximately 3 million pico curies per liter and the interstitial gas space in the solids may approach 40 million pico curies per liter. To deal with this concentration, the K65 material will be removed with a hydraulic mining pump which will contain the radon to a large extent as a soluble gas in the water and the vitrification plant itself will use activated carbon for removal of radon from the process gas streams. A small robotic device is planned for final cleanout of the heels in the tank so that the last traces of the spent ore can be removed before the silos are dismantled.

New analytical techniques are being tried and some are being custom designed to deal with the large range of radon concentrations that will be seen in the pilot plant. Concentrations are expected to range from environmental levels of around 1 to 4 PCi/L to over 60,000 PCi/L in the process itself. Advances in scintillation counting and in personnel monitors are being tracked as part of the project.

A new approach to high temperature vitrification furnace design is incorporated into the vitrifier for this facility because of the very high (approximately 1400 degrees C) temperatures expected to be needed for portions of the waste stabilization. The vitrification process will reduce the radon emanation rate by a factor of approximately 500,000 versus the silo material in its present form. The tighter glass structure of the vitrified product will retain the radon within the matrix so that it decays in place to a much larger extent that is presently the case in the powder in the silos.

The headspace in the K65 silos was very high in radon concentration (over 20 million picocuries per liter) and contributing to high levels of radon near the fenceline of the facility due to natural diurnal aspiration of the silos. A removal action was initiated to reduce the headspace concentration and thus reduce the overall release rate.

The approach selected was to cover the silo material with a cap of bentonite clay which acts as a barrier to diffusion of the radon from the underlying silo material. The radon was retarded in its ability to reach the headspace and the natural decay process of 3.8 days half life captured more of the radon progeny in the clay and silo material. The radon headspace concentration was reduced by approximately a factor of 10 to just over 2 million picocuries per liter so that the radon flux from the silos was reduced.

OPERABLE UNIT 5 - ENVIRONMENTAL MEDIA

Scope

Groundwater (Great Miami Aquifer)
Groundwater (Perched Water)
Surface Water
Soils (Not Associated with OU1 - OU4)
Sediment
Flora and Fauna

Status

RI and FS/PP Reports submitted
ROD submittal scheduled October 1995
ROD approval expected November 1995

Description of Remedy

Pump and treat ground water, place soils in cell where WAC is acceptable, ship hot spots off-site.

Highlights

The high degree of success of the OU5 RI/FS effort is directly attributable to the evolution of successful communication between DOE and the regulatory agencies. This has been developed through frequent meetings and discussions with the regulatory agencies during the preparation and implementation of work plans for field sampling programs, fate and transport model improvement process, and the development of procedures and protocols for risk assessment. Although initial efforts were tentative in the late 1980s, by 1993 a high level of communication had been achieved through technical information exchange meetings, informal data presentations and discussions between technical staffs which continue today. As a result, the reports and work plans submitted to the agencies by OU 5 have been accepted with a minimum of revision and comment by the agencies, because the work performed was consistent with agency expectations.

The second principal factor in the success of OU5 has been the use of a phased approach to conducting the remedial investigation and developing models for fate and transport in groundwater as well as the risk assessments. The 1988 RI/FS Work Plan set the goals of the investigation and the initial steps to be taken in the RI/FS. During the investigation, frequent review of the data as it was gathered resulted in work plan addenda that were focused on specific, narrowing, data needs. This approach ensured the best scientific and engineering practices were effectively applied to the investigation using the available resources. These reviews culminated in the 1993 field sampling programs in which remaining data needs were adequately addressed to complete the RI and conduct the FS.

These data reviews also led to the development of significant removal actions such as the South Groundwater Plume Removal Action. Implementation of the removal actions began the transition from RI/FS activities into actual cleanup activities well in advance of the ROD. Implementation of the removal actions has also provided for the phased development and scale up of treatment facilities based on operating experience with the constituents at the FEMP.

The size of the investigation area and the complex interplay of the pathways involving air deposition, surface water infiltration to perched groundwater, surface water transport and infiltration to the Great Miami Aquifer, and infiltration from perched groundwater to the Great Miami Aquifer resulted in the installation of over 1300 borings and 750 monitoring wells. Subsurface soil samples were collected from the borings and groundwater samples were collected from the wells. In addition, samples of surface soil, surface water, and sediment samples were collected. These samples were analyzed for one or more parameters from a list of radiological constituents, hazardous substances, and pesticides/PCBs. As a result a database of over 1,000,000 records of analytical data was organized, verified, and validated for the OU 5 RI and FS. The database includes RI data collected under work plans developed for each of the five operable units and incorporates pre-RI data and FEMP

routine environmental monitoring data with appropriate validation qualifiers. Environmental data collected during routine monitoring and RD/RA sampling for each operable unit at the FEMP will continue to be incorporated into this database. The database will be an invaluable resource to the development of RD/RAs for OU 5.
Fernald developed a successful ecological risk assessment strategy in conjunction with USEPA in early 1993, and incorporated the site-wide ecological risk assessment into the OU5 RI Report. Risks were evaluated in specified study areas of the FEMP to estimate potential risks to specific ecological receptors (as defined in the approved strategy). The risk assessment strategy was negotiated early with the regulators to facilitate prompt review and approval. These efforts were successful as reflected in the receipt of only minor comments from the USEPA, OEPA and support contractors.
Overall, a 17 volume RI Report, including an attached plate of over 350 maps, was submitted to the EPAs for approval. The document contained over 35,000 pages and represented the anthology of the more than 11 years of investigations of the environmental conditions at the FEMP and surrounding areas. Its approval represents a consensus on the part of all involved organizations that the nature and extent of environmental contamination at the FEMP site has been appropriately defined. Under a rigorous review by the regulatory agencies and their support subcontractors, the RI Report received only relatively minor review comments. The level of comments was reflective of the cooperative spirit that had been fostered between OU5 and the regulators through the use of this highly interactive document planning process.
The progressive data reviews associated with the field investigations program of the RI/FS led to the identification of near-term environmental issues. The identification of these issues facilitated the performance of a series of removal actions focused on attenuating the further migration of contaminants or minimizing the release of contaminants from the facility.
Issues relating to future use of the Fernald Site are mainly addressed in Operable Unit 5, and they incorporate input and recommendations from the Fernald Citizens' Task Force on future use.
Contaminated surface water controls
1986 - Storm water retention basin installed - Controlled the bulk of the contaminated runoff from the production area which was the primary source of contamination to the Great Miami Aquifer
1988 - Surface water control of the plant 1 pad - Rerouted contaminated runoff from the pad and periphery to the stormwater retention basin
1992 - Waste pit area runoff control (Removal Action No. 2) - Controlled contaminated runoff from the waste storage area (OU1) and the K-65 silo area (OU4)
1993 - Waste pit area containment improvement (Removal Action No. 22) - Involved minimizing the potential for wind and water erosion of contaminated materials by seeding exposed and stressed surfaces in the OU1 study area.
1993 - Collect uncontrolled production area runoff (Removal Action No. 16) -Controlled additional contaminated areas around the perimeter of the production area
Groundwater
1989 - Contaminated water below FEMP buildings (Removal Action No. 1) - Pumps highly contaminated perched water to reduce the potential for contamination to migrate to the Great Miami Aquifer - Water beneath plants 2/3, 6, 8, and 9 is being pumped and treated for VOCs and uranium
South Groundwater Contamination Plume (Removal Action No. 3) - implementation of its five parts is phasing into the OU5 remedy for groundwater contamination. See Fig. 4 for a schematic of the South Plume.
Part 1 - provide an alternate water source to an affected industry - completed
Part 2 - install a groundwater recovery well system to extract and pump groundwater back to the FEMP site for monitoring and discharge to the Great Miami River -Initiated Pumping August 1993. Also, installed a new HDPE outfall pipeline with fusion welded joints thus addressing the questionable integrity of the existing outfall and providing for future remediation waste water flow capacity.
Part 3 - construct an interim advanced wastewater treatment facility to remove additional uranium from site waste streams to reduce uranium discharges to the Great Miami River - Online since July 1992; treats 300 gpm from storm water retention basins (500 - 700 ppb to <.1 ppb total uranium) and up to 100 gpm other plant process/ storm water (1000 - 1500 ppb to approximately 10 ppb total uranium)

Part 4 - monitor groundwater more frequently and prevent use of contaminated groundwater - Ongoing, began in 1992
Part 5 - identify the location and extent of any remaining contamination attributable to the FEMP site (i.e., locate the leading edge of the plume exceeding the 20 ppb level) - Complete 1992
South Plume Interim Treatment project
  Dedicated treatment for 200 gpm South Plume groundwater
  Treats water containing 20-30 ppb uranium to <.1 ppb uranium
  Initiated continuous treatment in March 1994
Advanced Wastewater Treatment facility
  Scheduled to be online January 1995
  Phase I will treat 700 gpm of stormwater from SWRB or groundwater as capacity exists
  Phase II is 400 gpm treatment capacity for existing process waste water, South Plume groundwater, and future remediation waste water from other OUs
  Both Phases will focus on uranium removal
Provision of alternate potable water supplies to homeowners whose private wells were impacted by the South Plume - Supplies bottled drinking water to homeowners whose water supply has been affected by the FEMP (Uranium concentrations < 2.7 ppb).
Providing funding and technical support to the Hamilton County Department of Public Works to construct a reliable public water supply for residences around the FEMP.
SUMMARY
Fernald's environmental restoration program is well along the path from site investigation into genuine remediation. Success in this transition has been driven by innovations in regulatory relations; extensive stakeholder involvement; judicious application of technology; and innovative approaches to project management which have improved safety, accelerated schedules, and reduced costs.

8-3
DOE'S PERSPECTIVE: REACHING SUCCESS BY STANDING ON A THREE LEGGED STOOL
J. Phillip Hamric
Kenneth L. Morgan
U.S. Department of Energy
Ohio Field Office
ABSTRACT
Gridlock, inertia, conflict, outrage, bureaucracy, obstruction, media sensationalizing, courts, and politicians. These are the things that characterize any attempt to implement a public policy today.
It is worse today than it has ever been because the middle has dropped out of public opinion. We have today no consensus of public values. At Fernald, we have come to recognize that in order to achieve any success we must first build a public consensus about what success will look like.
We do this through a three-part approach we call the three legged stool. It includes public information, management involvement, and person-to-person communication. Each of these elements is essential.
PUBLIC INVOLVEMENT HELPS GET THINGS DONE
The reason we need to do public involvement is to make better decisions. Most of the Department of Energy's projects have failed or been stalled, not for technical reasons, but for political ones. In hindsight, we can say those projects were bad public policy decisions. This is not a phenomenon unique to the Department of Energy. All around the country, there are important projects that have failed because the appropriate political work has not accompanied the technical work. In Cincinnati there is a road like that. It was supposed to be a limited access inner belt across the north part of the city. It is called the cross-county highway. Unfortunately it doesn't cross the county. At one end of the county it begins, runs a couple of exits and then stops. At the other end of the county it begins, runs a couple or exits and then stops. The cross county highway never crosses the county. It would be more aptly named the highway at either side of the county. Good money was spent to begin this project and plan it. It would be a useful part of the highway net but the necessary political support for it was never generated.
Managers who believe that their only responsibility for their project is technical are likely to fail. In our society, ordinary citizens have the power to stop projects by demonstrating, lobbying their congressional delegation, going to court,

using the mass media, and even violence. In order to succeed, managers have to adopt good public policies. Good policies meet the needs of the majority without harming the minority. Such a policy is usually not clear. It is not clear to the public and it is not clear to us as managers. Although all too often we get an idea in our head that is all too clear and all too wrong. If we had better feedback we might not embark on cross-county highway disasters. Choosing a good public policy is a process of discovery and creation. At the same time it is also a process of promotion. The way to make the best decisions and get support for that decision is by public involvement.

People have a fundamental desire to participate in decisions that affect their lives. There are many people whose lives can be affected by our operations. Some of these are residents near our operations, business leaders, people concerned about the environment, and perhaps most important, our own employees. If these people feel they cannot participate in decisions that affect them they might not accept those decisions. If they don't accept them, they may try to get them overturned. At the very least they will passively resist them.

This one fact about human behavior would be enough to justify a vigorous public involvement program. But there is another reason. Time has shown that many minds, working together, can often come up with better solutions for problems. It may take extra time at the beginning to involve more people in decision making, but it can save time and money before the process is over.

WHAT IS PUBLIC INVOLVEMENT?

Public involvement is not a vote, or a popularity contest. At the outset, someone must accept responsibility for making policy decisions. Public policy decisions are often difficult because conflicting interests must be balanced. Public involvement can make these decisions a little easier and help predict the level of public acceptance for a particular decision. Public involvement is a process to give those officials the best information to make an informed decision. It also makes sure that all the people who have concerns are heard.

The three legs of public involvement

Think of public involvement as a three-legged stool. Leg one is public information. Leg two is management involvement. Leg three is person-to-person communication.

1. Leg one: Public information

When people think of public involvement, they often think of public meetings, brochures, video production, and displays. These are elements of a good public information program, but they are only one leg of the public involvement stool. In most operations, it is the strongest and most well-developed leg. We have a talented and experienced Public Affairs staff that do these things well. Do not imagine, however, that you have good public involvement by just holding good meetings and producing good brochures.

2. Leg two: Management Involvement

Public involvement starts to become a reality when managers accept it as their responsibility and make it a regular part of their decision-making process. That process has the following steps:

Identify the problem -- in clear terms.

Identify why it must be solved and whether or not you and your organization are theright people to solve it.

Identify the people and institutions like to be affected by the problem or your attempts to resolve it.

Speak to them and identify their concerns.

Identify a set of alternatives that show different ways of taking action. Every person affected should be able to see at least one alternative that includes measures to protect their interests.

Make sure the persons affected understand the alternatives and can see how at least one of the alternatives clearly addresses their concerns.

Evaluate and refine the alternatives. Show the effects on everyone's values of each alternative.

Give all affected parties an opportunity to say whether they think the alternatives have been described and evaluated accurately and fairly. Change the alternative if the new information warrants.

Make the decision.

Continue to evaluate progress using these same steps.

This may seem like a very long and complicated process. Sometimes it can be. For

large projects it may take many studies and several years. For other, simple projects, it may only mean a meeting and a few phone calls. The important thing is to make it a natural way of doing things. It will save time in the long run.
When management becomes involved in this way, the public involvement stool becomes much stronger. The first leg of the stool, public information, starts to become more effective and meaningful to the public. The second leg, management involvement, places responsibility for public involvement with decision makers.
3. Leg three: Person-to-person communication
The last leg of public involvement is person-to-person communication. This is communication through personal relationships between site employees and members of the public.
Our society is overwhelmed with information. Most people are bombarded day and night by information, most of it considered irrelevant and perceived as serving someone else's interest, or being just plain false.
People tend to trust someone they know over a newspaper article or a television show. Experience tells us that in most American communities, even big cities, there is a relatively small group of opinion leaders. The opinion leaders reflect the values of a group of people who share a common interest. If their concerns are addressed before a decision is made, the decision will rarely be overturned.
At Fernald, we have designated employees to act as representatives to opinion leaders. These employees are called envoys. It is their job to cultivate a relationship with one or more opinion leaders. In some cases, this is a natural development of existing relationships. The important thing is the relationship not the message. It is not their job to promote the site or sell a program. There most important job is to build and preserve a relationship of trust.
How the envoy concept works
For instance, the Fernald fire chief already has business contacts with fire chiefs and other emergency management people in the surrounding community. The envoy concept takes advantage of this relationship by making the fire chief the Fernald representative to the opinion group he or she is already contacting.
After all, the group naturally turns to the Fernald employee for information about site activities and related issues. Making that person the envoy merely recognizes that relationship and ensures that the envoy has complete, current and accurate information. Public Affairs gathers that information; envoys only need to tap into it.
Although the envoys can provide information,they should think of themselves as a pathway between the site and the public. Along this pathway travel messages, and concerns in both directions. Really important and complex issues may require dialogue between a site manager and some interested or concerned party. If the envoy has built trust in his relationships that trust will be, to some extent, extended to whoever the envoy introduces. Instant credibility. Because communication is two-way either through envoys or face-to-face management gets a much better understanding of the concerns of the public.
After each contact, the envoys report on what they have learned. Public Affairs then passes along that information to managers. The envoys then ask Public Affairs for any information they need to pass on to their groups. The envoys also prepare a debriefing report for Public Affairs.
The fire chief is just one example of how an envoy might be recruited. Thirty or so envoys would be a powerful communication tool. With envoys, public meetings become less important than one-on-ones, which then may only serve as group affirmation of understandings reached through person-to-person contacts. Brochures or fact sheets become calling cards to reinforce messages the envoys deliver.
The envoy system has proven useful in some unexpected ways.
It is an early warning system to alert project managers that their actions could become a cause of controversy or that bad feelings are being developed because of operations.
It has become a source of new ideas and solutions.
It is a powerful communication tool. Through the network of envoys information can be conveyed swiftly and effectively.
It reduces media attention to your operations. If something happens at our site, like an environmental spill, or an accident, we can get rapid, accurate information to community opinion leaders through a credible source. The outrage factor goes down, by the time reporters start getting quotable quotes, the quotes are less

likely to have anger toward us.
Other techniques to enhance public participation
The three-legged stool requires new communication techniques to support it. Traditional methods, most of which only promote one-way communication, are not sufficient to fully involve the public.
Although a certain level of public participation is required by various laws and regulations governing radioactive and toxic waste, most of these activities are retroactive; the public gets its say only after the initial recommendation has been made. As discussed earlier, the consequences of the public not supporting a particular decision can be time-consuming and costly.
At Fernald, we are changing the old way of doing things in order to maximize public involvement in an efficient and effective manner. While this requires more initial planning, the rewards promise to be great.
Some of the techniques we are introducing at Fernald modify traditional public information techniques to make them more interactive. Some of those include:
Publishing a community bulletin that summarizes the status of studies and activities supporting various phases of the Remedial Investigation and Feasibility Study, as well as other cleanup actions. For example, the bulletin would discuss all the disposal options being considered for the site, even before the actual studies are underway. The community bulletin is primarily an external communication tool.
Introducing a question-and-answer column in the monthly bulletin, much like the question-and-answer feature in the Fernald employee publication Focus. With a Q&A column, the public will have a way to get information about the site without having to wait for a public meeting. The benefit for technical managers is that they get specific feedback about site-related activities. For example, the Q&A can be a barometer of the community's acceptance and opinions on such issues as transportation options.
Inviting the public to comment on ideas as a partner in brainstorming sessions. Think of these public sessions as the CERCLA equivalent of NEPA scoping meetings. For example, if DOE decides to develop studies on various treatment options, there would be a public work session to solicit ideas and feedback from the community.
The creation of a citizens advisory board commissioned to solve specific problems. Public involvement supports the work of this board, the Fernald Citizens Task Force. When information is provided to the task force, it is given to the public. The intention is to thwart any potential tendency to see the task force as the only group of stakeholders worth listening to. While the task force's membership is a diverse and balanced group that typifies the major stakeholders for the Fernald site, it cannot possibly represent every interest without becoming too large and unwieldy. Sharing information with other constituencies, particularly those not directly represented on the task force, guarantees that public participation at Fernald is more than seeking consensus from the task force.
Disseminating a "management memo" that provides information about policy and site issues for supervisory personnel. The management memo is primarily an internal communication tool.
Creating a "newsroom" that provides accurate and up-to-date information about site activities and issues. This innovation, adapted from the operations of daily newspapers, is especially important for supporting the envoys. In the Fernald "newsroom," public affairs staff gather information from other divisions or departments, such as strategic planning, regulatory compliance, risk assessment, and construction. Envoys then draw upon that information as needed to fulfill the information needs of their constituencies.
The newsroom works like this:
Public Affairs staff -- primarily the counselors -- will gather information on all aspects of site operations and cleanup activities. Of course, anyone can be a "beat" reporter in the Public Affairs newsroom; managers may report information they received at a meeting or through other means. All managers or employees need to do is call or e-mail Public Affairs -- much the way members of the public call news organizations with news tips.
That information is compiled by the Public Affairs equivalent of a "city editor." The editor keeps the information in a easily accessible, centralized database. This database functions much like a "wire service," and serves as a source of information available electronically to managers, employees, and envoys as talking points for person-to-person contacts. The "wire service" information can be used for

internal or external publications and presentations.
In addition to compiling and maintaining the information database, the editor serves as a gatekeeper, making sure the information is complete, verified and timely. The information in the database is used for all public information tools, which ensures the consistency of the quality of information being disseminated to internal and external audiences.
At Fernald, these communication techniques are being developed with the goal of enhancing public involvement and providing accurate and timely feedback to managers. Although public involvement is the responsibility of program managers, public affairs specialists play an important role. At Fernald each project manager is assigned a public affairs counselor. These counselors draw upon their resources to help managers. They coach, train, and support. They help managers develop communication plans. They use their special communication skills in writing, graphics, video, and meeting facilitation to develop good communication tools for the manager. The counselors pay a special role in communicating through the mass media. Most importantly they integrate and coordinate the actions of the many different programs into a single site-wide public involvement program.
Public involvement is not a tidy process. It is not straightforward. There are no guarantees. However, huge public treasure has been lost because public policy was not accepted by the public. It is worth making the effort to use public involvement to discover and build support for a policy that will be accepted. The Fernald experience suggests that it is well worth the effort.
Planning for public involvement begins before a project starts
The DOE site manager and the Public Affairs staff use the information they get from the project plans to develop public involvement activities to support those efforts. They coordinate the many different public involvement demands of the various projects. That way we can avoid duplication or overkill and assure uniform quality. There are some site-wide activities that project managers can take advantage of as they develop their individual plans. The public involvement process will be simpler if project managers can take advantage of these site-wide activities for their own specific communication needs.
As soon as a project or change of direction starts to loom on the horizon, managers should consult with their Public Affairs counselors. When an activity requires public involvement, the Public Affairs counselors will prepare for their technical managers a communication plan. The communication plans average about 2 to 3 pages and specify the following information:
- Objective
- Audience
- Strategy & Messages
- Methods to deliver and receive messages
- Sensitivities

The Public Affairs counselors also create and maintain project-specific attachments that summarize community concerns. Because public involvement is a dynamic process, these attachments must be frequently updated.

PUBLIC PARTICIPATION AT FERNALD: THE TASK FORCE PROCESS
John S. Applegate
James B. Helmer, Jr.
Professor of Law
University of Cincinnati
Chair, Fernald Citizens Task Force
ABSTRACT
This paper focuses on the unique aspects of the Fernald Citizens Task Force process that have contributed to a largely successful public participation effort at Fernald. The Fernald Citizens Task Force passed quickly by many procedural issues. Instead, the Task Force concentrated on (a) educating itself about the site, its problems, and possible solutions, and (b) choosing a directed way to approach its mandate: To make recommendations on several "big picture" issues, including future use of the site, cleanup levels, waste disposition, and cleanup priorities. This paper presents the approach used at Fernald for establishing and running a focused site-specific advisory board, the key issues that have been faced, and how these issues were resolved. The success of Fernald in establishing a strong and

functioning site-specific advisory board serves as a useful model for other DOE facilities, although the Fernald model is just one of many approaches that can be taken. However, the approach presented here has worked extremely well for Fernald.

INTRODUCTION

Site-specific advisory boards (SSABs), of which the Fernald Citizens Task Force is one, have been established by the U.S. Department of Energy (DOE) at several of its major remediation sites across the country. In the last five years, there has been a growing demand for the creation of citizen advisory groups at DOE's major complexes. In 1991, the Office of Technology Assessment published Complex Cleanup, which argued that there was a "need for a decision-making process -- acceptable to all interested parties -- through which public concerns can be addressed and resolved" as a way to secure public acceptance of cleanup decisions and future courses of actions at DOE sites. Advisory boards were suggested as one option for creating avenues of meaningful participation for interested and affected community members. In 1993, the Federal Facilities Environmental Restoration Dialogue Committee published its Interim Report, "Recommendations for Improving the Federal Facilities Environmental Restoration Decision-Making and Priority-Setting Processes" (often referred to as the Keystone Report), which also recommended creating site-specific advisory boards to assist in the decision-making process.

The Department of Energy moved quickly to implement these recommendations, and SSABs are up and running at several major DOE sites that require remediation, including all of the most severely contaminated ones. DOE at the Fernald Environmental Management Project (formerly the Feed Materials Production Center), in cooperation with the U.S. Environmental Protection Agency (EPA) and the Ohio Environmental Protection Agency (OEPA), asked key stakeholders if they wanted a site-specific advisory board. DOE, the regulators, and local stakeholders decided that a site-specific advisory board would be useful as an additional component of Fernald's existing and extensive public participation program. The Fernald Citizens Task Force was established and, a little more than a year later, it has delivered its Interim Report containing recommendations on cleanup levels and future use of the site once remediation is complete. The Task Force is on track to deliver a Final Report in July 1995.

Nevertheless, the precise role of SSABs in public involvement within the DOE complex is still being defined. What is clear from Fernald's experience, however, is that SSABs have great value for incorporating citizen involvement in public participation at DOE sites. So far, the Task Force process has enabled DOE to establish the personal relationships that are essential to public acceptance of its work, and the Task Force recommendations have avoided the pattern of extreme demands and out-of-hand rejection that all too often characterizes the governmental relationship with the public in environmental issues.

BACKGROUND

The Fernald Environmental Management Project is located approximately 17 miles northwest of downtown Cincinnati. Surrounding properties consist primarily of agricultural and residential development. The facility was established in 1951 as the Feed Materials Production Center to produce uranium metals for weapons production. The facility operated in this capacity until 1989 and the end of the Cold War. In 1991, its mission was changed to environmental restoration. Production and disposal activities, wind, and runoff during its 38 years of operation have resulted in widespread contamination from uranium and other hazardous and radioactive chemicals both on and off the 1,050-acre property. Of greatest concern is uranium contamination of soils on site and above background levels up to five miles from the facility. Also, uranium contamination of a sole-source drinking water aquifer beneath the site affected off-site water wells in the area. As a result, strong grassroots citizen activity -- notably the Fernald Residents for Environmental Safety and Health (FRESH) -- was established in the mid-1980s to press for clean-up of the Fernald site and to prod DOE and its contractors to open the decision-making process to stakeholders. In 1989, the Fernald site was added to the National Priorities List.

Fernald, in sum, presents several important characteristics that suggest the value of an alternative to the traditional present-and-defend approach to public participation. First, there is an active, vocal, and skeptical public. Public involvement in cleanup activities at Fernald is sophisticated and long-standing. The Fernald Citizens Task Force has had to overcome a great deal of mistrust of DOE in

order to work effectively on the problems that beset the site.
Second, there are large volumes of waste. Returning Fernald to background conditions would require the disposal of tens of millions of cubic yards of radioactive soils and materials. Task Force recommendations must take into account all of the complex issues of on-site versus off-site disposal, acceptable land uses, acceptable risks and cleanup levels, and the efficacy of available treatment and disposal technologies.
Third, the site has resulted in immediate impacts on stakeholders. The accessibility of the Fernald property makes existing health threats very real to the community and eliminates options for locating disposal facilities outside of the public's view and reach. For example, storage silos containing the most hazardous wastes at the Fernald facility are only 1,000 feet from the site boundary and literally right across the street and visible from surrounding homes and farms.
Fourth, there has been demonstrated a greater need for stakeholder access. Like all of DOE, Fernald has gone through a metamorphosis with regard to public access and input to its activities over a relatively short period of time. It was not long ago that many of the activities at Fernald were secret. Public access was prohibited and little was known by neighbors about site activities; indeed, some neighbors thought "Feed Materials" referred to animal feed. As the Cold War ended and the need for public participation became apparent, information was released in enormous volumes as public comment was solicited on cleanup decisions in accordance with federal law. Stakeholders at Fernald still felt like victims in a "decide-announce-defend" system, only now they had to deal with information overload as well. Today, Fernald managers recognize the need to develop a decision-making process that provides for the bona fide involvement of all stakeholders to make credible and implementable decisions that will stand up over time.
Fifth, budget constraints pose limits on the extent of cleanup. Budget considerations, prompted by federal efforts at deficit reduction and cost controls, will have significant impacts on the level of cleanup that will be achievable as well as the length of time needed to achieve results.
The Goals of Establishing an SSAB
Against this backdrop, then, it was decided to establish an SSAB at Fernald. In designing a process for establishing and operating a citizens advisory board, it is essential to keep constantly in mind the desired characteristics of the advice that DOE is seeking.
First, the advice must come from a group that is both reasonably representative of the wide variety of stakeholder views at a complex remediation site, and also credible to those who are not directly represented on the SSAB. This requires both a good process for choosing members and good judgment in making the selection. To be useful -- and hence actually used -- the advice also must meet several other criteria. It needs to be relevant to the actual remediation problems that DOE faces. This usually means that specific issues must be identified upon which public input would be helpful. Citizens' recommendations must also be informed. Further, they must be timely, that is, given at a point when the decision is not final or effectively final. Last, the advice must be realistic, recognizing the political, technological, and financial strictures within which all environmental decisions are inevitably made.
To achieve recommendations that have these characteristics, both DOE and its stakeholders have responsibilities. These are summarized in the following table:
CHARACTERISTICS OF SSAB RECOMMENDATIONS

Characteristics of Recommendations	DOE's Responsibilities	SSAB's Responsibilities
Representative and credible	Seek the full range of stakeholder views; assure independence	Reach out to the broader community
Relevant and specific	Participate fully with citizens	Address agreed upon issues
Informed	Provide full information	Inform selves of needed information
Timely	Involve the public early	Remain focused on workplan
Realistic	Give genuine consideraton to recommendation	Be flexible and seek consensus

With these characteristics in mind, we now turn first to the convening process, in

which DOE establishes a board that is likely to produce recommendations with the above characteristics, and then to the activities of the SSAB itself, which should be designed with the same goal.

Convening the Advisory Board

The first question for a site must be whether an SSAB is desirable at all. This involves at least three subquestions: 1) Are there specific, locally resolvable issues that need to be addressed? Nuclear nonproliferation cannot be resolved at a local level; future site use cannot successfully be dictated from above. DOE, working with its regulators, must be sure that there are appropriate issues for the SSAB to consider. Without a clear sense of what is needed, the process is likely to be frustrating for all parties concerned. 2) Are these issues on which DOE and its regulators are willing to accept advice different from its current plans? The worst possible outcome of an SSAB process is for the public and the board to find that the decision for which advice was sought was a "done deal," that the decision had in fact already been made and that public input was mere window-dressing. 3) Is there enough time remaining before the decision must be made? Even when they are working smoothly, citizen advisory groups take time to get organized, to inform themselves of the key issues, and to come to consensus. Moreover, a group that meets on a monthly basis cannot make decisions on lots of relatively small, individual activities. Therefore, an SSAB should not be convened unless an issue can be identified that gives the group plenty of lead time.

One of the key decisions made in establishing the Task Force was to charge it with addressing specific issues: future use, waste disposition, clean-up levels, and priorities. They are broad and involve nearly every aspect of clean-up decisionmaking, but the issues give direction and they signal where public input will be most useful to DOE. At Fernald, the clean-up decisionmaking was well underway when the Task Force was convened, but several important issues remained. The most important and controversial issues -- groundwater protection and waste disposition -- were at least a year from being decided. These are issues on which the law permits different answers, and they were to be definitively answered at the site level, with sufficient lead time.

Representativeness and credibility were established by the convening process. At Fernald, this began with an independent, credible convener who was to select a broad-based membership and identify a strong, unbiased chair. This process was selected in consultation with the stakeholder community to best balance the interests that need to be represented on the board with the need to get a board up and running in a reasonable time. Focus was placed on selecting a convener who would be able to identify balanced and representative members and avoid biasing the board toward any existing stakeholder groups. A single individual from the University of Cincinnati with no prior relationship to DOE or any stakeholder group was retained by DOE to serve as the independent convener. This worked well at Fernald because the individual was widely respected within the community and did not have any interaction with the board or site after the convening process was complete; thus, the convener was able to avoid any potential conflicts of interest in performing her duties.

Other convening approaches -- including empaneling a steering committee to select members, having DOE or a state agency select members, or holding some form of election or lottery --were considered and rejected, either because of the potential for conflicts of interest or because of the length of time that would be required to establish a board. The way in which Fernald's site-specific advisory board was convened set the tone for the overall effectiveness of the group. The convening process worked within an established set of values that defined the goals of the board. The primary objective of the convening process in creating a focused site-specific advisory board at Fernald was to result with a board that represents broad stakeholder interests while at the same time has the potential to work effectively together to make the decisions required. The goal was not to achieve complete stakeholder consensus on every individual selected for the site-specific advisory board, but to get broad stakeholder acceptance of the process used to identify specific members. The timing of decision-making activities at the site also required that a board be established as soon as possible in order to have meaningful input to decisions.

A size limit of 15 members was established at Fernald before the convening process began. This obviously resulted in some very difficult choices; not everyone can be

afforded a spot on the site-specific advisory board. At Fernald, the result could have been some nay-sayers and skeptics rejecting the board; however, because the convening process was developed in consultation with stakeholders and was open to the public, the composition of the board went largely unchallenged. Focus also was placed on getting a balanced representation without requiring any strict quotas for membership. The Fernald Citizens Task Force reflects the demographics and socioeconomic conditions surrounding the facility and all stakeholder groups can broadly identify with one or more members of the board. Local representation was given top priority in convening the Task Force. Both DOE and local stakeholders agreed that the issues at stake were local, and national representation should only be included if directly requested by a local group or if a clear stake were identified that was not encompassed by local interests.

The Fernald convening process, however, does not eliminate the need to make hard choices, and to accept responsibility for them. Not everyone can or should be selected, and indeed not every single interested group can be. Rather, the tough job is to select the key interests and then encourage those selected to keep in touch with their constituents. For example, a site may have several unions or several townships: choosing all would skew the content of a small board. It is incumbent on the convener to choose the best representative of the unions or townships based on the above criteria; and it is incumbent on the representative to keep in touch not only with her own union/township but those who are not on the board. For example, area residents -- through the Task Force process at Fernald -- discuss the consequences of proposed courses of action and now share in the responsibility for recommendations on cleanup levels and other issues. Ultimately, however, DOE remains responsible for decisions. It cannot completely stand aside, because it is being asked to pay particular attention to this group. Thus, DOE will be held responsible by the general public anyway, and it is in DOE's long-term interest to ensure up front, to the extent possible, that the group will be accepted by the general public.

Finally, several elements of the Task Force process were implicit in the convening. In the future, these should probably be made express in the charter or other appropriate document. DOE must assure administrative support for the group, adequate information, and independence. All of these are essential, and all cost money. Mailing, organizing meetings, and generally coordinating activities requires one or two full-time staffers. At Fernald, contractor and DOE employees were detailed to the Task Force; at other sites, a separate staff was hired. Information, however, is the most important support that DOE provides. It must be forthcoming, and DOE must be willing to obtain new data (within reason) and to reorganize information it already possesses. While the vast majority of the information used by the citizens will come from DOE and its contractor FERMCO, the board must have the ability to assess it independently. The Task Force hired an independent technical advisor, who also serves as facilitator, to develop information, assess it, and present it to the group. This has seemed to bridge the gap well between independence and duplicating work already performed.

Getting Organized: The Future Use Approach

Once convened, the advisory board has its own set of responsibilities. First and foremost, it must get itself organized and working on the designated issues. As mentioned above, at Fernald they were: future use, clean-up levels, waste disposition, and clean-up priorities. After convening in September 1993, the Task Force held three meetings to orient itself to the issues and basic information about the site. In November, we decided to address future use first because a recommendation on future use could be the foundation for decisions on other strategic issues. Future use not only gave further direction to our efforts, but also it provided an overarching structure for considering specific issues. As we found, it also allows us to deal with the many ongoing activities at a complex site like Fernald -- we know which are central and which peripheral to the main task at hand.

The future use focus also allowed us to target our search for an outside consultant to someone with the appropriate expertise, whose job was to gather, analyze, and sift relevant information for the Task Force to use in coming to its conclusions. This was essential for the process of developing detailed information about the designated issues. The Task Force had to educate itself about central concepts, like risk; understand the models and assumptions that go into the data presented; and

integrate the information about various parts of the site. Developing expertise is mostly about obtaining information, but ultimately this is trust-building. By providing reliable data -- which can be used to ask hard questions -- DOE exemplifies openness and builds confidence in itself.

The Task Force also adopted a detailed work plan that would allow it to address the issues in time to make an impact. Ideally, of course, the SSAB would be constituted at the very beginning of the process, so that its recommendations could be submitted at or before the time of the general public comment. The goal is for a roughly parallel process, in which the citizen group's knowledge of the site follows closely after the government's, so that both are developing positions together, instead of responsively. At Fernald, this was impossible given the preexisting schedules, but, helped by the future use orientation, we were able to focus on later, cumulative decisions.

Each Task Force meeting focuses on a specific set of issues as laid out in the board's work plan. This approach allows members to fully explore the relevant issues in an incremental fashion, thus avoiding becoming overloaded with information. Task Force members discuss the information, and technical representatives are on hand to answer questions. An effort has been made to keep meetings informal and accessible, while maintaining focus on specific issues.

Because an SSAB is unelected and must necessarily be comprised of less than all of the people or points of view at a site, its recommendations are entitled to relatively little weight if they are supported by only small majorities of board. Conversely, consensus views are entitled to great weight, as they represent a position that a broad cross-section of the community agrees on after a thorough investigation of the issues. Consensus does not necessarily mean unanimity, and in practice few positions on truly controversial issues are likely to win unanimous acceptance. It is therefore advisable to back up a consensus-based process with voting. The board has an obligation to attempt to reach consensus on everything, and if that fails, on as much as possible. Moreover, it should report all views fairly and completely. Hard choices remain for DOE and the individual members of the Task Force -- for example, the use of an on-site disposal cell. It is not realistic to think that this process makes all decisions easy; DOE will still, in all likelihood, have to conclude that one choice is better than another. A good SSAB process, however, can lend strong support to a decision that follows the board's recommendation.

Another consequence of the selective nature of the SSAB is that it must constantly reach out to the constituencies that it directly represents, as well as to the general public. To begin with, all Task Force meetings are well publicized and open to the public; an opportunity for public comment is always provided. To supplement this, the Task Force holds regular special meetings with the public to discuss specific issues and to share some of the learning tools (for example, the FutureSite exercise) it uses. The Task Force uses these meetings to receive as broad an input as possible, to update the public about its own activities, and to inform the public about the issues under consideration.

Results So Far

The ultimate goal of the SSAB process is a recommendation that is realistic given the legal, technological, and financial constraints on environmental remediation. To achieve this, the Task Force followed an orderly program of understanding the conditions at the Fernald site, identifying options for future use, analyzing available technology for waste management and disposal, and developing values to guide all future use recommendations. The consensus values agreed to by the Task Force encompass environmental values, economic values, long term management values, social and human values, and general use values. After identifying these values, the Task Force developed specific criteria to weigh against potential future land use options. Some of those criteria include minimizing impacts on the environment during remediation and maximizing restoration of the environment after remediation; ensuring that any waste that may be left on site be controlled to prevent further contamination of the Great Miami Aquifer, air and soils on- and off-site; developing future uses that provide some level of continuing employment for area residents, but not necessarily in categories that have traditionally been present at the site, and creating a long-term mechanism to ensure citizen involvement in the control, management, and future decisions at the site.

The Fernald Citizens Task Force has reached several preliminary recommendations on

future use and cleanup levels for the Fernald site, and I think that they meet the criterion of realism. These recommendations are contained in an Interim Report, which was submitted to DOE, EPA, and OEPA on November 30, 1994. They cover groundwater remediation and protection, removal of contaminated soil, and exclusion of certain future uses.

Because protection of the aquifer was one of the Task Force's consensus values, it took an in-depth look at the options dealing with groundwater contamination. The Task Force rejected the option of not remediating the aquifer, because the contamination would impact as much as 4,000 surface acres and 32 billion gallons of water if left unchecked. Instead, it has recommended 20 parts per billion as the cleanup level for the aquifer, which is the MCL level, after considering the marginal risk of going below 20 ppb, the difficulty of detecting the background level, and the length of time that treatment to the background level would require.

For soil, the Task Force evaluated risk throughout the range of risks considered acceptable by EPA for Superfund cleanups across a broad spectrum of land uses in evaluating the overall level of cleanup for the Fernald site. Evaluating the impacts of applying different risks across different land uses allowed the Task Force to compare numerous factors, including total soil volumes requiring excavation; off-site disposal requirements; on-site disposal requirements and disposal cell size; total cost; environmental impacts, and technical, legal, economic, and social implementability. The most striking concern in making this decision was the volume of soil that would require excavation beyond the Fernald site property boundary if a 1x10-6 risk level for a residential scenario were chosen. At this risk level, a total of 5.2 million cubic yards of soil would be removed from off-property locations alone. Evaluating the construction risks of excavating this volume of dirt, the size of disposal facility or transportation risk required, and the short-term disruption of stripping off the most productive layer of soil in this agricultural and residential area, the Task Force adopted an off-site risk level of 10-4, albeit using a very conservative exposure model. On-site, the amount of soil to be removed was driven less by direct exposure to the soil than by the need to protect the aquifer. Noncarcinogenic hazards were also taken into account, and a middle-range risk level was chosen.

The Task Force has not yet determined the specific use or uses for which the site is best suited. It must first fully evaluate the viability of on-site waste disposal and develop its own recommendations with regard to waste disposition before coming to detailed conclusions regarding land uses. The proximity to a long-term disposal facility and the Task Force's desire for a margin of safety make it unlikely that the Task Force would recommend uses that allow for intensive activities at a high level of exposure.

CONCLUSION

In these recommendations, and in the recommendations to come on waste disposition and priorities, the Task Force has tried hard to consider the values it developed, as well as all of the consequences of remediation decisions. It has informed itself, answered the questions put to it, and done so in a timely fashion. The members' willingness to put preconceived ideas aside and to remain flexible resulted in unanimous recommendations that are well within DOE's power to implement at a local level.

More broadly, the Task Force's deliberations have formed the basis of a relationship of trust among DOE, the regulators, and their stakeholders. A working relationship has developed not only between top management and the public, but also with the individuals who are doing the work to provide information for these decisions. The result is greater confidence in the remediation decisions that are being made and the people making them. By establishing a forum for informed, open, and easy communication among key stakeholders, DOE, and regulators, the Task Force allows decisions to be reached as a developing consensus, rather than as adversarial presentation and response. Moreover, the Task Force appears to be an excellent way to have public involvement during decision making post-Records of Decision at CERCLA sites; CERCLA and its implementing guidance provide only minimal mandated public involvement activities. The habits of cooperation and openness formed as part of the Task Force process are already in place and can continue easily. In the long run, this may be the most valuable product of the SSAB process.

ABSTRACT

The Fernald Environmental Management Project (FEMP) is a DOE facility near Fernald, Ohio, which operated from 1952 to 1989 to support United States defense programs. The FEMP occupies about 1050 acres, and is located about 18 miles northwest of downtown Cincinnati. The primary mission of the FEMP was to process, refine, and machine high-grade natural uranium ores into high-purity uranium metal. The storage and disposal of large quantities of wastes at the site and the potential for impacting human health led to the site being placed on the National Priorities (Superfund) List. Over 3 million cubic yards of contaminated material and a significant plume of uranium-contaminated groundwater must be managed at Fernald. In an effort to improve public involvement in the site restoration decision making process, the DOE has established site specific advisory boards, of which the Fernald Citizens Task Force is one. The Fernald Task Force is focused on making recommendations in four areas: 1) What should be the future use of the site? 2) Determinations of cleanup levels (how clean is clean?) 3) Where should the wastes be disposed of? 4) What should be the cleanup priorities? Because these questions are being asked very early in the decision-making process, the answers are necessarily qualified, and are based on a combination of preliminary data, assumptions, and professional judgement. The requirement to make progress in the absence of accurate data has necessitated FERMCO and the Task Force to employ an approach similar to sensitivity analysis, in which a range of possible data values are evaluated and the relative importance of the various factors is assessed.

Because of its charter to provide recommendations of future site use, the Task Force has developed a sitewide perspective, compared to the more common operable unit specific focus of public participation under CERCLA. The sitewide focus and accelerated schedule for public involvement have resulted in the exploration of technical project management issues far in advance of their traditional project sequence. Due to the early consideration of key issues, coupled with the sitewide perspective and sensitivity analysis, there has been a rapid progression from the esoteric realm of the CERCLA process to the early identification of the important decisions to be made and their specific consequences.

The relationship between FERMCO and the Task Force is evolving toward one of partnership with DOE in managing the obstacles and hidden opportunities for success. The Task Force likely will continue to participate in the Fernald project long after its initial recommendations have been made. DOE already has made the commitment that the process of public participation will extend into the Remedial Design phase. There is substantial reason for optimism that continuing the Task Force process through the design phase will assist in developing the appropriate balance of cost and engineered protectiveness.

INTRODUCTION

This paper presents observations and preliminary conclusions on the unique and still evolving relationship between the Fernald Citizens Task Force and FERMCO, the U.S. Department of Energy's (DOE's) environmental restoration contractor at Fernald,

Ohio. After a brief introduction to the site, specific examples are discussed of how the expanded public participation process at Fernald works and influences decision making.

THE PROJECT SETTING AND BACKGROUND

The Fernald Environmental Management Project (FEMP) is a DOE facility near Fernald, Ohio, which operated from 1952 to 1989 providing uranium metal products to support United States defense programs. In 1989 the mission of the facility was changed to one of environmental restoration. Also in 1989, the facility was placed on the National Priorities List ("Superfund List"). The FEMP is the subject of an Amended Consent Agreement between DOE and the U.S. Environmental Protection Agency (EPA), under authority of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), and a Resource Conservation and Recovery Act (RCRA) Consent Decree from the Ohio Environmental Protection Agency (OEPA).

The FEMP occupies about 1050 acres, and is located about 18 miles northwest of downtown Cincinnati. The primary mission of the FEMP was to process, refine, and machine high-grade natural uranium ores into high-purity uranium metal. The metal was shipped to other DOE or U.S. Department of Defense facilities for use as "feed materials" in the nuclear weapons program. These uranium production activities generated large quantities of waste materials. The storage and disposal of wastes at the site and their potential for impacting human health led to the site being placed on the National Priorities List.

The CERCLA Remedial Investigation/Feasibility Study (RI/FS) process has found that at least 3 million cubic yards of contaminated material must be managed at the site, and that groundwater has been contaminated. The Fernald site is located above the Great Miami Aquifer, a sole source drinking water aquifer. Off-property drinking water wells in the area have been contaminated with uranium.

The CERCLA process has defined five operable units at the Fernald site, each with its own schedule for completion of the RI, FS, and Record of Decision (ROD), per the Amended Consent Agreement. Operable Unit 1 is comprised of the Waste Pit Area, which includes about 700,000 cubic yards of contaminated material, including process wastes. Operable Unit 2 is comprised of a landfill, two surface impoundments, a flyash pile, and two uncontrolled disposal areas. Operable Unit 2 includes about 300,000 cubic yards of contaminated material. Operable Unit 3 is comprised of the above-grade structures at the site, which are about 200 in number and range from large, former ore processing and manufacturing facilities to small outbuildings. Operable Unit 4 is comprised of four waste silos, which contain about 15,000 cubic yards of waste process sludges. Operable Unit 5 is comprised of the site media, which include contaminated groundwater, sediment, and approximately 2 million cubic yards of contaminated soil.

CERCLA AND THE FERNALD CITIZENS TASK FORCE

Under the CERCLA Amended Consent Agreement, the decisions on the cleanup of the five operable units are made individually and sequentially, with each operable unit's ROD following the previous one by a few months. This has necessitated that much of the RI/FS work for all operable units be done concurrently. In order for the individual operable unit studies and decisions to be consistent and protective of human health and the environment, a common set of assumptions regarding the future use of the site was needed. For example, will the cleanup need to be protective of future resident farming families or will people be excluded from the property? In addition to the obvious effects of alternate future site uses on contaminant cleanup levels, there are also impacts on the evaluation of remediation technologies. In-situ containment and certain engineered disposal facilities, to cite two examples, may be incompatible with some desired future land uses.

The CERCLA process provides for public involvement in remedial decision making. Under CERCLA, there are specific time periods set aside for public comment on the remediation plans that have been developed previously. Although all comments are considered, the fact that the comment period comes late in the decision making process limits their range and impact. In an effort to improve public involvement in the decision making process, the DOE has established site specific advisory boards, of which the Fernald Citizens Task Force is one. The Task Force is focused on making recommendations in four areas that are important to remedial decision-making for each operable unit:

1) What should be the future use of the site?
2) Determinations of cleanup levels (how clean is clean?)

3) Where should radioactive and hazardous wastes which are generated as a result of site restoration activities be disposed of?

4) What should be the cleanup priorities?

To be truly effective in assisting the decision-making process, the Task Force must make these recommendations relatively early in the CERCLA process. Therefore, the Fernald Citizens Task Force becomes involved much earlier than in the traditional public comment period under CERCLA, and hence needs to obtain information from DOE and more specifically DOE's contractor, FERMCO, far in advance of the customary public comment period.

FERMCO AND THE FERNALD CITIZENS TASK FORCE

A traditional relationship between the public and a government contractor usually is constrained by relatively formal processes. However, the Department of Energy has directed FERMCO to cooperate fully with the Task Force and that Task Force needs should be given immediate priority. This, combined with the Task Force's broad charter and accelerated schedule, has resulted in a relationship between the public and contractor that is unusually direct and comprehensive in scope.

One of the initial functional departures from the traditional relationship was the need for FERMCO to provide the Task Force with preliminary data, estimates, and conclusions, whereas in a traditional relationship only final, carefully reviewed information would be released. For example, FERMCO was requested to provide its best guesses at final site cleanup levels and waste material volumes far in advance of our having the data to support definitive calculations. By responding with best, good faith efforts and honestly revealing the inaccuracies and uncertainties associated with the information being supplied, FERMCO has helped the Task Force focus on key site management issues, and equally importantly, gained a significant measure of mutual goodwill and trust.

The next phase of interactions went beyond the exchange of information into an exploration of indirect consequences of seemingly straightforward management decisions. One prominent example is the proposed on-property waste disposal facility. As discussed above, the cleanup of Fernald will result in the need to dispose of large quantities of contaminated materials. One alternative being considered for the less-contaminated fraction of material is construction of an on-site disposal facility. In order to carefully consider this alternative, the Task Force needed to know some basic facts. Why is on-site disposal needed? How large would the facility be? Where would it be located and what would it look like? How long would it be necessary and how long would it last?

Because these questions were being asked very early in the decision-making process, the answers were necessarily qualified, and were based on a combination of preliminary data, assumptions, and professional judgment. A good example is the question of the size of the potential on-property disposal facility. The size of the facility is a function of the quantity of contaminated material that meets the waste acceptance criteria for the disposal facility and the contaminant cleanup levels for the site. The necessary data normally are obtained through the CERCLA process: data on the nature and extent of contamination are developed through the Remedial Investigation and the cleanup levels are developed through the Feasibility Study and are finalized in the Record of Decision. However, at the time the Task Force needed the information, the relevant Remedial Investigation Reports, although on schedule, were not near completion. Feasibility Study and Record of Decision information was months to years away.

In order to make progress in the absence of accurate data, the Task Force, DOE, and FERMCO adopted an approach similar to sensitivity analysis. In the case of disposal facility size, the possible minimum and maximum sizes (material volumes) as well as the most probable size range were estimated from available data and the key assumptions for each estimate were documented. Naturally, the relatively high uncertainty led to a wide range of volume estimates. This very preliminary range was from 1.5 - 8.5 million cubic yards with a most probable volume of about 2.5 million cubic yards. The critical variable was found to be the cleanup levels (and hence volume) for the Operable Unit 5 soils in potentially contaminated, off-property locations.

The early estimation of a range of contaminated material volumes for potential on-property disposal enabled an evaluation of the required site area that would be dedicated for the facility within the context of the site's future use. The relative site space requirements or "footprints" for disposal facilities of 2.5 million and

8.5 million cubic yards are shown in Fig. 1.
The Task Force's consideration of possible disposal facility locations at Fernald was interesting and indicative of the technical planning issues on complex remediation projects. One of the insights gained from the earliest Task Force activities, especially through the use of the FutureSite exercise (Applegate 1995), was that the public, and in particular those persons living near the site, were especially concerned about project activities and future site use commitments that would occur near the site borders, compared to the interior of the site.
Concern about the relatively undisturbed border areas of the site led to the initial and informal public perspective that the preferred location for a potential disposal facility would be in the central area of the site. Given that a substantial portion of the property's interior already had been developed as the former process area, this location was suggested to FERMCO as an area that should be carefully evaluated for the disposal site location.
Clearly, a suitable hydrogeologic setting is essential for locating a disposal facility, and Ohio EPA has set appropriate technical requirements. However, if a large enough area of suitable hydrogeology were available, then DOE and FERMCO would have some flexibility in selecting the specific footprint to accommodate the preferences of the public. Regardless of hydrogeological conditions, other important factors associated with different potential locations could be evaluated.
Two of the potential locations for a typical 2.5 million cubic yard disposal facility are shown in Fig. 2. In the figure, Location A covers mostly unused land and is within 300 feet of the eastern property border and Location B is within the former process area, over 1,500 feet from any property border. At the integrated project level (as opposed to the operable unit level) the requirements for the sequencing of activities are very different for the two locations and have very different cost implications. For example, disposal facility construction is not physically constrained at Location A, whereas at Location B disposal facility construction cannot be implemented until the existing buildings are safely shutdown, decontaminated and demolished, and the contaminated foundations and soil beneath and around them are excavated. This would require the interim storage of any building debris to be disposed of on-site, as well as the stockpiling of the contaminated soil from the former process area and other site areas that would be remediated prior to the availability of the disposal facility.
The cost implications of the differences in project sequencing are significant. Additional costs are required for Location B due to double handling of the building debris; double handling of the process area soils and other site soils; construction of appropriate interim storage facilities for the soil and debris; monitoring and environmental control of the stored, contaminated material; and demolishing and disposing of the interim storage facilities. Given that over one million cubic yards of soil and debris would be stored and double-handled, the additional cost of locating the disposal facility in the central portion of the site would be on the order of $50-100 million. The Task Force will use this information in reaching its recommendations on future land use and waste disposition, which are due in the summer of 1995.

INITIAL CONCLUSIONS

Although the ultimate assessment of the utility of site specific advisory boards is years away, it is possible to draw initial observations and conclusions based on the experience at Fernald. The Fernald Citizens Task Force is providing input from the public to the decision making process far in advance of the traditional public participation process. Because of its charter to provide recommendations of future site use, the Task Force has developed a sitewide perspective, instead of the more common operable unit specific focus of public participation under CERCLA. The sitewide focus and accelerated schedule for public involvement have resulted in the Task Force's exploration of technical project management issues far in advance of the availability of accurate data.
The requirement to make progress in the absence of accurate data has necessitated an approach similar to sensitivity analysis, in which a range of possible data values are evaluated and the relative importance of the various factors is assessed. For example, in predicting the size of a potential on-site disposal facility it was determined that the key factor would be the final cleanup levels for the soils in Operable Unit 5, especially for the off-property areas that are under study. Another way of looking at this particular case is that the sitewide long-term

impacts of different cleanup levels for Operable Unit 5 were made tangible to the public at an early stage, and that FERMCO and DOE project managers obtained highly useful information months ahead of the time it would normally be developed. Similarly, in the case of evaluating different locations for an on-property disposal facility, the public and project planners were able to assess sitewide interactions and interferences far in advance of their traditional sequencing. In both cases, there was rapid progression from the esoteric realm of the CERCLA process to the early identification of the important decisions to be made and their specific consequences.

The Fernald Citizens Task Force is considering many more issues than the few that are discussed here, and to make informed recommendations the Task Force needs site data and cost and schedule information pertinent to each issue. Particularly helpful in this regard has been the use of state-of-the-art Geographical Information System (GIS) and three-dimensional, color imaging software to realistically depict possible future site conditions such as changes in site topography due to excavation of contaminants, or to simulate the appearance of a disposal facility from a public road. To quickly evaluate the cost and schedule impacts of several alternatives, an integrated site master schedule and cost model are essential.

The Task Force, DOE, and FERMCO must continue to be willing and able to develop, qualify, communicate, and accept the limitations of an information base that consists of preliminary data, assumptions, and professional judgment. One problem that has emerged as the result of doing so much, so fast, based on assumptions is that teams working on different specific issues may make different assumptions about the same site condition or assume different technical approaches for similar remediation tasks. These inconsistencies are best identified and corrected through regular integrated project planning meetings that result in a single set of documented management guidance for project personnel.

The relationship between FERMCO and the Task Force is evolving toward one of partnership with DOE in managing the obstacles and hidden opportunities for success. The enhanced public participation through the Fernald Citizens Task Force has led to an accelerated focus on sitewide technical and management issues and, through a project-level sensitivity analysis, has identified major opportunities to be managed. The Task Force likely will continue to participate in the Fernald project long after its initial recommendations have been made. DOE already has made the commitment that the process of public participation will extend into the Remedial Design phase at Fernald. There is substantial reason for optimism that continuing the Task Force process through the design phase will assist in developing the appropriate balance of cost and engineered protectiveness.

ABSTRACT

The Fernald Environmental Management Project is a Department Of Energy (DOE) facility near Cincinnati, Ohio which provided high purity uranium metal products to support United States defense programs. Production operations were halted in 1989 to focus available resources on environmental restoration activities at the facility. Operable Unit 3 (OU3) is the designation given to the production area and production-associated facilities and equipment, including, but not limited to , all above and below ground structures, equipment, and utilities.

In late spring of 1994, two decisions were made that established the long range strategy on how remedial designs (RD) and the bidding of remedial actions (RA) are

approached for the decontamination and decommissioning (D&D) of the Fernald facilities. The first was to fast track the remediation design and bidding process for the first three D&D packages; and the second was to use standard performance specifications to streamline the decontamination and decommissioning process. This paper describes these strategies, identifies the key elements involved, and discusses the lessons learned that were associated with the approaches. A brief synopsis of these elements is as follows:

A facility complex which groups facilities into blocks of work was used for the bid packages.

A task force approach involving the required functional organizations was used to fast track the design and bidding process.

Standard Performance Specifications have been developed for each task to establish minimum acceptable criteria and yet provide the subcontractor flexibility to be creative within these boundaries. This approach also dramatically decreases costs for future D&D packages.

A key feature of value engineering has been the use of construction methods and techniques to drive the D&D cost significantly lower.

The bid package was structured around a modified IFB approach. This provides the successful bidder the opportunity to incorporate innovative ideas within the performance specification guidelines. In addition, several innovative concepts such as prequalifications of bidders, preparation of a task based bid package, and use of video and still shots were used to create a comprehensive bid package.

The D&D approach was structured to decrease safety risks by emphasizing mechanical methods over manual methods.

This paper will present the lessons learned in these strategies and illustrate how the various concepts described above were translated into a four month fast track design bid process, how the overall project costs were significantly reduced, and how safety risks were significantly mitigated.

INTRODUCTION

In Spring 1994, an opportunity was seized to establish the long range strategy on how remedial designs (RD) and the bidding of remedial actions (RA) are approached for the decontamination and decommissioning (D&D) of the Fernald facilities. Several key concepts contributed directly to this opportunity:

First, the CERCLA process provides for an Interim Record of Decision (IROD) in situations where RA can be performed that mitigates potential threat to public health or the environment, yet doesn't prevent regulatory and public participation in the ultimate remedy selection. Such is the case with building demolition at Fernald. Second, it was observed that the typical bidding process was too long, and that significant schedule gains could be made by fast-tracking the design and bid process. Lastly, it was concluded that we could successfully employ standard performance specifications to streamline the overall engineering design process, instead of specific procedures for each facility.

This paper describes these approaches, identifies the key elements, and discusses the lessons learned that were associated with these efforts.

FACILITY COMPLEX APPROACH

Initially various methodologies were created to prioritize the sequence of D&D of the 232 structures/facilities at Fernald. These included ranking and weighing of each facility with factors such as contamination levels, use, location, D&D difficulty, etc. However, these approaches ultimately resulted in using a simple approach based on three criteria: 1) Group the facilities into blocks of adjacent facilities which have obvious geographic boundaries. 2) Schedule those blocks that are available first. 3) Schedule the blocks to achieve the early start of a sub-surface cleanup taking into account site drainage and underground utility feeds. This resulted in the grouping of above-ground facilities into approximately 24 (3 underground) project packages called complexes.

COMPLEX DESCRIPTIONS

The initial complexes included in this approach are the Pilot Plant (12 Structures), Plant 4 (1 Structure) and Plant 1 (11 structures). The Pilot Plant has two large concrete framed structures and 10 steel framed structures. Plant 4 is a very large steel framed structure with asbestos transite panels. Plant 1 is composed of a large steel framed structure with asbestos transite panels, 1 masonry block structure and 9 smaller structures. Each of the complexes requires remediation activities for dismantlement of pipe, ductwork, electrical removal (1400 components); interior and

exterior transite siding and exterior features (doors/windows): structural steel/concrete framing removal including interior/exterior concrete slabs and walls and masonry walls and built up roofing systems.

TASK FORCE APPROACH

To accomplish a fast track design and bid process, a remediation task force was established to ensure that engineering, design, construction, safety, quality, regulatory, waste management, environmental, procurement, DOE input, schedule and budget aspects were considered in each remediation design package. The team was commissioned to participate in all aspects of the project, including but not limited to the inception of the design, Certification for Construction, contract award, execution of the remedial action, completion of the contract and the final verification report.

DEC (Design, Engineering, Construction) Team

Members of the CERCLA RCRA Unit 3 staff participated using representatives from functional groups to formulate an aggressive design package which included scope definition of the engineering, construction, and waste disposition aspects of a specific project. A work plan of construction tasks was prepared and brainstorm sessions including lessons learned from past and ongoing projects were incorporated into the approach to the work. Value engineering and constructability studies were performed and shared with the design engineer. Particular emphasis was placed on performing the remediation work in a safe, quickest and least cost method.

Fast Track Schedule

The work plan formed a basis for design specifications; a design/construction/waste management preliminary schedule; a task based safety matrix; waste stream characterization and documentation; quality plan and labor determination. A fast track schedule for the development of the Certified for Construction Package (CFC) was determined to be approximately ten (10) weeks. This period is combined with an additional two weeks for final preparation of the bid package; a four week bid period, a three week bid evaluation period and a two week DOE bid evaluation period. These are the components of the fast track schedule to award a contract for the remediation of the complexes in five to six months.

Integration of Environmental and Permitting Requirements

As the work plan described above was prepared, representatives from environmental, regulatory and safety and health divisions provided comments in parallel to the development of the design specifications. This ensured that regulatory requirements for construction plans were incorporated during the design process.

USE OF STANDARD PERFORMANCE SPECIFICATIONS

Generic performance, procurement specifications and project scope drawings were created to form a Certified for Construction design package to be issued for bids. The task force developed work planning packages based on the D&D work tasks. The design engineer then used these work planning packages to create specifications related to specific Decontamination and Dismantling construction tasks. Major standard specifications included dismantling actions such as asbestos, asbestos transite, piping, electrical components, ductwork, process equipment, concrete, and structural steel. Other specifications included methods and special requirements for rigging, mobilization, decontamination, site preparation, demobilization and waste handling.

A key decision to the fast track remediation design process was to develop a set of standard performance specifications. The foundation for standard performance specifications is built around two basic concepts:

1) Establish the minimum acceptable boundaries (performance standards) in which a task is to be accomplished.

2) Allow the performing subcontractor the flexibility to exercise creativity within these boundaries.

The objective is accomplished by breaking the project into discrete, homogeneous tasks. For each task category, a set of criteria is set forth in the form of standard performance specification that establishes the baseline requirements for accomplishing the respective category of work. The specification sets the requirements to accomplish the task in a manner that protects the individual and the environment, and also meets the site operating criteria. An example of the former would be dust control methods for removing concrete, and of the latter would be size reduction requirements for steel and associated appenditures to meet packaging criteria for shipping boxes.

The use of a standard specification eliminates the requirements to redesign the specification for each facility. For example, once a specification is developed for removing process piping, transite siding, and structural steel, it applies wherever that task is performed. A specification for a facility demolition then only requires the assembly of those specs that apply and the preparation of specifications for which a standard specification does not exist.

VALUE ENGINEERING AND D&D CONSTRUCTION METHODS

A key aspect of value engineering for D&D remediation projects is in the use of cost saving construction methods. There is a fundamental difference in the approach to design of a new facility versus the design for D&D of the same facility. New design requires specific calculation of loads, flows, stresses, etc. to establish size and configuration of equipment and facilities. This process results in a detailed set of drawings and specifications to describe these requirements. There is almost always no description of the construction methods that will be used to build the facility. However, in de-construction, the process is almost totally based on the construction methods that will be used to dismantle the equipment and the facility. The emphasis both from a safety and from a cost standpoint needs to focus on the construction methods and equipment to be used. Construction experts need to be involved in the early phase of the remedial design process to bring in the construction expertise that is required for a safe, successful, and low cost project.

BID APPROACH

Prequalification

In parallel to the design specification activities, prequalification of bidders was conducted. This consisted of preparing a Notice of Prequalification published in the Commerce Business Daily which included the key criteria to evaluate bidders in light of the type of work included in the three complexes to be bid. These criteria included performing government work (experience with government contracts); demolition experience (asbestos and regular); rigging experience; radiation experience (worker safety issues); safety experience (EMR rating in the industry) and verifiable proof of self performing 45% of the past qualified work. Prequalifications were evaluated and bidders were notified accordingly.

Modified Invitation for Bid (IFB)

A modified IFB consisted of the preparation of a bid package using performance specifications. The IFB package consists of commercial bid and award terms, general terms and conditions, special terms and conditions, the project agreement, the statement of work (including the work scope, performance criteria), drawings, specifications, photographs, videos, safety program (including the safety matrix), and the quality plan criteria. The successful bidder is required to incorporate innovative ideas within the guidelines of the performance specification to form a bid. While the award is made to the lowest, responsible, responsive bidder, the bidder must meet all the criteria specified in the performance specifications. After the award, the successful subcontractor submits detailed work plans for approval which incorporate the contractor's unique approach to meeting the performance guidelines.

Task Based

The entire construction process is built around discrete tasks of like work (i.e., ventilation, duct dismantling, transite siding removal, process equipment removal). The bid package as well as the management systems used to support the work are all structured to support the task concept. As was discussed previously, a standard performance specification is developed for each discrete task category. The estimate and schedule are developed to uniquely depict each of these tasks. This does not preclude greater detail than at the task level; however, the detail must uniquely roll up into the specific task. For example, the task may be transite siding removal, and the contractor may prepare a more detailed schedule that shows siding removal on all four sides of the building. The contractor's individual pay items are also established at the task level. In addition, safety and quality matrixes are developed at the task level to specify the safety and quality requirements that are required for the performance of each task.

Video and Picture Book

The use of videos and picture books greatly facilitate fast track remediation bidding. Typically, bid packages have reference drawings that the bidders use for a bid take off. The cost involvement in up dating these reference drawings to present as-built conditions is costly and time consuming. A detailed videotape which shows

inside and outside of the structures, miscellaneous outside structures, utilities, side photography, and construction boundaries is sent out with each bid package. A photo book showing a panoramic overview of each floor of the structure and outside of the structure is also sent out with each bid package. The use of videos and a picture book does the following: 1) reduces cost of engineering and drafting; 2) reduces bidder clarification questions; 3) reduces number of tour visits by the bidders; and 4) is used as a tool on claims and changes.

Bottoms Up Estimating

During the work plan development in the design phase, the estimate is based on D&D quantities and the associated construction methods, techniques and materials. This type of D&D work is approximately 70-80% craft labor; therefore, the duration to perform the tasks is based on the methods and manpower required to perform the tasks. Materials, construction equipment, indirect costs, overhead and profit were estimated based on a task based preliminary schedule. This schedule formed the basis of the contractor pay items.

By focusing all the management systems on the specific tasks, the bid package establishes the framework for success during the actual de-construction phase. The probability of success on a project is significantly enhanced if it is well planned and the management systems are "pulling in the same direction" as the work to be performed.

Finally, prior to the performance of a specific task, the subcontractor is required to submit a detailed work plan which embodies how the work is to be performed and how safety and quality issues are to be addressed.

EMPHASIS ON SAFETY APPROACH

Mechanical vs. Manual

D&D construction activities have one of the highest recordable incident rates in any industry. In order to cope with this reality, owners, construction managers, and engineering must find ways to reduce this liability and still get the job done. In reviewing the type of accident that occurs during D&D activities, most are caused by material and equipment removal and handling. Some accidents which occur during the activities include: slips, falls, pinch points, scrapes, bruises, burns, etc. These are all inherent with manual D&D tasks. A good safety program along with a good work plan reduces these dangers.

By emphasizing mechanical material handling methods, further reductions are achievable. Some mechanical methods that can reduce the manual labor in D&D tasks are:

1. Mechanically tripping of the structure can be accomplished by making strategic cuts on the structure, connecting cables to it and pulling the structure down using heavy equipment.
2. Shaped charges can also be utilized to use gravity to trip the structure. Shaped charges strategically placed on structural columns, beams, X-bracing, etc. can remove selective structural members so that the building will fall to the ground in a safe, controlled manner.
3. Large mechanical shears mounted on large track hoes can cut structural steel in almost any size and configuration vs. manual torch cutting.
4. Inside the structure smaller mechanical shears can remove piping, ducting, electrical conduit, etc.
5. Small "bob-cats" outfitted with grapples can eliminate manual handling and loading of debris.

By utilizing mechanical construction methods in removal and handling activities, the project cost and safety requirements are greatly enhanced.

Multiple Work Area - Fast Track Work

Radiological D&D work must be accomplished in a safe, controlled manner. The outer shell (siding and roofing) is used for primary containment. The sequencing of work tasks is somewhat straight forward: safe shutdown of the structure (utility disconnect, removal of holdup/hazardous waste material, etc.), asbestos abatement, construction debris removal (piping, equipment, conduit, ducting, etc.), interior wall panels, final decontamination of the outer shell (transite paneling, brick, block, steel sheeting), and finally structural steel.

Some of these activities can be accomplished concurrently to expedite the schedule. On multi-story structures, asbestos abatement can proceed on one floor while construction debris removal is ongoing on another floor. On a one story structure, this asbestos abatement work area can be sealed off and other D&D work performed on

the same floor as long as two different entrances and exits are established. The same goes with debris removal in one area while removing interior transite wall panels in another. It is important that work plans are comprehensive, integrated into the construction D&D schedule, reviewed by appropriate personnel, and that the work plan is followed. This allows simultaneous performance of multiple work tasks in a safe, productive manner.

LESSONS LEARNED

Keep it Simple

D&D work is not highly technical work. Use of basic demolition techniques with appropriate environmental controls will enhance wherever possible. Our experience shows that elaborate approaches have been unsuccessful, are costly, and create increased safety risk for the worker.

Involve Construction from the Beginning

Early involvement of Construction input will result in an integrated approach to a final product which meets the DOE, FERMCO (contractor) and stakeholders' requirements.

Involve Outside Expertise

When developing the scope of work for a D&D package, all construction methods must be evaluated, and the best one chosen. Even though you have a qualified construction staff, it is sometimes necessary to bring in outside expertise on a specific field (e.g., use of shape charges). This expert can help evaluate specific construction methods, review work plans, review specifications, evaluate safety concerns, and specify dust control measures. By bringing in outside expertise early on in the planning stage, you can evaluate each D&D method and select the appropriate technical approaches for the bid documents.

Key is Construction Techniques

The key to de-construction lies in the construction techniques. While a new facility requires great emphasis on analysis of loads, process flows, process control, etc., the emphasis for de-construction is on construction equipment and methods. Therefore, it is important to have construction expertise play a key role from the beginning of the remedial design process.

Bid Multiple Facilities

Grouping individual buildings into complexes by geographic area is an efficient and low cost way of performing D&D work. This is based on the following factors:

1) From a logistics standpoint, peripheral buildings and facilities must be removed prior to the removal of the main building.

2) Many main facilities are structurally connected, which requires a specific dismantling sequence.

3) The design and bidding costs for small, medium, and large contaminated structures is almost the same. By grouping facilities, the bid and design costs are significantly reduced.

4) Management and support costs are significantly lower for a complex of facilities than for the same set of facilities sequenced for D&D on an individual basis.

SUMMARY

Accelerating decommissioning projects can mean different things to different people. In the context of our demonstrated successful work at Fernald, accelerating decommissioning work means delivering projects to our clients safer, faster and for lower cost.

Our approach has yielded the following key results:

Improved safety performance. Employing this process on our recently completed Plant 7 dismantling project resulted in zero lost-time accidents, as compared to a nationwide incident rate for the construction industry of 6.5 lost time accidents per 200,000 hours worked;

The task force approach has yielded a structured design, engineering, and construction (DEC) team concept that has been formalized at Fernald by a standard operating procedure. The involvement of on-site internal stakeholder participation in the planning process greatly facilitates a smooth project flow;

Fast-track schedules can be achieved with this approach within the CERCLA and DOE arenas. Shorter project durations result in lower overall project costs. Our recently completed Plant 7 project was completed approximately $5M and 1 year ahead of its baseline estimate;

The specific task, performance specification approach yields improved change control. Subcontract change orders for the Plant 7 project (pending resolution) are

near 5% of the subcontract value, a goal of the project at the outset. Accelerating decommissioning activities can be achieved. To date, our experience with this approach leads to the conclusion that applying these identified concepts can result in a win-win situation for all.

FERNALD WASTE MANAGEMENT AND DISPOSITION

Michael L. West
Leigh A. Fisher
Matthew L. Frost
Fernald Environmental Restoration Management Corporation
David M. Rast
U.S. Department of Energy - Fernald Area Office

ABSTRACT

Historically waste management within the Department of Energy complex has evolved around the operating principle of packaging waste generated and storing until a later date. In many cases wastes were delivered to onsite waste management organizations with little or no traceability to origin of generation. Sites then stored their waste for later disposition offsite or onsite burial. While the wastes were stored, sites incurred additional labor costs for maintaining, inspecting and repackaging containers and capital costs for storage warehouses. Increased costs, combined with the inherent safety hazards associated with storage of hazardous material make these practices less attractive.

This paper will describe the methods used at the Department of Energy's Fernald site by the Waste Programs Management Division to integrate with other site divisions to plan in situ waste characterization prior to removal. This information was utilized to evaluate and select disposal options and then to package and ship removed wastes without storage.

INTRODUCTION/FERNALD HISTORY

The Fernald site is located approximately 20 miles northwest of Cincinnati and has been managed by Fernald Environmental Restoration Management Corporation (FERMCO) since December, 1992. For more than 37 years, the facility manufactured uranium metal products for use at other DOE sites to satisfy Defense Program demands. Production operations were suspended on July 10, 1989 due to a sharp reduction in the demand for uranium metal products by user sites and continuing problems in achieving full regulatory compliance. Following necessary Congressional notifications, the facility was formally shut down on June 19, 1991 when its mission became environmental restoration.

The primary law regulating cleanup of the Fernald site is the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) as amended by the Superfund Amendments and Reauthorization Act (SARA) in 1986. Another major regulation, the Resource Conservation and Recovery Act of 1976 (RCRA), governs the generation, transportation, treatment, and disposal of the hazardous waste at the site. A Consent Decree was signed by the State of Ohio and the DOE in December, 1988, establishing milestones to bring the FEMP into full compliance with RCRA and other regulatory requirements. Amendments establishing additional milestones regarding the management of hazardous waste were later proposed to the Consent Decree, and in January 1993, the amendments were approved, resulting in the Consent Decree and its Stipulated Amendments (SACD).

In July 1990, the United States Environmental Protection Agency (USEPA) and the DOE entered into a Consent Agreement establishing milestone schedules for the completion of necessary studies to support the CERCLA clean-up process. The agreement established schedules for implementing near term clean-up actions (Removal Actions) while final clean-up solutions were being evaluated and selected. In September 1991, the DOE and USEPA jointly signed the Amended Consent Agreement establishing revised milestones for the completion of the required studies and identifying a series of additional near-term actions for implementation by the DOE.

The overall mission of the FEMP is to provide the safe, least-cost, earliest, final cleanup of the Fernald site, within applicable DOE orders, regulations and commitments in a manner which addresses stakeholder concerns. To support this objective, the FEMP is currently conducting Remedial Investigation/Feasibility Studies, remedial design activities, removal actions, waste management operations, and other compliance and clean-up initiatives.

This paper discusses the reorganization of the Waste Programs Management Division of FERMCO and its integration with Removal Action #19 - Plant 7 Dismantling.

WASTE PROGRAMS MANAGEMENT REORGANIZATION

Historically, waste management within the Department of Energy complex has evolved around the operating principle of packaging waste and storing until a later date. In many cases wastes were delivered to onsite waste management organizations with little or no traceability to origin of generation. Sites then stored the wastes for later disposition offsite or for onsite burial. While the wastes were stored, sites incurred additional labor costs for maintaining, inspecting and repackaging containers and capital costs for storage warehouses. Increased costs, combined with the inherent safety hazards associated with storage of hazardous material make these practices less attractive.

In FY94, FERMCO organized its waste management factions, at the time spread across several organizations, into one Division that encompassed both professional and labor forces. The reorganization included the formation of 10 Departments. The Waste Programs Management organizational chart (with functional areas) is included as Fig. 1. The reorganization was a result of the need to bring together key personnel to improve the methods in which wastes were managed. The FEMP was realizing the problems stated above, maybe not to the degree of other sites, but the site definitely had a problem of deteriorating containerized "legacy wastes" monopolizing valuable storage space. Wastes were being introduced into the waste management system with little or no warning and identified or characterized only a portion of the time. This taxed resources (personnel and equipment) to the point where containers eventually had to be repackaged due to the waste not being characterized and deteriorating conditions of the containers.

A strategy was implemented as to how information flows within the WPM organization. Figure 2 displays the flow of information and the four distinct areas of activities: integration, planning, operations, and disposition. A central group within the WPM Division is responsible for integrating with other Divisions to assist in planning what WPM services will be needed for projects when wastes are generated. This ensures that information is passed on to the appropriate support organizations within the Division so work can be planned and budgeted effectively. This setup has allowed for fewer surprises (i.e., containers of uncharacterized waste) being introduced into the WPM system, resulting in a more efficiently run organization. The strategy not only saves time and money from a WPM perspective, but also for the project.

FY94 ACCOMPLISHMENTS

Major accomplishments were realized as a result of the reorganization of WPM into a Division. These accomplishments were tied to award fee milestones that required they be implemented by dates agreed upon by FERMCO and DOE. If the milestones were met FERMCO realized a certain percentage of fee, or award. Missing a milestone meant that FERMCO would not only lose the opportunity to gain fee, but could also potentially lose money if performance was deemed below acceptable. Therefore, the accomplishments were highly scrutinized for compliance by DOE and FERMCO. Some of the major accomplishments include:

Life Cycle Cost Analysis Program

Waste Minimization and Pollution Prevention (WMPP) principles were introduced to the site as a Life Cycle Cost Analysis Program instituted by WPM. All site project engineers and managers received training developed by WPM. The main theme of the program was to incorporate waste minimization principles and practices into the planning phases of a project. This has proven successful in that several waste minimization opportunities were incorporated into Removal Action #19 (D&D) as well as other ongoing and new projects.

Clean Trash Program

An effort that was initiated in late FY93 as a pilot program was the Clean Trash Program. This program involved segregating trash from selected radiologically controlled office areas. One hundred percent of the trash was frisked by hand and released to a local landfill if no contamination was discovered. In FY94, this effort was expanded to include all office areas, restrooms, and breakrooms from the radiologically controlled areas (excluding contamination zones). The trash is collected and 10% is hand frisked for contamination. If no contamination is detected, the entire 100% is released for disposal at a local landfill. The volume of the radiologically controlled area trash being diverted from the contaminated

trash waste stream was increased from 0% to 49%, realizing a cost savings of $140,000 to date. This has proven to be a successful process and other sites are emulating the program.

Hazardous And Mixed Waste

The Hazardous and Mixed Waste Program was able to reduce the mixed waste inventory by 31,234 ft3. This was realized by shipping to Envirocare 3,552 ft3 of mixed debris waste; consolidating mixed debris waste for a reduction of 932.4 ft3; and properly recharacterizing 26,751 ft3 as low-level radioactive waste. These efforts significantly reduced the amount of mixed waste to be managed, thus reducing management costs such as inspections, repackaging, and facility (warehouse) costs.

Waste Tracking

Development of an integrated waste tracking database system that incorporated several ancillary databases that were being maintained onsite. The system provides a singular location for information related to tracking of waste from the point of generation to disposal (cradle to grave). The implementation of the system will allow for a reduction in data entry redundancies and ensure more complete and accurate information is available to assist in the day to day management of site wastes.

Waste Storage

Waste operations were improved from a perspective of sheltered container storage. The main storage pad at the site (Plant 1 Pad) was upgraded in order to consolidate a majority of the waste containers being stored. Plant 1 Pad operations were able to segregate, inspect, overpack and relocate 28,000 drums of waste in support of the upgrade. As a result of the upgrade, the amount of containers in unsheltered areas was reduced by 43%. By consolidating a majority of the site's waste containers to one pad a reduction in pad management costs is realized.

Waste Shipping

Low Level Waste shipping operations were able to ship 582,595 ft3 of low-level radioactive waste to Nevada Test Site during FY94. This represents 78% of LLW disposed of at NTS for the year. The weekly average amount of waste shipped equated to 11,000 ft3. The FEMP also received approval in FY94 to ship four additional waste streams.

INTEGRATION WITH REMOVAL ACTION #19 - PLANT 7 DISMANTLING

Background

Plant 7 was constructed in May, 1953 to house the processes involved in the reduction of uranium hexafluoride (UF 6) to uranium tetrafluoride (UF 4). The seven story "Hexafluoride Reduction Plant" was designed to an established production rate converting 12 tons of UF 6 to UF 4 per 24-hour period. Production operations were initiated in June, 1954 but the plant has been idle since 1956, when its production processes were halted.

In 1967 the UF 6 reduction process was declared obsolete, and the equipment was dismantled and removed along with the majority of the process piping. The ammonia separation process, two 75,000 cubic feet per minute blower units and associated ducting, and several motor control centers were abandoned in place. Plant 7 was then used to store drums of intermediate product (UF 4) on the first and second floors, and empty drums on the third, fourth, and sixth floors. The use of this building to store low-level radioactive materials, as well as the previous process operations, resulted in the corresponding presence of radiological contamination. The presence of asbestos containing material and bird droppings, which presented a biological hazard, were additional factors which were considered in recommending the removal of this building.

The dismantling of Plant 7 included: relocation of the drums and debris to an alternate storage area; decontamination (surface cleaning to remove radiological contamination); removal of asbestos containing material (ACM); dismantling the structure; segregation of materials; size reduction of materials; packaging and certification of wastes; placing waste packages into interim storage (staged for shipment); and off-site disposal of low-level radioactive waste (LLW).

Planning

To coordinate these activities, a Design, Engineering and Construction (DEC) Team was formed that consisted of several Divisions within FERMCO. Participation on this team by Waste Programs Management (WPM) was essential for all waste management related activities to be effectively coordinated. A formal group was formed within WPM to integrate and coordinate all WPM activities and participate on the DEC Teams.

This group is/was involved in the project from start to finish to maintain a consistent interface. The purpose of the DEC Team was to include each organization that would be involved in the project to ensure everyone knew what to expect as the project progressed. The functions of Waste Programs Management were: identify, characterize and provide volume estimates of the waste streams; provide and coordinate the delivery of waste containers; remove full waste containers from the project queuing area; place waste into interim storage (stage for shipment); store any hazardous waste; and disposition the LLW to NTS.
The first function of WPM was to identify and characterize all waste streams generated from the project prior to the actual dismantling of the building. Prior to D&D activities, random sampling points were chosen in Plant 7. The areas with the greatest potential of having RCRA hazardous waste were identified based on historical use and process knowledge. Samples were collected and submitted for Toxicity Characteristic Leaching Procedure (TCLP) metals analysis. The results of these tests were used to verify the lack or presence of RCRA hazardous waste. The following sample media were sampled for either hazardous waste determination or to determine the disposition options: decontamination waste/residues; steel and metals; miscellaneous equipment; concrete/debris; and transite. The only hazardous waste identified was the lead bolt caps used to fasten the transite to the structure and the lead flashing around the windows.Once the waste streams were characterized, volume estimates of each waste stream were calculated based on data from "as-built" drawings. This information is included in a site-wide waste forecasting database that is utilized to provide volume estimates of media from all structures onsite. This information, waste stream characterization and volume estimates, is compiled onto a Project Waste Indentification and Disposition (PWID) Form. This form is utilized by the project engineer to assist in the planning and budgeting process. For instance, by estimating the bulking factors of the different material types, the number of containers needed can be determined. Also, based on the characterization, the disposition options are indicated on the PWID form. Therefore, the PWID provides the project with a complete synopsis of the types and amounts of wastes to be incurred and of the disposition options.
Another deliverable to the project was the Material Segregation and Containerization Criteria (MSCC). The MSCC details each step of the D&D effort and what waste streams will be anticipated as a result of that activity. The MSCC utilized segregation categories that allow the sub-contractor to combine certain waste materials that are compatible depending on the disposition options. The MSCC was developed specifically for dismantlement activities and was provided to the D&D sub-contractor in order to assist them in segregating the categories of waste. The MSCC also directed the sub-contractor what type of container was to be utilized for each waste stream, and what waste streams could be consolidated into one container. The MSCC proved very useful because all waste streams were known prior to the commencement of dismantlement and the number and type of containers needed was known in advance.
There were several waste minimization opportunities realized throughout the life of Removal Action #19. One major opportunity is the recycling of approximately 710 tons of structural steel. This effort involved the packaging of the structural steel framework of the building into reusable roll-off containers. The steel will be shipped to a recycling vendor where the decontamination of the surfaces will occur and the steel recycled into the free market. Other opportunities include restricting the sub-contractor to bringing only the necessary equipment and materials for the project to minimize the potential for contamination. Also, used wooden skids were utilized to prepare containers for shipment to NTS in lieu of purchasing new ones.
Operations
Waste Programs Management also provided field support (Waste Technician) during the construction phase of the Plant 7 D&D project to coordinate work and assist in the completion of paper work related to containers. A container staging area was established adjacent to the project where empty containers were delivered and full containers were removed. The staging area was sized to provide a three day capacity of both empty and full containers in the event that transportation of the containers was inhibited. The Waste Technician was responsible for coordinating the delivery of empty containers to the project and removal of full containers for shipment or interim storage. The Waste Technician's responsibilities also included completing the paperwork necessary to verify the contents and track the type and amount of waste in each container. Another function of the Waste Technician was to ensure that

filling of the containers is done as efficiently as possible (another waste minimization opportunity).
Other operations support included scheduling the containers of LLW into shipments for offsite disposition to NTS and movement of containers into onsite interim storage. This involved scheduling the personnel and equipment necessary to move the containers on-site and prepare the containers for offsite shipment (i.e., labeling, inspection). The scheduling of these activities was very often done on a short turnaround in order to meet the sub-contractor's needs which were weather and schedule dependent. The sub-contractor often worked four 10 hour days, whereas FERMCO was on a different schedule. However, for the most part, the on-site operations services were able to keep up with the sometime accelerated pace of the sub-contractor.
Disposition
Three distinct disposition alternatives existed for the Plant 7 Dismantling project: LLW shipments to NTS; the recycling of 710 tons of structural steel; and the restricted reuse of lead flashing.
All of the LLW from the project is scheduled to be shipped by February 15, 1995 in support of a milestone associated with the project. The total volume of containerized LLW to be shipped to NTS equates to 70,392 ft3. Part of the support in the area of waste shipments included the final preparation and labeling of the containers, weighing the containers, and loading onto shipments. The subsequent paperwork was certified to the NTS Waste Acceptance Criteria by FERMCO Quality Assurance in support of WPM shipping activities.
The structural steel remains onsite for shipment to the vendor facility for decontamination and free release. The structural steel will be shipped to the recycling facility by the vendor. The current shipment schedule to the recycling facility is March 28, 1995 through May 19, 1995. As a result of the decontamination process, hazardous waste in the form of lead based paint and grit blast will be shipped back to Fernald and stabilized for disposition to Envirocare of Utah. Approximately 163 ft3 of lead flashing remains onsite and is awaiting disposition through a potential recycling vendor. The lead was the only hazardous waste generated from the Plant 7 Dismantling project.
CONCLUSIONS
The reorganization of WPM and its integration with Removal Action #19 has proven that up-front involvement on a project to properly plan and coordinate activities is successful. Characterizing the waste prior to generation allowed for proper measures to be taken in planning for the packaging and disposition of the waste. The number of waste containers needed was determined utilizing "as-built" drawings and applying bulking factors, depending on the container used. The containers were then ordered in advance and ample supply was available for the project when needed. With one central group responsible for integration and planning efforts, the required information was passed along to the respective Departments within WPM to ensure that all activities were covered. This involved field support at the project site, movement of waste containers to and from the project, storage of containers, and shipment of LLW to NTS. Other integrated efforts include the recycling of 710 tons of structural steel.
The major key to success during this project and others currently ongoing is constant communication. The formation of the DEC Team allowed for the channels of communication to remain open and was the avenue for all project information to be distributed throughout the organizations involved.

TECHNOLOGY DEVELOPMENT AND APPLICATIONS AT FERNALD
Paul J. Pettit, Ph.D.
Michael C. Skriba
Fernald Environmental Management Corporation
Rodney D. Warner
Department of Energy, Fernald Area Office
ABSTRACT
At the Fernald Environmental Management Project (FEMP) northwest of Cincinnati, Ohio, the U.S. Department of Energy and contractor Fernald Environmental Restoration Management Corporation (FERMCO) are aggressively pursuing both the development and the application of improved, innovative technology to the environmental restoration

task. Application of emerging technologies is particularly challenging in a regulatory environment that places pressure on operational managers to develop and meet tight schedules. The regulatory and operational needs make close communication essential between technology developers and technology users (CERCLA/RCRA Unit managers). At Fernald this cooperation and communication has led, not only to the development and demonstration of new technologies with applications at other sites, but also to application of new technologies directly to the Fernald clean up. New technologies have been applied to improve environmental safety and health, improve the effectiveness of restoration efforts, and to cut restoration costs.

The paper will describe successful efforts to develop and apply new technologies at the FEMP and will emphasize those technologies that have been applied and are planned for use in the clean up of this former uranium production facility.

Assistant Secretary of Energy Thomas P. Grumbly has emphasized the application of new technology to environmental restoration as an important key to cleaning up DOE facilities more quickly and cost effectively. Saving money through improved technology meets a strong need during these times of limited budgets.

The paper will summarize a range of technologies being developed or applied at Fernald but which may be applicable to many other DOE sites and commercial locations. These include a robotic trimmer/excavator to reduce risks in treating high level tank wastes, soil washing and supporting technology, real-time instrumentation that reduces characterization and sampling costs, first-of-a-kind development of horizonal grout barriers, controlled detonation for cost-effective and safe demolition of contaminated buildings, minimum additive waste stabilization for more efficient and cost-effective stabilization of multiple streams of radioactively contaminated wastes, post closure monitoring technologies, solid block modeling, and advanced decontamination technologies.

The authors will bring together in one paper the perspectives of both technology developers and technology users, and will outline how Fernald has successfully overcome obstacles to achieve an aggressive, productive Technology Program. Managers responsible for remedial actions have a paramount need for technologies with ascertainable performance, cost, and schedule, while managers responsible for identifying and developing innovative technologies must maintain a balance between the role of independent advocate and the role of "partner" with operations managers. In addition to introducing Waste Management '95 attendees to the new technologies emerging at Fernald, this paper will conclude with lessons learned about specific technologies and management/development methods that can be applied by other projects facing cleanup under stringent operations needs and compliance deadlines.

INTRODUCTION

At the Fernald Environmental Management Project (FEMP) northwest of Cincinnati, Ohio, the U.S. Department of Energy and contractor Fernald Environmental Restoration Management Corporation (FERMCO) are aggressively pursuing both the development and the application of improved, innovative technology to facilitate the mission of the site environmental restoration. The FEMP is a DOE-owned, former uranium production facility which is in the early stages of restoration operations.

Implementation of new technologies to restoration operations is particularly challenging in the current regulatory environment that places pressure on operations managers who are legally bound to meet tight remediation schedules. Managers responsible for remediation (technology users) have a paramount need to use methods with ascertainable performance, cost, and schedule. Although new technology can offer the potential to substantially reduce cost and schedules, remediation managers frequently are reluctant to entertain risks associated with new approaches. Because of the potential for improvement, a comprehensive restoration effort, such as the one at Fernald, employs technology developers whose role is to act as independent advocates and promote the use of new, improved technological approaches. The challenge is to maintain a balance between technology user and technology developer that achieves the most advantaged restoration effort.

At Fernald technology users and developers have achieved a special communication and cooperation that has led to the development, demonstration, and application of new technologies directly to the Fernald environmental restoration effort. Innovative technologies have been applied to improve environmental safety and health, improve the effectiveness of restoration efforts, and to cut restoration costs.

This paper describes successful efforts to develop and apply new technologies at the FEMP and emphasizes those technologies that have been applied and are planned for

use in the restoration of Fernald. The application of new technology to environmental restoration is an important key to cleaning up DOE facilities more quickly and cost effectively. Saving money through improved technology meets a strong need during these times of limited budgets.

This paper presents the perspectives of both technology developers and technology users, and outlines lessons learned on how Fernald has successfully overcome obstacles to achieve an aggressive, productive, user-oriented technology program.

MINIMUM ADDITIVE WASTE STABILIZATION

The Minimum Additive Waste Stabilization (MAWS) demonstration, which was conducted at Fernald during calendar year 1994, is illustrative of a number of key issues in the coordination of technology development and environmental remediation. Vitrification has been widely identified as a preferred method for stabilizing high-level radioactive waste. At the time the MAWS demonstration was initiated no vitrification plant was operating in the United States, however, vitrification was considered a potential technology for application at Fernald. Demonstration of feasibility was necessary to gain the commitment of operations management, regulators, and engineers to proceed with this technology.

The MAWS demonstration plant was built at Fernald to treat as many waste streams as possible from the contaminated areas of the site, while minimizing the addition of non-contaminated materials to the vitrification process. The primary waste stream processed was comprised of sludge from Fernald waste pits. Pits 3 and 5 contain approximately 350,000 cubic meters of residues from uranium ore processing. To provide the properties required for satisfactory classification of this sludge, a source of silica was needed. Fernald's uranium-contaminated soil provided a suitable source for this ingredient. To maximize recovery of non-contaminated materials, soil washing technology was employed. Contaminated soil was treated to concentrate the uranium-bearing fraction with the silica-bearing fraction, and to separate these constituents from the bulk of the soil. The contaminated silica fraction was then blended with sludge from the waste pits and heated to produce glass "gems." These flattened marbles of black glass constituted a more stable waste form which was easily packaged and transported, more stable, and was significantly less volume than the original waste. In addition to the soil washing and vitrification furnace technologies, the MAWS plant incorporated an ion exchange waste water treatment system to recycle water used in the soil washing process.

Before termination of the demonstration, the MAWS facility was processing at a rate of 300 kilograms of glass output a day. The work demonstrated that waste pit volumes could be reduced by up to 70 percent, a substantial potential for cost savings. In addition, soil was cleaned to a condition allowing return of the clean portion as backfill for pits or other use. The sludge, which is classified as "mixed waste" for regulatory purposes, was converted to "low level waste." Mixed waste disposal costs run in the vicinity of $360/cubic foot compared with a current cost of under $20/cubic foot for low level waste disposal.

The MAWS demonstration was conducted largely by the technology suppliers. GTS Duratek Corporation provided the vitrification furnace and waste water treatment system. Lockheed Environmental Management Systems Corporation provided the soil washing technology. Catholic University of American performed the glass composition development and testing, while Argonne National Laboratory conducted long-term durability and performance testing of the glass. FERMCO provided facility support, as well as technical and project support.

In the CERCLA regulatory environment, Operable Unit (remediation) managers are driven primarily by schedules established under Consent Agreements. Although new or emerging technology may have the potential to improve schedules, reduce costs, or provide a better quality outcome, the remediation manager often faces a dilemma in accepting new technology. The remediation manager cannot commit to new technology until performance and cost aspects have been clearly demonstrated. For new technology to be applied, technology demonstration timing must accommodate the remediation manager's timing for preparing and negotiating the remedial action plan. The remedial action benefits from flexibility to allow the introduction of the new technology late in the process. CERCLA provides sufficient flexibility to allow the substitution of new technologies after approval and publication of the Record of Decision. Moreover, in the case of Fernald, the Ohio Environmental Protection Agency encourages the application of new technologies. The pragmatic implication of these circumstances is that technology development managers and remediation managers must

operate on coordinated, parallel paths to pursue a common goal: improvement.

VITRIFICATION PILOT PLANT

Successful demonstration of vitrification through the MAWS project provided the validation to support selection of vitrification as the preferred alternative for stabilization of waste from Fernald's K-65 silos. Located within Fernald Operable Unit 4 (OU4), Silos 1 and 2 contain radium-bearing sludge which emits radon gas. A vitrification pilot plant to handle the OU4 silo wastes is currently under construction and is scheduled to begin processing material from the silos in late 1995. The plant will incorporate a new furnace concept to reach higher temperatures, "stretching" state-of-the-art electrode technology. The plant will also require integration of a system for handling radon off gases. Currently, carbon absorption appears to be the most promising technology for addressing radon, but alternatives need to be evaluated, as carbon systems have intrinsic deficiencies.

SOLID BLOCK MODELING

Solid Block Modeling technology has been used on the Fernald project to produce three dimensional images of subsurface contamination and geologic conditions. Using an Oracle relational database along with Intergraph CAD/CAM hardware and software, the FEMP has been able to map the contaminated groundwater plume, calculate volumes of contaminated material, and map layers of clay and sand to identify potential disposal facility sites. Application of Solid Block Modeling resolved the question of the primary source of aquifer contamination. The major contributor of contamination was identified as the Southfield Landfill. It also was established that contribution to the regional aquifer contamination from the solid waste landfill was minimal.

The improved understanding of complex data interrelationships gained through application of Solid Block Modeling resulted in significant schedule and cost savings. Savings were amplified in 1994 when data acquisition was enhanced through use of a cone penetrometer. The Site Characterization and Analysis Penetrometer System (SCAPS) was brought to Fernald to provide characterization data for both OU1 and OU2 under auspices of the Uranium in Soils Integrated Demonstration and the Characterization Integrated Program, both sponsored by the Department of Energy Office of Technology Development. SCAPS is a modified cone penetrometer mounted on a truck which was specifically developed for use at environmental restoration sites. The unit pushes a two-inch diameter probe into the ground to gather geological information deep below the surface.

The SCAPS assessed characteristics of waste in three OU1 pits and collected data needed for the Dewatering Excavation and Evaluation Program. For OU2, the unit gathered geological data on the eastern area of the site to evaluate geological conditions for potential siting of a disposal facility. The unit also conducted tests with a prototype radiation probe in the Fernald Southfield area, providing information to support further development of the technology. The cone penetrometer project at Fernald demonstrated an effective partnership of field application in parallel with technology development. Both parties, user and developer, profited. The OU1 and OU2 managers each obtained valuable data, while the developers were able to demonstrate the feasibility of the penetrometer under radioactive field conditions. Companion data were obtained by standard geophysical methods for comparison with the cone penetrometer results. By replacing slower laboratory analysis of samples with real-time field analysis, the cone penetrometer achieved significant cost and schedule savings on the actual remediation project. Cost savings were calculated at more than $620,000 compared to 1994 baseline cost, with additional savings expected in 1995. In addition, data from the penetrometer measurements were fed into the Solid Block Modeling system to more accurately model subsurface conditions.

OTHER APPLICATIONS FOR COST AND SCHEDULE SAVINGS

Application of Micro-Purge technology to groundwater sampling has also begun producing cost savings at the Fernald site. Micro-purge technology reduces the volume of water that must be purged from a well each time a sample is taken. This reduces the time required for sampling, increases sampling accuracy, and reduces the volumes of contaminated waste water. During 1994, savings of $100,000 at Fernald were demonstrated. Savings from this technology will continue to be realized for the life of the project. Pioneered at Fernald, the micro-purge technology will have applications throughout the DOE environmental restoration network.

In the summer of 1994, Fernald's tallest building, Plant 7, was removed using

implosion technology. Implosion uses shaped charges to remove structural columns and splice plates on various floors so that the building will fall in on itself. The shaped charges act as a cutting tool by delivering approximately three million pounds of cutting force on the structural member.

Implosion was selected at Fernald because it offered a technical approach that eliminated worker exposure to heights (the height of the building was 110 feet), it reduced exposure to burning of lead paint from 640 manhours to 25 manhours, reduced worker time in a radiation area by four weeks, and reduced torch cutting of steel coated with lead paint from 3,420 feet to 90 feet. Early concerns with the public perception of use of explosives on a contaminated structure were overcome when the DOE and FERMCO worked closely with stakeholders and explained the safety advantages and reviewed the mechanics of implosion in several public forums. Public confidence with the FERMCO-DOE approach supported implosion as an innovative approach in environmental restoration.

The superstructure take-down required two implosions, but was the fastest and least-cost method that reduced the risks to craft personnel. Schedule improvement approximated six months, compared to baseline, and actual cost savings were calculated at approximately $5,000,000 from the innovative approach.

ROBOTICS APPLICATIONS FOR SAFETY ENHANCEMENT

The FEMP has also aggressively pursued the use of robotics to reduce human exposure to radioactive or hazardous materials and risk situations. In the recent past, Fernald has had two incidents of mower capsize. While no one was injured, these incidents represent a significant hazard that must be reduced. In addition to time expended donning and removing protective clothing, during summer months workers can be at risk of heat related disorders and discomfort during mowing operations. During 1994, a remote control lawn mower, as illustrated in Fig. 1, was tested at Fernald to perform vegetation control in areas of the site which are contaminated or have dangerous slopes. Following successful field trials, the equipment was accepted by FEMP site operations management for use by workers entering contaminated areas where protective clothing is required. While remote-control mowing may not seem revolutionary at first consideration, use of the advanced mower reduces costs, and, more importantly, reduces risks to workers.

A robotic waste retrieval device, dubbed "Houdini" by the developers, is currently being planned for use in the cleanup of three silos at Fernald (See Fig. 2). Silos 1 and 2 contain K-65 waste, a putty-like radium-bearing material. The robotic device is being developed to excavate "heel" and other hard-to-reach wastes, and thereby supplement the main hydraulic excavator, a sluicing pump, for the primary removal of wastes from the silos. The Houdini mechanism also will be designed to retrieve small objects which block the intake of the main excavator. Houdini consists of a folding, tracked base vehicle with a heavy-duty six-axis arm. The unit will be equipped with several tools, including a gripper, shears, hose reel assembly, and a scoop. The unit can be collapsed to enter openings as small as 24 inches in diameter. It will be environmentally and radiologically hardened, and designed to be easily decontaminated.

In Fernald Silo 3, which contains dry, powdery metal oxides, the robot will serve as the primary waste removal system, manipulating a vacuum nozzle to remove material form the silo. In all three silos, the innovative robot will be operating in environments where human entry is prohibited.

Robotics development represents a good example of where technology users are relying on developers to provide a product for application of an improved remediation method. The advance was made possible by development of a good working relationship between the Fernald developer and user, and by the generous support and guidance of the DOE Office of Technology Development Robotics Program.

HORIZONTAL GROUT BARRIER

A wide range of technologies are being demonstrated at Fernald. Among those with potential broad application in both the DOE and private sectors is the Horizontal Grout Barrier. This promising new technology may be the solution to one of the most perplexing problems of environmental restoration. Leaching of contaminants from surface or near surface sources is one of the most serious threats to aquifers. Placing an impermeable barrier beneath the contamination source to block movement of contaminants into the aquifer has long been a goal of engineers. Fernald is pioneering efforts to develop enabling technology for installing horizontal grout barriers intended to provide a solution to total in situ containment of wastes. The

Horizontal Grout Barrier combines directional drilling technology with advanced grouting technology developed in the oil service industry. Using directional drilling rigs, holes are drilled under the contaminated source. The holes are parallel and extend completely under the contamination source. The steel drill rods are then used to pull the grout injection system beneath the waste. Grout, injected at high pressure, cuts through the soil and mixes with it to form a continuous slab beneath the contamination source.

URANIUM IN SOILS INTEGRATED DEMONSTRATION

The most comprehensive technology demonstration at Fernald has been the Uranium in Soils Integrated Demonstration (USID). The uranium contamination in the soils at Fernald provides the appropriate conditions for demonstrating technologies for all stages of the restoration of uranium-contaminated soils. Since 1990, Fernald has supported demonstrations of technologies for real-time characterization of uranium contamination in soils, excavation and separation of the contaminated fraction from the soil, disposal of the contaminated fraction, and evaluation of treatment effectiveness. Soil washing technologies demonstrated at the site are under consideration for application to some of the cleanup challenges at Fernald. Although onsite storage is the current leading remedial alternative for restoration of Fernald soils, many technologies developed by the USID are being implemented in direct support of the Fernald restoration, including technologies for characterization and risk models. Many of the technologies will also undergo further development in DOE's "Landfill Focus Area." The new Focus Area approach is designed to bring the technology developers into closer dialog with users to assure that end-user requirements can be met by developments, an approach similar to the method Fernald has used to successfully implement new technologies.

CONCLUSIONS

The demonstration and application of new technologies to the challenges of environmental restoration are essential if the costs of restoration are to be brought down. The technology program at Fernald offers an example of how development work can be conducted to yield a measurable, positive return on investment (savings). New technologies also promise to reduce risks to workers, provide quicker solutions to cleanup challenges, and improve the overall quality of environmental restoration. The regulatory drivers for environmental restoration, however, force remediation managers in the field to make compliance with schedules a primary goal. Pragmatically, this means that environmental restoration managers will have little time to focus on potential application of unproven technologies. The authors believe that the following approach will facilitate development and application of new technologies to environmental restoration problems:

Field restoration and demonstration of new technologies must be pursued on separate, parallel tracks, with close schedule integration.

The overall technology development program must operate as a service organization that treats the technology user as a true "client."

Technology users must work with developers to articulate definitive performance requirements and companion needs to be integrated into development efforts.

Technology developers must place the end-users' needs foremost, including the need to be confident that new technologies will meet schedules.

There must be a "champion" for technology in the user organization who will aggressively advocate new technologies.

Environmental restoration managers should have technology application included in their performance standards.

Technology development efforts must accommodate stakeholder considerations from the outset.

The DOE-FERMCO Technology Program has provided innovative and improved technologies to directly support FEMP restoration, which has resulted in demonstrated cost reductions, schedule savings, and improved operational safety. The measured savings and improvements at Fernald indicate the potential for significant cumulative savings and increased efficiencies through further applications at other sites.

IAEA ACTIVITIES IN DEVELOPING AND IMPLEMENTING SAFETY PRINCIPLES AND CRITERIA FOR

GEOLOGICAL DISPOSAL OF RADIOACTIVE WASTE

Ivan F. Vovk
Gordon S. Linsley
International Atomic Energy Agency

ABSTRACT

For decades, the IAEA has played an important role in fostering the cooperation and the coordination of activities that can be best handled at the international level to establish, reach consensus on and publish Safety Standards, Guides and Practices for the safe management and disposal of radioactive waste. Over the past several years, a special series of safety documents is being prepared within the framework of the RADWASS programme, which covers all aspects of radioactive waste management. A new Safety Standard on geological disposal, based on the safety principles developed within the RADWASS programme, is being prepared. The draft Safety Standard specifies the objectives and defines general requirements to be considered in geological disposal of radioactive waste, including legal, regulatory and administrative questions, organization and responsibilities, radiological and environmental protection, characteristics of acceptable waste and sites, design, construction and operation of disposal facilities, their closure and post-closure issues, safety and environmental impact assessments, quality assurance. It provides the basis for developing Safety Guides and Safety Practices that contain detailed guidance on its implementation.

While the RADWASS programme is planned to document the existing international consensus on approaches to radioactive waste management and disposal, the IAEA has also established a forum at which any unresolved issues may be discussed. This is known as the INWAC Subgroup on Principles and Criteria for Radioactive Waste Disposal. Recently the Subgroup has prepared and published a report "Safety Indicators in Different Time Frames for the Safety Assessment of Underground Radioactive Waste Repositories". The report concludes that the long-term safety case can be made most effectively by the combined use of several safety indicators, such as risk, dose, environmental concentration, biosphere flux, flux through barriers, and time, recognizing, however, that risk and dose remain the most fundamental of the indicators of safety. It also draws conclusions on the nature of the safety assessments and the types of safety indicators to be used in the different timeframes of interest in relation to radioactive waste disposal.

INTRODUCTION

In the past the IAEA has published a number of Safety Series documents on geological disposal, (1, 2, 3). Lately, as a contribution to the process of demonstrating that radioactive waste can be managed safely, the IAEA has engaged upon the Radioactive Waste Safety Standards (RADWASS) programme in which it intends to document the internationally agreed approaches to safe radioactive waste management, including disposal, and provide Member States with a comprehensive series of documents to assist in the derivation of and to complement national criteria, standards and practices (4). The RADWASS programme has been organized as a complete body of 55 planned publications on safety of radioactive waste management with hierarchical structure following the general framework of the IAEA Safety Series documents (5). The importance of the programme has been reaffirmed by the Agency's General Conference, which, at its thirty-eighth regular session held in September 1994, invited the Board of Governors and the Director General "to maintain the emphasis given to radioactive waste management, especially with regard to RADWASS, to commence with planning activities for a convention on the safety of waste management and begin the process of collecting relevant background information (including appropriate RADWASS documents) that would be useful in drafting the convention". While the RADWASS programme is intended to document the existing consensus in radioactive waste management, it is recognized that there are some issues of philosophical nature which require further discussion before a consensus can be reached. For this reason the IAEA has established an international forum where these issues can be discussed. The forum is with the INWAC Subgroup on Principles and Criteria for Radioactive Waste Disposal (PCRWD). To date, the Subgroup has prepared a report on safety indicators and timeframes (6) and has developed position and discussion papers on several other issues.

In this paper we describe the progress on the parts of the RADWASS programme relevant to geological disposal and also the work of the INWAC Subgroup on Principles and Criteria for Radioactive Disposal.

RADWASS SAFETY PRINCIPLES

The radioactive waste management safety principles, as defined in the draft version of the RADWASS Safety Fundamentals document "The Principles of Radioactive Waste Management", recommended for publication by the extended INWAC meeting in January 1995, are:

Principle 1: Protection of human health. Radioactive waste shall be managed in such a way as to secure an acceptable level of protection for human health.

Principle 2: Protection of the environment. Radioactive waste shall be managed in such a way as to provide an acceptable level of protection of the environment.

Principle 3: Protection beyond national borders. Radioactive waste shall be managed in such a way as to assure that possible effects on human health and the environment beyond national borders will be taken into account.

Principle 4: Protection of future generations. Radioactive waste shall be managed in a way that predicted impacts on the health of future generations will not be greater than relevant levels of impact that are acceptable today.

Principle 5: Burdens on future generations. Radioactive waste shall be managed in a way that will not impose undue burdens on future generations.

Principle 6: National legal framework. Radioactive waste shall be managed within an appropriate national legal framework including clear allocation of responsibilities and provision for independent regulatory functions.

Principle 7: Control of radioactive waste generation. Generation of radioactive waste shall be kept to the minimum practicable.

Principle 8: Radioactive waste generation and management interdependencies. Interdependencies among all steps in radioactive waste generation and management shall be appropriately taken into account.

Principle 9: Safety of facilities. Safety of facilities for radioactive waste management shall be appropriately assured during their lifetime.

In the implementation of these principles, the relevant recommendations of international bodies, such as IAEA and ICRP are typically taken into account. In particular, the recommendations related to radiological protection incorporated in the "International Basic Safety Standards for Protection against Ionizing Radiation and for the Safety of Radiation Sources" (BSS) (7) are relevant.

In order to assist countries in implementing the above safety principles the IAEA is working to formulate as Safety Standards the definition of technical and safety requirements for each of the six RADWASS subject areas 1) Planning, 2) Predisposal, 3) Near surface disposal, 4) Geological disposal, 5) Uranium/thorium mining and milling waste, 6) Decommissioning/environmental restoration).

RADWASS SAFETY STANDARD ON GEOLOGICAL DISPOSAL

The objective of the Safety Standard on geological disposal is to set out the internationally agreed basic requirements for safe disposal of radioactive waste in suitable geological media at an appropriate depth (hundreds of meters) below the earth's surface. It is intended primarily to be applied to the disposal of solid high level and other long lived radioactive waste, in particular spent nuclear fuel (if disposed as a waste), the highly radioactive waste from reprocessing spent nuclear fuel and alpha bearing waste, in mined facilities and in deep boreholes. It is evident, however, that geological disposal systems, acceptable on a safety basis for disposing of high level and long lived waste, can be also used for disposing of solid low and intermediate level waste, provided the latter is properly conditioned and a country chooses this option.

Structure

The structure and the content of the document are still being developed. For the purpose of consistency, and reflecting the fact that a number of requirements for both near surface and geological disposal of radioactive waste are similar, the main structure of the already prepared Safety Standard on near surface disposal was preserved in the draft Safety Standard on geological disposal. Proper attention has also been devoted to harmonization of this Safety Standard with other RADWASS publications. Accordingly, the draft Safety Standard on geological disposal is structured in thirteen Sections, including an overview of the basic waste management principles, as they are stated in the Safety Fundamentals (Section 2), national framework for radioactive waste management (Section 3), an outline of the organization and responsibilities for each of the parties involved (Section 4), safety and environmental protection (Section 5). Sections 3, 4 and a part of the Section 5 represent incorporation into this Safety Standard of the basic radioactive

waste management requirements as they are formulated in the Safety Standard on "Establishing a National System for Radioactive Waste Management". They are followed by a description of specific technical and safety requirements for disposal components and activities, in particular, acceptable waste (Section 6), acceptable site (Section 7), design of disposal facilities (Section 8), construction (Section 9), operation (Section 10), closure (Section 11), post-closure (Section 12) and requirements for quality assurance during all disposal activities, from the planning through to the post-closure phase (Section 13).

Safety and Environmental Protection

For consideration of safety and environmental protection issues the lifetime of a geological disposal facility is subdivided into three phases: pre-operational, operational and post-closure. The pre-operational phase includes siting, design and construction. The operational phase includes commissioning, operations and closure. The post-closure phase may include institutional and post-institutional control periods. These phases may occur separately, or may overlap, in part. During all of these phases, safety of the facility relies on the appropriate application of several types of protective measures including multiple barriers, quality assurance procedures and administrative controls to prevent releases of radioactive materials to the environment and to mitigate their consequences should this occur.

The draft Safety Standard emphasizes that during the operational phase of a disposal facility humans and the environment must be protected against unacceptable levels of ionizing radiation in compliance with BSS requirements. For application to the post-closure phase of geological disposal additional requirements to those provided in the BSS are needed for dealing with exposures which are not certain to occur [2, 6, 8, 9]. The exact nature of the guidance in the Safety Standard on radiological and other safety criteria for disposal is still under discussion but it may be noted that in a previous IAEA Standard (2) a reference value of about 10-5 of annual risk, which should not be exceeded by an individual of the critical group from all radiation sources, was specified. A fraction of this value was said to be applicable to waste disposal.

Comprehensive safety and environmental impact assessments are considered in the draft Safety Standard to be key elements in ensuring safety and environmental protection. They are required to be performed and updated, as necessary, in support of an application to the regulatory body for approval to construct, to operate and to close a geological disposal facility and if significant changes in approved conditions appear. It is also required that these assessments consider the radiological and non-radiological safety and environmental impact within and beyond national boarders with particular attention being given to regulatory requirements and that waste is disposed in a manner that adequately ensures protection of humans and the environment without imposing undue burdens on future generations.

Other issues

Other issues of importance for geological disposal considered in the draft Safety Standard include retrievability, security arrangements and safeguards, closure of the repository and post-closure institutional arrangements and keeping records.

Although geological disposal means waste emplacement in an approved specified facility without the intention of retrieval, some countries may prefer to keep the possibility during a shorter or longer period of time for, a maximum, hundreds of years, to retrieve waste already emplaced in a repository. It is emphasized, however, that, if the ability to retrieve waste is a design requirement, provisions should be made for retrievability at the start of the project to exclude any threat to long term repository performance.

All reasonable security arrangements should be made to prevent unauthorized actions that jeopardize safety of the repository. In particular, provisions should be made to detect, delay and prevent any unauthorized entry into the security sensitive areas. Waste that does not meet the criteria for the termination of safeguards, must be subject to safeguards control during the operational phase of a disposal facility. Safeguards verification activities should obviously be matched with the disposal operations and should not have any negative impact on the operational and long term safety.

Permanent closure of a disposal facility comprises a set of systematic actions, after the waste emplacement operations are completed, with the objective of finalizing the isolation system. It may include sealing of engineered openings such as boreholes, tunnels, shafts and drifts and decommissioning of surface facilities.

Partial backfilling and sealing of the emplacement areas may already have been done during the operational phase. After the completion of the closure actions, a geological disposal facility is brought to its post-closure status. No further engineering measures are then expected to be necessary to ensure proper future performance of the disposal facility.

In accordance with the principle of limiting the burden on future generations, geological disposal of radioactive waste should, to the extent possible, not rely on any institutional arrangements or actions as a necessary safety feature. However, monitoring of the repository in the post-closure phase is not precluded for a limited period of time if it is justified and does not impair the safety of disposal. Safety can be enhanced by institutional control measures, for example, by the prevention of intrusion. The country hosting a geological disposal facility should consider the need for post-closure institutional arrangements and actions and the allocation of responsibilities and resources for such activities. Some Member States may be compelled to introduce long term institutional measures with respect to repositories containing spent nuclear fuel in response to international safeguard obligations.

Keeping records of the repository and site markers above and/or below ground is considered as a cost-effective way to maintain awareness of the potential long term hazard and is recommended as a measure to reduce the probability of inadvertent intrusion into the repository. Records are to be maintained of the layout of the repository, facility design, as built structures, waste inventory including location and physical form details, package identification, backfill materials, site characterization data, safety assessment results, models and computer codes used, environmental monitoring results, and data on the closure of the disposal facility.

Companion Documents

The Safety Standard on geological disposal will be accompanied by three Safety Guides and four Safety Practices documents. One of them, Safety Guide "Siting of Geological Disposal Facilities" has been published (10), the other two Safety Guides "Design, Construction, Operation and Closure of Geological Repositories" and "Safety Assessment for Geological Disposal" as all four Safety Practices documents "Validation and Verification of Models for Long Term Safety Assessment of Radioactive Waste Disposal Facilities", "Procedures for Closure of Radioactive Waste Disposal Facilities", "Waste Acceptance Requirements for Geological Disposal of Radioactive Waste" and "Selection of Scenarios for Safety Assessment of Geological Disposal Facilities" will be prepared and published later.

ACTIVITIES OF THE INWAC SUBGROUP ON PRINCIPLES AND CRITERIA FOR RADIOACTIVE WASTE DISPOSAL

As explained earlier, the INWAC PCRWD Subgroup plays an important role in examining unresolved issues related to radioactive waste disposal. Details of its terms of reference and the activities during the initial period are given in (11). Since then, two Subgroup meetings (October 1993 and November 1994) have been held at the IAEA Headquarters in Vienna.

Safety indicators and timescales

Recently the first report of the Subgroup was published (6). It examines the question of what type of safety assessment is needed to cover time periods far into the future and also what sort of safety criteria (or safety indicators) are appropriate at such times. The motivation for this discussion is the need to substantiate the principle of protection of future generations given the difficulties in showing compliance with safety criteria over long time-scales because of the increase with time of the uncertainty associated with the results of predictive models. On the other hand, the radiotoxicity of the wastes decreases with time due to radioactive decay. These contrary trends suggest that the meaningfulness of and the need for detailed quantitative assessments become less and less the further into the future the assessment is carried. It is generally considered appropriate, however, to continue assessments sufficiently far into the future to ensure that any peak in potential impact of the disposal facility has been taken into account. The only adjustment to this principle might arise if qualitative studies were to show the peak impact to be so low as to be considered trivial.

The results of the discussion provided in the report are summarized as follows:

1. The assessed long term consequences of disposal systems in terms of risk and dose can only be considered as indicators of safety.
2. The long term safety case can be made most effectively by the combined use of

several safety indicators, such as risk, dose, environmental concentration, biospheric flux, flux through barriers and time recognizing, however, that risk and dose remain the most fundamental of the indicators of safety.
3. Indicators become particularly valuable when they are supported by observations from natural analogues.
4. In the time period up to around 104 years after repository closure, the safety case should be based on quantitative safety assessments using dose/risk calculations supported by calculations involving other safety indicators.
5. In the period from around 104 years to about 106 years after repository closure, the safety case should be based either on quantitative safety assessments or on qualitative assessments using a combination of safety indicators. The emphasis may be expected to shift increasingly towards qualitative assessments as 106 years is approached.
6. Beyond about 106 years little credibility can be attached to integrated safety assessments.

Several position and discussion papers have been prepared and discussed at the Subgroup meetings. They include papers on: "Interface Issues between Nuclear Safeguards and Radioactive Waste Management", "Position Paper on Post-Closure Issues", "Optimization of Radiation Protection in Application to Radioactive Waste Disposal" and "Regulatory Decision Making in the Presence of Uncertainty". The publication of several of these was approved at the last meeting of the PCRWD Subgroup.

CONCLUSION

We have described some of the IAEA activities related to the solution of the problem of disposal of high level and long lived radioactive waste. Their results demonstrate that Agency has contributed to and can further assist in the solution of this problem by: 1) putting radioactive waste management and disposal into a global context; 2) documenting the existing international consensus on the approaches and methodologies for safe radioactive waste management and disposal; 3) providing a forum for discussion of principles and criteria for safe management and disposal of radioactive waste and creating a mechanism to establish consensus where it does not yet exist; and 4) providing Member States with a comprehensive series of internationally agreed documents to complement or set up national standards and criteria.

9-2

INTERNATIONAL PERSPECTIVE ON U.S. HIGH-LEVEL WASTE LICENSING REQUIREMENTS

Stephan J. Brocoum
U.S. Department of Energy
Miguel A. Lugo
TRW Environmental Safety Systems

ABSTRACT

In support of the National Academy of Sciences (NAS) study required by Section 801 of the Energy Policy Act of 1992, the U.S Department of Energy (DOE) developed, in April of 1994, specific recommendations pertaining to a standard for a potential repository at Yucca Mountain. These recommendations are summarized as follows:

The standard should be health-based.

The standard should focus on protecting those people who will be living in the vicinity of the potential repository.

The standard should require a quantitative demonstration of compliance for no more than 10,000 years.

The standard should provide qualitative requirements related to reducing the potential for inadvertent future human intrusion to cause radionuclide releases.

The quantitative aspects of the standard should be stated in deterministic terms, with probabilistic analyses used to demonstrate compliance.

A standard expressed in terms of individual dose would be appropriate, provided that the following aspects are clearly specified in a regulation or associated guidance:

- The individual dose limit should be commensurate with current dose limits for individual members of the public as specified in 10 CFR Part 20, and with recommendations of national and international advisory groups.
- The dose limit should be applied to an average individual in the population living in the vicinity of Yucca Mountain.
- Assumptions related to the future biosphere should be specified. These should include a water use scenario for the average individual which is based on the current practices of people living in the Amargosa Valley.

These recommendations are consistent with existing national and international standards and guidance. Most of the national and international community expresses the primary radiation protection criterion in terms of annual individual dose, with a range from 10 to 100 mrem/yr (0.1 to 1 mSv/yr), and over a time frame of 10,000 years.

BACKGROUND

In the Nuclear Waste Policy Act (NWPA) of 1982 (1), the Congress of the United States directed the Department of Energy (DOE) to characterize potential repository sites and to design, construct, license, and operate a geologic repository for spent nuclear fuel and high-level radioactive waste. The same act directed the Environmental Protection Agency (EPA) to promulgate generally applicable standards for protection of the general environment from offsite releases of radioactive material from repositories. Furthermore, responsibility for implementing this standard through the development and application of licensing requirements was assigned to the Nuclear Regulatory Commission (NRC). In 1985, the EPA issued repository standards in the form of the final rule 40 CFR Part 191, "Environmental Standards for the Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Radioactive Waste" (2). In 1987, the United States Court of Appeals for the First Circuit vacated and remanded 40 CFR Part 191; while the management and storage aspects were reinstated on appeal, the disposal standards were left in remand. Also in 1987, the Nuclear Waste Policy Amendments Act (3) redirected the DOE program toward the characterization of only one potential site for a geologic repository - the Yucca Mountain site in Nevada. The Energy Policy Act of 1992 (4) directed the EPA to contract with the National Academy of Sciences (NAS) to conduct a study to provide findings and recommendations on reasonable standards for protection of the public health and safety. The 1992 law also directed the EPA, based on the recommendations of the NAS, to promulgate public health and safety standards for protection of the public from releases from radioactive materials stored or disposed of in the repository at the Yucca Mountain site. Furthermore, the NRC was directed to modify its requirements to be consistent with the EPA standards. The NAS formed the Committee on Technical Bases for Yucca Mountain Standards to prepare its recommendations to the EPA. The committee held public meetings in May,

August, November, and December of 1993, and in April of 1994. A committee report, containing recommendations to the EPA, is expected some time in 1995.
In May of 1993, the DOE proposed to the NAS that a standard for the potential geologic repository at Yucca Mountain should be implementable, to allow the DOE to carry out its obligations to the citizens of the United States, and understandable, to foster public confidence in the safety of geologic disposal. The DOE noted that a standard should require a scientifically supportable demonstration of compliance, and should be consistent with other radiation standards and regulations. In April of 1994, the DOE provided more specific recommendations to the NAS on a health and safety standard, which will be discussed later in this paper. (5)

GENERAL CONSIDERATIONS IN DEVELOPING A STANDARD

A standard could be expressed in a variety of forms, including the number of expected health effects on future populations, doses to individuals or populations, and the amount of radionuclides released to the accessible environment. Whatever the form, demonstrating compliance with such a standard will necessarily involve making quantitative projections of repository performance far into the future. There is considerable uncertainty inherent in these long-term performance projections for any repository. Dealing with that uncertainty must be considered in the development of the standard itself. In some cases it will be appropriate to specify, as a part of the standard or associated regulatory guidance, how the uncertainty is to be treated. In particular, the characteristics of future human society are a major uncertainty that should be dealt with up front, in the NAS recommendations to the EPA, rather than during a licensing proceeding.

DEPARTMENT OF ENERGY RECOMMENDATIONS

With the general considerations discussed above in mind, in April of 1994, the DOE developed specific recommendations pertaining to a standard for the potential repository at Yucca Mountain. These recommendations are discussed below:

The standard should be health-based.

A health-based standard is considered preferable largely because it is easier to understand the link to public health and safety, and to compare risks between a repository and other human endeavors. A health-based standard should assist in fostering public confidence in the safety of a geologic repository. In addition, it should be noted that a health-based standard is consistent with both the express language and legislative history of the Energy Policy Act of 1992. While the EPA is given final discretion to promulgate the appropriate standard, it is nevertheless required to promulgate a health-based standard, absent a finding by the NAS that such a standard is unreasonable. (6)

The standard should focus on protecting those people who will be living in the vicinity of the potential repository.

A standard might focus its protection in a variety of ways. These include: an individual at the boundary of the accessible environment, people living in the vicinity of a repository, the world population, groundwater, or plants and animals. Due to the nature of geologic disposal in general and the Yucca Mountain site in particular, the people who will be living in the vicinity of a repository are those most at risk, and they are the proper focus of protection. Protection of a hypothetical, maximally-exposed individual living at the boundary of the accessible environment is an unrealistic, overly conservative worst case for the arid, isolated Yucca Mountain site. Protection for people in the vicinity of the repository must include consideration of exposure to radiation via a groundwater pathway. Therefore, no additional groundwater protection provisions are needed. Also, world population protection through release limits or population dose limits is superfluous so long as the people in the vicinity of the site are adequately protected. Population protection, if provided, should allow the truncation of very small doses to large numbers of people.

Consistent with the discussion above, a standard incorporating a single performance measure focused on protecting those people in the vicinity of a repository would make demonstration of compliance more straightforward in a licensing proceeding. Conversely, a standard specifying multiple long-term performance measures (such as the subsystem performance objectives in NRC's 10 CFR Part 60) (7) would complicate the licensing process without providing significant benefit in terms of public health and safety. Hence, the licensing regulations should not include quantitative subsystem requirements.

The standard should require a quantitative demonstration of compliance for no more

than 10,000 years.
The time period of regulatory concern is ultimately a policy decision. Other EPA regulations include time frames of 1,000 years for the regulation of uranium mill tailings (8), and 10,000 years for the regulation of underground injection of hazardous waste (9). The 10,000 year time frame of EPA's 40 CFR Part 191 was upheld in Federal court as adequately justified. Furthermore, it has been endorsed by the NRC as a practical time period for determining compliance (10). The DOE recognizes that health effects from a repository may be projected to occur at times greater than 10,000 years after permanent closure. However, the uncertainty in calculated quantitative results increases with the time of the projection, to the point that extremely long-term performance calculations may have no value beyond rough comparisons between alternative sites or designs. If time frames longer than 10,000 years are addressed in a standard, then the associated requirements should be qualitative, as opposed to quantitative total system performance assessment limits.

The standard should provide qualitative requirements related to reducing the potential for inadvertent future human intrusion to cause radionuclide releases. The DOE believes that the uncertainties associated with predictions of human intrusion are so great that including such calculations in the demonstration of compliance would significantly increase regulatory costs without any corresponding contribution to reasonable assurance of the long-term safety of disposal. For example, predicting the probability and effects of inadvertent human intrusion could involve forecasting the characteristics, technologies, and habits of human societies far into the future. Intrusion should be addressed with qualitative design requirements and active and passive institutional controls. Detailed specification of these requirements (e.g., numbers and types of permanent markers, land-use restrictions, records) can be deferred until near the time of permanent closure of the repository. At that time the appropriate specifications can best be determined, based on the information and technology available.

The quantitative aspects of the standard should be stated in deterministic terms, with probabilistic analyses used to demonstrate compliance.
It is recommended that the primary radiation protection criterion (e.g., dose, release, etc.) contained in a quantitative standard be stated in deterministic terms. In other words, the primary criterion would be stated in terms of a single value, not limits that are a function of the probability. This approach is easier to understand and would be easier to defend in a licensing proceeding. Even with a deterministic standard, the DOE proposes to perform a probabilistic calculation of future repository performance. Results would be presented as a range of values and associated probabilities (i.e., a probability distribution function), rather than a single number. This will allow consideration of low probability, high consequence events as a part of the evaluation. The DOE would compare the calculated results, a range of values with associated probabilities, against the deterministic value specified in the standard. This calculation would include both disturbed and undisturbed performance, but not human intrusion scenarios (see previous recommendation). It is recognized that there may be some probability of the calculated performance exceeding the specified limit. The demonstration of compliance would be required to show that the probability of exceeding the limit is acceptably low. The quantitative safety case for the repository would be supplemented by other arguments such as comparison to natural analogs and defense-in-depth. In this manner, based on the weight of all the evidence available, the DOE would demonstrate with reasonable assurance that the health and safety of the public are adequately protected.

A standard expressed in terms of individual dose would be appropriate, provided that certain aspects are clearly specified in a regulation or associated guidance. There are a variety of ways in which a health-based standard could be expressed. These include: acceptable risk, individual dose, radionuclide releases, subsystem performance, and specific engineered or natural system requirements. All of these are potentially acceptable, provided that they are expressed in a manner that provides for a demonstration of compliance that can be defended during the licensing process. The major difference between the options is the amount of derivation from the ultimate basis of the standard, which should be one of public health.
For a dose standard, three key aspects that need to be specified are:
- The individual dose limit should be commensurate with current dose limits for individual members of the public as specified in 10 CFR Part 20, and with

recommendations of national and international advisory groups (i.e., on the order of 100 millirem/year or less). (11,12,13)
- The dose limit should be applied to an average individual in the population living in the vicinity of Yucca Mountain.
- Assumptions related to the future biosphere (i.e., practices of humans in the future) should be specified.

COMPARISON TO OTHER NATIONAL AND INTERNATIONAL STANDARDS

As indicated above, the DOE recommended to the NAS that the new standard for the Yucca Mountain site should be consistent with other standards and regulations. This section compares the DOE recommendations with other national and international standards and guidance. This comparison is focused on three key characteristics: 1) the form of expression of the standard, 2) the limit for the primary radiation criterion, and 3) the disposal time frame regulated. Table I summarizes these characteristics for other national standards and guidance for nuclear facilities, while Table II presents this information for international standards and guidance.

The Form of Expression of the Standard

With respect to the form of expression of the standard, Table I shows that most of the national standards express the primary criterion in terms of annual individual dose. While EPA's 40 CFR Part 191 has, as its primary criterion, a radionuclide release standard, it does contain an individual dose limit for undisturbed conditions. While Canada and the United Kingdom use an individual risk objective as their primary criterion, Table II shows that the primary criterion used internationally is predominantly an individual dose limit.

Limit for the Primary Radiation Criterion

Since for the most part the primary radiation criterion being used is an individual dose limit, based on the discussion above, this comparison will be focused on these limits. For national standards, Table I shows that the range for such limits is 15 to 100 mrem/yr (0.15 to 1 mSv/yr). These numbers focus on normal operating conditions and undisturbed postclosure performance. National standards covering disturbed postclosure performance in terms of an individual dose limit have not as yet been established in this country. Within the international community, Table II indicates that the range of limits on individual dose is from 10 to 100 mrem/yr (0.1 to 1 mSv/yr). Again, these limits focus on undisturbed performance. For handling disturbed performance, several of the countries use the individual risk criterion of 10-6/yr.

Disposal Time Frame Regulated

With respect to the time frame regulated for disposal, 10,000 years appears to be the predominant time period. For the national standards in Table I, EPA's 40 CFR Part 191 is the only standard that applies to postclosure performance, and the time frame regulated is 10,000 years. In Table II, for those countries that explicitly specify a postclosure time frame, 10,000 years is the limit, but assessments for longer periods are required on a qualitative basis.

CONCLUSIONS

The process of promulgating a standard for high-level waste disposal is a complex one, and touches on many technical as well a policy considerations. This paper summarized the DOE recommendations regarding certain characteristics of a standard that, if incorporated, would result in a reasonable and implementable regulatory framework for disposal of high-level nuclear waste in this country, a framework that would ensure the protection of the health and safety of the public. When the DOE recommendations are compared to other national and international standards and guidance, this comparison demonstrates that the recommendations are within the range of existing national and international standards and guidance, and are consistent with the direction in which the global technical and policy community is headed.

WHICH WAY TO YUCCA MOUNTAIN (STANDARDS)

Washington, DC 20460-0001

ABSTRACT

The U.S. Environmental Protection Agency (EPA) has recently begun the process of establishing environmental radiation protection standards for the potential repository at Yucca Mountain, Nevada. The standards are being developed under the author of the Energy Policy Act of 1992. It had been anticipated that the report from the National Academy of Sciences which was required by Federal law to provide advice to EPA would have been received in time to be the basis of this paper. Since that report has not been received, this paper will examine the history leading up to this new standards-setting process, EPA's initial positions on various issues, the status of the standards-setting project, and the future steps.

HISTORY

In 1985, the Environmental Protection Agency (EPA or "the Agency") issued 40 CFR Part 191, Environmental Radiation Protection Standards for the Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Radioactive Waste (1). These standards were issued under the authority of the Atomic Energy Act of 1954, as amended, (2) and Reorganization Plan No. 3 of 1970 (3). The standards are generic and apply to all facilities for the management, storage, and disposal of the named wastes. The Nuclear Regulatory Commission (NRC) must adopt these standards into their licensing regulations for commercial facilities and the Department of Energy (DOE) must follow these standards for their disposal facilities. The disposal portion of Part 191 was vacated and remanded by a Federal court in 1987. The remanded portions included release limits, assurance requirements, and individual and groundwater protection requirements. The Agency pursued the reestablishment of the disposal standards until October, 1992.

At that time, two Federal laws were enacted which significantly affect the approach the Agency would take in writing environmental standards for spent nuclear fuel (SNF) and high-level radioactive waste (HLW). First was the Waste Isolation Pilot Plant Land Withdrawal Act of 1992 (WIPP LWA) (4). Section 8 is the part of the WIPP LWA which pertains to EPA's standards for SNF and HLW. It reinstated most of the disposal standards in Part 191. However, it also stated that the Part 191 standards

"shall not be applicable to the characterization, licensing, construction, operation, or closure of any site required to be characterized under section 113(a) of Public Law 97-425." Public Law 97-425 is the Nuclear Waste Policy Act of 1982; the only site being characterized under its provision is Yucca Mountain, Nevada.

THE ENERGY POLICY ACT OF 1992

The second law is the Energy Policy Act of 1992 (5). Section 801(a)(1) of the act directs the Agency to establish standards for Yucca Mountain:

"... the Administrator [of EPA] shall, based upon and consistent with the findings and recommendations of the National Academy of Sciences [NAS] promulgate, by rule, public health and safety standards for protection of the public from releases from radioactive materials stored or disposed of in the repository at the Yucca Mountain site."

There were two requirements given for the contents of the Yucca Mountain standards. One, as stated in the preceding quote, was that the standards be "based upon and consistent with the findings and recommendations of the National Academy of Sciences." The second was that the standards "shall prescribe the maximum annual effective dose equivalent to individual members of the public ...."

These requirements were further delineated in Section 801(a)(2). It requires the Administrator to "contract with the National Academy of Sciences to conduct a study to provide ... findings and recommendations on reasonable standard for protection of the public health and safety ...." Section 801(a)(2) further mandates answers to three specific questions i.e., the NAS is to provide "findings and recommendations on reasonable standards including -

A) whether a health-based standard based upon doses to individual members of the public from releases to the accessible environment ... will provide a reasonable standards for protection of the health and safety of the general public;

B) whether it is reasonable to assume that a system for post-closure oversight of the repository can be developed, based upon active institutional controls, that will prevent an unreasonable risk of breaching the repository's engineered or geologic barriers or increasing the exposure of individual members of the public to radiation beyond allowable limits; and

C) whether it is possible to make scientifically supportable predictions of the probability that the repository's engineered or geologic barriers will be breached as a result of human intrusion over a period of 10,000 years."

The contract between EPA and NAS was signed in February 1993. Shortly thereafter, the NAS established the Committee on Technical Bases for Yucca Mountain Standards ("the Committee"). The Committee is administered by the Board on Radioactive Waste Management of the NAS. This committee has fifteen members including the chairman Dr. Robert W. Fri of Resources for the Future. The members are a mixture of personnel from academia, contractors, consultants, and one member from a foreign radioactive waste management program.

FURTHER SUGGESTIONS FROM EPA TO THE NAS

Before the formation of the Committee, the Director of the Office of Radiation and Indoor Air, the EPA office in charge of radiation standards, sent a letter to the Staff Director of the Board on Radioactive Waste Management to provide "a clear sense of the questions EPA would like answered so that your study can be of the most use ..." (6). The letter was organized based upon the three questions (quoted above) posed by Congress in the Energy Policy Act. These questions will be referred to as Energy Policy Act Questions A, B, and C.

Regarding Energy Policy Act Question A (whether a health-based individual dose limit would provide for the health and safety of the general public), the Agency requested that the Committee examine the comparative effectiveness of various types of standards, i.e., individual, collective, or other types. Also, the Committee was requested to consider the implications and anticipated results, including collective dose, resulting from application of different levels of individual dose standards at Yucca Mountain. The range of dose limits should include 0.01 to 0.25 millisieverts [1.0 to 25 millirem] (mrem) per year (mSv/yr). The type of individual standard should also be indicated, e.g., probabilistic (risk), deterministic, expected value, maximum individual or average of a critical population group. Finally, the Committee might want to consider:

the uncertainty in the relationship between individual and collective dose;

the impact of different periods of assessment and the relationship of those

periods to individual and collective dose or other types of limits;
  whether a "static biosphere" is desirable and, if so, what it should include; and,
  the protectiveness of an individual or population dose standard or other types of limits in light of the possibility of natural or human-initiated disruptive events.
Energy Policy Act Question B asked if post-closure active institutional controls could be developed which would prevent an unreasonable risk of breaching the repository's barriers or increasing individual doses beyond allowable limits. The Agency suggested that the Committee considerations include different types of active control measures and their cost. Also, that the Committee might want to determine the types of intrusive events possible at Yucca Mountain and evaluate the effectiveness of different active controls to mitigate resulting releases. In addition, possible issues to consider were:
  types of actions considered to be "active institutional controls" and what credit for prevention or remediation these actions should be given;
  the historical record of institutional controls to prevent problems at other disposal sites; and
  durability of active institutional controls over time and how society could assure continuous control during any particular time.
The final Energy Policy Act Question, C, asks if "scientifically supportable predictions of the probability" of human intrusion breaching the repository's barriers over a 10,000-year period are possible to make. The Agency hopes to get a clear definition of "scientifically supportable predictions of the probability." In examining this issue, other issues to consider include:
  comparison of such predictions between human intrusion and naturally occurring disruptive events;
  is the determination of "scientifically supportable predictions of the probability" dependent on the probability value; and
  can "scientifically supportable predictions" result from simplifying assumptions about future human behavior which could be made to reduce uncertainty.
EPA'S CURRENT VIEWS OF THE ISSUES
It had been anticipated that the report from the National Academy of Sciences would have been received in time to be the basis for this paper. Since that report has not been received, in this section of the paper, rather than initial reactions to the findings and recommendations in the report, we will discuss the Agency's pre-report view of the issues. It should be understood that these positions could change based upon future input from the NAS as well as other parties.
The Agency is responsible for setting the environmental standards for Yucca Mountain and is required to use its own discretion and expertise during the formulation of those standards. The NAS input will, of course, be an integral part of the EPA deliberations. However, for the NAS input to be most useful, it must be accompanied with adequate background information and reasoning. In addition, there must be clear rationale because the EPA must base its decisions on the clearest, most technically based information, and, therefore, legally defensible reasons, available for the bases of provisions in the final standards.
The questions in the Energy Policy Act could be answered generically even though Section 801 of the Act is focused upon Yucca Mountain. Those familiar with studies such as the NAS study know that such groups rarely feel constrained by written guidance. It is clear that the committee's activities fit into this paradigm. According to the opening statement of the committee chair, Dr. Fri, " ... we are free to question all assumptions and evaluate all options with regard to the technical bases for EPA's standards. Everything is on the table. We have no preconceptions about the subject of our study" (7). This is understood and encouraged by EPA but it is important that the NAS makes it clear as to which type of guidance is being provided.
Finally, it is important that the NAS deal with the precedent of 40 CFR part 191. Any differences between the existing generic standards and the site-specific standards for Yucca Mountain must be clearly addressed. The most useful manner to deal with this would be for the NAS to clearly explain any advice that could lead to the establishment of standards different from the provisions in 40 CFR part 191. This does not mean that the NAS technical advice or the Yucca Mountain standards cannot differ from Part 191 but the differences must be recognized, clearly explained, and justifiable.
Energy Policy Act Question A

The Agency believes that an individual dose standard alone is not sufficiently protective and cannot replace the need for other requirements. First, an individual dose limit would not necessarily protect groundwater. The First Circuit Court of Appeals remanded 40 CFR Part 191 partly on the basis of inconsistency with the Safe Drinking Water Act. Rationale for solely an individual dose limit must conclusively demonstrate why, at Yucca Mountain, groundwater protection is not required or how it will be provided.

Second, use of an individual dose limit could encourage dilution since that could be the easiest method to comply with an individual dose limit. However, this could also lead to many people receiving a small dose. This could lead to a large number of health effects in the larger population. The EPA believes that the goal of these standards is to protect life and the environment as well as to assure that no one person is excessively exposed. A standard which keeps individual risk levels low but results in a large number of health effects is not adequately protective. Advice to develop an individual dose standard must consider the resulting risk to the population and how it would allow no more than an acceptable number of health effects.

Finally, an individual dose standard cannot easily take human intrusion scenarios into account. The existing 40 CFR Part 191 individual protection requirements do not include human intrusion mainly because the intent of the containment requirements is to keep the waste confined to the original emplacement location. This means that an intruder would likely receive very large doses, certainly larger than any reasonable dose limit. Such a high limit would not be protective for nonintrusion scenarios. Further, a reasonable limit would not allow for any intrusion events. A circumstance which the Agency currently believes is unrealistic.

If the NAS answers the question with a "yes," there are a number of issues the Agency would like addressed:

define the scientific basis for determining a "reasonable standard of protection" and explain why an individual dose standard provides it;

explain in detail the approach to setting the individual dose standard that is being suggested;

explain why protection of groundwater is either unimportant or irrelevant;

explain if Yucca Mountain is unique or if the NAS is generally endorsing dilution as an acceptable method of waste disposal; and

how human intrusion should be considered in relation to an individual dose stands.

Energy Policy Act Question B

The Agency believes that active institutional controls cannot be assumed to exist, not to mention provide significant protection, for long periods into the future. The concept of active controls assumes the direct and continuous involvement of governments or societies. No human institution has lasted through all of recorded history, approximately 5,000 years, which is only half the time of the 40 CFR Part 191 standards. Some monuments have survived for long periods but the governments that existed at the time they were built have not. History has many examples of powerful governments which, at their time, appeared invincible. For example, the Roman Empire, the Chinese dynasties, and, more recently, the Soviet Union.

In the relative short term, even over tens of years, economies and priorities, and therefore, budgets and government programs change. Many large projects in the United States have not been finished such as the breeder reactor and the supercollider. If these ambitious projects have not been finished, how can it be assumed that a government or society, even if they could exist that long, would support a program which should show no results or activity for hundreds or thousands of years?

Energy Policy Act Question C

The EPA believes that te answer to this question is yes. Many different approaches could be taken to form a reasonable regulatory basis. For example, one could assume that future drilling rates will continue as they have in the past. This would be similar to an approach which has been widely discussed with regard to future human beings and society for purposes of calculating releases of radionuclides and resulting doses, i.e., that they will remain the same in the future as they are now. To answer the question, NAS should define the phrase "scientifically supportable predictions of probability" and address the scientific bases of the regulatory assumptions necessary to implement the answer. If the NAS's answer to the question is "yes," there needs to be an explanation of how such estimates could be done. If the NAS's answer is "no," there should be an explanation of the scientific basis for

regulatory treatment of human intrusion and a recommended process for estimating its expected rate.

STATUS

The Agency is not as far along toward the establishment of the Yucca Mountain standards as had been planned. The report from the NAS has not been received. Until the time that it is received, it would not be responsible of the Agency to proceed vigorously. The report is expected to be received in April. The major activity thus far has been general discussions of procedures and preliminary steps necessary within the Agency to begin the rulemaking.

FUTURE STEPS

The EPA is planning to study and evaluate the NAS report upon its receipt in order to assess the need for additional work and related analytical support. There will also be an inter-EPA-office work group. The work group is the staff-level method used by the Agency to provide input from EPA program offices. It is expected to include personnel from the Offices of Water; Solid Waste and Emergency Response; General Counsel; Regional Operations and State/Local Relations; Research and Development; Policy, Planning and Evaluation; and Enforcement and Compliance Assurance. In addition, the Agency will involve interested parties from outside of EPA early in the process. The exact mechanism for this has not been decided but could include public meetings, early drafts of potential standards, or one-on-one or small group meetings.

Expressions of interest are solicited anytime by writing to the address given at the top of this paper.

Prior to issuing final standards, the Agency will publish proposed standards, in the Federal Register, for public comment. This will be followed by public hearings in the vicinity of Yucca Mountain. After considering all comments received, the final standards will be promulgated. Until the NAS report has been received, the Agency will not know what its schedule will be for issuing the standards. However, it will do so in the most expeditious manner possible while taking into account all points of view, the amount of resources available, and the technical and legal bases. The Energy Policy Act set a year from the receipt of the NAS report to accomplish promulgation. This will be our goal.

PROTECTION OF MAN AND NATURE

Some Criteria for Acceptance of Nuclear Waste Repositories.

Mikael Jensen
Gunnar Johansson
Carl-Magnus Larsson
Swedish Radiation Protection Institute
171 16 Stockholm

ABSTRACT

The Swedish Radiation Protection Institute, SSI (Statens Strlskyddsinstitut), presents tentative criteria which will lead to promulgation of regulation for the disposal of high level waste.

In defining these criteria a general goal is that man and the environment must be ensured adequate protection today and in the future, including a distant future to account for the necessary protection of long-lived nuclides. SSI employs the general principles of the International Commission of Radiological Protection, ICRP, i. e. Justification, Optimization and Dose Limitation. The Institute considers that

optimization must refer to the whole chain of waste handling, which implies that the quantity which must be minimized include both doses to personnel and to the general public in a distant future.
Sub-criteria including various dose limits in existing Swedish legislation must be met. The dose limit for personnel is 20 mSv/a averaged over 5 years (50 mSv in a single year), the dose to an individual from the public must be below 0.1 mSv/a, and additional global collective dose criteria must be met (1 mSv = 100 mrem).
Protection of the environment must focus on protection of biodiversity. Protection of biodiversity is not restricted to well known endangered species, but also to the intricate web of interactions, nutrition and energy flow etc of which the ecosystem is built. Biodiversity can be assumed to be ensured in conditions where the organisms in the ecosystem are protected. To achieve this level of protection, it is usually assumed adequate to protect populations rather than individual organisms. To ensure protection of populations, however, criteria may have to be defined that will protect individuals. This is also relevant in cases of marginal populations with limited gene flow from the population's main habitat, endemic species, certain domestic or crop species, etc.
The long-term performance for a nuclear waste repository described in the licensing application should be judged by the treatment in 3 phases, a) the first 1000 years, b) the first 10 000 years, and c) the period after 10 000 years. The first two periods up to 10 000 years must be studied in detail, and special emphasis must be placed on the efforts to protect the environment in the first 1000 years during which time the activity decreases by 99%, largely due to the decay of caesium-137 and strontium-90.

BACKGROUND

The Swedish Radiation Protection Institute, SSI (Statens Strlskyddsinstitut), is responsible for defining criteria for radiation protection in society where several authorities and bodies coordinate their work, such as for nuclear waste handling and disposal in Sweden. The Institute is in the process of defining criteria for nuclear power reactor waste repositories and would like to stimulate the discussion of these issues by presenting some important components of the regulatory system.
SSI is responsible for defining criteria for radiation protection in society where several authorities and bodies coordinate their work, such as for nuclear waste handling and disposal in Sweden.
Pursuant to the Swedish Radiation Protection Act, SSI has already promulgated regulation for radiation protection from nuclear installations
- to personnel in nuclear installations,
- to individuals in the general population,
- for releases to the environment from nuclear power plants, and
- for releases from the Swedish repository for low and medium level waste.

The SSI employs the general principles of the International Commission of Radiological Protection, ICRP, i. e. Justification, Optimization and Dose Limitation. In principle, the decision to accept the practice which produces waste includes an acceptance of the justification of waste handling processes associated with this practice.
The justification principle is therefore not addressed here. The other two principles, Optimization and Dose Limitation, are applicable in the regulation of waste disposal. In addition to this, the latest formulation of the Radiation Protection Act includes provisions for protection of both man and nature.

A GLOBAL VIEW OF OPTIMIZATION

SSI requires that all societal practices using ionizing radiation are carried out so that man and nature are adequately protected. Doses (effective doses) should be held not only lower than stipulated limits but also as low as reasonably achievable. In this optimization, SSI considers doses from the whole fuel chain, today and in the future, and doses both in Sweden and abroad.
It is not enough to focus on one component in the chain, such as waste transport, encapsulation or the long term performance of the repository. Similarly, doses to personnel and to the public must be viewed as an integral whole in the optimization. It is therefore not acceptable - for example - that a change in the construction of spent fuel canisters should imply large doses to the personnel involved in the construction, in order to achieve a hypothetical dose limitation in the far future if a future dose reduction cannot be credibly substantiated.

DOSE LIMITS

Doses to Personnel

Nuclear waste installations and their transport systems must be designed and constructed with the same personnel effective dose limits as for nuclear power plants, that is

- 50 mSv per year,
- 100 mSv for a 5 year period, and
- 700 mSv as a lifetime dose.

This must also include a collective dose limit to personnel of 2 person-sievert per year and gigawatt installed electrical effect. It is now stated that the waste handling and disposal must be included in the same collective dose budget.

Doses to individuals in the general public

Nuclear installations and their transport systems must be designed and constructed so that it is unlikely that the dose exceeds the limit for the dose to the Critical Group. This implies that the protection is source-related and that the dose is less than 0.1 mSv/year. The Critical Group consists of individuals who may be expected to receive the highest dose resulting from a release from a nuclear installation.

In addition to this, the expected global collective dose must not exceed 5 personSv per operational year and per gigawatt installed effect. The collective dose must be integrated over 500 years. This collective dose requirement is added to ensure that the mean global individual dose is not likely to exceed 1 mSv after 500 years production of nuclear power. The long term perspective for releases from a repository is discussed below.

PROTECTION OF NATURE

SSI acknowledges that protection of man indirectly protects species in the important pathways for dose to the Critical Group. SSI feels, however, that this is too narrow a goal for practices which fall under the Radiation Protection Act which specifically requires protection of both man and nature.Since there is little consensus in this area, this section is held as a discussion putting forward examples of potentially useful and acceptable approaches.

General Considerations: Focus on Biodiversity

Expressed in general terms, measures taken by Swedish authorities to protect the natural environment focus on protection of human health, biodiversity, the production potential of biological resources, and the (agri)cultural landscape (1). We propose that emphasis should be put on protection of biodiversity in assessments of impact of geological nuclear waste repositories on the natural environment. Human health is already covered by the criteria discussed above. The term biodiversity (biological diversity) has been defined by the Rio conference on economy and development as "the variability among living organisms from all sources including, inter alia, terrestrial, marine and other aquatic ecosystems and the ecological complexes of which they are part; this includes diversity within species, between species and of ecosystems" (2). The fact that the ecosystem level is mentioned is interesting, since it implicates that not only particular organisms but also the transfer of material, energy, etc that constitutes the ecosystem back-bone are considered important. This highlights the importance of all organisms, not only certain conspicuous or in other respects publicly "interesting" species.

With "biological resources" is understood, again in the terminology of the Rio documents, the "genetic resources, organisms or parts thereof, populations, or any other biotic component of ecosystems with actual or potential use for humanity" (2). Biological resources are intimately coupled to biodiversity in a number of ways; biodiversity contributes to genetic resources of potential use, and the production potential of the natural environment as well as its capacity to withstand or recover from natural stress conditions is usually considered correlated to biodiversity. The (agri)cultural landscape is somewhat ambiguous to include in assessments of impact of geological repositories on the natural environment, also when considering the time-scale involved. However, in diverse uses of arable land, the concept of biodiversity is partially applicable, and the agricultural landscape is also considered in the exposure pathways to man. In conclusion, it appears that biological diversity has general relevance in environmental impact assessments in relation to nuclear waste repositories.

SSI is well aware, however, that biodiversity can not in all situations be considered an ultimate goal for efforts directed to environmental protection. It would seem possible that increased levels of ionizing radiation in the environment could increase biological diversity while at the same time being detrimental to

human health. Furthermore, there is no interest in protection of organisms that are in some way (e.g. for health reasons or on economic grounds) harmful to man. Finally, monitoring - or prediction - of biodiversity are non-practicable options when defining criteria for nuclear waste repositories. Measures directed to protection of the natural environment will rather have to ensure that the conditions for maintained biodiversity remain favorable.

Target Organizational Level

Biological life can be arranged in a hierarchy according to the level of organization, ranging from the molecular level to ecosystems. Although distinctions are not straight-forward in all cases, it appears justified to define a target organizational level for actions taken to protect the natural environment, so that higher organizational levels, by inference, should be automatically protected. The traditional view (3) is that for non-humans, populations should be protected. However, populations may be small, isolated, or have restricted gene exchange with other populations of the same species. Under such circumstances, protection should be directed towards individuals. We propose that rather than using different organizational levels for different organisms, the individual organism should be generally considered as target organizational level.

Criteria: is There Justification for Quantitative Criteria in Protection of the Natural Environment?

Quantitative criteria are helpful in assessments of environmental impacts of nuclear installations, and may also aid in defining the area around a waste repository that is likely to be significantly affected. Ideally, the area influenced by a repository should during the operational and post-closure phases not exceed the physical boundaries of the repository itself, i.e. the damage to natural life in the long run should not exceed that caused by the construction per se. Predicted harmful effects outside this area could, depending on magnitude of area and predicted effects, be interpreted as signs of warning or even failure of the chosen storage concept. Quantitative criteria are accepted elements when discussing protection of man, and are supported by a large body of scientific information that enable calculation of risk factors for e.g. cancer and genetic disease. In setting quantitative criteria for protection of nature, the goal(s) cannot normally be the same as for man. It is also evident that radiation sensitivity of the vast majority of the probably 30 to 40 million non-human species that exist on earth is by no means as well-documented as it is for man. However, it can be argued that the material is solid enough to indicate a range of biological sensitivities among organisms and developmental stages that would be of relevance for setting criteria. It is unlikely that these ranges will be substantially modified with more research into the subject, although increased insight in these problems would be interesting in its own right.

Targets for Criteria

The effect on the abiotic environment can be assessed using the environmental increment as a criterion. This defines the increment in radiation from individual nuclides in relation to the natural occurrence and variation, or inferred variation, of these nuclides in the environment (4). In cases where negligible environmental increments can be predicted, further assessments may be unnecessary. If required, further assessments will have to be based on predicted doses to generic target organisms occupying soil, water, air or vegetation, largely in accordance with an assessment concept developed by AECL (3). The choice of generic target organism has to be justified by the applicant and/or operator of the repository.

Setting Quantitative Criteria

A view on quantitative criteria could be developed along the following lines. Although variation between organisms and developmental stages is enormous, experimental data suggest that doses in the range 1 to 5 Gy per year are unlikely to cause observable detrimental effects in most organisms. It is proposed that a safety factor of between 100 and 1000 should be used to account for the fact that experimental studies usually do not consider the possible effects of long-term low-level radiation (consequently, risk estimates are scarce), and also to account for a reasonable compliance with the precautionary principle. This reasoning would lead to the conclusion that a quantitative criterion should be set within the range 1 to 50 mGy per year. A working hypothesis at the present is that 20 mGy per year could be possible to use as a quantitative criterion when assessing the feasibility of nuclear waste repositories.

Comparison can be made with "limits" set by the Swedish Radiation Protection

Institute for doses received by man caused by operation of nuclear facilities. As mentioned above, these are 0.1 mSv per year for individual members of the critical group and 20 mSv per year as a five-year average for occupational exposures.
It is interesting to note that the range thus defined corresponds to the maximum expected doses to organisms implied by a the current ICRP standard of a maximum dose of 1 mSv annually to members of the critical group (3). However, while protection of man will often protect other species, we feel that the applicant should go to reasonable length to prove that most species are adequately protected. Although further analysis is required, the standard set for man and discussed for organisms in the natural environment in this communication seem compatible.

THE LONG TERM PERSPECTIVE

Radiation protection must be similar in all areas in society. This implies that the same protection principles must apply to future and present generations.
For future releases from the repository, after closure, a discussion must be held addressing different time periods separately, as given below. For reasons relating to the decay of the different redionuclides these periods cannot be treated the same way in the analysis. The judgement of this analysis will take into account the uncertainty in the calculations which increase with distance to the discussed time period. For periods reaching more than 1000 years into the future, SSI considers that the protection philosophy must to the extent possible follow protection principles established for other genotoxic agents.

a) The First 1000 Years

This is the most important period considering the waste's potential danger. Special consideration must be given to assessment of the protection of man and the environment the first 1000 years after closure. The assessment must include the protection for people living near the repository site.

b) The Time Period from 1000 Years After Closure to the Next Expected Ice Age

The next epoch range from 1000 years up to the time for the next glaciation, that is of the order of 10 000 years (depending on where in Sweden the site is located). In this time perspective the nuclides caesium-137 and strontium-90 are short-lived; they have for all practical purposes decayed along with other nuclides with shorter half-lives. The activity from long-lived nuclides is large enough to warrant isolation from the environment during many thousands of years. With the distance to the time concerned, the uncertainty increases considering the barriers, society and nature. After a few 1000 years the Scandinavian peninsula may resemble a cold tundra and the beginning glaciation may be evident in the northern areas.

c) The Time Period from the Next Glaciation Onwards

The problems of assessing the repository's environmental impact are fundamental during this period. For this interval, SSI sees several difficulties in describing the repository quantitatively and in detail. Primarily, fundamental limitation of science as a predictive tool stand in the way of a credible detailed and quantitative description.
SSI will require quantitative analysis for the epochs a) and b) of dose to the critical group under different conditions. The calculations must include the environmental impact using biosphere modeling using the state of the biosphere prevailing at the time of closure. Assessments of doses to the critical group must be made using best, not over- or under-, estimates. The use of the period 10 000 years as the main time period for quantitative judgement is in line with views and regulations held by other environmental protection authorities, for instance in the USA, Canada and Germany. For epoch c), during and after the next glaciation of Scandinavia, a description must be made of the repository. The large uncertainties for any assessment during this period must also be described and SSI judgement of that description will be largely qualitative.

INTRUSION AND ACCESS

The method of waste isolation implies a risk to an intruder who may receive a dose in excess of existing dose limits. The possibility of a high dose cannot be used in the assessment of radiation protection from the repository, since it flows directly from the strategy of waste isolation.
SSI holds that there is no alternative to the principle that future societies must take responsibility for their own conscious actions. A conscious intrusion into the repository cannot be prevented. No actions should be taken to facilitate or prevent intrusion if such actions should impair the protection capability of the undisturbed repository.

ANALYSIS OF SAFETY CRITERIA FOR HIGH LEVEL WASTE DISPOSAL

Volkmar Braeuer
Manfred Wallner
Federal Institute for Geosciences and Natural Resources (BGR)
Hannover, Germany

ABSTRACT
The suitability of a deep geological formation for radioactive waste disposal mainly depends on its isolation potential. In Germany, radiological safety is expressed by a individual dose limit of 0.3 mSv/y for all reasonable radionuclide release scenarios. Parallel to the geological exploration program at the Gorleben site, BGR is currently evaluating a catalog of site selection criteria for alternative host rock formations. The purpose of the paper is to update the procedure for demonstrating the suitability of different types of host rock, and to explain specific steps of the site selection and the geological exploration program. Both geological host rock formations under consideration, that is a domal salt formation as a potential encapsulating system, and the granitic rock as a typically fractured formation can be explored in a way that an appropriate design for the repository can be established to satisfy the basic radiological safety criterion. The natural barrier of an intact salt formation provides a self-sealing system. The isolation potential of the crystalline formation depends on its low permeability. The geotechnical barriers as part of the multibarrier system become more important for crystalline rocks. The different role of the natural barrier in both host rocks requires an adequate geological exploration process.

INTRODUCTION

In accordance with the salient objectives for the disposal of high-radioactive wastes, namely (1):

to isolate radioactive wastes from the biosphere over long time scales without giving the responsibility to future generations to maintain the integrity of the disposal system, or imposing upon them significant constraints due to the existence of the repository, and

to ensure long-term radiological safety, that is to protect humans and the environment against inadmissible radiation in accordance with agreed radiation protection principles

world-wide national nuclear waste programs prefer a concept in which heat-generating high level wastes are considered to be disposed of in deep geological formations. The suitability of a particular site is achieved if the entire repository system fulfills the above mentioned protection aims. These objectives imply that no inadmissible release of radionuclides to the accessible environment may occur. The repository system therefore in particular must guarantee that its barrier function is able to prevent transport of radionuclides into the biosphere.

The necessity to keep risks associated with practices involving the radiation exposure of humans to acceptable levels forms the basis for a system of dose limitation developed by the International Commission on Radiation Protection (ICRP) (2). This system has been incorporated in the IAEA Basic Safety Standards (3) and has been accepted by many national authorities.

In Germany, the Reactor Safety Commission (RSK) has published recommendations on safety criteria for the disposal of radioactive wastes in a repository mine (4). With the understanding, that the safe design of the geological repository is determined by the site specific non-standardized geological situation the recommendations only establish the protection aims. These protection aims have to be converted into geological and geotechnical criteria for the site under investigation. With respect to the radiological safety as the ultimate protection

aim in Germany, all reasonable release scenarios must not lead to individual doses exceeding the limit of 0.3 mSv/y. This is the only quantitative criterion given in the recommendations. Willingly and intentionally, these recommendations allow for a margin of expert judgment. No formal procedure is specified. On the contrary, the realization of compliance with site specific criteria is demanded in the context of the application documents submitted by the applicant to the licensing authority. These application documents must therefore be appropriate to the current state-of-the-art and must be in agreement with the scientific knowledge at the time of submission of the documents.
This requirement implies that design supporting R&D-work has to be carried out parallel to the elaboration of the application documents. A research based design and in particular a research based demonstration of safety is requested by this demand.
In Germany, a comprehensive geological exploration program has been performed to assess the suitability of the Gorleben salt dome as a permanent repository for radioactive wastes. As a supplement, the Federal Institute for Geosciences and Natural Resources (BGR) is currently evaluating a catalog of site selection criteria for alternative host rock formations (crystalline rocks) for the disposal of high level wastes.
In accordance with the above mentioned principle, and to compare the different requirements for different host rocks, the purpose of the paper is:
to state our current knowledge about site selection,
to update the procedure for demonstration the suitability of a particular site, and
to explain how radiological safety criteria give the basis for geological and geotechnical criteria, and shall be converted to specific steps of the geological exploration program.

MAIN CRITERIA FOR SITE SELECTION IN GERMANY

Final disposal of heat-generating high level radioactive waste in Germany requires specific site selection criteria which are supposed to be applied for both rock salt and crystalline rock as potential host rocks. In principal the disposal drifts of the repository have to be excavated about 500 m deep in the host rock formation not exceeding the depth of 1200 m because of the expected higher rock temperature.
During the preselection process criteria that exclude a site from further consideration have to be examined (basic requirements in Fig. 1). Considering the situation in Germany, we can roughly distinguish between the following basic requirements:

Ecological factors:
- protected areas
- industrial areas and overcrowded regions
- areas with large water reservoirs
- areas with unsuitable hydrogeological prerequisites,

geologic factors:
- zones of tectonic and seismic activity
- high density of fractures
- zones of high vertical and lateral movements
- zones of recent or expected magmatism,

geotechnical factors:
- insufficient area (< 10 km)
- intense open pit mining and/or underground mining
- significant change of host rock properties.

All regions and areas which have not been excluded after application of the preselection factors are declared to be potentially suitable sites and have to undergo a subsequent process of site selection. This mostly host rock specific process requires two additional categories of criteria allowing the statement of a first hierarchic sequence of potentially suitable sites:
Criteria making the site favorable for further consideration (Cat. A) and
criteria permitting the site to be considered, but with reservations (Cat. B).
Whereas the category A - criteria are reflecting directly on the positive properties of a potential site, the B - type criteria require either an improvement of the isolation capacity by engineered barriers or have to be adjusted due to the results of further investigations.

BARRIER CONCEPT

The disposal of radioactive wastes into deep geological formations claims credit of the host rock to provide a sufficient barrier against the biosphere. However, the shafts as entries to the underground repository, perforate the natural barrier.

Therefore, one cannot rely on the only functioning of the natural barrier rather than on a multibarrier system (Fig. 2). The multibarrier system becomes even more important if the natural barrier given by the host rock and the geological formation has local imperfections or discontinuities with unacceptable permeability. However, it is the common understanding of competent experts that a multibarrier system in principle can be designed in a way that the release of radionuclides through the multibarrier system will be limited to the admissible dose rate even over long time frames. Obviously, the guarantee for the multibarrier function requires both a comprehensive knowledge of the properties of the host formation and qualified measures to build engineered barriers such as the waste package or various seals.
The overall disposal system consists of both the natural barrier and the engineered barrier. The properties of the natural barrier like mechanical integrity and permeability have to be explored. Since these properties can only be improved to a certain extent, local weakness of the natural barrier demands for special design requirements with respect to the engineered barriers. From this viewpoint it is worthwhile to distinguish between two different natural barrier systems, namely a salt type and a granite type.
Fig. 3. Natural barrier systems
The long-term tightness of intact rock salt is proven through the encapsulation of gases and fluids in salt formations over very long time. The natural barrier of a repository in an intact salt formation therefore may act as an encapsulating system, and may provide the ultimate barrier with the shaft sealing as the only important engineered barrier in this case.
The natural barrier of a repository in a granite formation, which is always fractured, will be incapable of protecting the waste from fluids over long time. However, a granite formation may possibly have large blocks of very low permeability which is sufficient to satisfy the protection aims in connection with engineered barriers.
Deep geological disposal has its advantages also in the case of a fractured natural barrier, namely with respect to the following aspects:
- The waste is disposed in areas sufficiently far away from major disruptive processes.
- Rates of natural processes affecting the waste are slow.
- Engineered barriers are protected.
- Radionuclide migration is retarded.

SAFETY ASSESSMENT
The methodology of the safety analysis with particular regard to the post-operational period of high level waste repositories, in our view, has already its impact on the site characterization procedure and therefore also on the judgment of suitability of a potential repository site. The assurance of compliance with safety objectives requires a dualism of safety demonstration (proof) (5), namely:
a) demonstration (proof) that the required quality (integrity) of the host rock is effective,
b) demonstration (proof) that risk conditions (scenarios) with respect to the barrier efficiency are non-evident or acceptable at a residual risk level.
Furthermore, the scenario analysis involves the identification of phenomena and processes which could initiate and/or influence the release and transport of radionuclides from the waste to man. Obviously, this is one of the major challenges of site specific geological exploration. Likewise, this is also valid for the demonstration of the efficiency of engineered barriers. With this in mind, one can question the differences with respect to the foundations of the scenario analysis either for a homogeneous formation (encapsulating systems, e.g. given by a diapiric salt formation), or a fractured formation (open systems containing blocks of low permeable rock, distinct water paths and extended engineered barriers).
For a repository in a salt diapir at respective depth there is evidence for the existence of a tight geological barrier all around the planned repository. It is therefore of great importance to prevent damage of this natural barrier during the exploration of the site. If this can be achieved, only the serviceability (stability) of the intact salt barrier over the lifetime of the repository as a prerequisite for its tightness has to be analyzed. This can be done by a stability computation.
Starting from a well characterized initial state of the natural barrier all further impact on the integrity of the salt barrier can be studied in a deterministic

analysis. The stability computations have to demonstrate that the important properties of the natural barrier remain unchanged. The analysis of system behavior can even be based on conservative assumptions, e.g. regarding events with random occurrence. A probabilistic analysis becomes not necessary. Probabilistic features, however, can be applied within the deterministic analysis to study the sensitivity of parameter uncertainty (6).
If we have to consider the barrier behavior of fractured rock the deterministic analysis cannot sufficiently be applied. Since it becomes already impossible to completely describe the exact initial spatial distribution of rock permeability, not to mention the mostly time dependent alteration due to termomechanical impact, probabilistic analysis including its inherent greater difficulties has to be applied.

GEOLOGICAL EXPLORATION

The ultimate objective of site-specific geological exploration is the determination of the suitability of a particular site for the purpose of nuclear waste disposal. In order to be able to fulfill this task the following sub-objectives are to be met (7):

- development of a geologic model for the host formation and the geologic environment based on a documentation and description of all relevant geological features,
- evaluation of all relevant data to perform safety assessment analysis, and identification of further geologic scenarios affecting the barrier function of the host rock.

As a consequence of the previous discussion, the methodology for site-specific geological exploration will differ with respect to the basic behavior of the host formation:

- rock salt as a typically encapsulating system,
- fractured rock mass as a typical permeable system.

Exploration of a salt diapir as an encapsulating system has to be carried out under the strict demand of a protection of the natural barrier. As an advantage, in principle only one set of data for one homogeneous host formation has to be provided. Certainly, the possible scatter of data and its origin has to be determined and taken into account for further investigations. As an example, for the Gorleben site in Germany, only a few slightly differing homogeneous domains have to be anticipated within the Zechstein 2 formation. Therefore, the exploration with respect to geotechnical data aims at confirming the expected data and identifying abnormal domains.
From a geological point of view, a main effort during the exploration at the Gorleben site will be taken to define the extension of the favorable Zechstein 2 formation against the extremely folded anhydrite structure and to ensure a safe distance to the brittle and potentially permeable anhydrite. Reliable measures to detect the anhydrite layer during exploration, like detailed mapping and geophysical testing are available.
Unlike the principle of the encapsulating system in rock salt, the function of the natural barrier in crystalline rocks is based on the assumption of a low permeable host rock and means direct consequences to the objectives of the exploration program. The main objectives of the site selection in crystalline rocks consist of searching, identifying and exploring already existing fixed natural conditions which satisfy the demands of the disposal concept (natural barrier). On the contrary to rock salt, the engineered barriers as a more important contribution to the multibarrier system have to be developed and improved according to the particular geological situation.
Although only 10% of all fractures are thought to be water-conducting, the disposal drift geometry has to be designed with respect to their density and spatial distribution. Exploration of a fractured rock mass is therefore characterized by the necessity to identify all major release paths (design controlling fractures), and to find domains of sufficiently low permeability. The basic aim of an investigation program is to create a conceptual model of the potential site (8). Geological criteria adapted to that include the following identifications:

- the size and depth of the rock formation,
- blocks of low permeability (solid host rock formation) bordered by fracture zones, major water-conducting faults,
- local heterogeneities and water-conducting features with their orientation and

their hydraulical and mechanical properties.
In addition, characterizing of the hydraulic parameters of the host formation dominates the evaluation of data. Since a fractured formation requires a probabilistic safety analysis, statistical data have to be elaborated so that a probabilistic model can be developed on that basis.

CONCLUDING REMARKS

In Germany, the basic requirements for the preselection of a site for disposal of heat generating high level waste in deep geological formations are established as valid for any type of host rock.
The subsequent site selection process, however, is dependent on the particular geological situation and therefore on the properties of the different types of host rock. Both geological host rock formations under consideration, that is a domal salt formation as a potential encapsulating system, and the granitic rock as a typically fractured formation can be explored in a way that an appropriate design for the repository can be established to satisfy the basic radiological safety criterion.
For domal salt in Germany, the geological/geotechnical criteria are well developed. Adequate criteria for a crystalline formation in Germany have still to be established in more details.
In principal, the isolation potential of rock salt and crystalline formations is very different. The natural barrier of an intact salt formation provides a self-sealing system, whereas the isolation potential of the crystalline formation depends on its low permeability. Therefore, the geotechnical barrier as a part of the multibarrier system becomes more important for crystalline rock.
The different role of the natural barrier in both host rocks requires an adequate geological exploration process. The main objectives of the exploration are to collect all necessary informations for the development of a geological model, and to evaluate all relevant data for the safety analysis. However, for a salt diapir the exploration aims must coincide with a careful protection of the salt barrier. The exploration of a crystalline rock, on the contrary, is concentrated on the identification of insufficiencies of the natural barrier and its spatial distribution.

PROPOSED WIPP COMPLIANCE CRITERIA (40 CFR 194)

Mary Kruger
Caroline Petti
U.S. Environmental Protection Agency

ABSTRACT

The Environmental Protection Agency (EPA) is in the process of promulgating compliance criteria for the Waste Isolation Pilot Plant (WIPP). The criteria, which are officially titled "Criteria for the Certification and Determination of the Waste

Isolation Pilot Plant's Compliance with Environmental Standards for the Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Radioactive Wastes," will be codified at 40 CFR 194. The proposed compliance criteria was signed by the Administrator on January 11, 1995 and is expected to be published in the Federal Register in late January 1995. During the presentation of this paper, EPA will offer insight into the different points of view on the key compliance issues.

BACKGROUND

EPA regulates the release of radionuclides from the management, storage and disposal of radioactive waste in order to protect public health and the environment. The Waste Isolation Pilot Plant, under development by the U.S. Department of Energy (DOE), is a potential geologic disposal system for defense transuranic (TRU) radioactive waste. The WIPP is a mined salt repository 2100 feet below the surface in southeastern New Mexico, near the city of Carlsbad. It is designed to hold 6.2 million cubic feet of waste, which translates to about 800,000 55-gallon drums. Under the 1992 WIPP Land Withdrawal Act, EPA is required to perform several activities including, but not limited to: (1) finalizing safety standards for radioactive waste disposal, (2) issuing criteria for judging whether the WIPP complies with the radioactive waste disposal standards, (3) certifying whether the WIPP complies with the standards before waste disposal can begin, and, if EPA certifies that the WIPP complies with the disposal standards, (4) determining whether the WIPP continues to be in compliance every five years after initial receipt of waste and throughout the waste emplacement phase.

In December 1993, EPA accomplished the first of these activities by issuing the final radioactive waste disposal standards (40 CFR 191), which place limits on the releases of radionuclides from waste management, storage and disposal facilities. In January 1995, EPA issued proposed compliance criteria (40 CFR 194), which will implement the 40 CFR 191 disposal standards specifically at the WIPP. Since the WIPP is a first-of-a-kind facility, and the most likely to be considered for radioactive waste emplacement in the near future, EPA has taken extra steps to ensure that diverse viewpoints are presented, stakeholder input is considered, and relevant data are analyzed.

The promulgation of the compliance criteria represents the first time the Agency is implementing 40 CFR 191. EPA's approach at the WIPP may set precedent for future approaches taken at other radioactive disposal facilities. Many of the nuclear waste issues that are of considerable concern to the public will be addressed in this EPA rulemaking.

IMPLEMENTATION

EPA's proposed compliance criteria are specific to the WIPP and its compliance with the disposal standards found in subparts B and C of 40 CFR 191. The primary goal of the criteria is to make compliance at the WIPP as straightforward as possible. The criteria are also aimed at clarifying the requirements of the radioactive waste disposal standards and explaining the procedural aspects of EPA's certification or determination of compliance at the WIPP. The proposed criteria are intended to support a "reasonable expectation" of compliance and include four subparts: General Provisions, Compliance Certification and Determination Applications, Compliance Certification and Determination, and Public Participation.

Subpart A -- General Provisions

The General Provisions address the purpose, scope and applicability of the criteria, definitions of terms not already defined in 40 CFR 191, communications, and conditions of compliance certification and determination, which state that any certification or determination of compliance is subject to modification, suspension or revocation by EPA for cause. This provision requires DOE to inform EPA of changes in the disposal system and notify EPA of releases or expected releases.

Subpart B -- Compliance Certification and Determination Applications

This subpart discusses the general format and content of compliance applications. For example, DOE is required to provide a complete description of the disposal system, input parameters, waste acceptance criteria, climate conditions, background radiation, results of compliance assessments, topographic maps, and other information that demonstrates that the compliance application meets the requirements of the compliance criteria. This subpart also specifies the requirements for subsequent compliance determination applications, which must be submitted every five years if initial compliance certification is granted. In general, DOE must provide EPA with information regarding monitoring results, a description of waste emplaced

in the disposal system, and changes regarding the disposal system's performance.
Subpart C -- Compliance Certification and Determination
Subpart C can be considered the "core" of the compliance criteria. It outlines, in detail, the technical components EPA expects to see in a complete DOE compliance application. Like the disposal standards, Subpart C of the compliance criteria includes General Requirements, Containment Requirements, Assurance Requirements, and Individual and Ground-Water Protection Requirements. Each of these requirements are further divided into specific sections and discussed below.
General Requirements
The General Requirements include inspections, quality assurance (QA), models and codes, waste characterization, future state assumptions, expert judgment, and peer review. The inspections section provides for EPA access authority to the WIPP, provided EPA personnel follow applicable security guidelines. In performing inspections, EPA may gain access to written records and obtain samples from the facility. In the last few months, Agency staff have been participating in inspection and auditing training courses so they will be prepared to conduct DOE facility inspections when necessary.
A major focus of any auditing/inspection program is quality assurance. The compliance criteria require that all data that support compliance applications be collected in accordance with an approved QA program. The 40 CFR 194 proposal requires DOE to institute a QA program that is equivalent to the American Society of Mechanical Engineers' (ASME) NQA-1, 2 and 3 standards. EPA is further proposing that certain quality indicators be applied to the data, such as accuracy, precision, and comparability.
Models and computer codes will be employed in assessing whether the WIPP disposal system will comply with the 40 CFR 191 disposal standards, which require predictions of disposal system performance over 10,000 years. The compliance criteria state that DOE must provide a complete listing and description of all models and codes employed. The models and codes must be quality-assured so EPA can judge if the conceptual, mathematical, numerical and computer models used to support compliance applications are appropriate.
Waste characterization, another general requirement, has generated a great deal of discussion throughout this rulemaking process. In predicting the WIPP's performance over the 10,000-year time frame, it is necessary to have a comprehensive understanding of the characteristics of the waste proposed for disposal in the repository. The proposed compliance criteria require an analysis of the effects of certain waste characteristics on the containment of waste. A question still unanswered is the level of detail the Agency should require in DOE's waste characterization analysis and what specific characteristics should be evaluated for their significance to containment of waste over the 10,000-year time frame. Another issue before the Agency is the role of "process knowledge," which is the examination of waste generation documentation and associated records. In February 1995, these questions and others will be placed before experts attending an EPA-hosted technical workshop on the compliance criteria rulemaking.
The Agency recognizes that environmental and societal conditions are likely to change in significant and unforeseeable ways over 10,000 years. Because it is impossible to predict such changes, EPA is proposing that, unless otherwise specified in the criteria, future states will be assumed to remain what they are today. This approach will enable compliance assessments to focus on more predictable and significant features of disposal system performance. However, certain characteristics, such as geologic, hydrologic and climatologic conditions will not be held to the future state assumption. Climate change, for example, is a debatable topic slated for discussion during the February technical workshop.
The last two general requirements are expert judgment and peer review. EPA recognizes that in some cases actual data may not be available and, instead, expert judgment may have to be employed to obtain information. The Agency is proposing, however, that use of expert judgment be limited only to those situations where actual data are not reasonably attainable through data collection or experimentation. The compliance criteria describe the requirements of expert judgment elicitations, such as formal documentation procedures and independent panel selection. Peer review, sometimes confused with expert judgment, is a documented, critical review performed by peers who are independent of the work being reviewed. EPA believes that peer review can be helpful in validating information contained in

compliance applications and has specified in the proposed compliance criteria certain instances in which peer review is required.

Containment Requirements

In addressing the Containment Requirements of 40 CFR 191, the proposed compliance criteria articulate methodologies for considering inadvertent human-initiated processes and events and conducting probabilistic performance assessments. The containment requirements limit cumulative releases of radionuclides over 10,000 years and specify that there be less than one chance in ten of cumulative releases exceeding the limits specified in Appendix A of 40 CFR 191, and less than one chance in 1,000 of cumulative releases exceeding ten times those limits. The curie content of the waste inventory proposed to be disposed at the WIPP must then be determined. In the compliance criteria, EPA is proposing that the expected curie activity 100 years after disposal of the waste in the WIPP be used in calculating the release limits. The 100-year mark was chosen because it represents the point at which most of radioactive materials with short half-lives will have decayed to relatively low levels. The remaining waste will be the focus of attention because it is that waste that poses the biggest threat to public health and the environment.

The proposed criteria indicate that performance assessments consider all natural and human-initiated processes and events that may affect the disposal system; however, scenarios that have less than one chance in 10,000 of occurring over 10,000 years need not be considered.

Perhaps the most critical aspect of the compliance criteria is the consideration of human-initiated processes and events. The methodology by which to ascertain the likelihood of inadvertent human actions that may affect the WIPP's performance has been the subject of considerable research and discussion. The proposed approach considers the site-specific characteristics of the WIPP while incorporating many of the assumptions which underlie the containment requirements of 40 CFR 191. The Agency believes that the most productive consideration of inadvertent human-initiated processes and events concerns those realistic possibilities that may be usefully mitigated by disposal system design, site selection, and institutional controls. Therefore, the Agency is proposing that inadvertent drilling for resources (other than those resources provided by the waste in the disposal system or any engineered barriers designed to isolate the waste) be the most severe scenario considered.

Because drilling events do not necessarily have to penetrate the disposal system to have an impact on performance, the human-initiated processes and events considered should not be limited to those drilling operations that actually penetrate to the depth of the waste in the disposal system. For example, since drilling can create new pathways for ground-water flow and alter the geology of the site even if the repository horizon is not penetrated, non-penetrating drilling operations should also be considered.

The Agency is proposing to divide human-initiated processes and events into two distinct categories, "human intrusion" and "human activity," and is proposing a separate process to establish the drilling rate for each. "Human intrusion" includes those drilling events that reach the level of the waste in the disposal system or below, such as exploration for and development of oil and natural gas resources. The second category of human-initiated processes and events, "human activity," includes drilling events that may affect the disposal system, but do not reach the level of the waste in the disposal system. These drilling events may include exploration for potash, withdrawal of water and drilling for other resources. It is important to note that a given resource may exist at levels above and below the level of the waste in the disposal system and may therefore be included in establishing the rates for both human intrusion and human activity.

EPA is proposing that consideration be given to the record of human-initiated processes and events in the Delaware Basin (the largest contiguous area that shares similar geologic and hydrologic conditions with the WIPP site) over the past 50 years. Once the 50-year time period has been considered, EPA proposes that the rate of occurrence for each type of human-initiated process and event be held constant at the rate determined according to the method explained below for the duration of the regulatory time frame -- consistent with the "future state assumptions" discussed earlier.

In assessing the consequences of human-initiated processes and events, the Agency is proposing that the processes and events be assumed to occur at random intervals in

time and space throughout the regulatory time frame. The consequences of each process and event must be calculated in terms of the projected impact on the WIPP disposal system. If more than one process or event is predicted to occur, the consequences of any which occur subsequent to initial ones must be added to the consequences from previous disruptions. This cumulative consideration should be realized to take into account the fact that every drilling event introduces potential changes to the disposal system.

The Agency is proposing different criteria for establishing the frequency of "human intrusion" and the frequency of "human activity." While both are based on the historical record of resource exploration over the past 50 years in the Delaware Basin, an upper and lower limit is placed on the rate of human intrusion, while the rate of human activity is not limited to a set range. The rate of human intrusion is determined by identifying past occurrences in the Delaware Basin over the past 50 years. The sum of the individual rates of human intrusion for each resource then becomes the rate of human intrusion to be used in performance assessments, provided that the sum is not less than 25 and not greater than 62.5 boreholes per square kilometer per 10,000 years. In the event that the calculated total rate is less than 25, then the rate of human intrusion to be used in performance assessments should be adjusted upward proportionally to yield a total rate of 25. Likewise, if the calculated total rate exceeds 62.5, then the rate of each type of human intrusion should be adjusted downward proportionally to yield a maximum rate of 62.5.

By placing an upper and lower limit on the rate of human intrusion, the Agency is adhering to the assumptions made in formulating the containment requirements of the disposal standards as promulgated in 1985. As part of the development of the disposal standards, the Agency estimated the range of future human intrusion and human activity for the general case of a repository in bedded salt, the geologic setting of the WIPP. Assumptions were made about the presence near a repository of different types of resources -- including oil, gas, minerals and water -- though it was assumed that the most significant resources present would be oil and gas. Using drilling data from the contiguous 48 states as a rough guide, the Agency estimated that a region of bedded salt would experience 25 to 62.5 boreholes per square kilometer per 10,000 years.

Should DOE wish to forego the process of analyzing the historical rates of human intrusion events in the Delaware Basin, DOE can assume the maximum rate of 62.5 boreholes per square kilometer per 10,000 years. After the rate is calculated, it may be reduced in accordance with the criteria pertaining to institutional controls; however, in no instance will EPA assume that institutional controls will eliminate the likelihood of human intrusion.

For consideration of "human activity," the historical record of drilling must be examined, but without placing pre-set limits on the rates. The Agency recognizes that for some resources, such as water, use may depend upon the quality of the specific reservoir that is being exploited. A given reservoir of water, for example, may not be of potable quality but may still be usefully withdrawn for controlling dust. Therefore, it may be possible for DOE to demonstrate to EPA that a certain resource found within the controlled area differs in quality and drilling rate from the same resource found in rest of the Delaware Basin. Therefore, when examining the historical record of human activity associated with that resource, only that human activity that has been associated with resources of quality similar to that found within the controlled area need to be considered. As in the case of human intrusion, the rate of human activity may also be reduced in accordance with the criteria pertaining to institutional controls.

In assessing the results of performance assessments required under the containment requirements of 40 CFR 191, the Agency is proposing to require that the results be displayed as complementary cumulative distribution functions or "CCDFs." These CCDFs should display the releases of radionuclides and their probability over 10,000 years after disposal. In developing the radioactive waste disposal standards, EPA recognized that because of the long time period involved and the nature of the processes and events of interest, there will inevitably be substantial uncertainties in projecting disposal system performance. In conducting performance assessments, there will be many parameter values that can affect the results. Therefore, the Agency is proposing to require the development of probability distributions for parameter values which represent the probability of different values of the parameter occurring.

Assurance Requirements
The quantitative containment requirements set forth in the Agency's radioactive waste disposal standards are accompanied by a set of qualitative requirements to further assure that the desired level of protection will be achieved. EPA included these "assurance requirements" in the disposal standards to complement the numerical requirements because they can provide additional confidence in the performance of disposal systems. The first of these assurance requirements is active institutional controls. In accordance with 40 CFR 191, active institutional controls over disposal sites should be maintained for as long as possible after disposal; however, performance assessments cannot consider contributions from active institutional controls for more than 100 years after disposal. The proposed compliance criteria require that any application for certification of compliance contain detailed descriptions of proposed active institutional controls, their location and the period of time they are proposed to remain active. In addition to active institutional controls, 40 CFR 191 requires that "disposal systems shall be designated by the most permanent markers, records, and other passive institutional controls practicable to indicate the dangers of the wastes and their location." The standards define passive institutional controls as "1) permanent markers placed at a disposal site, 2) public records and archives, 3) government ownership and regulations regarding land or resource use, and 4) other methods of preserving knowledge about the location, design and contents of a disposal system." The Agency is proposing in the compliance criteria that any application for certification of compliance include detailed descriptions of the measures that will be employed to preserve knowledge about the location, design and contents of the disposal system.
A difficult question facing EPA is the extent to which the Agency should allow performance assessments to consider contributions from passive institutional controls in reducing the likelihood of human-initiated processes and events that may affect the disposal system. While the disposal standards address contributions from active institutional controls (up to 100 years), they do not specifically address contributions from passive institutional controls. The Agency may be willing to consider contributions if a persuasive case can be made that the passive institutional controls can be expected to endure and act as a deterrent to potential intruders for 10,000 years. Because of the uncertainty concerning the effectiveness of passive institutional controls in terms of influencing human activity, EPA must carefully scrutinize information about the controls. The Agency has considered the fact that markers exist in the world today that are thousands of years old. This would tend to support the view that passive institutional controls can survive for very long periods of time. Nevertheless, it is possible that markers have been created in the past and were destroyed or disintegrated. The actual percentage of surviving markers is thus unknown. Further uncertainty in the effectiveness of markers derives from the possibility that even if markers survive, they may not necessarily be understood by future generations.
Evaluating the effectiveness of institutional controls in deterring future human actions is one of four key compliance issues which will be addressed at EPA's planned Technical Workshop in February. In addition, EPA will continue to participate in key international discussions convened under the auspices of the Organization for Economic Co-operation and Development's Nuclear Energy Agency regarding consideration of future human actions at geologic disposal sites and the role of institutional controls in deterring such actions.
Since the predictions associated with long-term compliance with the disposal standards of 40 CFR 191 are inherently uncertain, a provision was included in the disposal standards which requires monitoring of disposal systems to confirm that they are performing as predicted. The proposed compliance criteria require that the WIPP be monitored after disposal (i.e., when all of the shafts are backfilled and sealed) to detect substantial and detrimental deviations from expected performance. The monitoring must be done with techniques that do not jeopardize the isolation of the wastes. EPA is proposing that monitoring programs be designed to detect the movement of radionuclides toward the accessible environment at the earliest practicable time. Any compliance certification application must include a detailed plan for monitoring the performance of the WIPP after disposal. At a minimum, this plan must identify parameters that will be monitored and how baseline states will be determined; indicate how each parameter will be used to evaluate the performance of the disposal system; and discuss the length of time over which each parameter will

be monitored to detect deviations from expected performance.
EPA is proposing that pre-closure monitoring of disposal system parameters be conducted to establish baseline performance. The Agency believes that baseline monitoring can provide important information about the disposal system and that such information can be used to verify the assumptions which form the basis of a compliance assessment. Since there may be additional disposal system parameters important to the containment of waste, EPA is proposing that DOE undertake a study to determine the effect of various disposal system parameters on the performance of the disposal system.
The assurance requirements of 40 CFR 191 require that disposal systems use different types of barriers to isolate the wastes from the accessible environment. 40 CFR 191 defines the term barrier as "any material or structure that prevents or substantially delays movement of water or radionuclides toward the accessible environment." For example, a barrier may be a geologic structure, canister, waste form, or material placed over and around waste. If designed properly, engineered barriers can significantly reduce the potential for waste migration away from the disposal system. While the disposal standards require use of engineered barriers, they do not specify how many or what kinds of engineered barriers must be used. The Agency is, therefore, proposing WIPP compliance criteria for selecting engineered barriers. Specifically, EPA is proposing that DOE complete a study of engineered barrier alternatives and their benefits and costs. The results of the study will be used to justify both the selection and rejection of engineered barriers at the WIPP.
EPA's disposal standards require that resource-rich places be avoided in selecting disposal sites. Resources to be considered include minerals, petroleum or natural gas, valuable geologic formations, and ground water that is either irreplaceable because there is no alternative source of drinking water available for substantial populations or that is vital to the preservation of unique and sensitive ecosystems. The criteria go on to state that sites potentially rich in resources may not be used for disposal of radioactive wastes unless the favorable characteristics compensate for the unfavorable characteristics, such as the greater likelihood of being disturbed in the future. EPA is therefore requiring DOE to demonstrate that the favorable characteristics of the WIPP compensate for the presence of resources and the likelihood of human-initiated process and events that may occur as a result of the presence of those resources.
The last assurance requirement included in the 40 CFR 191 disposal standards involves the removal of waste from the disposal system. Specifically, 40 CFR 191 mandates that disposal systems should be selected so that removal of most of the wastes is not precluded for a reasonable period of time after disposal. In order to address this requirement, EPA is proposing criteria that require a plan for removing waste from the disposal system using the best technology available at the time of application.
Individual and Ground-Water Protection Requirements
The individual protection requirements of 40 CFR 191 limit committed effective doses of radiation to members of the public to no more than 15 millirem per year. The ground-water protection requirements limit releases to ground water to no more than the limits set by the maximum contaminant level for radionuclides established in 40 CFR part 141 under section 1412 of the Safe Drinking Water Act (SDWA), 42 U.S.C. 300g-1. Both of these requirements are concerned with human exposure to radionuclides from disposal systems and, like the containment requirements, both limit exposure for 10,000 years.
EPA is proposing that any application for certification of compliance must include information which identifies the processes, events, or sequences of processes and events considered in compliance assessments. Once the processes and events have been identified, they must be incorporated into compliance assessments of the disposal system. The disposal standards require compliance assessments to include consideration of the uncertainties associated with the undisturbed performance of the disposal system. To do this, it is necessary to identify all disposal system parameters that can affect the performance of the WIPP, as well as to identify the uncertainty associated with each parameter.
When the disposal system parameters and their associated uncertainties have been identified, probability distributions must be developed for each parameter. In compiling compliance assessment results, computational techniques must be used which draw random samples from across the full range of probability distributions for

parameter values used in compliance assessments. This will help assure that all possible values of a parameter have been considered.
It is important to note that a "reasonable" expectation of compliance with the individual and ground-water protection requirements of 40 CFR 191 will not be based solely on a final statistical estimate of doses to individuals or radionuclide concentrations in ground water. A reasonable expectation of compliance will be determined by EPA based on the full record before the Agency and a thorough consideration of the methods and assumptions that produced compliance assessment results. For instance, in certifying and determining compliance, the Agency will consider certain factors, such as the reasonableness of the processes and events considered, the appropriateness of any expert judgment elicitation used to provide inputs to the assessments, the adequacy of peer review, the quality of the models, and the merit of data inputs to those models.
Subpart D -- Public Participation
The Agency intends to involve the public as much as possible in its regulatory oversight of the WIPP. Throughout the compliance criteria rulemaking process, EPA has interacted with stakeholders on all aspects of the criteria. EPA is committed to achieving logical, reasonable WIPP compliance criteria that are protective of the public and the environment. To this end, EPA has worked, and will continue to work, to gather input and promote understanding among key stakeholders. For example, the Agency: 1) circulated and obtained comments on an early draft of the criteria in January of 1994, 2) participated in open technical meetings with DOE on relevant topics, 3) will host a technical workshop on several key compliance-related issues, 4) will solicit comment on the proposed criteria and hold public hearings in the State of New Mexico, and 5) will convene a meeting of the National Advisory Council for Environmental Policy and Technology after the public comment period.
CONCLUSION
The WIPP must be designed to provide a reasonable expectation of compliance with 40 CFR 191. EPA will make a certification decision based upon performance assessments that demonstrate that the cumulative releases of radionuclides to the accessible environment for 10,000 years after disposal from processes and events that may affect the disposal system will not exceed specified quantities. DOE must also demonstrate that the WIPP will meet the assurance requirements of the disposal standards and be designed to provide a reasonable expectation that, for 10,000 years after disposal, undisturbed performance cannot cause any member of the public to receive a committed effective dose in excess of 15 millirems per year. Finally, the WIPP must be designed to provide a reasonable expectation that 10,000 years of undisturbed performance after disposal will not cause levels of radioactivity in any underground source of drinking water in the accessible environment to exceed maximum contaminant levels specified in the Safe Drinking Water Act.
EPA drafted the proposed WIPP compliance criteria for compliance with the final radioactive waste disposal standards. Once promulgated, the criteria will be codified at 40 CFR 194 and will specify the procedures by which DOE will submit its certification application and documentation of continued compliance under the Land Withdrawal Act. As long as DOE submits a technically and administratively complete application as specified in the compliance criteria, EPA expects to be able to evaluate the application and certify whether or not the WIPP will comply with the disposal standards.
EPA plans to finalize the compliance criteria approximately one year after the proposal, after comments from interested parties are considered. When the final criteria are promulgated, EPA will be responsible for assuring that the criteria are properly implemented.

INTRODUCTION
This paper is the Environmental Evaluation Group's initial evaluation of the U.S.

Environmental Protection Agency's draft Criteria for the Certification and Determination of the Waste Isolation Pilot Plant's Compliance with Environmental Standards for the Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Radioactive Wastes (40 CFR 194) (1). We discuss various provisions in the proposed criteria and remaining unresolved issues.

WIPP & TRU WASTE

The Waste Isolation Pilot Plant (WIPP) is a repository for disposal of defense-generated transuranic (TRU) waste, including chemically hazardous components. The WIPP is located in southeastern New Mexico, 40 km east of Carlsbad. The repository is in bedded salt of the Permian age, some 650 m below ground surface, in a 600-m thick salt formation. Work on WIPP began in 1974 and several miles of drifts and tunnels have been excavated. The U.S. Department of Energy (DOE) plans to ultimately dispose 178,000 m3 of contact-handled transuranic waste containing 3.3 x 1017 Bq along with 7100 m3 of remote-handled waste containing 1.85 x 1017 Bq.

Before waste disposal can begin at WIPP, the DOE must demonstrate that the WIPP will comply with the Environmental Protection Agency's (EPA) Environmental Standards for the Management and Disposal of Spent Nuclear Fuel, High-Level and Transuranic Radioactive Wastes (40 CFR 191) (2).

COMPLIANCE

The proposed criteria (40 CFR 194) are limited to consideration of the WIPP's compliance with the disposal regulations found in subparts B and C of 40 CFR 191, addressing containment requirements, assurance requirements, individual protection requirements, and groundwater protection requirements. These compliance criteria do not address compliance with the management and storage regulations found in subpart A of 40 CFR part 191.

The original standards (40 CFR 191) apply to both high-level and transuranic waste. For the spent nuclear fuel and defense high-level waste repository, the standards were implemented into licensing procedures by the U.S. Nuclear Regulatory Commission (3). However, the WIPP is exempt from regulation by the U.S. Nuclear Regulatory Commission. The WIPP Land Withdrawal Act (4) requires EPA to certify and determine whether or not the WIPP will comply with the Agency's radioactive waste disposal standards. Thus the certification/compliance criteria may be viewed as equivalent to 10 CFR 60, for the WIPP. The draft compliance criteria, published in the Federal Register on January 30, 1995, provide a public comment period until May 1, 1995. The EPA expects to issue the final compliance criteria early in 1996.

THE ENVIRONMENTAL EVALUATION GROUP

The Environmental Evaluation Group (EEG) was established in 1978 to perform independent analyses of health, safety and environmental issues related to the WIPP. From 1978 to 1992, the EEG was the only full-time technical oversight group for the WIPP.

THE DRAFT COMPLIANCE CRITERIA

The draft compliance criteria (1) provide elaboration on the standards. The criteria contain procedural requirements for the certification application, guidance on doing performance assessments to show compliance with the containment requirements, as well as guidance for meeting the assurance requirements. The following evaluation is divided into these three sections.

Procedural Provisions

The procedural part of the draft criteria deals with applications for certification and determination, EPA's access to WIPP, quality assurance, and public participation, among others. Procedures are given for the initial certification for compliance, and periodic renewal of compliance, known as determination. The draft covers contents of applications, and conditions which will be contained in certification. The draft also covers denial, suspension and revocation of certification. The public participation provisions follow that of the Administrative Procedure Act, in so much as certification amounts to a rule making

One of the conditions of certification and determination, 194.04(b)(6), requires that if the DOE determines that a release of waste from the disposal system to the accessible environment is in excess of what is permitted under the disposal regulations has occurred or is likely to occur, the Department shall notify EPA, who shall determine if emplacement of waste may continue and whether to modify, suspend, or revoke any previously issued certification or determination of compliance.

Because the disposal regulations, subparts B and C of 40 CFR 191, deal only with

cumulative releases to the accessible environment over 10,000 years, there is no reliable way to determine if any particular release will be in excess of what is permitted. For this requirement to be realistic, there has to be a different and additional measure of radioactivity discharge.

Compliance with the Containment Requirement

Most of the draft criteria is about the conduct of performance assessments to show compliance with the containment requirement, which can be expressed as follows. For all i nuclides, each with calculated release of Qi and EPA prescribed limit of RLi, the EPA containment requirement is

Eq. (1)

Eq. (2)

Performance assessment represents the risk of a geologic disposal system as

Eq. (3)

where Si are the scenarios, or what can happen,
pSi are the scenario probabilities, or how likely things will happen,
cSi are the consequences or outcomes of what can happen, and
nS is the number of scenarios.

Performance assessment involves the calculation of risk as

Eq. (4)

which says risk is a function of a vector of imprecisely known variables , such as rock permeability, human intrusion rates, and retardation coefficients of radionuclides.

We discuss below the specific requirements in the draft criteria.

Scenarios to be analyzed: The draft criteria allow some scenarios [Si in eq. (3) and (4)] not to be analyzed:

Performance assessments need not consider processes, events, or sequences of processes and events that have less than one chance in 10,000 of occurring over 10,000 years [194.32(b)].

This provision is consistent with the guidance for implementation of the former subpart B (now subpart C) of the disposal regulations, and we support it.

Radioactivity Baseline: The disposal regulations give release limits [RLi in eq (3) and (4)] in terms of radioactivity allowed per unit of radioactivity emplaced. However, the time to measure the amount of radioactivity emplaced was not given. Because radioactive waste decays, it is necessary to specify a standard time for determining the amount of radioactivity emplaced. The draft criteria specify that initial radioactivity is to be determined at 100 years.

The expected curie activity 100 years after disposal of the waste proposed for disposal in the disposal system shall be used in calculating applicable release limits under Appendix A of 40 CFR 191, Table I, Note 1(e) [194.31].

The EEG supports this sensible action.

Future States: Demonstrating compliance with the disposal regulations over 10,000 years involves calculating the transport of radionuclides from the disposal system to the accessible environment. Because of the long-term nature of these evaluations, uncertainty of values for many parameters important to the analysis may be very large. Environmental conditions and living habits of future populations and individuals may change in significant and unforeseeable ways over the lengthy timeframes that will be analyzed for compliance.

In light of the difficulty of assigning appropriate values with confidence, the EPA is proposing that, unless otherwise specified, applications for compliance shall assume that characteristics of the future remain what they are today, except for parameter values related to long-term geologic, hydrologic, or climatologic conditions of the repository and its vicinity.

Because the future state of civilization would fall under this future states assumption, one would assume that future technology, radioactivity exposure pathways, dietary habits, and population distribution would be identical to the present day. This also means that the applicant cannot project that radioactivity will no longer cause cancer years from now; but that oil and gas drilling rates near the repository will stay the same for the 10,000-year regulatory period.

The EEG reluctantly accepts this provision of the future states assumption, because we recognize the difficulty of alternative provisions. We urge this assumption be rigorously applied, with respect to the positive and negative consequences that might result.

Human Intrusion: For the WIPP, the chief disruptive event is human intrusion (5).

The 1985 guidance for the implementation of subpart B [40 CFR 191, Appendix B] suggested that human intrusion rate by drilling need not be
greater than 30 boreholes per square kilometer of repository area per 10,000 years for geologic repositories in proximity to sedimentary rock formations....
The draft criteria divide human-initiated processes and events into two distinct categories, "human intrusion" and "human activity," and propose a separate process to establish the drilling rate for each. "Human intrusion" includes those drilling events that reach the waste in the repository. Such events would include, but would not be limited to, exploration for and development of oil and natural gas resources. "Human activity" includes all drilling events that may affect the disposal system, without disturbing the waste in the disposal system. Such drilling events may include, but would not be limited to, exploration for potash, and withdrawal of water. EPA proposes examination of the record of human-initiated processes and events in the Delaware Basin over the past 50 years, and holding the rates constant throughout the future, consistent with the future states assumption above. The sum of the individual rates of human intrusion for each resource then becomes the rate of human intrusion to be used in performance assessments, provided that the sum is not less than 25 and not greater than 62.5 boreholes per square kilometer per 10,000 years. If the DOE does not analyze the historical rates of human intrusion events in the Delaware Basin, the Department shall assume the maximum rate of 62.5 boreholes per square kilometer per 10,000 years in performance assessment.
The drilling rate for any resource in the last fifty years in the Delaware Basin is certainly the highest for all time, and to extend that rate over the next 10,000 years betrays our understanding of minerals economics. The rational approach is to adopt a time-dependent drilling rate, that incorporates the history of drilling in this area, and the concept of mineral depletion (6). This suggestion was not accepted by the EPA because it is not consistent with the future states assumption. Another argument for not projecting future rates of drilling based only on the present experience is that we have no way of knowing what future societies may drill for, just as 200 years ago it would have been difficult to predict current drilling for oil, gas and potash.
In the draft criteria, EPA proposes to allow DOE to take credit for passive institutional control by reducing the rate of human intrusion!
(c) Any application for certification of compliance may include a proposed credit (which may vary over the regulatory time frame) for reducing the rate of human-initiated processes and events calculated using the procedures enumerated in 194.33. The Administrator shall allow such credit, or a smaller credit, to be taken if the Department demonstrates that such credit is justified because the passive institutional controls can be expected to endure, be understood, and act as a deterrent to potential intruders throughout the regulatory time frame. In no case, however, shall passive institutional controls be assumed to eliminate the likelihood of human-initiated processes and events entirely.
By using a time-dependent credit, the EPA can arrive at a drilling rate very much like we suggested (6), and step away from the simplistic assumption of a constant drilling rate for 10,000 years, projected on the basis of 50 years of data. However, we understand the need to uniformly apply the future states assumption, and we look to a rigorously applied future states assumption.
Models, Codes and Data: Computation for performance assessment is usually done by a series of computational models. Each model consists of a conceptual model, a computer code and related input data. The EPA requirements in the draft criteria deal with all three. The EPA proposes to require the applicant to show all conceptual models considered and how and why a particular model was chosen. This is a very important and wise requirement. The DOE has already started down this path with the Position Paper on technical issues in the systems prioritization method.
As for computer codes, the EPA requires full documentation as required in NQA-2a (7). Complete documentation is required for people who did not author the software to understand and pass judgment on the work. The EPA will also require the computer codes to be peer reviewed, a routine requirement in software quality assurance.
A model is only as good as the input data. For performance assessment, data required include waste characteristics, geologic site characteristics, and characteristics of rocks in the projected flow paths. The draft criteria address the topic of data obtained before quality assurance was adopted, and use of expert judgment.
The EEG participated in the collection of some early site data, before quality

assurance programs were in place. State-of-the-art methods were used. The EEG has no problem with a sensible approach to qualify data collected this way.
In EEG-57 (8) and elsewhere (9) we pointed out the fallacy of using so-called expert judgment in place of experimental data. The EPA agrees, saying
...expert judgement does not substitute for information that could reasonably be obtained through data collection or experimentation [194.26].
Upon the completion of performance assessments, the results have to be compared to the containment requirement. Under a myriad of assumptions, and using Monte Carlo simulation to investigate the effect of parameter uncertainty [in eq. (3) and (4), there will be many complementary cumulative distribution functions (CCDF) generated. Which of the CCDFs should be compared to the containment. The draft criteria specifies
Any application for certification of compliance shall provide information which demonstrates that there is at least a 95% level of statistical confidence that the mean of the population of CCDFs meets the requirements of section 13(a) of 40 CFR part 191 [194.34].
Our interpretation of this requirement is shown in Fig. 1. A family of compliance CCDFs is generated. Statistical moments can be generated for these curves. On the mean curve there is estimation error, shown by the bell-shaped curves. The mean curve can actually extend further to the upper right-hand corner, closer to the containment requirement. The draft criteria says use the mean curve, plus as much error as would be incurred for a 5% one-way Type-I error, to compare with the containment requirements, as shown in Fig. 1.
We find this requirement quite reasonable.
Compliance with the Assurance Requirements
The guidance in the draft criteria could have been much more specific in telling the applicant when they have satisfied these qualitative requirements. For example, the draft criteria could have specified that records for the WIPP will be placed in the National Archives, the New Mexico State Library, the Carlsbad Public Library, and all public libraries within 100 km of the WIPP. The draft criteria could have adopted an engineered barrier release rate requirement similar to the Nuclear Regulatory Commission's (3) to measure the contribution of engineered barriers at the WIPP. The draft criteria could have defined active institutional control as 3-meter high barb wires around the controlled zone. More specific guidance is needed and should be in the final criteria.
Uncharted Territory
The draft criteria also provides guidance on showing compliance with individual protection and ground-water protection provisions. Whereas DOE has published four iterations of performance assessments to show compliance with the containment requirement, we know of no published analysis showing calculation of dose to individuals. Thus requiring compliance analysis to consider all potential exposure pathways is next to meaningless. More specific guidance should be given in the final criteria.
CONCLUSION
The draft criteria for evaluation of applications for certification of compliance with the EPA standards is a major advance in terms of spelling out what EPA expects in an application. However, major uncertainties remain. Several provisions should be clarified and made more specific in the final criteria.

ABSTRACT

Citizen advisory groups are in vogue in both the public and the private sectors. This paper discusses six issues that arise with advisory groups: 1) their specific functions and underlying purposes, 2) how they can be structured to achieve their objectives, 3) implementation details that should be thought out in advance, 4) whether guidance concerning the establishment of advisory groups should be prescriptive or performance-based, 5) special situations that can affect the need for a group and the participation of certain members, and 6) how and why the effectiveness of advisory groups should be evaluated. These issues are discussed within the context of a proposal by the U.S. Nuclear Regulatory Commission to require advisory boards during the development of restricted use decommissioning plans. The issues are broadly applicable, however, and should be confronted whenever an advisory group is contemplated.

INTRODUCTION

On August 22, 1994, the U.S. Nuclear Regulatory Commission (NRC) released its proposed rule for radiological criteria for decommissioning (1). This rule has potentially broad applicability: there are approximately 22,000 facilities in the United States that are licensed to use radioactive materials. In its rule, the NRC proposed the establishment of "site-specific advisory boards" (SSABs) in certain instances -- specifically, to provide advice to licensees that intend to develop "restricted use" decommissioning plans. Licensees that are likely to propose limitations on the future uses of their sites as part of their decommissioning plans comprise only a small subset of the total number of licensees. Nevertheless, they undoubtedly will include some large facilities -- nuclear power plants, for example, as well as other fuel-cycle facilities and some non-fuel cycle facilities.(2)

In proposing the establishment of SSABS for the development of restricted use decommissioning plans, the NRC drew upon a concept popularized by the Federal Facilities Environmental Restoration (FFER) Dialogue Committee, a national, 40-member committee initiated in 1992 by the U.S. Environmental Protection Agency and facilitated by the Keystone Center. The FFER Dialogue Committee articulated the concept of SSABs in its February 1993 interim report, "Recommendations for Improving the Federal Facilities Environmental Restoration Decision-Making and Priority-Setting Processes."(3) While having local advisory boards to federal sites was not an altogether new concept -- at some U.S. Department of Energy (DOE) and U.S. Department of Defense (DOD) sites, for example, it had been tried in various forms for several years -- the FFER Dialogue Committee report brought it to national attention, and it is now being explored by other agencies such as the NRC.

The NRC recognized, however, that the SSAB concept could not be transferred wholesale from the FFER Dialogue Committee's report, partly because the NRC was intending to put the concept to rather different purposes: one involving private companies, not federal facilities, with the advisory group to serve only on a temporary, ad hoc basis. Thus, the NRC sought ideas on how to flesh out the concept of SSABs for restricted use decommissioning plans. As part of this effort, we were requested to provide a background paper for a NRC workshop held in December 1994. In doing so, we drew on the wisdom of NRC staff; on comments made during earlier workshops on decommissioning (4); on the prior experience of somewhat similar advisory groups convened by DOE, DOD, and others (5); and on our own past work in this field (6).

Whenever an advisory board is contemplated, a multitude of questions need to be answered. Most critically, these include:

Why is the board being established? What topics will it address, and for what underlying reasons?

What authority will the board have? Is it simply advisory, or will it make decisions in some instances?

To whom will the board's advice be directed? What response to the advice will be required?

How will the board give its advice -- as a group, or as individuals?

Who should be on the board? How should its members be selected?

How can the board be operated to maximize its effectiveness? If the board is being set up at the behest of a public agency, how much control should that agency exert over how the board is established and run?

When will the board be terminated?

How can evaluations of the board's operation and output provide the greatest help both to the board and to other, similar efforts?

In the paper developed for the NRC workshop, we discussed six issues that together address these and other questions. While directed toward the possibility of SSABs for restricted use decommissioning plans (herein referred to as licensee advisory boards, or LABs), much of what is said below could apply to other advisory boards.

SIX KEY ISSUES

Issue 1. Specific Functions and Underlying Purposes

What specific functions and underlying purposes should a LAB serve?

According to the proposed rule, LABs could have such functions as recommending ways to reduce residual radioactivity, providing advice on proposed institutional controls, and advising on whether the licensee has provided sufficient financial assurance for necessary future site maintenance. But LABs might perform other functions as well: for example, advising licensees on special mechanisms for public input during a decommissioning plan's development and implementation, and airing environmental justice issues that otherwise might go unacknowledged. Some functions might be "off-limits," however: for example, prescribing who subsequent site owners should be, or otherwise infringing on various parties' authority and responsibility to carry out the decommissioning plan.

In performing its functions, a LAB could serve one or more underlying purposes. For example, it could 1) improve understanding of the decommissioning process and of its consequences through a sustained information exchange with representatives of key stakeholder interests; 2) improve the quality of the decommissioning plan by bringing to bear both the knowledge and the values of LAB members; 3) promote widespread acceptance and ownership of the decommissioning plan, by having it developed in a participatory fashion; and 4) promote the ideals of environmental justice, by empowering stakeholders that historically have lacked political and economic clout. But there may also be inappropriate underlying purposes for LABs: for example, co-optation of key stakeholders, or use of a LAB as mere "window-dressing" or as a substitute for other meaningful public input.

Issue 2. Achieving Objectives

What are the general objectives of a LAB, and how can they be achieved?

The primary goal of a LAB is to create a representative process that provides timely, useful input. In achieving this, a number of objectives arise. These concern the adequacy of stakeholder representation; the degree of LAB responsibility; the form, use, and timeliness of the advice; how the problem under consideration is characterized; and the LAB's ability to address the problem. But, as noted further below, it may not be possible to realize all objectives; instead, tradeoffs may be

necessary.
Adequacy of stakeholder representation. Achieving broad stakeholder representation of affected interests poses a dual problem: first, of deciding which interests merit representation, and second, of deciding who can speak for those interests. With a LAB, it may be necessary to have representation of such diverse interests as those of the licensee, subsequent site owners or managers, state or tribal officials, local officials, and people living near the site now or in the future, as well as non-human, ecological interests.
Given this array of interests, the simplest approach could be to appoint opinion leaders, including elected or administrative officials. A potential disadvantage, however, is that all of the affected interests may not be well-represented. For example, some interests (e.g., ecological interests) are associated with the welfare and well-being of the community at large, rather than being linked to specific individuals. To correct for this, opinion surveys could be used to identify such broad community interests, and may lead to the identification of particular individuals or groups able to represent those interests.
An additional problem arises if there are so many interests requiring representation that the size of the LAB would be cumbersome. This problem is addressed under Issue 3.
Degree of LAB responsibility. For a LAB to be effective, its degree of responsibility needs to be made clear. One option is for the LAB to be charged with deciding aspects of the licensee's proposed decommissioning plan. This would invest the LAB with authority, but it would burden the LAB with greater accountability, both to the licensee and, possibly, to other constituencies. A second option is for the LAB to simply offer recommendations. This reduces the LAB's responsibility, but it decreases its influence. As a third option, a hybrid is possible: the LAB could make general recommendations about the plan as a whole, but representatives of organizations with authority over parts of the plan could specify the acceptability of those parts. Form, use, and timeliness of LAB advice. The LAB could provide its advice as either a group or a set of individuals. If it is to provide advice as a group, then its "decision rules" must be made clear. For example, if a discrete judgment is sought, a voting procedure might be appropriate, whereas if the charge is to conduct open-ended discussions, then a consensus-type procedure might be more suitable. Both have pros and cons: reaching consensus often takes considerable time and can be especially difficult to achieve with a large group but produces fairly unified advice; voting procedures are usually more time-efficient and can be readily conducted with large groups but are likely to produce minority opinions.
At a minimum, the results of LAB deliberations on the proposed plan should be used by the licensee informally, to develop and refine the plan. Alternatively, as suggested in the proposed rule, the licensee could be required to include in the proposed decommissioning plan the disposition of the LAB recommendations. In reaching its decision on the proposed plan, the NRC might also be required to comment on LAB recommendations that it has decided not to follow. This has the advantage of demonstrating that all explicit, written LAB recommendations have been given consideration. However, if a recommendation is made by an individual LAB member, the licensee and the NRC may be unsure of the extent to which the recommendation is supported by the group (although having licensee and NRC representatives at LAB meetings would help to address this concern).
One reason for having a LAB is to provide a mechanism for early stakeholder involvement. To this purpose, the LAB could be created and its advice sought when the licensee has just begun to weigh possible decommissioning options. This might complicate LAB/licensee interactions, however, particularly if the licensee has not yet formulated a clear set of options. But the further along the decommissioning plan is, the more likely it is that the LAB's advice will not be readily entertained. As an intermediate approach, the LAB could be set up early on, with the understanding that it would hold off on options analysis and would assume as its first tasks developing its operating procedures and its background understanding of the site and related issues.
Problem characterization. To provide advice, a LAB will need to understand the dimensions of the problem before it. Doing so may require access to studies and analyses pertinent to the proposed decommissioning. These analyses may differ in many respects. Some may be more detailed than others. All are likely to reflect the goals and methodological preferences of their authors -- e.g., the licensee, state

or local agencies, or special interest groups. The LAB will need to assess the quality of these analyses, using such criteria as adequate explanation of technical language, specification of the full range of consequences for various scenarios posited, indication of the reliability of technical analyses, and identification of potential sources of bias.

Deliberative capability. Especially if the LAB is to provide group advice rather than simply individual opinions, its members need to deliberate together effectively. Deliberation involves a weighing of facts, values, and arguments in reaching conclusions. There are two general approaches. The first is informal: the group thinks through a topic or problem intuitively, using whatever means are readily available. The second is more formal: the group employs structured tools such as decision analysis and Delphi techniques. Informal deliberation has the advantage of requiring little or no outside expertise or technical support. However, it can result in the omission of important factors. Formal analysis helps ensure completeness and may make clearer distinctions between facts and values. However, it requires more external support and may be inappropriate for some problems, particularly those that do not lend themselves to quantification (e.g., the assessment of social impacts of decommissioning).

Apart from the analytic methods employed, the quality of the LAB's deliberations will be affected by the ability of individual members, first, to understand the proposed plan and its related analyses, and second, to tease out issues that might go unnoticed. A LAB composed mainly of experts on aspects of the decommissioning plan may succeed on the first score but fail on the second. At issue is how much technical expertise LAB members should have, individually and collectively, and whether technical expertise can be incorporated by means other than membership on the LAB.

Group interactions may be enhanced if external meetings between two or more members outside the group setting are discouraged. This may be especially important if group consensus is sought: by exchanging views and information only as a group, the LAB may be more likely to develop a shared viewpoint. However, this approach may be inefficient on highly technical issues, or it may lead to stalemates on volatile issues. In such cases, the LAB may be better able to deliberate in subgroups, possibly composed not only of LAB members but also of other experts or interest representatives.

Tradeoffs among objectives. While maximally achieving such objectives as broad stakeholder representation, timely establishment of the LAB, and optimum deliberative capability would be desirable, it may not be possible. For example, ensuring that the LAB is fully representative of stakeholder interests may make it so large as to impair its deliberative capability. To address the problem of tradeoffs among objectives, the licensee and/or NRC could consider ranking objectives according to the central concerns associated with the particular site involved. Alternatively, the NRC could decide a priori to emphasize one or more objectives, while giving the licensee discretion in the degree to which others are met.

Issue 3. Implementation Details

What implementation details need to be considered when establishing a LAB?

Once the need for a LAB is identified, someone must take responsibility for its start-up, operation, and termination. Success with implementation details will allow the LAB to focus on its main goal: providing sound advice to the licensee. Failure can lead to organizational problems that can jeopardize the entire advisory process. Inattention to implementation details may also call into question the licensee's and/or NRC's commitment to the LAB process. While it is assumed here that the licensee would be responsible for implementation, the NRC and others could share responsibility. Thus, allocation of responsibilities is one question discussed below.

Start-up. Start-up decisions include determining when to form the LAB, as discussed under Issue 2; how to announce its formation and invite stakeholders to participate; whether LAB members need to make any commitments, written or otherwise, to the LAB process and/or the licensee as a condition for membership (e.g., commitments not to disclose confidential business information); and whether to reimburse expenses (e.g., for travel and child care) and pay honoraria for participation. The question of honoraria merits especially careful consideration. On the one hand, honoraria may contribute to the impression that participants are being bought off; on the other

hand, honoraria may be needed if participation by some members would be precluded because they can not take time off from their paid jobs.

Perhaps the greatest challenge is to ensure that the LAB is large enough to permit representation of all relevant stakeholder interests yet small enough to permit meaningful interaction and deliberation. While there is no formula for determining optimum size, as a general rule a group of more than 10 to 15 members is likely to find informal interaction difficult. To address the problem of size, it may be necessary to consider, first, whether some interests are more crucial than others; second, whether some members of the LAB can represent more than one set of interests; and third, whether there are ways to informally involve peripherally affected parties without expanding the size of the LAB (e.g., through periodic open workshops, or by inviting representatives of certain interests to attend LAB meetings when topics particularly germane to them are to be addressed).

During the start-up phase, rules for participation may be needed: e.g., who has the final say on specific appointments to the LAB once stakeholder groups have been identified (the stakeholder groups, the licensee, the NRC, an independent third party?); whether alternates can serve in the absence of appointed members; and how appointed LAB members will be replaced if they terminate their LAB membership once the process has begun. Some of these "groundrules" may need to be specified by the licensee or by an independent third party; others can be developed by the LAB once it is operating.

Operation. Operational decisions include when and where to hold meetings, how agendas should be set, and whether meetings should be public or private (or a mix, depending on the topic under discussion). Decisions also need to made about how the LAB will be led (e.g., by a chair appointed by the licensee or by LAB members); whether the LAB should have an outside facilitator to help structure discussions and lead brainstorming sessions, and if so, how one should be selected; and, as discussed under Issue 2, how decisions on group advice should be made (e.g., by consensus, by majority vote, etc.) and advice communicated.

Administrative, staff, and technical support. The LAB may require administrative support, including meeting space, office supplies, copiers, phones, and fax machines. To disseminate information, prepare correspondence, compile reports, etc., it may require staff support. The LAB may also require technical support internally (e.g., someone to collect information and maintain an information data base) and externally (e.g., outside consultants to provide independent reviews of technical studies). Without some minimal level of support, the LAB's ability to deliberate effectively and provide useful advice to the licensee may be compromised. However, the LAB probably should not seek to (or be expected to) replicate credible scientific and technical studies conducted by the licensee and others. A good working relationship between the licensee and the LAB would help to ensure the timeliness and cost-effectiveness of administrative, staff, and technical support.

Cost drivers. The past experience of advisory groups suggests that there are five basic factors affecting advisory board costs: the advisory group's size, the frequency of its meetings, how long the group remains in existence, the extensiveness of support required, and the distances involved in convening members, support personnel, consultants, etc. The licensee's ability and willingness to bear LAB costs may be influenced by several factors -- in particular, the licensee's financial health and the perceived benefits of having a LAB. In some instances, it may be very important to the licensee to anticipate and control LAB costs. Means of controlling LAB costs could include, for example, using video or audio teleconferencing to reduce the number of meetings, and having a fixed annual budget (lump sum or itemized), with the LAB responsible for securing any additional funding desired through outside grants.

Conflict resolution. If differences arise between the licensee and the LAB (and, possibly, among LAB members), various approaches to conflict resolution could be considered. Optimally, the LAB, together with the licensee, should develop a strong working relationship with a shared sense of ownership in the outcome of the process and with the ability to resolve differences one-on-one, by negotiating with each other. Some issues may be fairly intractable, however, and an outside mediator may be needed to help reach compromise. While the prospect of using an independent third party to help resolve differences may erode the licensee's and group's sense that they are working together, mediation may help to ensure that the LAB process does not get stalled. Not all issues are suitable for mediation, however, and a degree of

cooperation from participants will be required. A first step is to have the prospective mediator assess whether the situation is appropriate for mediation.
LAB termination. Termination could become a divisive issue if the licensee wants to terminate the LAB but its members (individually or collectively) want to continue, or vice versa. To allow for this, forethought may be needed about who will make the final decision to terminate, and about whether consensus is required for continuation. Controversy over termination may be minimal, however, if all other issues have been handled properly. Then, it may be self-evident to all concerned that the LAB's mission has been completed. Notification of any future plans by the licensee to solicit advice from the public might still be needed, however. This could be done at the time of the LAB termination.
Allocating implementation responsibilities. The licensee, the NRC, or a neutral outside party or steering committee (possibly selected by the licensee in consultation with the NRC and the state) could take sole responsibility for initiating the LAB process, providing support services, offering guidelines on LAB operation, and managing the LAB termination process. Alternatively, these tasks could be allocated according to who would be most appropriate. For example, a steering committee could be established to select LAB members and offer guidelines on LAB operation; the LAB could expand upon those guidelines (and possibly its membership) in consultation with the licensee; the licensee could be responsible for providing a fixed LAB budget limit, with discretion for the expenditure of funds left to the LAB; the NRC, in consultation with the LAB and the licensee, could be responsible for determining when the LAB should terminate. Any number of combinations is possible. The main point is to decide who has the highest likelihood of implementing a part of the process in a manner that will meet the fundamental goal of the LAB concept.
Issue 4. Prescriptive v. Performance-based Rulemaking
In rulemaking concerning LABs, is a prescriptive or a performance-based approach preferable?
Prescriptive approaches to rule-making are means-oriented, whereas performance-based approaches are ends-oriented. Prescriptive approaches try to anticipate which design features and methods of implementation are most likely to realize certain objectives -- e.g., to ensure representativeness, a prescriptive approach might specify the size and composition of a LAB. The prescriptive approach ensures that a licensee will not overlook or ignore important considerations in the establishment and operation of an LAB. However, because variations among licensees and affected communities cannot be fully taken into account in rulemaking, highly prescriptive rules can be "Procrustean": they can force all licensees and LABs to fit a limited number of molds. In doing so, they may be burdensome and inefficient. They also may fail to achieve the objectives driving the rulemaking.
In contrast, performance-based approaches to rulemaking focus on the objectives themselves and permit a good deal of implementation discretion -- e.g., in a performance-based approach it might simply be stated that representation of all significant interests should be sought. The performance-based approach avoids the inflexibility inherent in a highly prescriptive approach. It allows the licensee and the affected community to tailor the LAB to their particular circumstances by granting a large measure of discretion in determining how the LAB should be set up and operated (and, perhaps, whether one is needed at all or whether another group can fulfill the LAB's roles). With a performance-based approach, however, explicit verification and evaluation measures become especially important. Without them, there is no objective means of determining whether the licensee has actually met the spirit of the regulatory objectives.
There is, in reality, no bright line between prescriptive and performance-based approaches. Even with prescriptive approaches, objectives are usually articulated and the prescriptions usually include a measure of flexibility. And even with performance-based approaches, certain design features and methods of implementation may be recommended. In addition, rules rarely spell out all of the details of implementation; they usually are supplemented with regulatory guidelines and other documents. To the extent that rules focus on objectives, with implementation details contained in non-mandatory guidelines, more flexibility is introduced. Thus, the distinction between prescriptive and performance-based approaches is usually one of degree, and in fact, hybrids of the two are the norm.
As suggested in the proposed rule, a two-step process for establishing a LAB could

be adopted -- a process which balances between the prescriptive and the performance-based. According to this process, when the licensee submits notification of intent to have a restricted use decommissioning, a plan for establishing and operating a LAB is also submitted. Following NRC approval, the licensee implements the LAB and develops the decommissioning plan. This two-step process allows the licensee to tailor the LAB approach but reduces the likelihood that the approach would be found deficient after a decommissioning plan had been developed and submitted. Pre-approval of a LAB plan could also tackle early on, before a LAB had been initiated, the problem of necessary tradeoffs between LAB objectives discussed under Issue 2.

Issue 5. Special Situations

Are there special conditions affecting the need for a LAB, or the ability of public officials to be members of a LAB?

The NRC has proposed that a LAB be established if a restricted use decommissioning is contemplated. However, some sites proposed for a restricted use decommissioning might not justify the effort and expense of establishing a LAB: for example, sites where the restrictions on future uses are to be temporary, short-lived measures. In addition, at some sites where the LAB requirement would apply, establishing a LAB could be unnecessary because existing organizations such as local environmental review boards could be adapted to provide advice on decommissioning issues. Substituting an existing organization has, however, both potential assets and potential drawbacks. Doing so could be time- and cost-efficient and could downplay questions that may arise concerning membership, but it could run the risk of distorting or trivializing the LAB's mission by tying it to existing agendas, and furthermore, the existing group might not have the appropriate composition or expertise.

In contrast with situations where exemptions from the LAB requirement might be considered, some sites not proposed for a restricted use decommissioning might still merit the establishment of a LAB. For example, a LAB might be needed on at least an interim basis if, at the time of the licensee's notification of intent to decommission, it cannot be determined whether the site can be cleaned up to permit unrestricted use. Another special situation where a LAB might be appropriate concerns licensees who plan to retain their licenses, but in an amended or modified form: e.g., licensees undertaking actions preparatory to decommissioning while not yet seeking license termination. In this situation, a LAB-like body might be needed to provide advice on the arrangements being made toward the eventual prospect of decommissioning, especially since these arrangements could immediately or prospectively affect human health, property values, and local jobs.

In addition, there may be impediments to the participation of members -- particularly state and local officials -- on LABs. Public agencies may have regulations that restrict employees from participating in activities that pose a potential conflict of interest with their work. In those cases, participation would have to be written into their jobs. Officials may also have concerns about tort liability -- i.e., liability for the consequences of decisions or non-action -- in instances where they are not clearly protected by sovereign immunity. One remedy is to have representatives of public agencies sit ex officio on the LAB. This would temper their liability concerns, but it also might lessen their input. Fundamentally at issue is whether public agency officials are to serve as representatives of their agencies or in their personal capacities.

Issue 6. Evaluating Effectiveness

How should the effectiveness of LABs be evaluated, and what are the regulatory implications of LAB evaluations?

In thinking about how the effectiveness of LABs might be evaluated, there are several considerations. First, evaluations could be done either of individual LABs, to make mid-course corrections or as "post-mortems", or of a suite of LABs, to suggest to the NRC whether changes in regulations and guidelines might be advisable. Second, an evaluation could have several purposes: it could be concerned with process (e.g., to identify difficulties in a LAB's initiation or operation), or it could be concerned with outcomes (e.g., to determine whether LAB advice has made a difference in subsequent licensee and NRC decisions). In either case, indicators of effectiveness need to be specified, and methods for their measurement established. Third, someone must be responsible for conducting the evaluation, which raises the question of whether an independent evaluator or a participant in the process is

preferable. Fourth, the results of an evaluation are often affected by its timing. Preliminary evaluations could be performed while the LAB is in process, but its overall impacts may be more readily assessed at the conclusion of its efforts. And fifth, there may be circumstances under which there is little point in conducting an evaluation: for example, if a LAB is convened only fleetingly. Also, if a particular decommissioning site is unusual, a LAB evaluation might be useful for "self-help" purposes, but its results probably would not be generalizable.

Evaluation results could be used in many ways. As noted above, cumulative evaluations of several LABs could contribute to an NRC decision to continue, abandon, or modify the LAB approach, and the NRC also might decide that the LAB approach should be extended to other circumstances, in either its current or a revised form. In addition, LAB evaluations could be used to provide informal guidance for licensees just embarking on their decommissioning planning, to inform them about LAB approaches that do and don't work. Similarly, when a LAB is convened its members might wish to review evaluations of other LABs. In any case, the ways in which evaluation results are reported should take into consideration who will use them. For example, licensees and LAB members may benefit most from case studies. In contrast, the NRC may be most interested in evaluations that systematically characterize and discuss findings from a number of LABs along several dimensions.

CONCLUSION

The small-group approach to stakeholder input is currently much in favor in the public and private sectors. It is not, however, an approach that should be undertaken blithely, without careful thought given to why and how it is to be carried out.

In our paper for the NRC workshop, and in the summary given above, we do not attempt to provide a template for how advisory boards should be set up and operated. To do so would ignore the many different circumstances that should be taken into account in establishing advisory groups. We do, though, seek to lay out the critical issues -- issues that should be resolved before an advisory group is established. With careful forethought, pitfalls may be avoided or minimized, and the advisory group is more likely to realize its goal of provide useful, timely advice.

In addition, if an advisory group approach is well-constructed and well-executed, it can over time help to overcome barriers that sometimes exist between individuals and groups with different perspectives. It can lead to a greater understanding of -- and possibly a greater appreciation for -- dissimilar views. But mutual understanding and respect is not an automatic outcome of advisory groups. They also can result in increased factionalization and distrust. There are no guarantees that advisory groups will not backfire, but they are less likely to do so if they are conceived and executed with care. In particular, the group's purpose must be made clear, members must be carefully selected, adequate information must be provided to the group, and those seeking advice must indicate how they have responded to the advice given.

Finally, it should be noted that advisory groups should not be regarded as substitutes for broader forms of citizen participation. This point has been recognized by the NRC and other federal agencies considering SSAB-like approaches, but it is worth reiterating. While the advice that can be obtained from the sustained, intensive efforts of a small group may be invaluable, it should be complemented with approaches that invite the opinions of the larger citizenry. It should augment, not replace, the concept of participatory democracy.

ABSTRACT
Ion exchange materials used for decontamination of nuclear power plant primary system water is often referred to as wet waste. Wet wastes consist mainly of organic resin loaded with radionuclides such as Co and hazardous components such as Cr. Ideally, the radionuclides and hazardous components should be concentrated into a small stable waste form. One such waste form due to its high density and the large volume reductions available upon vitrification of the wet waste is glass. Glass is also a very stable material, both mechanically and chemically, making it a desirable form for the storage of highly radioactive low-level wastes. Presented in this paper are the results of pilot-scale melter runs where greater than an order of magnitude volume reduction was achieved with the formation of a stable waste form as defined by the Toxic Characteristic Leaching Procedure (TCLP) and Product Consistency Test (PCT). In addition, off-gas emissions for these high organic content wastes can be controlled to less than 20 ppm CO, and less than 35 ppm NOx and SOx.
MELTER DESIGN
Joule-heated ceramic melters have been extensively developed for the vitrification of high-level radioactive wastes. In fact, they have become the internationally-preferred means to treat high-level radioactive liquid wastes (1) and the U.S. Environmental Protection Agency's Best Demonstrated Available Technology. Similar melters in our facility are based on high chromium-containing glass contact materials such as Inconel 690 and Monofrax K-3 refractory. These contact materials are backed by Zirmul AZS refractory and 95% alumina castable. The entire glass containment basin is housed in an interior liner constructed from Inconel. The interior liner permits the installation of a substantial refractory ceramic fiberboard insulation package around the melter to mitigate heat losses through the melter sidewalls. The upper plenum sidewalls are constructed of Zirmul Refractory, and backed by insulating fiberboard. Ceiling construction is from multiple layers of refractory ceramic fiberboard protected by an Inconel plate. The outer shell of the melter consists of 304L stainless steel.
Two routes of glass discharge exist: airlift and bottom drain. The airlift discharges glass through the sidewall to an Inconel 690 riser and pour trough for continuous melter runs. The bottom drain is used for batch mode operations.
Power is provided to the melter from four sources: electrodes, lid heaters, discharge heaters, and bottom drain heaters. The first set of pilot-scale experiments was performed in a melter with a nominal glass output of 10 kg/day, known as the DuraMelter 10.
The melter itself is only a small part of the DuraMelter system. Figure 1 is a schematic of the entire DuraMelter system, consisting the melter and off-gas train. The off-gas train consists of a quencher, scrubber, and filters to clean the off-gas

emissions from the melter. By adjusting the solution in the quencher and scrubber, various compounds, such as NOx, SOx, Cs and Co, can be filtered. The baghouse and HEPA filter capture particulates in the off-gas. Gas and particulate emissions are monitored after the main blower.

RESULTS AND DISCUSSION

Simulated feeds of anion, cation and mixed bed resins were prepared and fed to the DuraMelter 10. Anion resin consists mainly of amine groups while cation resins consist mainly of sulfonate groups. Mixed bed resin normally consists of 60% by volume of anion and 40% by volume of cation. However, since waste by nature is heterogeneous, the extremes were tested in addition to a mixed resin composition. The first tests with the DuraMelter 10 used pure anion and then pure cation to examine the extremes that could challenge the control of NOx and SOx emission, and the extreme in organic content per liter of resin, thus the extreme in heat formation. Table I presents the results of a pure anion and a pure cation run. Using an average feed rate of 1.4 liters of resin per hour for 40 hours, stable glass temperatures were maintained in addition to low CO and NOx emissions using pure anion resin. There is no sulfur in anion resin, therefore SOx was not monitored for the pure anion resin run. However, a typical cation resin contains 4.3 lbs of sulfur per cubic feet of resin. During the pure cation runs, the ability to control SOx emissions was assessed. Table I shows that by using the DuraMelter system, there were low CO, NOx, and SOx emissions, and heat generation was controlled as demonstrated by stable glass temperatures.

Having tested the high-end of sulfur- and nitrogen-containing wastes, mixed bed resin was then tested. A dirty resin was simulated by loading with the appropriate amounts of Na and Fe plus Co and Cs (using non-radioactive Co and Cs) at greater than eight orders of magnitude higher levels than reported by nuclear utilities. The high loading of Cs and Co was used to obtain accurate distribution data.

Figure 2 shows a schematic of wet waste vitrification. The melter is started with an appropriate high conductivity glass, and then chemicals are added to obtain a low-conductivity, high-viscosity glass. After adding 60 liters of wet waste, the conductivity of the melt will increase and the viscosity of the glass will decrease due to the sodium and iron from the wet waste resin. Studies are made to determine which compositions will remain processable throughout 60 liters of wet waste vitrification. After processing 60 liters of wet waste resin, zeolites, used in cleaning the scrubber and quencher, are added to the melter. This will produce a total of 10 kg of glass or 4 liters of waste glass (using a typical glass density of 2.5-2.7 g/ml); a volume reduction of 15.

The off-gas data for the mixed resin run is also presented in Table I. Using an average feed rate of 1.4 liters of mixed resin per hour, both the off-gas emissions and the glass temperature were under control during the entire 40-hour run. Off-gas emissions for CO were less than 20 ppm, while off-gas emissions for NOx and SOx were both below 35 ppm.

In addition to obtaining large volume reductions, vitrification has the advantage of producing a mechanically and chemically stable waste form. Glasses are known to have very high compression strengths, and their chemical durability often exceeds those of other stabilized waste forms. Glasses produced from the simulated wet waste were subjected to two different chemical durability tests: the EPA Toxic Characteristic Leaching Procedure (TCLP) and the High-Level Nuclear Waste Program's Product Consistency Test (PCT). These results are shown in Table II and Fig. 3a , (Fig. 3b) respectively. Wet waste glasses were spiked with 1000 ppm of Cr, Ni, Ba, Cd, Zn, Co, and Cs. This level of Cr, Ni, Ba, Cd, Zn, Co, and Cs is two to nine orders in magnitude higher than the contents expected in the actual waste corresponding to zero to seven orders of magnitude higher than for the actual waste glass. These high concentrations of all of the hazardous components and simulated radioactive components were used in order to clearly see the distribution of these components between waste glass and leachate. These glasses were then subjected to the EPA TCLP test. Analysis of the leachates after the TCLP test shows very small amounts of both hazardous and radioactive components. The leaching of hazardous components is certainly much less than the US EPA limits, as shown in Table II. Regarding the radioactive components, note that for Co, only one part in 10,000 leached out of the glass, and for Cs, only one part in 20,000 leached out of the glass. The same proportion of Co and Cs should leach out in the real waste glass, but the actual amounts will be orders of magnitude less since the actual Co and Cs concentrations

in the real waste glass is seven orders of magnitude and six orders of magnitude smaller, respectively.
The EPA TCLP test uses a surface area to volume ratio of 20 m-1. A more stringent leach test, the Product Consistency Test (PCT), uses a longer leach period (at least seven days and up to 2 years) and greater surface area to volume ratio (2000 m-1). For this test, the leach rate for the major components of glass (Si, B, and Na) are compared to the high-level nuclear waste glass standard, SRL-EA. Figure 3 presents the leach rate of eight of these wet waste glasses compared to the high-level nuclear waste glass standard, SRL-EA. These eight glasses represent compositional variations of wet waste glasses due to variation in wet waste compositions. All eight glasses produce a lower leach rate after seven days with respect to B, Na, and Si than the high-level nuclear waste glass standard. Similar data have been obtained for these glasses after 28 days of leaching. These glasses will continue to be monitored for at least two years.

SUMMARY

We have shown that by using the DuraMelter system, wastes with high organic contents can be vitrified to produce a stable waste form with at least an order of magnitude volume reduction. Vitrification is an ideal method for disposing of these low-level radioactive wastes due to the large volume reduction obtained when vitrifying wet wastes and due to the resulting waste form (glass), which is both mechanically and chemically stable. A major concern in the vitrification of these high organic content wastes is heat generation and CO, NOx, and SOx emissions. All of these problems have been addressed using the DuraMelter system.

VITRIFICATION OF LOW-LEVEL RADIOACTIVE MIXED WASTE AT ARGONNE NATIONAL LABORATORY

Argonne National Laboratory
Argonne, IL, 60439

ABSTRACT

Argonne National Laboratory-East (ANL-E) is proceeding with plans to use vitrification to treat low-level radioactive mixed wastes (LLMW) generated on-site. The objective is to install a full-scale vitrification system at ANL-E capable of processing the entire annual generation of selected LLMW streams. Crucible glass studies with actual mixed waste streams have produced sodium borosilicate glasses under conditions achievable in commercially available melters. These same glass compositions, spiked with toxic metals above the expected levels in actual wastes, pass the Toxicity Characteristic Leaching Procedure (TCLP) test. Earlier evaluations of the likely off-gases that will result from vitrification indicated that the primary off-gases will include compounds of SOx, NOx, and CO2. These evaluations are being experimentally confirmed with a mass spectrometer analysis of the gases evolved from samples of the ANL-E wastes. The composition of the melter feed can be adjusted to minimize volatilization of some components, if necessary.
The full-scale melter will be designed to handle the annual generation of at least three LLMW waste streams: evaporator concentrator bottoms sludge (ECB), storage tank sludge (STS), and HEPA filter media. Each waste stream is mixed waste by virtue of its failure to pass the TCLP test with respect to toxic metal leaching. Additional LLMW streams under consideration for vitrification include historical mixed waste glass from past operations and spent abrasive from a planned decontamination facility.

INTRODUCTION

Argonne National Laboratory-East (ANL-E) is proceeding with plans to use vitrification to treat low-level radioactive mixed wastes (LLMW) generated on-site. The objective is to install a full-scale vitrification system at ANL-E capable of processing the entire annual generation of selected LLMW streams. We had previously established the feasibility of using vitrification as a treatment technology for the remediation of historical and current wastes generated at ANL-E (1). We reported that the ANL-E mixed waste streams studied were amenable to treatment by

commercially available vitrification technology.
The decision to proceed with this project was based on several factors, regulatory and technical. Section 105 of the Federal Facilities Compliance Act of 1992 (FFCA) requires all DOE facilities are required to prepare an inventory of existing and planned mixed waste and to develop plans for mixed waste treatment. The Department of Energy (DOE) is also required by Section 3021(b) of the Resource Conservation and Recovery Act (RCRA), as amended by the FFCA, to prepare plans describing the development of treatment capacities and methods for treating mixed wastes. The project described here is one of these treatment options.
The major technical factors that supported the decision to proceed with vitrification include the overall volume reduction achieved by the process (roughly a factor of eight) and the lower disposal costs (50% reduction) resulting from the stabilization of the waste from a mixed waste to a low-level radioactive waste. The total cost savings will be determined after the waste streams are treated and their total and annual volumes are finalized.
This project is in the process of producing a range of processible glass compositions from actual mixed wastes and low-cost additives. Emphasis is on maximizing the waste loading in the glass (currently up to 90 wt%) and reducing the overall waste volume, while producing a stabilized low-level radioactive waste glass. In crucible glass studies with actual mixed waste streams, sodium borosilicate glasses have been formed under conditions achievable in commercial melters. Some of these same early glass compositions, spiked with RCRA metals above the expected levels in actual wastes, pass the Toxicity Characteristic Leaching Procedure (TCLP) test. These results provide the technical evidence that the vitrification system and the glass waste form will be robust enough to accommodate expected variations in the ANL-E LLMW streams. Approximately 30 crucible melts are being made to establish a compositional envelope for vitrifying ANL-E mixed wastes.
EXPERIMENTAL
Representative samples of LLMW streams generated at ANL-E were used in this study. Three different waste streams were studied: evaporator concentrator bottoms sludge (ECB), storage tank sludge (STS), and HEPA filter media. The radioactive component of these waste streams included radionuclides such as 232U, 239/240Pu, 237Np, 210Po, 241Am, 137Cs, and 60Co, while the hazardous component included Ag, As, Ba, Cd, Cr, Hg, Se, and Pb at levels above the Environmental Protection Agency (EPA) limits for hazardous materials, as determined with the TCLP. The typical composition of each of these waste streams is given in Table I. The glass-forming compositions of HEPA and ECB are not expected to vary significantly, except for the amount of radioactivity or hazardous metals (hundreds of ppm). There will be considerable variation in the composition of STS. Scanning electron microscopy with energy dispersive x-ray spectroscopy (SEM/EDS) analyses of representative samples of STS found compositional variations much larger than what could be attributed to analytical error of the instrument and technique. The values reported in Table I were assumed to be typical of the material and were used in formulating glass compositions. The STS is a brown material, with the appearance of moist dirt clods that contains occasional root-like organic pieces, some up to 1 cm in diameter. This material has a moisture content of about 45 wt%. The ECB is a sticky yellow sludge-like material that is approximately 25% moisture and has the consistency of moist paste. The HEPA is dry, has a paper-like consistency, and has been shredded down to 1 cm2 squares. Some HEPA filters contained aluminum foil spacers, which make up about 5% of the total filter.
Two composite waste streams were blended from STS, ECB, and HEPA. Composite waste stream A was mixed in the ratio (by weight) of 4:1:1, STS:ECB:HEPA, and B was mixed in the ratio of 4:2.5:1, STS:ECB:HEPA. These formulas are based on estimated annual generation rates of waste streams STS, ECB, and HEPA at ANL-E. Feeds for crucible melts were prepared in the following manner. The waste stream, either A or B, was weighed out, according to the specifications of the formulation. The glass-forming materials were then added, and the mixture was blended to a degree representative of the conditions that may exist during full-scale vitrification. The material feed was neither dried nor processed any further. The mixture was immediately transferred to an alumina crucible, and melting was initiated.
All melting was performed in an electric resistance furnace at 1100C, with the melts being held at temperature for approximately two hours. This temperature was selected since it is readily achievable with commercial vitrification technology (1). Upon termination of the melt test, the glass was poured onto a graphite or stainless

steel surface, neither of which significantly interacted with the melt. The cooled glass was transferred to a clean container until analysis. Each of the glasses was examined with SEM/EDS approximate composition, and structure of the final glasses. The TCLP was performed according to standard procedures with high-density polyethylene leaching vessels. The leachates were semi-quantitatively analyzed for As, Ba, Cd, Cr, Hg, Se, and Pb with an inductively coupled plasma/mass spectrometer. Samples of the melter feed stream are being subjected to evolved gas analysis with a mass spectrometer. These analyses will allow us to experimentally determine which species (both radioactive and hazardous) are evolving from the melt and provide data that can be used in designing an off-gas control system for the full-scale vitrification system. Typically, milligram quantities of a glass formulation (melter feed and glass-forming additives) are gradually heated in a vacuum with a resistance furnace. The evolved gas is introduced into the mass spectrometer, where three values are continuously monitored and stored on a computer: temperature, the atomic mass associated with the analyzed signal, and the analyzed signal. A computer program controls the spectrometer so that a range of atomic masses is continuously scanned and recorded. The data are later processed to identify the evolved gases and their temperatures of evolution.

RESULTS

The glass formulations that have been made to date are summarized in Table II. The first ten melts were used to identify glass compositions that the three waste streams passing the TCLP criteria for a non-hazardous final waste form and meeting the criterion that the material be easily poured from its crucible immediately after removal from the 1100C furnace. Five spiked crucible melts were subsequently produced: melts 11, 12, 13, 14, and 15. These melts had compositions close to the processible formulations 2, 4, 5, and 9. The hazardous metals added to the formulations (Table III) consisted of reagent grade oxides of Ag, As, Ba, Cd, Cr, Pb, and Se or metallic Hg and Cd. These spiked melts all had acceptable viscosities at 1100C and passed the TCLP and are now low-level wastes.

Each of the melts formed a black to dark green glassy material. The volume reduction from the unmelted mixtures was approximately a factor of eight. Melts 3, 7, and 8 formed viscous glasses that could not be poured from their crucibles. Melts 7 and 8 did start to flow but not enough to remove glass from the crucible, probably the result of high melting temperatures and rapid cooling. Melt 3 melted but did not show any evidence of pouring. Examination of these glasses by SEM indicates that melt 8 is a phase-separated glass, while melts 3 and 7 are homogeneous. Since these glasses did meet the TCLP criteria, as discussed below, they may still be useful if a melter technology is identified that can handle mixtures with high viscosity and high melting temperatures. However, at this point they are excluded from the compositional envelope. Optical evaluations of the ten compositional envelope glasses (melts 1-10) and three of the spiked glasses (melts 13-15) indicated that a glassy material with no visible inhomogeneities had formed. Melts 11 and 12 contained inhomogeneities.

The SEM/EDS analyses provide a means of semi-quantitatively verifying the homogeneity and compositions of the glasses produced during crucible melting. In general, these analyses indicate that the compositions of the crucible glasses are approximately those calculated from the component materials. The variations could be attributed to analytical error in the SEM/EDS system, volatilization of elements during melting, or variations in the compositions of the as-received waste samples. The analyses of the crucible glasses indicate that, on a scale that can be probed with the SEM/EDS system, most of the glasses are homogeneous. Exceptions to these observations were melts 11 and 12. Analytical data from melt 11 are shown in Fig. 1. The qualitative composition of the entire area in the photograph is depicted by the SEM/EDS spectrum labeled "Bulk Glass" at the top of the figure. The middle figures shows light-colored phases in a dark matrix at a microscopic level. Typical SEM/EDS spectra for each of these components are presented in the bottom figures. These spectra indicate that the light-colored phase is composed primarily of calcium and phosphorus. Preliminary trace element analyses further indicate that the light-colored phase preferentially sequesters arsenic from the dark matrix. A similar light-colored phase was found in melt 12. The composition of these two phases, as measured by SEM/EDS, is presented in Table IV.

The results of TCLP testing of the crucible melts are summarized in Table V. The row labeled "Untreated HEPA" presents TCLP data for the HEPA sample blended in A. This

row indicates how the unvitrified (as-received) HEPA portion of A performed in a TCLP test when it failed for cadmium leachability. It also provides a measure of the effectiveness of vitrification in stabilizing the hazardous elements in this material, especially with the spiked melts 13, 14, and 15. Also presented in this table is the leachant concentration limit that is used by the EPA to define whether a material is hazardous. Except for melt 1, all glasses passed the TCLP for each of the listed RCRA metals. Melt 1 leached mercury at the TCLP limit, which would exclude this glass from the compositional envelope. These analyses and this glass formulation are being further examined to evaluate whether analytical errors for mercury of the TCLP leachate produced this result.

DISCUSSION

Figure 2 is a ternary diagram for the system SiO_2+Al_2O_3:B_2O_3:R_2O, where all values are in weight fraction, and R represents alkali metals. The stars depict the individual waste streams STS, ECB, and HEPA. Also labeled are waste streams A (STS:HEPA:ECB ratio of 4:1:1) and B (STS:HEPA:ECB ratio of 4:1:2.5). The light-shaded region is the known glass-forming region for alkali borosilicate glass (2). Each numbered point corresponds to a glass in Table II. The glasses represented by white numbers and black backgrounds were made with LLMW for compositional development, while the glasses represented by black numbers and white backgrounds are formulations with added amounts of RCRA metals (see Table III). Melts 1, 2, 4, 5, 6, and 9 define the current compositional envelope of glasses for ANL-E LLMW vitrification (the region filled in with the dark shading). These melts form a region of alkali borosilicate glasses that can contain large amounts of ANL-E wastes (72 to 90 wt%), have good viscosities at 1100C, and pass the TCLP criteria for being nonhazardous. Furthermore, melts with similar compositions and spiked with relatively large amounts of hazardous metals also have these same characteristics. Therefore, this region of the alkali borosilicate glass system will be included in the compositional envelope for full-scale vitrification of ANL-E wastes.

The TCLP results suggest that vitrification can successfully treat mixed waste streams with concentrations of RCRA metals much greater than those typically encountered at ANL-E. The results also suggest that the production of additional crucible melts will demonstrate that the entire compositional envelope will likely be able to accommodate mixed waste streams from ANL-E. This is not the final compositional envelope since fabrication and testing of five additional melts are planned. The remaining five melts will be used to expand the existing compositional envelope beyond the existing boundaries, which would provide additional flexibility to the eventual users of the full-scale vitrification system.

CONCLUSIONS

The results of this study have identified a range of alkali borosilicate glasses that meet the acceptance critiera: glasses that melt, are easily poured from their crucibles at 1100C, and pass the TCLP test. The glasses that make up the compositional envelope were produced with relatively small amounts (7 to 28 wt%) of glass-forming additives, and the glass-forming additives that were used (borax, boric acid, and sodium carbonate) are easily handled materials. The compositional envelope will be expanded after the next phase of crucible melting.

Characterizations of the final waste forms with SEM indicate that most of the glasses that comprise the compositional envelope are homogeneous. This finding suggests that hazardous metals are uniformly distributed into the glassy matrices of each glass. Several glasses spiked with RCRA metals are not homogeneous, but still are processible and pass the TCLP, characteristics that do not preclude them from inclusion in the compositional envelope.

The results achieved with the spiked melts indicate that the identified compositional envelope will be able to accommodate unusually hazardous waste streams. The spiked melts provide compelling evidence that alkali borosilicate glasses are a robust waste form. Furthermore, the identified compositional envelope is broad enough to allow ANL-E to treat a diversity of composite waste streams, not only composite waste streams similar to A or B.

Completion of our off-gas analyses will provide a technical basis for designing an off-gas control system for any identified radioactive or hazardous species generated during vitrification.

VENDOR VITRIFICATION PROGRAMS FOR THE SAVANNAH RIVER SITE

Bradley W. Bowan, II
Mark H. Clements
GTS Duratek, Inc.
8955 Guilford Road, Suite 200
Columbia, MD 21046

ABSTRACT
Two programs are underway, which will provide waste vitrification services to the Savannah River Site in South Carolina. The first of these programs, is a model privatized waste remediation effort, which will provide the on site vitrification of nearly 700,000 gallons of mixed wastes currently in storage at the M area portion of the site. The second program, evaluates two vitrification technologies: joule melting and plasma melting, for their possible use to destroy asbestos containing materials targeted for remediation thought the Savannah River Site. This paper provides an overview of both programs currently managed by GTS Duratek, Inc. Under contracts with the Westinghouse Savannah River Co.

SAVANNAH RIVER M AREA WASTE VITRIFICATION

Currently, mixed wastes (hazardous and radioactive) are stored in nine tanks of the Interim Treatment/Storage Facility (IT/SF) and in the Mixed Waste Storage Shed (MWSS) by the Reactor Materials Department (M Area) of the Savannah River Site. These wastes are aqueous-based sludges generated from a nickel plating line process and contain uranium, which respectively classify them as hazardous (listed F006) and radioactive. GTS Duratek will couple a single-stage treatment unit (vitrification glass melter) to these tanks and, with the addition of common glass-forming chemicals, convert these wastes into a smaller volume of chemically durable glass. The glass generated during production will be regularly tested to guarantee the converted waste form satisfies TCLP release criteria to a high statistical certainty (95%). It is anticipated, that the approximately 2,960,000 kg of wastes will be reduced to approximately 1,081,000 kg of solid glass in the time frame of one year. A total waste volume reduction of 82.4% is expected. At the conclusion of the vitrification process, the storage tanks will be decontaminated to RCRA clean closure standards. A more detailed overview of this treatment strategy using a subcontracted vendor has been provided by Pickett, et. al. (1) Some initial vitrification tests on these wastes have been performed by Jantzen. (2) This program will be a model privatized commercial-scale waste remediation effort when vitrification operations begin in 1996.

In the 1960s, vitrification first gained popularity in the U.S. as a means to stabilize high-level liquid nuclear waste. (3) By the mid 1980s, slurry/liquid feeding to a joule-heated electric melter had become the preferred international approach to immobilizing high-level radioactive liquid wastes. (4) The process to be utilized for the SRS M Area waste solidification is an evolution of the technology developed for high level waste vitrification. The cost of the process has been substantially reduced, and it is more tolerant of a wider range of waste compositions. The process described below is a larger-scale version of one GTS Duratek has placed at the Fernald Environmental Management Project to process mixed waste (5) and one constructed to process asbestos wastes located at the Vitreous State Laboratory of The Catholic University (Washington, D.C.). (6) The off-gas treatment system of this system has been modified to accommodate NOx released during

the calcination of nitrate salts contained in the M Area wastes.

Waste Feed Preparation

The wastes stored at the M Area site partially occupy three 500,000-gallon tanks, six 35,000-gallon tanks, and about 125, 55-gallon drums (Watts Plating Solution, and Mark 15 Filtercake). Prior to vitrification, these wastes will be blended into two larger batches of waste which will be nearly the same composition. Due to the limited available space in the existing tanks, blending the wastes into a single volume is not possible. It is planned to consolidate all the wastes into two large "master batches" in two of the 500,000 gallon tanks. When processing begins, glass forming chemical additives will be mixed into the waste in one week batches prior to delivery to the melter.

Vitrification Melter

The waste feed slurry mixture described above is pumped to a single-stage vitrification unit (DuraMelterTM 5000). The slurry enters the melter through water-cooled entrance ports and is deposited on the surface of a molten glass bath. Heat from the glass bath is transferred vertically through the accumulated feed pile and evaporates free water from the slurry, calcines inorganic salts to metal oxides, and fuses the resultant mixture into a uniform melt which mixes with the molten glass inventory. All organic species in the feed are oxidized to carbon dioxide and water.

The DuraMelterTM 5000 is an electric, joule-heated, refractory-lined melter, which will convert the M Area wastes into leach-resistant solid glass. The melt basin will hold 1,950 liters of molten glass. This glass pool is heated by parallel submerged electrodes. Nominally, the glass bath will be controlled to 1150oC and can be discharged through either of two side exiting pour spouts. The two pour spouts are coupled to machines to produce glass gems (glass pieces resembling flattened marbles, about 1.5 cm in diameter). Each pour spout can be activated by an airlift, for controlled glass discharge. The melter is also equipped with two bottom drains for complete removal of the glass inventory at the conclusion of the M Area waste processing. In the plenum space of the melter (area above the glass pool), are lid heaters to provide supplemental power during start-up and operation. The DuraMelterTM 5000 is also equipped with a patented air bubbling and stirring system, which accelerates melter production capacity and oxidizes any organic and metallic inclusions in the waste feed stream. This melter will produce a minimum of 5 tons glass/day, with a maximum capacity of 15 tons glass/day. The mass balance for normal plant operations will be based on the 5 ton/day minimum.

Vitrification Off-Gas System

The melter is coupled to a multistage off-gas treatment system, which maintains the melter at a constant slightly negative pressure (-5 in. w.c.) and entrains and treats emissions resulting during processing. The reactions that occur when the slurry enters the melter generate steam, a variety of gases (NOx, SOx, CO2, and trace halides), and particulate. The front end of the off-gas system is composed of a water spray quencher followed by two aqueous-based packed bed towers connected in series.

Periodically the scrubber sump solutions will be transferred to the existing SRS M Area Dilute Effluent Treatment Facility (DETF). This stream will be routed through one of the empty 35,000-gallon tanks in the IT/SF building, which in turn are coupled to an existing supernatant transfer line to the DETF. Analyses of these solutions will occur prior to transfer to the DETF to determine the necessary treatment required. Primarily this return stream will contain water, sodium nitrate and sodium nitrite. Other species will also be found in this stream in lesser quantities.

Following the packed bed scrubbers is a dry filtration process which assures the absence of particulate radionuclides (uranium) in the final process exhaust. These filtration units are baghouses and high-efficiency particulate air (HEPA) (99.5%) filters. Redundant parallel filtration trains are provided to enable servicing of the equipment without interruption of the process. A sampling port is provided after the HEPA filters for air monitoring. The final exhaust will contain steam, carbon dioxide, and NOx.

Vitrified Glass Waste Form

The waste glass produced is a borosilicate glass designed to meet the TCLP release rate requirements while maintaining a high waste loading (large waste volume reduction). Nominally, the ratio of final glass volume to initial waste sludge

volume is expected to be 0.176. Development glass formation studies will continue until processing begins to lower this ratio while maintaining the TCLP requirements. This will ultimately yield less final waste volume. Adjustments in glass composition do not impact the performance of the process or the total mass composition of the secondary waste streams (off-gas sump solutions and exhaust stack emissions). However, increasing the waste loading can increase the rate at which some species are generated.

The glass gems will be poured directly into 71-gallon steel drums. Any void space in the container resulting from the gems will be filled with inert sand (silicon dioxide). This mixture will provide structural integrity to the drum for stacking. The 71-gallon drum has a square cross-section which allows for a higher drum-packing density.

COMPARISON OF JOULE-HEATED AND PLASMA ARCVITRIFICATION OF ASBESTOS

Asbestos-containing materials (ACM) from abatement operations are highly heterogenous. Asbestos fibers are normally dispersed in composite matrices which may be inorganic, such as portland cement in pipe or boiler insulation, or organic, such as tar in mastics used for waterproofing and vinyl in floor tiles. Thus, ACM can contain substantial quantities of portland cement, gypsum, tar, plastics, metallic objects, a variety of other construction materials, and materials contaminated during abatement, such as workers' protective clothing. ACM is normally collected in standard double polyethylene bags in a wetted condition to insure safe removal, handling, and transport. The amount of water can vary from 10% to about 80% by weight.

Vitrification of asbestos-containing materials (ACM) has been explored in the past.(7) The crystalline structure of all known asbestos fibers is destroyed above 900o C to form benign oxide compounds, suitable for glass forming. Vitrification is a thermal process which converts waste into glassy materials. GTS Duratek and its developmental partner, the Vitreous State Laboratory of the Catholic University of America, made major (patented) advances in the vitrification of a variety of low-level radioactive and hazardous wastes for the U.S. Department of Energy. More recently, GTS Duratek has been working with Plasma Energy Corporation to commercialize plasma arc vitrification for a wide variety of hazardous and asbestos-containing wastes.

We have repeatedly shown that vitrification completely destroys asbestos fibers, eliminating their hazard, while producing a recyclable product. At elevated temperatures, the crystalline asbestos fibers melt and the chemically bound water of crystallization is evaporated, producing a molten pool of non-hazardous magnesia and silica oxides and salts. This destruction of the asbestos fibers eliminates their hazard and the need for special landfill disposal. With appropriate additives, the molten oxides and salts cool to form glass which can be recycled to the glass industry as cullet. Without additives, the mixture will cool to produce a glassy slag (if not glass) which can be used as construction aggregate or filler. Most importantly, the process eliminates the continuing liability associated with landfilling of ACM.

Vitrification not only destroys the asbestos fibers, it also melts the other components of ACM wastes. Non-combustible co-contaminants, such as heavy metals, are chemically bonded into the structure of the glass product and become non-leachable, meeting the requirements of the Resource Conservation and Recovery Act (RCRA) Toxicity Characteristic Leachate Procedure (TCLP) for non-hazardous material. Any combustible co-contaminants, such as organic compounds, in the ACM are also fully destroyed at the high temperatures at which vitrification occurs. Other components of the ACM wastes are incorporated into the glassy matrix. This is due to the powerful solvating of molten glass materials and their resulting ability to dissolve a wide range of inorganic materials.

Commercially, the benefits of ACM vitrification are significant. It competes effectively with the current method of landfill disposal, especially when a value-added end product is produced. The vitrified product can be used as high-quality, light-weight aggregate, inexpensive glass blocks, or fiberglass wool. More importantly, vitrification ends the liability associated with the current disposal techniques.

Durameltertm Vitrification Systems

GTS Duratek is working with both joule-heated and plasma arc vitrification systems, capitalizing on the advantages of each for specific waste treatment problems. Both

vitrification systems are capable of destroying asbestos fibers in waste materials.

Joule Heated Ceramic Melter

GTS Duratek's large-scale Joule Heated Ceramic Melter (JHCM), the patented DuraMelterTM 1000, is designed to produce glass at a rate of up to 3,000 kg per day. The main melting cavity in the DuraMelterTM is constructed of Monofrax K3 ceramic refractory. The melt chamber holds over 60 liters of molten glass. The glass pool is maintained at a temperature of 1,150oC. Heating is provided by passing electricity through the bath across two pairs of Inconel 690 alloy electrodes located on opposite faces of the melt chamber. 200 kW of power is available to the electrodes, if needed. Inconel 690 and Monofrax K3 were chosen as the molten glass contact materials due to their high chromium content and their resistance to glass attack. Electric plenum heaters (30 kW total heating capacity) are located above the melt pool for initial start-up of the melter and for supplemental heating of the feed during operation, if needed. Temperature monitoring is also performed from above, via thermowells inserted through the melter lid and submerged into the molten glass bath. The thermowells are made of Inconel alloy and contain standard commercial Type K thermocouples which are connected to electronic read-outs. The vitrification melter, including the feed chute, is maintained under a negative pressure to prevent the release of asbestos fibers or other contaminants from the melter. The off-gas treatment system incorporates a wet scrubber, mist eliminator, baghouse particle filters, and a HEPA filter, and can treat a wide range of exhaust contaminants.

Full bags of asbestos are dropped into the melt chamber through a double air lock chute located at the top of the melter. The inlet to the feed chute is located in an adjacent Asbestos Containment Room. The air from this room is continuously exhausted through HEPA filters to prevent the release of any asbestos fibers into the work area or the atmosphere. The bags of asbestos waste fed into the melter fall directly onto the molten glass pool. A separate port is used to feed a complementing blend of glass forming additives onto the molten glass. The plastic bag containing the asbestos waste rapidly burn upon encountering the elevated temperatures within the melter, releasing the asbestos wastes. Other organic materials also burn away rapidly. Upon contact with the molten glass, the chemically bound water in the asbestos fibers evaporates, inorganic salts are calcined to oxides, and the asbestos fibers are thermally destroyed through dehydroxylation. The resultant mixture melts into the molten bath of glass. Glass is discharged from the melt chamber via an air lift operating through a side exiting orifice (located near the floor of the melter), which connects to a riser and pour trough.

The DuraMelterTM incorporates a patented gas mixing device. This system injects air into the bottom of the molten glass pool to (a) more efficiently mix the glass components with the feed, (b) control the oxidation potential of the molten glass, and (c) increase the electrical resistivity of the molten glass for more efficient heating. The net result is a significantly higher throughput and lower cost than other joule heated melter systems.

Plasma Arc Vitrification System

Plasma arc vitrification is conducted by Plasma Energy Corporation (PEC) using one of their Model PT-250 Field Convertible Plasma Arc Torches. This will allow for plasma arc operation in both transferred and non-transferred modes of operation. Air and nitrogen are routinely used as the plasma gases. Direct current power for the plasma arc torch is supplied by a 1 KHz power source designed for operation from 10% to 100% of rated capacity while maintaining a 0.9 power factor for high efficiency performance. The plasma system is water-cooled in a closed-loop system. The torch's cooling water flow, pressure and temperature are continuously monitored. Interlocks are provided to automatically shut down the system if these safety parameters go out of range.

The plasma arc vitrification reactor is a metal shell approximately 6 feet in diameter with a refractory lining of insulating bricks (six inches thick) anchored to the water-cooled shell of the reactor. The roof is insulated with a central opening for the plasma torch. Commercial refractory crucibles are located inside the insulating brick to hold the molten asbestos waste materials. The roof provides additional openings for the bagged asbestos waste feed, and an observation port. The furnace exhaust exits through the upper side wall of the reactor.

The ACM is fed into the reactor inside unopened cardboard delivery drums containing the bags of asbestos-containing materials. The cardboard drums are loaded into a chute, passing through alternating slide gates (to prevent escape of reactor gases)

into the furnace just above the melt. This procedure eliminates any potential for escape of asbestos fibers into the environment.
The reactor is fitted with thermocouples strategically placed around the periphery of the reactor crucible to monitor the temperature in the molten glass pool. The molten glass pool will be maintained at a temperature of approximately 1,300oC to ensure complete destruction of the asbestos fibers. Optical pyrometer temperature measurements will also be taken through the view port. The molten vitrified product exits the furnace through a water-cooled underflow/overflow spout on a continuous basis at a rate of 250-900 kg/h. The molten product is then chilled on a water-cooled conveyor and stored.

ACM DESTRUCTION OPERATIONS

ACM from Commercial Sources and the White House

The commercial ACM was obtained from two asbestos removal job sites - insulation materials from a boiler and pipes at a school in Maryland, and ceiling and wall insulation from a hospital in Washington, D.C. In addition to the asbestos-containing materials, cement, other friable materials, plastics, pieces of metallic objects including remediation tools, and workers' protective gear were also present. The hospital ACM contained approximately 30% to 50% fibrous materials which were identified as amosite, chrysotile, anthophllite, and termolite. The school ACM contained approximately 20% to 40% fibrous materials which were identified as orthochrysotile and anthophyllite. The ACM from the White House was asphaltic roofing material containing 10-45% chrysotile asbestos fibers. The organic content of this material was approximately 50 percent.
The polyethylene bags were not presorted or opened except for random sampling. Whole bags, pre-weighed, were fed one at a time into the melter. Observation of bag contents came from random sampling and observation of the contents as they spilled from the burning bags onto the surface of the molten glass pool.
The details of commercial ACM tests were discussed earlier. (8) The temperature of the molten glass was maintained between 1080o C to 1155o C during the feeding period. The plenum temperature varied from 750o C to about 1000o C depending upon the extent of the cold cap and combustion of organics in the plenum area.
Approximately 1,230 kg of the ACM from the school and the hospital, contained in 100 bags, were fed to the melter. The mass of the bags varied from 5 kg to 20 kg with an average of about 12 kg. The White House ACM was contained in 60 polyethylene bags weighing just under one ton.
The bags of commercial ACM were fed at two different feeding rates. In the first campaign, the average feeding rate was about 50 kg/hr (1.2 tons/day) and increased to about 72 kg/hr (1.7 tons/day) in the second campaign. The residence time in the melter was about 40 hours at 1.2 tons/day feed rate and 28 hours at the 1.7 ton/day feed rate.
The bags fell directly onto the surface of the molten glass pool and immediately began to burn. The combustion process was usually completed in 1 to 5 minutes leaving inorganic materials on the surface of the molten glass which were consumed in an additional 5 to 10 minutes.
Significant amounts of wire of varying thicknesses were observed on top of the glass pool. On one occasion, a large metal screen (at least 6 in. x 6 in. x 18 in.) was seen. It was observed to simply dissolve into the glass pool. During operation, it was observed that the electrical power required to maintain temperature dropped at higher feed rates. This is largely due to the heat of combustion of the plastic bags. Table I summarizes the operational conditions of the DuraMelterTM 1000 during both campaigns.(8)
During all tests, samples were taken frequently from the discharged glass, scrubber sump solution, and off-gas stream. Glass samples were ground and analyzed in accordance with the EPA Transmission Electron Microscopy (TEM) procedure.[9] Several glass samples, including the last output of the melter during each campaign, were examined. No asbestos fibers were found in any of the samples.

DOE Savannah River Site

A series of test campaigns are being conducted with ACM from the Department of Energy's (DOE) Savannah River Site (SRS) to compare the performance of joule-heated and plasma arc vitrification systems. A total of five campaigns will be conducted with each vitrification system. The feeds presented to each vitrifier will be comparable, using characterized and pre-sorted bags of asbestos wastes. This series of campaigns will present a range of feed compositions encompassing the range of

asbestos waste materials available at the Savannah River Site, including:
- Naturally occurring asbestos fibers
- Transite
- Asbestos containing floor tile
- Pre-formed thermal insulation
- Spray-on insulation
- Asbestos containing mastic
- Other miscellaneous ACM construction products

These parallel campaigns are designed to provide the necessary data to assess and compare the two vitrification technologies on the basis of asbestos waste destruction performance, costs, and regulatory compliance.

A wide range of data will be collected during each campaign, including:
- Operating Conditions - temperatures, pressures, flows
- Operating Costs - electricity, additives, maintenance and repair
- Operability and Reliability - maintenance and repair actions
- Performance - any residual asbestos fibers in the glass or other outputs

The data obtained will provide a complete evaluation of the effectiveness and suitability of each vitrification system to treat asbestos wastes. They will also provide sufficient data to reliably scale the performance and costs (capital and operating) of future asbestos waste vitrification systems.

CONCLUSION

Two ongoing programs centered on the use of vitrification for the remediation of wastes at the Savannah River Site have been reviewed. The M area vendor treatment facility will convert nearly 700,000 gallons of mixed wastes into durable glass using a new plant collocated at the waste storage site, and wholly managed and operated by a subcontractor to the site's management and operating contractor. A vitrification development program is also underway, where the destruction of SRS asbestos containing materials will be compared using two melting technologies: joule heated and plasma heated. This second program will highlight the benefits of both technologies for use in further consideration of vitrification as a treatment method for these types of wastes.

ABSTRACT

Since the middle of 1970-th a low- and intermediate-level waste vitrification process was being developed in Scientific & Industrial Association (SIA) "Radon". There were proposed to vitrify both liquid and solid wastes with formation of borosilicate and aluminosilicate-based glass or glass ceramics. An activity was being trained as follows: development of glass and glass ceramic compositions suitable for production by electric melting and final disposal; development of vitrification flow sheet; selection of melter type, melter design, development of batch preparation method and design; calculations of optimized electrical and heat process variables; development of process automated control system; experimental study of vitrification process on lab-scale and pilot plants; product testing under natural conditions; development of full-scale plants, their installation and testing. The process basic principles are based on maximum of waste volume reduction and ecological safety and were assigned as follows: waste oxide content in final product has to be as high as possible; minimum non-radioactive additives to waste must be utilized; joint vitrification of liquid and solid wastes is preferable; radionuclide losses during the processing and storage have to be minimized; a chemical durability of final product may be similar one to bituminized waste or higher; the leach rate of radionuclides from the glass or glass ceramic wasteforms has not to be increased by one order of magnitude after the gamma-irradiation to absorbed dose of 100 kGy (such dose will be accumulated by product for 300 years of storage). From these points of view total waste oxide content in final wasteform can be carried to 80-90 or even 100% maintaining its chemical durability on the level of bituminized waste (10-4-10-5 g/(cm2 day)). By this waste volume reduction factor at vitrification is higher than one at bituminization by factor of 5-10. Solid residue of liquid waste contain mainly sodium salts (nitrate, carbonate, ortho-phosphate, sulfate, chloride and metaborate in the case of VVER waste from Nuclear Power Station) as well as calcium-magnesium bicarbonates and corrosion products. Solid wastes as incinerator ash, contaminated soil, spent inorganic ion-exchangers (zeolites, clays), asbestos materials, spent lining and heat isolation contain mainly high fusible oxides as network-formers - SiO2, Al2O3, P2O5 and ceramic forming species - CaO, MgO, Cr2O3, ZrO2, TiO2 etc. Thus, common vitrification of liquid waste from regeneration of ion-exchangers and contaminated soil (loam, clay, sandstone) results in production of almost homogeneous glass on either aluminosilicate or aluminoborosilicate basis. No any non-radioactive additives are used. These glasses may be produced in both Joule-heated ceramic and coreless induction (cold crucible) melters. Melting temperature is ranged between 1000 and 2000oC depended on liquid to solid wastes ratio. Chemical durability of glass also depends on glass composition. Vitrification of flux free incinerator ash results in formation of glass-ceramics. The nature of basic crystalline phase, its content in material and crystal dimensions depend on initial ash composition. Melting of "Radon" incinerator ash containing phosphates yields apatite-based glass ceramics. As far as glass forming agents are added to ash the glass fraction is increased. A borosilicate or aluminosilicate glass produced from liquid waste salts and contaminated soil may be used as glass forming additive. In this case total waste oxide content remains 100%. Spent inorganic ion-exchangers, asbestos materials, spent lining and heat isolation can be melted themselves in cold crucible at temperatures over 1500oC yielding glass-crystalline or fully crystalline materials as well as vitrified in common with low melted liquid waste salts. Contaminated metal reinforcement to be consolidated by direct either electroslag or induction melting. Small metal parts may be either subjected to oxidizing following by incorporation of oxides in glass and glass ceramics or embedded in glass matrix by nesting in containers following by molten glass filling. The most intimate waste processing takes place in plasma-heated shaft furnace. High temperature treatment of various solid wastes (organic, inorganic and metallic) results in production of metal-slag composite. Waste column in shaft prevents the radionuclide losses. Total radioactive cesium loss does not exceed 1-2%. A chemical durability of this wasteform is approximately the same as glass. High temperature treatment of various types of low- and intermediate-level wastes gives rise to opportunity to replace the

bituminization and cementation processes by melting/vitrification. Volume of vitrified block is smaller than bituminized block by a factor of 3-6 and smaller than cemented block by a factor of 10-20 at the same incorporated activity.

INTRODUCTION

Moscow government organization SIA "Radon" is concerned with collection, transportation, processing and final disposal of low- and intermediate level wastes as well as spent radiation sources in Central Russia.

Until 1990 the basic methods of waste immobilization were cementation (for low salt low level liquid waste), bituminization (for high salt, low- and intermediate level liquid waste), incineration (for burnable waste) and burial (for spent radiation sources and contaminated metal). Incinerator ash as well as another types of inorganic solid wasted were also immobilized by cementation. Above-mentioned methods are not fully safe and do not ensure maximal waste volume reduction coefficient.

Since the middle of 1970-th a low- and intermediate-level waste vitrification process was being developed in SIA "Radon". A works were directed to develop a method of immobilization of liquid waste in borosilicate glass. Natural calcium borosilicate (datolite), sandstone and loam clay were used as glass forming agents (1,2). A Joule-heated ceramic melter was used as basic unit of the vitrification plant. Primarily only liquid waste vitrification was considered. In the beginning of 1980 incinerator ash was proposed to be vitrified (3). Simultaneously boron-free aluminosilicate glasses and glass-crystalline materials (GCM) was proposed to be applied (2,4). A development of the vitrification process was restrained by the absence of reliable, safe and remotely operated melters are being able to be operated at high temperatures with a great life time. In the middle of 1980 such type of melter was found and being under design. This is so-called "cold crucible" - induction melter not containing any refractories and electrodes contacting with the melt. The cold crucible design has been described in detail (5). Since effective melter for the processing of high temperature materials has become available a conception is being similar to minimum additive waste stabilization project (6) was proposed. According to this conception various types of solid inorganic radioactive wastes (contaminated soil, spent ion-exchangers, lining, heat-isolation (for example asbestos materials), incinerator ash etc. should be utilized as additives to liquid waste alkali-containing salts at the vitrification. Until the present time this conception is partially realized. The liquid waste vitrification process was developed and the installation of the industrial-scale plant is being finished now. The solid wastes melting/vitrification processed are under development primarily on the stage of pilot plants. Some processes are under investigation now and the lab-scale plants are under exploitation.

RADON WASTE PROCESSING CONCEPTION

Block diagram of integrated waste processing developed in Radon is shown on Fig.1. Inorganic and organic radioactive wastes coming to Radon may be conventionally classified as liquid inorganic (water solution or suspension of salts), solid inorganic (contaminated soil, spent inorganic ion-exchangers, spent lining and heat-isolation, filter materials), solid organic (wood, paper, plastics, biomaterials, coals, rubber etc.), liquid organic (spent oils and extractives) and metallic (spent radiation sources, contaminated metal) wastes.

Liquid inorganic waste with low salt content is purified by reagent free methods for example electro-dialysis. High-salt waste contains various sodium salts such as nitrate, carbonate, borate (VVER waste), chloride, sulfate, calcium-magnesium carbonates as well as minor quantities of potassium, aluminum, phosphorus, transition metal compounds and organic impurities (Table I). The main radionuclides in this waste are betha-gamma emitters such as Cs-137 and Cs-134 (~90%), Sr-90 (~8%), Co-60 (~1-2%), REE radionuclides (<1%). Alpha-emitters (U,Pu) content is insignificant (<<1%). An average specific gamma-activity is 10-1000 MBq/m3.

Solid inorganic waste contains a very wide set of components and its chemical composition is widely varied. These materials lose a chemically bound water, volatile anions and organic constituent at calcination. The residue consists of high-fusible oxide compounds (SiO_2, Al_2O_3, CaO, MgO, TiO_2, ZrO_2, Cr_2O_3, MnO, FeOn, NiO occurred as oxides, silicates, titanates, spinels, calcium-magnesium phosphates, aluminates, aluminosilicates, ferrosilicates etc. - Table II). These wastes may be contaminated by both betha-gamma- and alpha-emitting radionuclides in comparable quantities.

Solid organic radwaste consists of cellulose (wood, paper, cardboard, clothes),

polymers and plastics (polyethylene, polypropylene, polyvinylchloride, teflon, plymethylmetacrylate, rubber etc.), biomaterials (trial animals, human pathology waste), spent active carbon, graphite, spent ion-exchange resins. More-over, inorganic and metallic constituents (glass and ceramic pieces, cables, reinforcement) occur in solid waste packages. Liquid organic waste is represented by spent oil and contaminated organic solvents and extractives (tributyl phosphate). Common incineration of solid and liquid burnable wastes yields incinerator ash (slag) whose composition depends on inorganic impurities content. The main components are SiO2, Al2O3, CaO, MgO, P2O5 (Table III). Both betha-gamma- and alpha-emitters may be occurred in this waste. Sometimes alpha-emitters are significantly predominant. The specific activity of alpha-emitters in some ash lots may reach to 100 MBq/kg while specific activity of betha-gamma-emitters is only 0.1-1 MBq/kg.

Radioactive metal waste may be divided into spent radiation sources (cesium, strontium, cobalt) and contaminated metal reinforcement (ferrous and non-ferrous metals). Spent radiation sources is incorporated in low-fusible metal matrix. Usually, contaminated lead and tin are used as matrix (7). The ferrous and some non-ferrous (aluminum, zinc, titanium) metal scrap may be oxidized or dissolved in recycled nitric acid and oxides or salts produced may be admixed to liquid inorganic waste (see Fig. 1) to be vitrified. The level of contamination of metal waste may be widely varied.

THE BASIC PRINCIPLES

The process basic principles are based on maximum of waste volume reduction and ecological safety and were assigned as follows:

- the vitrification process must be as simple, safe and reliable as possible;
- the waste oxide content in final product has to be as high as possible;
- minimum non-radioactive additives to waste must be utilized;
- common vitrification of liquid and solid wastes is preferable;
- radionuclide losses during the processing and storage have to be minimized;
- a chemical durability of final product may be similar one to bituminized waste or higher;
- the leach rate of radionuclides from glass or glass-crystalline wasteforms has not to be increased by one order of magnitude after the gamma-irradiation to absorbed dose of 100 kGy (such dose will be accumulated by product for 300 years of storage).

PROCESS UNITS AND EQUIPMENT

Liquid waste vitrification.

Process involves the steps as follows: waste preparation, batch preparation, vitrification itself, glass blocks annealing and off-gas purification with nitric acid recycling.Flow sheet of liquid waste vitrification plant was described in (8,9) in detail. Liquid waste from the waste tank is pumped to interim storage tank to be processed. This waste portion is concentrated in rotary evaporator to salt content of 1000-1100 kg/m3 following by the concentrate transfer to the batch mixer. Contaminated soil (sandstone, loam clay) is used as glass-forming additive to the waste salts. The batch containing clay particles with moisture of 20-25% possess by the plasticity, tyxotropy and is able to be transported within significant distance and to be stored for the long time in sealed reservoirs without segregation. So, the separation of the batch preparation and melting/ vitrification stages may be realized. The batch is fed into the melter by continuous or semi-continuous mode. At the stage of process development Joule-heated ceramic melter was used as basic unit. But then a more advantageous type of the melter was developed. This is high frequency induction melter - "cold crucible" not involving refractories and internal electrodes. At the present time three streams operating at the frequency of 1.76 MHz and output power of 160 kW per each are under operation now. Molten glass is poured into containers located in the pouring zone of a tunnel furnace for the solidified glass annealing. The containers with glass annealed are headed for the final disposal. Off-gas is purified and discharged to atmosphere. From time to time when it is necessary a melt portion is discharged in granulator to be pelletized. Silicate or borosilicate glass granules are used as glass-formers (flux) at incinerator ash vitrification. The main process variables are given in Table IV. The same plant can be used for NPP liquid, for example VVER, waste vitrification. Some problems at batch preparation arising from crystallization of sodium hydroxylmetaborate were successfully resolved by installation of an additional heating of feed line.

Solid waste melting/vitrification.
Solid radwaste contaminated by mainly Sr-90 and alpha-emitters or chemically bonded cesium is suggested to be melted/vitrified in plasma melter. Various constituents of solid radwaste is fed into the plasma melter which is ceramic vessel cooled from outside. Arc torch plasmatrones are used as a source of heating. Waste constituents ratio is maintained so as melt and solidified product to be optimized for the properties. The melt is poured into canisters which then is sealed and headed for ultimate disposal. The plant is supplied by off-gas system. This method is suitable for processing of solid wastes not containing the great quantities of volatile components to avoid a volatilization of radionuclides with off-gas. This is considered as candidate method for processing of contaminated soil, spent inorganic ion-exchangers (zeolites, clay minerals etc.), spent lining (refractory materials) and heat isolation (asbestos materials, glass and ceramic fibers), spent filter materials (silica gel, keramzit etc.), materials formed at Nuclear Power Plant decommissioning (concrete, construction materials). These materials have a high melting points. Process variables are represented in Table IV.
Solid and liquid burnable wastes are subjected to incineration in chamber furnace with fuel heating. Waste decomposition results in gases release and formation of incinerator ash residue including inorganic residue of burnable waste and inorganic impurities finding way into the solid waste packages. Incinerator ash may be also melted/vitrified in the plasma melter. However, its melting point is not so high. Moreover, ash contains significant quantity of cesium radionuclides. The ash processing at very high temperatures commonly with another types of solid wastes can results in elevated cesium loss. A possibility of ash processing by this way is also considered. But at the present time other method of ash processing is employed now. Vitrification of incinerator ash is conducted in induction melter of cold crucible type supplied by dumping bottom for the discharge of collected metal. Borosilicate or aluminosilicate glass granules prepared from vitrified liquid waste are utilized as glass forming additives (fluxing agent) to ash. Total ash oxides content reaches 70-80 wt.%. The principal process variables are given in Table IV.
Before the vitrification in cold crucible, incinerator ash is subjected to separation on coarse and fine fractions. Fine fraction is directly headed for the melter. Coarse fraction is charged into containers and filled by melt from cold crucible. Metallic impurities are collected on the crucible bottom and periodically discharged in containers by a hinging bottom out. Incinerator ash vitrification process in cold crucible was described in detail in (8,9).
Solid waste processing in plasma-fuel heated shaft furnace with liquid slagging
This process offers common treatment of burnable, non-burnable and some fraction of inorganic wastes. Waste packages containing cellulose, biological, polymer, carbon materials and inorganic impurities (glass, ceramics, soil, metal etc.) are charged into the shaft furnace heated by plasma-fuel torches. Organic constituent is subjected to heating, melting, gasification, pyrolysis and decomposed yielding gaseous phase and coke. Inorganic constituent undergoes a complex transformation including solid phase reaction under reducing condition with mineral formation yielding a slag. Off-gas is reburned in an after-burning chamber heated by plasmatrone. Slag is partially melted on the bottom of the shaft at temperature of 1400-1500oC and poured into containers. The main process variables are shown in Table IV. A significant process advantages are the solid waste processing in single unit and very low radionuclide (particularly cesium) loss (1-2% and lower) (10).
PRODUCTS CHARACTERIZATION
As a result of waste processing in cold crucibles, plasma melter and plasma shaft furnace three types of wasteforms are produced: glass, glass-crystalline and predominantly crystalline materials (Table V).
Vitrification of liquid radioactive waste in cold crucible yields a vitreous materials not containing appreciable quantity of crystalline phases. Based on X-ray diffraction and electron microscopy techniques these materials may be characterized as glasses. Infra-red and electron paramagnetic resonance study showed that structural basis of glasses is random network of SiO_4 and AlO_4 or SiO_4 and BO_4 tetrahedra as well as BO_3 triangles for aluminosilicate and borosilicate glasses respectively. Waste elements occur mainly as cation-modifiers (Na, K, Cs, Mg, Ca, Sr, Fe, Co, Ce, Nd etc.). Actinides content in glass is deficient to conclude correctly about their state in glass structure.
Vitrification of incinerator ash in cold crucible yields a glass-crystalline

materials (GCM) where vitreous to crystalline phases ratio is widely varied depending on waste components ratio. An investigation of waste elements partitioning between the phases has shown that most of sodium, potassium and cesium as well as a some fraction of strontium and iron enter the vitreous phase but most of calcium, strontium, iron, cobalt, nickel, rare earth elements occur in various crystalline phases (silicates, silicophosphates, spinels, intermetallic compounds etc.). Alpha-emitting radionuclides (primarily U-238, Pu-239 and Am-241) enter both vitreous and crystalline phases.

Slag product from plasma shaft furnace is glass-crystalline. As in the case of ash vitrification, it contains both vitreous and crystalline (apatite-based) phases. Their ratio is depended on the waste composition. Waste elements partitioning between the phases of this product is similar to one in vitrified ash.

Plasma melting of solid inorganic waste results in formation predominantly crystalline material with minor quantity of vitreous phase. Mineral assemblage is strongly depended on the waste composition. Cesium radionuclides tends to be transferred to the vitreous phase.

The properties of the wasteforms produced are shown in Table V. The greatest losses of radionuclides during the process were observed from plasma melter due to the highest operating temperature and opened melt surface. The least losses are at liquid waste vitrification because the lowest process temperature (1100-1200oC) and the presence of the batch layer on the melt surface.

Cesium radionuclides are the most mobile in all cases. The leach rate of Cs-137 from alumino-silicate glass, containing 40 and 50 wt.% of liquid waste oxides is approximately 3 10-11 and 1 10-9 kg/(m2 s) respectively (measured by IAEA technique (11)). These values are lower by 1 to 3 orders of magnitude than found for bituminized waste with the same incorporated radioactivity. Gamma-irradiation of glass to absorbed dose of 100 kGy (such dose will be accumulated by glass for 300 years of the storage) did not increase the leach rate of cesium more than by a factor of 3-5. The leach rate of cesium from borosilicate glasses is found to be on the same level. The leach rates of strontium, cobalt and actinides were approximately by 1-2 orders of magnitude lower than cesium. They were almost not increased after the gamma-irradiation to dose of 100 kGy.

The leach rate of cesium from GCM produced at the incinerator ash vitrification in cold crucible as well as the waste processing in plasma shaft furnace is slightly lower compared to glass. It is probably connected to partial incorporation of cesium in slag minerals. The leach rates of strontium, cobalt and REE were very low due to their predominant accumulation by slag minerals with high chemical durability. An effect of gamma-irradiation on leach rate of Sr, Co and REE is negligible.

The leach rates of Sr, Co, Fe and REE from fully crystalline materials produced at solid inorganic waste processing are very low and often they are lower than detection limit. The final wasteform has a great radiation stability.

The highest waste volume reduction factor was reached at solid organic waste processing with liquid slagging or ash vitrification. It reaches of 300-500. The volume of vitrified incinerator ash compared to volume of initial ash is less by a factors of 3-5. Volume reduction factor at liquid inorganic waste vitrification is 3 to 4. It is approximately the same at the solid inorganic waste plasma melting. Thus the volume of glass or GCM block is smaller than the volume of waste-bitumen or waste-cement block with the same activity by a factors of 3-5 and 10-20 respectively.

CONCLUSION

The melting/vitrification of low- and intermediate-level radioactive wastes is more preferable method of their immobilization compared to bituminization or cementation. This method converts almost of any types of radioactive wastes in stable, compact and chemically durable form suitable for a long-term storage and final disposal. A significant volume reduction is reached. Common vitrification of the different types of radioactive wastes excludes as far as it is possible utilization of an inactive additives. In that case the waste oxide content reaches up to 100% and the waste volume reduction factor can reach of 3-5 to more than 500.

ABSTRACT

An experimental program has been designed to examine the chemical durability of a large glass composition space derived from the vitrification of simulated wastewater treatment sludges. These sludges represent the majority of low-level mixed wastes currently in need of treatment by the U. S. Department of Energy. The major oxides in these model glasses included SiO_2, Al_2O_3, B_2O_3, Na_2O, CaO, and Fe_2O_3. In addition, three minor oxides, BaO, NiO, and PbO, were added as hazardous metals. FeO was formed during melting. The major oxides were each varied at two levels resulting in 32 experimental glasses. The compositions of these glasses represented the extreme vertices of a five-dimensional "hyperspace." The chemical durability was measured by the 7-Day Product Consistency Test and normalized sodium release rates (NRRNa) of these glasses ranged from 0.01 to 4.99 g.m-2.d-1. The molar ratio of the glass-former to glass-modifier (F/M) was found to have the greatest effect on durability. Glass-formers included SiO_2, Al_2O_3, and B_2O_3, while Na_2O, CaO, BaO, NiO, FeO, and PbO were glass-modifiers. As this ratio increased from 0.75 to 2.0, NRRNa was found to decrease between one and two orders of magnitude. Another important factor was the Na_2O/CaO ratio. As this ratio increased from 0.5 to 2.0, NRRNa increased up to two orders of magnitude for the glasses with the low F/M ratio but almost no effect was observed for the glasses with the high F/M ratio. Increasing the iron oxide content from 2 to 18 mole percent (4 to 35 weight percent) was found to decrease NRRNa about one order of magnitude for the glasses with low F/M but iron

had little effect on the glasses with the high F/M ratio,The durability also increased when 10 mole percent Al2O3 was included in low iron oxide glasses but no effect was observed with the high iron glasses. The addition of B2O3 at levels up to 9 percent had little effect on durability. The effects of other composition parameters on durability are discussed as well. In addition, a strong positive linear relationship between pH and log NRRNa was also observed when leachate pH was greater than 11.

BACKGROUND

The Mixed Waste Integrated Program (MWIP) at the U. S. Department of Energy (DOE) has taken a serious look at vitrification for treatment of low-level mixed waste streams. This was prompted, in part, by the fact that the EPA has declared that vitrification is the Best Demonstrated Available Technology for the disposal of high-level radioactive waste (1). Among the low-level mixed waste streams within the DOE complex, which are under consideration for vitrification, are wastewater treatment sludges at the Savannah River Site (SRS), Oak Ridge Reservation (ORR), Rocky Flats Plant (RFP), and Los Alamos National Laboratory (LANL). These sludges typically contain low levels of radioactive and hazardous metals, water, and additives from the waste treatment process itself. The treatment additives normally include precipitating and flocculating agents such as sodium, calcium, magnesium, and iron compounds or siliceous filter aids from the dewatering process. These treatment additives tend to be soluble in silicate glass and are thus amenable to vitrification.

The compositions of these sludges vary not only according to the original waste but also according to the wastewater treatment process. Stored in M-Area at SRS, is a wastewater treatment sludge from their aluminum and nickel cladding operations. Even though uranium and nickel are the chief radioactive and hazardous species in this waste, the sludge is primarily comprised of sodium hydroxide from the precipitation process and perlite and diatomaceous earth from the dewatering process (2). These two filter aids are comprised chiefly of silica and alumina. Vitrification has already been chosen as the treatment for this sludge (2). Another candidate mixed waste is stored at the West End Treatment Facility (WETF) at ORR. Species targeted for immobilization include uranium and various hazardous metals but the majority of the waste consists of calcium and aluminum hydroxides from the precipitation process (3). An example of a RFP waste is the aqueous sludge from the plutonium recovery operations. In addition to small amounts of uranium, plutonium, and americium and several hazardous metals, this waste consists primarily of sodium, calcium, magnesium, and iron hydroxides from the treatment processes and some siliceous filter aid material from dewatering. The process water from decontamination operations at LANL contains small amounts of uranium, plutonium, and americium. The resulting sludge from the wastewater treatment process is comprised chiefly of calcium hydroxide from precipitation and alumina and silica from the spent filter aids (4). A summary of the major oxide constituents in these mixed wastes is shown in Table I.

Pilot-scale vitrification testing of these wastes is currently being carried out at Clemson University (5). To date, tests have been carried out on surrogates of the M-Area sludge and the WETF sludges. This resulted in the production of glasses which passed the Toxicity Characteristic Leaching Procedure (TCLP) as per the Land Disposal Restrictions (6,7). Formulations for the glass compositions used in these tests included glass-forming siliceous materials such as perlite, diatomaceous earth, and precipitated silica and fluxes such as sodium tetraborate or sodium carbonate. Results, so far, indicate that these sludges may be good candidates for vitrification.

A large glass composition space has been developed in these studies which is intended to bracket most glass products that might result from the vitrification of wastewater treatment sludges currently in storage at DOE sites throughout the United States. Glasses have been prepared with simplified compositions and tested for chemical durability by the 7-Day Product Consistency Test. This should provide not only target composition ranges for each of these waste types but also a data base from which to predict the behavior of glassy products resulting from the vitrification of a wide variety of mixed wastes.

EXPERIMENTAL

Experimental Design

A glass composition space has been developed to serve as a simplified model for

studying the durability of the products which might result from the vitrification of wastewater treatment sludges. This mixture is composed of six variable components SiO2, Al2O3, B2O3, Fe2O3, Na2O, and CaO. Three hazardous species, BaO, PbO, and NiO were also included at fixed levels. These components are classified into three groups depending upon their role in the glass structure. The first group, glass-formers (F), includes SiO2, Al2O3, and B2O3. The second group, glass-modifiers (M), includes Na2O and CaO plus the hazardous species BaO, PbO, and NiO. Lastly, Fe2O3 is grouped by itself. The sum of the six variable oxides always totals 95 mole percent while the BaO, PbO, and NiO levels are fixed at 2, 1, and 2 mole percent, respectively.

With the aid of ternary phase diagrams and exploratory experiments, a large glass-forming region was identified which is illustrated in the F-M-Fe2O3 ternary phase diagram shown in Fig. 1. The four vertices of the region represent the compositions given in Table II, labeled 1, 2, 3, and 4. Note that Fe2O3 content is either 2 or 18 mole percent. These correspond to about 4 and 35 weight percent, respectively. At the low iron level, the ratio of glass-former to glass-modifier (F/M), is either 42/56 or 63/35. At the high iron level, F/M is either 35/47 or 56/26. These four vertices of the glass-forming region can then be represented by two independent compositional variables, the Fe2O3 content and the F/M ratio. This two-dimensional composition space is further expanded by the substitutions of Al2O3 and B2O3 for SiO2, giving rise to two additional compositional variables. B2O3 is added at 0 or 1/7 mole percent of the total glass-former content. Al2O3 is substituted for SiO2 at either 0 or 10 mole percent of the total glass composition. A final compositional variable, the Na2O/CaO ratio, is either 0.5 or 2.0. This increases the number of independent compositional variables to five, resulting in a five-dimensional space consisting of 32 vertices. This composition space is referred to as "Hyperspace." The target glass compositions of these 32 vertices are given in Table III, in oxide mole percent.

The scheme used to identify these glasses is comprised of a number followed by three letters. Two of the compositional variables are identified by the number and the remaining three variables are identified by the three letters. The number refers to either of the four vertices of the two-dimensional space in Fig. 1. But after expansion, these vertices become three-dimensional "subspaces." Subspaces 1 and 2 each contain 2 mole percent Fe2O3 while the compositions in Subspaces 3 and 4 contain 18 mole percent Fe2O3. Subspaces 1 and 3 contain the lower F/M ratios, 42/56 and 35/47, respectively, while Subspaces 2 and 4 contain the higher F/M ratios, 63/35 and 56/26, respectively. These four subspaces are arranged in Fig. 2 to illustrate the vertices of the five-dimensional Hyperspace.

Within each subspace, the Na2O/CaO ratio, the B2O3/F ratio, and the Al2O3 content vary similarly. The first letter is either an L or H depending on whether the Na2O/CaO mole ratio is low or high, i.e. 0.5 or 2.0. The second letter is either O or H depending on whether the B2O3/F mole ratio is 0 or 1/7. The last letter is either O or H depending on whether the Al2O3 content is 0 or 10 mole percent. This scheme is summarized in Table II and all 32 vertices of the Hyperspace are depicted in Fig. 2. To illustrate this scheme, the compositional variables of Glass 1LOO are given as follows: F/M, 42/56; Fe2O3, 2 mole %; Na2O/CaO, 0.5; B2O3/F, 0 mole %; and Al2O3, 0 mole %, while the hazardous metal oxides are always fixed at: BaO, 2 mole %; PbO, 1 mole %; and NiO, 2 mole %. The target oxide compositions for all the glasses are given in Table III. The glasses representing the compositions of all 32 vertices of this five-dimensional space were prepared in order to study their durability. Four of the compositions, 4LOH, 4LHH, 4HOH, and 4HHH, did not result in a homogeneous melt and their compositions had to be modified by lowering the iron content. The adjusted compositions for these glasses are indicated in Table III.

Glass Preparation

Glasses were prepared according to the target compositions in Table III. Reagent grade oxides or carbonates were mixed and then melted in high purity alumina crucibles for two hours at 1350C in a bottom-loaded glass melting furnace manufactured by Deltech, Inc. of Denver, CO. Afterwards, each melt was quenched on a stainless steel plate. The resulting glass was milled to a -35 mesh powder which yielded about 1 kg of glass. The resulting powders were then remelted in platinum crucibles at 1350C for 2 hours and cast into graphite molds to produce disks 40 mm in diameter. The glass disks were immediately placed in an annealing furnace at 450C and allowed to gradually cool to room temperature.

Glass Analysis

The elemental composition of each glass disk was determined by wavelength dispersive XRF spectrometry. Each glass disk was first polished to a 600 grit finish. This analysis was performed on a Rigaku Model 3271 Sequential XRF spectrometer utilizing a "standardless" fundamental parameters software routine developed by Rigaku. The instrument description and conditions have been previously described (8). Selected glasses were also analyzed by wet chemical techniques (9) to confirm the XRF results (10). The redox nature of the glass was estimated by the determination of the Fe2+/Fe3+ ratio (11). In this procedure, a powdered glass sample was mixed with ammonium vanadate to preserve the redox stoichiometry and then dissolved in hydrofluoric and hydrochloric acids. The Fe2+ content was determined colorimetrically after complexation with FerroZine iron reagent. Total iron content was then determined the same way following reduction of any Fe3+ with citric acid. Chemical durability testing was carried out by the 7-Day Product Consistency Test (12). This test measured the concentrations of all nine cations released from the crushed glass (75-150 m) into the leachate after heating in deionized water at 90oC for seven days. The normalized elemental release rate (NRRi), in g.m-2.d-1, was determined from Eq. 1,

Eq. (1)

where Ci is the concentration of element i in the leachate, in gm-3, VL is the volume of the leachate, fi is the weight fraction of element i in the original glass, SAg is the surface area of the glass, and t is leaching time. The SAg/VL ratio is assumed to be 1950 m-1. This PCT test was carried out in triplicate for each glass and the average pH and elemental release results are reported.

RESULTS AND DISCUSSION

The chemical oxide content of the glass products, representing the vertices of the composition space, were determined by XRF spectrometry and are presented in Table IV. These results were compared to results from the analysis of several glasses by wet chemical dissolution followed by ICP and AA spectroscopy (10). This comparison showed no statistical difference in the results between the two analytical methods which confirmed the accuracy of the XRF method. This appears to be one of the first reported uses of XRF spectrometry for an extensive quantitative chemical analysis of waste glasses. The simplicity of this technique over the more tedious wet chemical methods greatly facilitated waste glass analysis and should be exploited more in the future.

The measured compositions are in close agreement with the intended target values from the experimental design. One minor exception is the higher than expected alumina content which is presumably due to corrosion of the alumina crucibles during the first melting step. Another difference is the presence of FeO in the glasses which resulted from reduction of the Fe2O3 during melting. Nevertheless, since the actual glass analyses are similar to the target values, the original target compositional variables will be used in the following discussions. These discussions on durability will focus on the following five composition variables.

- glass-former to glass-modifier ratio (F/M)
- iron oxide content Fe2O3
- Na2O/CaO ratio
- B2O3 to glass-former ratio (B2O3 /F)
- Al2O3 content

The results from the 7-Day Product Consistency Test are presented in Table V as normalized elemental release rate, in g.m-2.d-1. The variability in the individual release rates (NRRi) is due either to selective leaching of one element over another or reprecipitation. However, in phase separated glasses or glasses with crystalline phases, leaching variability can also result from the difference in durability of the different phases present. As expected, the highest release rates are for sodium (NRRNa) and it is these values which probably best reflect the relative durabilities of the various glasses. The NRRNa is presented again in Table VI.

There is no PCT benchmark by which low-level mixed waste glasses are judged for chemical durability. In the absence of a durability criteria, comparisons can be made with high-level waste glasses, for which the PCT test was developed. The durability of several high-level waste glasses, including SRL 131 and SRL 165, have been studied extensively and appear to be quite durable. The NRRNa for these glasses is 0.04 and 0.02 g.m-2.d-1, respectively (13). The Environmental Assessment (EA) glass, which has a sodium release rate of about 1 g.m-2.d-1 represents the minimum

acceptable durability for HLW glass at the Defense Waste Processing Facility at the Savannah River Site (14).

Relationship between pH and Normalized Sodium Release Rate

The relationship between leachate pH and log NRRNa is plotted in Fig. 3. Above a pH of 11, this glass system exhibits a strong positive linear relationship between these two parameters. Below a pH of 11, no such correlation existed and the line in the figure is not fitted to these points. This correlation is not surprising. The leachate pH is expected to increase upon dissolution of silicate glasses because the dissolution mechanism involves the exchange of protons from the leachate for sodium ions in the glass. This results in an increase in pH and an increase in the sodium content of the leachate.

Effect of Glass-Former to Glass-Modifier Ratio on Durability

There are four F/M ratios examined in this composition space. For the low iron glasses, the glass-former to glass-modifier ratios are 42/56 and 66/35. The F/M ratios for the high iron glasses are 35/47 and 56/26. When the corresponding sodium releases for low iron glasses are compared, one finds that the NRRNa increases by up to two orders of magnitude as F/M decreases. Therefore, with low iron glasses, durability is quite sensitive to the F/M ratio and decreases significantly as F/M decreases, regardless of the other compositional variables. Examination of NRRNa reveal that all compositions with low iron and high F/M have comparable durability to the HLW glasses such as SRL 131 and SRL 165 (13). The NRRNa values are all below 0.30 g.m-2.d-1. However, five of the eight glasses with low iron and low F/M ratio have release rates in excess of 1.0 g.m-2.d-1. Therefore, in the vitrification of low iron oxide-containing glasses, special attention must be paid to the F/M ratio in order to ensure a consistently durable product.

For the high iron-containing glasses, the effect that F/M has on durability depends upon additional compositional variables, especially the Na2O/CaO ratio. The F/M ratio significantly affects NRRNa when the Na2O/CaO ratio is high, the durability, however, does not appear to be affected when the ratio is low. This suggests that sodium release rates would not be as sensitive to composition fluctuations in the F/M ratio if the glasses had both a higher iron oxide content and lower Na2O/CaO ratios.

The sodium release rates for all glasses with the high F/M ratios are all less than 0.30 and most are below 0.10 g.m-2.d-1. The durability of these glasses is comparable to that of the HLW glasses. The NRRNa for glasses with low F/M ratio and high Na2O/CaO ratios range between 0.96 and 4.99 g.m-2.d-1.

Effect of Iron Oxides (FexOy) on Glass Durability

The majority of glasses in this composition space had iron oxide contents of either 2 or 18 mole percent. The FeO and Fe2O3 content in these glasses are given in Table IV. The resulting FeO to FexOy ratio in these glasses ranged from 0.08 to 0.49 indicating that the glasses were mostly oxidized. No attempt was made to examine the effect of iron redox state on glass durability.

The NRRNa values for the glasses with high iron content were all below 0.10 g.m-2.d-1, except for the glasses that had both low F/M and high Na2O/CaO ratios. These four glasses had sodium release rates near or above 1.0 g.m-2.d-1. The low iron glasses displayed a similar trend; the majority of the release rates were below 0.29 gm-2d-1, again however, the glasses with both a low F/M ratio and a high= Na2O/CaO ratio all had NRRNa values above 2.5. In addition, the low iron glasses, 1LOO and 1 LHO, had NRRNa values of 1.16 and 0.65, respectively.

The effect of increasing the iron content on release rates is discussed. For the glasses with a high F/M ratio, i.e. Subspaces 2 and 4, the iron content has little affect on NRRNa. The only measurable effect is with the high Na2O/CaO ratio glasses, but the effect is minimal. For the glasses with a low F/M ratio, i.e. Subspaces 1 and 3, the durability does show a significant dependency on iron content, the NRRNa decreases as the iron content increases. So increasing the iron content from 2 to 18 mole percent does significantly reduces leaching if the F/M is 0.75; but there is little effect if the F/M ratio is up around 2.0.

Effect of Na2O/CaO Ratio

The Na2O content in the 32 glasses of this study ranges from about 6 to 30 weight percent. The glasses with the Na2O content between 6 and 12 weight percent, all have release rates below 0.1 gm-2d-1 while the glasses with higher soda content tend to have considerably higher release rates.

The glasses all have Na2O/CaO mole ratios of either 0.5 or 2.0. Glasses with the

lower ratio tend to have lower release rates, as expected. The effect of the Na2O/CaO ratio on the NRRNa is variable and depends upon the F/M ratio in the glass. When the F/M ratio is high, the Na2O/CaO ratio has little effect upon the release rate, i.e. all the glasses have relatively low NRRNa. But when the glass-former content is low, the Na2O/CaO ratio has a strong influence on durability as discussed previously. Values for NRRNa tend to increase one to two orders of magnitude as the Na2O/CaO ratio increases from 0.5 to 2.0.

Effect of B2O3

In half of the glasses in this study, B2O3 was substituted for SiO2 at levels between 6 and 10 weight percent; the other half contained no B2O3. The addition of B2O3 appears to have no significant effect on durability. Since B2O3 has a tendency to lower glass viscosity, advantage can be taken of this to improve melt processing without sacrificing durability. The effect of adding B2O3 at levels above 10 weight percent were not examined but are expected to decrease glass durability.

Effect of Al2O3

Aluminum oxide has been substituted for SiO2 at levels between 11 and 18 weight percent. The glasses without added Al2O3 typically contain less than 2 percent, resulting from corrosion of the alumina crucible during the first melting procedure. The effect of added Al2O3 on release rates is dependent upon the iron content in the glass. The durability is improved when Al2O3 is added to the low iron-containing glasses but showed no effect when added to the high iron-containing glasses.

CONCLUSIONS

A large glass composition space has been developed which is intended to bracket most glass products that might result from the vitrification of wastewater treatment sludges currently in storage at DOE sites throughout the United States. These surrogate glasses attempt to simulate the actual waste glasses with nine of the more representative oxides. The major oxides include SiO2, Al2O3, B2O3, Fe2O3, Na2O, and CaO. In addition, three minor oxides, BaO, NiO, and PbO, are included to represent hazardous metals. The levels of the six major oxides were varied in this mixture and, as a result, five independent variables were selected. These five composition variables included the glass-former to glass-modifier ratio (F/M), the iron oxide content, the Na2O/CaO ratio, the B2O3/F ratio, and the Al2O3 content. Glasses were made whose compositions corresponded to the 32 vertices of the resulting five-dimensional "hyperspace." The chemical durability of these glasses were determined by measuring the sodium release rates (NRRNa) by the 7-Day Product Consistency Test.

A comparison of the normalized sodium release rates for these glasses showed that their chemical durability can be quite sensitive to changes in the F/M ratio, the iron oxide content, and the Na2O/CaO ratio. The F/M ratio had the greatest effect on durability for the glasses examined in this study. As F/M increased, the durability of all the glasses improved by one to two orders of magnitude. Furthermore, among the glasses with a low F/M ratio, it was found that raising the Fe2O3 content from 2 to 18 mole percent (4 to 35 weight percent) increased the durability by about one order of magnitude. On the other hand, increasing the Na2O/CaO ratio from 0.5 to 2.0 decreased the durability about one order of magnitude. The B2O3 content had very little effect, while the effect of Al2O3 was mixed, with some glasses showing improvement in durability and others showing no change.

All of the glasses with the F/M ratios greater than one, had normalized sodium release rates below 0.3 and most were below 0.1 g.m-2.d-1. These release rates were comparable to the durable SRL 131 and SRL165 HLW glasses from the Savannah River Site. Glasses with the lower F/M ratios were much less durable, however, one durable composition region was detected for glasses with a low F/M ratio. It was found that relatively durable glasses could be produced with a low F/M ratio if they also had a low Na2O/CaO ratio and contained 10 mole percent Al2O3 (~14 weight percent).

This sensitivity in glass durability to composition fluctuations necessitates the need for careful control of the glass composition during vitrification. Furthermore, these waste streams can be quite inhomogeneous. And this inhomogeneity can lead to significant deviations from the target glass compositions resulting in production of a glass with poor durability. And so, implementation of a strategy to control glass composition is mandatory, if glass durability is to be consistently maintained during vitrification.

This paper reports the first in a series of studies intending to fully characterize the durability of a large range of glassy products which might result from the

vitrification of wastewater treatment sludges. Work is presently underway to prepare and test additional glass compositions within this space and to test these glasses after they have been heat treated to simulate slow cooling rates and greater devitrification. All of these glasses are being further analyzed for phase composition in an effort to characterize the effect of cooling rates and devitrification on durability. Future work will also report on the TCLP results of these glasses. Finally, an attempt will be made to develop an empirical model to predict durability from glass composition and cooling rate.

ACKNOWLEDGMENT

The authors would like to thank Dr. Arthur Jurgensen for the elemental analysis of the glasses by x-ray fluorescence spectrometry. We also thank David Bennert for his support. ABSTRACT

This program demonstrates that waste forms composed of a glass-crystal composite can be applied to a much wider range of waste streams than those amenable to homogeneous glass production alone. With this approach, radioactive constituents (U and Ce, the latter as an analogue for Pu) and hazardous metals (such as Cr, Cd, and Ni) have been strongly partitioned into corrosion-resistant mineral phases, with Pb also showing limited incorporation in minerals as well. A variety of corrosion tests have shown the glass-crystal composite to be more durable than high-level nuclear waste glasses, such as SRL 202.

INTRODUCTION

Waste forms made of a glass-crystal composite (GCC) are being evaluated at Argonne National Laboratory for their potential use in the disposal of low-level nuclear and hazardous waste materials. This waste form is being developed within the framework strategy of DOE's Minimum Additive Waste Stabilization (MAWS) Program. The MAWS protocol involves the blending of multiple waste streams to achieve an optimal feed composition, which eliminates the need to use large amounts of additives to produce an acceptable waste form. The GCCs have a particularly useful utility in their ability to incorporate waste streams with high metal contents, including those that contain large amounts of scrap metals, and in their potential for sequestering radionuclide and hazardous constituents in corrosion-resistant mineral phases.

This paper reports the results from tests conducted with simulated feeds representative of potential DOE and industry waste streams. Topics addressed include the partitioning of various radioactive and hazardous constituents between the glass and crystalline portions of the waste form, the development of secondary phases on the altered sample surfaces during corrosion testing, and the fate of waste components during corrosion testing, as indicated by elements released to solution and microanalysis of the reacted solid samples.

EXPERIMENTAL

Sample Casting

Eighteen samples representing a wide range of potential waste streams and contaminant compositions have been produced in crucible melts thus far. Test samples were formed by blending pre-dried (at 500C) Idaho National Engineering Laboratory (INEL) soil with various chemical additives to derive a desired sample composition (Table I). Simulated amounts of EPA listed toxic and carcinogenic metals (Pb, Cr, Ni, Cd, and Cu) and the radioactive elements U and Ce (the latter as a surrogate for Pu) were also added to the samples.

The sample mixtures were powdered in a ball mill and then added to a 99.8% Al_2O_3 crucible for melting. Samples were heated to temperatures of 1300 to 1500C for 40 min, cooled to 1000 to 1200C, held at this temperature for three hours, and then allowed to cool in the test furnace to room temperature. The 3-h temperature hold saturated the melt with respect to certain crystal phases, allowing crystal formation to proceed at an accelerated rate. Times and temperatures used for individual melts are indicated in Table I. All samples were subsequently annealed at 500C for one hour to remove thermal stresses that built up during solidification. Volatilization of materials was noted by comparing the weight differences of the starting powder and final sample weights. Results from chemical analysis of the solidified samples will be compiled in the future to determine which constituents were lost and in what proportions.

Test Procedures

The GCCs have been subjected to vapor hydration tests at 200C and Product Consistency Tests (PCT) at 90C so that the GCC durabilities could be compared against other waste forms. Toxicity Characteristic Leaching Procedure (TCLP) tests were also performed to determine the applicability of GCCs for EPA licensing as a

nonhazardous waste.
Disk-shaped monoliths (1-mm thick, 10-mm dia), polished to a 600 grit finish, were used in the vapor hydration tests. Tests were initiated by suspending two monoliths by a Teflon wire inside a 304L stainless steel Parr reaction vessel (22 mL capacity) held closed by a compression fitting. High-purity deionized water was added to each vessel in an amount (0.25 mL) necessary to achieve 100% relative humidity at test temperature, but limited enough to prevent dripping of condensed fluid from the samples. This latter aspect was deemed necessary to prevent the dripping of leachate from the samples and a resultant loss in corrosion products. After completion of the prescribed test interval, the sample vessels were removed from the oven, cooled in an ice bath, and opened. Reacted sample monoliths were examined first by optical microscopy, followed by detailed scanning electron microscopy/energy dispersive X-ray spectroscopy (SEM/EDS), X-ray diffraction (XRD), and analytical electron microscopy (AEM) analysis. Surfaces of the altered samples were characterized with respect to both the fate of the primary crystalline and glassy components of the waste form and the formation of alteration phases.
The 200C temperature and high ratio of sample geometric surface area/liquid volume (SA/V) (~106 m-1) used in these tests accelerate the reactions occurring at the sample surface and thereby induce the formation of a long-term corrosion sequence of minerals during a relatively short interval. Previous studies have shown that 50,000- to 140,000-year alteration trends produced during volcanic glass alteration in near-surface (~25C) geologic environments may be replicated in 200C vapor hydration tests in as little as 21 days (1). This similarity also suggests that the reaction mechanism controlling the corrosion of glass remains unchanged within the temperature range of 25-200C.
Static corrosion tests used in this study followed a modified format of the PCT. Sample fractions of 100 to 200 mesh size (75 to 150 mm) were reacted in deionized water, in sealed Teflon vessels, at a SA/V of 2000 m-1, a temperature of 90C, and for periods of 7, 28, and 91 days. The sample size fraction used in these tests produced particles with mean diameters that were often less than those of the primary melt crystals. Under these circumstances, the corrosion rates of the waste form, as determined during the PCTs, may be artificially accelerated by increasing the exposed SA/V ratio of the crystal. For this reason, the effect of crystal size on corrosion rates will be determined largely from the data generated in the vapor hydration tests.
After completion of the prescribed PCT intervals, sample aliquots were withdrawn, at test temperature, for various solution analyses. Carbon content was measured with a Dohrman Total Carbon Analyzer, cations by inductively coupled plasma/mass spectroscopy (ICP/MS), and pH with a combination electrode. All analytical measurements, including pH, were made at room temperature. Cation accuracy and precision are both <10%, carbon accuracy is <5%, while analytical drift over the time period required for pH analyses is typically less than 0.02 pH units. Reacted surfaces of a limited number of PCT solids were also examined by SEM/EDS and AEM analysis.
The TCLP tests were conducted at room temperature following established EPA testing procedures (2). This test measures the leachability of eight toxic metals (Ag, As, Ba, Cd, Cr, Hg, Pb, and Se) after reaction in an agitated sodium acetate buffered solution for 18 hours. The TCLP tests are used to determine whether a sample meets EPA regulatory release requirements for hazardous wastes, which are set at a solution concentration equal to 100X the established drinking water limits for each hazardous metal. The leaching characteristics of nickel were also examined, with the land-based disposal limit for this element set as the targeted leachate level.
RESULTS
Waste Form Composition and Mineralogy
The unaltered GCC samples can best be described as porphyritic, with relatively coarse-grained crystalline phenocrysts suspended in a predominantly glassy matrix. The mineral phases exhibited a variety of shapes, including blocky, trigonal, lath, and round-shaped crystals. The distribution between glassy and crystalline regions was generally nonuniform, with both glass- and crystalline-rich regions occurring in most samples. Sample compositions with very high proportions of crystalline phases sometimes resulted in samples that fractured during sample preparation.
The crystalline phases that formed were dominated by the spinel group minerals. The SEM/EDS compositional analysis suggests that magnetite (Fe3O4) was the most common

spinel formed, with this phase incorporating variable amounts of Cr, Ni, Al, Ca, Zn, Cd, and Ti in its lattice structure. Other types of spinels formed when the melt composition was varied. These additional spinel phases included hercynite ($FeAl_2O_4$) in Fe- and Al-rich melts, and franklinite ($ZnFe_2O_4$) in Fe- and Zn-rich melts. Zirconolite ($CaZrTi_2O_7$) and a Zr-U oxide phase were formed in melts to which Zr and Ti were added. Zirconolite was able to incorporate up to 11 elemental wt.% uranium and 7 wt.% cerium in its mineral structure, while the Zr-U phase contained up to 10 wt.% uranium and 3 wt.% cerium. In melts where zirconium was not added, uranium was incorporated in unidentified uranium oxide, U-Ca-oxide, or U-Na-Ca-oxide phases. In addition to zirconolite, other titaniferous phases were formed, including rutile (TiO_2), titanite ($CaTiSiO_5$), perovskite ($CaTiO_3$), an unidentified Fe-Ti-oxide [possibly pseudobrookite (Fe_2TiO_5)], and unidentified Ca-Fe-Si-Ti and Ti-Ca-Ce-Fe phases. Perovskite also contained up to 9 wt.% cerium and trace amounts of uranium. Anorthite [a calcium-rich feldspar ($CaAl_2Si_2O_8$)] was formed in melts with high Ca-Al contents. Trace amounts of lead have been detected in anorthite, while the feldspar minerals also have the potential to incorporate barium, a hazardous element; and sodium and potassium, two elements that generally reduce the durability of waste glasses through the formation of nonbridging oxygen bonds. Augite [$(Ca,Mg,Fe,Ti,Al)_2(Si,Al)_2O_6$)] was also detected in some samples, occurring as elongated crystals with a density and composition not too unlike the surrounding glass matrix material.

All glass matrix regions were dominated by the presence of Si, with lesser amounts of Al, Ca, Fe, and K. The residual glass matrix was enriched in Si and Al relative to the compositions of many high-level waste glasses, a feature that is expected to result in the formation of a relatively durable glass matrix. The following constituents were detected in trace amounts: Ti, Mg, Cr, Ni, Mn, Zr, Na, Zn, Cd, U, Pb, and rare earth elements (including Ce). It is not known for certain if all of these elements were actually dissolved in the glass network or were present as crystals that were too small to be detected during SEM/EDS analysis (<100 nm). The AEM examinations of glass-rich regions from some samples revealed the presence of tiny crystals from regions of samples that appeared to be completely vitreous during the preceding SEM examinations. These crystals probably formed as the melt was allowed to cool to room temperature.

Bulk distribution ratios were calculated for Cr, Ni, Fe, U, and Ce, as determined by using SEM/EDS analysis of the crystalline and glassy regions of the samples. These results indicate that Fe, Ni, and especially Cr are strongly partitioned into the spinel crystals (Table I). Uranium and cerium were also strongly partitioned into crystals, especially when zirconolite formation was induced by the addition of Zr and Ti to the melt.

Durability Testing

The release of selected components from the GCC samples during PCT runs are presented as normalized elemental release values (NLi) in Fig. 1. These values reflect the release of a specific element i normalized to both the SA/V ratio of the test and the proportion of element i contained in the solid material. Results can thus be used to directly compare release rates from waste materials with different compositions and tests conducted at different SA/V ratios. Note that the NLi values can be influenced by several parameters including the release rate of an element from the waste form, precipitation of alteration minerals containing element i, and/or differential release rates from primary phases contained in the GCC wastes. The PCT results indicate that the GCC waste has favorable NLi rates when compared to simulated nuclear waste materials, such as the SRL 202U high-level nuclear waste (HLW) borosilicate glass. The NLi rates for most alkali and alkaline earth elements overlap with those of the SRL 202U glass. For example, NLCa data from the GCCs are nearly identical to those of the SRL 202U glass (Fig. 1a), while NLK values also overlap with the SRL 202U glass but display more variability among the different samples (Fig. 1b). Release rates for both Si and U are significantly lower than those of the SRL 202U glass (Figs. 1c and 1d). Silicon is primarily contained within the glass matrix, so its reduced NLi reflects a more durable glassy material in the GCCs relative to the SRL 202U glass. The low NLSi exhibited by the GCC tests can be attributed to the solution pH values that result from the leachate being in contact with the samples. The leachate attains pH values of 8.9 to 9.9 for most GCC samples during test periods of 7 to 182 days. A pH of ~9 represents a minimum for the solubility of silicic acid in these systems. Thus, the lower pH values in these

tests is reflected by lower silicon release rate. By contrast, the pH for the SRL 202U glasses averages between 10.0 and 10.4 for test periods of 7 to 540 days. These slightly higher pH values have resulted in a greater degree of glass dissolution relative to the tests with the GCCs.

The NLU values from the GCC samples are also significantly reduced relative to the rate of the SRL 202U glasses (Fig. 1d). This trend may reflect the reduced solubility of the silicon-rich glass matrix as discussed above or, alternatively, the incorporation of uranium in corrosion-resistant mineral phases. This latter hypothesis was further examined by comparing NLU values from two samples with a similar overall composition, except that one sample (G2) had Zr and Ti added to induce the formation of zirconolite, while the other (G4) did not. A comparison of the NLU patterns for the two samples indicates that uranium release was reduced by a factor of 5 to 15 when the uranium was preferentially partitioned into the zirconolite phase (Fig. 2). The release of Ca and Ti was also significantly reduced, while cerium was only slightly reduced as a consequence of its incorporation in zirconolite. Both the G2 and G4 samples also have NLU values that are still lower than those of the SRL 202U glass doped with a similar concentration of uranium.

Results from vapor hydration tests also suggest that the GCCs are a durable waste form. Overall appearances of the reacted sample surfaces after testing and the compositions of the alteration phases suggest that the iron-rich crystalline phases are relatively inert to chemical attack when compared to the glassy matrix. On most samples, the slightly corroded crystals are surrounded by depressed surface regions that mark the locations of more rapidly corroded glass matrix regions. The minor alteration of the spinel phases that does occur probably results in the formation of iron-oxide precipitates on the sample surface.

The SEM/EDS investigations revealed only minimum development of secondary reaction products on the G2 samples at 7, 28, and 91 days, with most of the phases being composed of clays, iron oxides, and calcite ($CaCO_3$). Radionuclide and hazardous element contents in these alteration phases are also minimal, indicating that these components are being retained in the GCC waste form. Lead was present in trace quantities in the alteration phases deposited on samples in which lead was added, a feature that probably reflects its release from the glass regions during corrosion. Cerium was also present in alteration phases on samples where the glass matrix was the primary host for this element. When crystalline phases such as zirconolite and perovskite hosted cerium, its release was diminished to the point where it was no longer detected on the sample surfaces. Similarly, uranium was not detected in any of the alteration phases observed. This suggests that uranium was retained in the primary waste form, despite the very corrosive conditions of the tests.

The TCLP results indicate that release rates for hazardous elements are generally below EPA established limits for hazardous waste declassification (see Fig. 3 for Ni, Pb, Cd, and Cr results). Exceptions occur when waste loadings of specific elements are very high, for example, 16% NiO (sample G19) and 20 to 25% CdO (samples G14 and G15). These high metal concentrations were included in the study to aid in identifying host crystals and to bracket the maximum waste loadings allowed for the respective hazardous elements. These concentrations are not necessarily representative of the compositions expected for DOE waste streams.

DISCUSSION

Experiments to date have shown that simulated waste streams containing Cr, Ni, Pb, Cd, U, and Ce (as a surrogate for Pu) can be incorporated into GCCs, with all elements except lead being strongly partitioned into the crystalline phases. The results from this study indicate that Cr and Ni are partitioned almost exclusively into spinel crystals that are resistant to chemical attack, resulting in these elements being immobilized in the waste form. Similarly, U and Ce can be isolated in crystalline phases such as zirconolite and perovskite. Crystal phases also have the potential to incorporate a wide array of other hazardous elements into their structures, including Ag, As, Ba, and Th, and glass network-breaking elements, such as Na, F, S, and P. With homogeneous glass waste forms, the addition of significant quantities of metal and network-breaking elements may significantly diminish the waste form durability. With the GCCs, however, these elements are incorporated into a variety of crystalline materials, thereby leaving the residual glass material enriched in silicon. High-silicon glasses have been shown to be resistant to corrosive processes.

Of key interest to this study is the fate of the various hazardous and radioactive

components during exposure of the GCC waste form to corrosive fluids. Results from durability tests indicate that the GCC has corrosion- resistant properties that are similar to, or better than, those of simulated HLW glasses. Solution results from static PCTs show NLi rates for Al, Na, K, and Ca that are comparable with those of SRL 202U glass reacted under similar test conditions, while NLi values for Si and U are significantly lower than those of the SRL glass. Samples that have incorporated uranium into crystalline phases, such as zirconolite, have the lowest overall NLU levels. This reflects the high durability of the crystalline phases relative to predominantly glassy materials (Fig. 2).

Sample reactions on the vapor hydration tests offer an interesting insight into the mobility of the GCC components during corrosion testing. Elements that are released from the altered samples in these tests rapidly accumulate in the thin film of water that is present on the sample surface. Various minerals will precipitate in this film of water, as their respective solution concentrations increase, thus recording the preceding release of elements from the solid samples. Hazardous and radioactive elements that are partitioned into the crystalline phases during melt solidification are nearly absent from the altered sample surfaces, and this indicates a strong retention by the primary crystal hosts. Elements that are present largely in the glass matrix occur in greater abundance in secondary alteration products on the sample surface but still are relatively uncommon, and this indicates a high degree of chemical durability for the glass matrix as well.

CONCLUSIONS

The test results indicate an exceptional potential for the development of a low-cost MAWS process for disposing of mixed waste streams with high metal content. This process would form a highly durable waste product that should easily exceed the minimum disposal performance criteria. The production of a durable tailored GCC waste form depends on proper processing parameters, such as waste stream composition, melt temperature, and cooling rate. However, tests conducted thus far suggest that these processing parameters are relatively flexible and allow GCCs with acceptable durabilities to be produced with a minimum of processing requirements and additives.

Crystalline phases formed in GCC wastes include spinels, zirconolite, perovskite feldspars, and Fe-Ti oxides. Most of these phases are also resistant to aqueous corrosion; thus, their formation is responsible for the low amounts of hazardous and radioactive elements released from these waste forms during sample alteration. Results from durability tests indicate that the GCC waste form has corrosion-resistant properties that are similar to, or better than, those of simulated HLW glasses such as SRL 202U.

The glass fraction of the GCC serves as a binder for the crystalline phases and also incorporates elements excluded from the crystal structures. Minor amounts of U and Ce, as well as the majority of the lead present, have been detected in the glass matrix. The release rates of glass matrix components to solution also appear to have been lowered relative to tests with high-level waste glass, presumably because of fractional crystallization processes that increased the Al and Si concentrations of the residual glass matrix material.

The reduction in waste volumes associated with the elimination of the need for glass additives during GCC formation will be a great economic benefit during the disposal of large volumes of low-level radioactive waste materials. The high durability of the GCC waste form also indicates excellent potential for its application in the processing to other DOE waste streams, including intermediate- and high-level nuclear waste materials; DOE wastes with high levels of Na, P, S, Ba, and As; and plutonium-laden defense wastes associated with weapons production and dismantling activities. The use of a GCC waste form offers an attractive and economical alternative to waste disposal by using homogeneous vitreous materials.

VENDOR VITRIFICATION PROGRAMS AT THE FERNALD ENVIRONMENTAL MANAGEMENT PROJECT

Ian S. Howard
Bradley W. Bowan II
GTS Duratek, Inc.

ABSTRACT

During the past three years, two separate and distinct low-level waste vitrification projects have been initiated at the Fernald Environmental Management Project: The Minimum Additive Waste Stabilization (MAWS) demonstration project and the CRU 4 Pilot Plant program. The projects are technically and contractually distinguishable and serve two very different needs in the DOE complex. This paper contrasts the technical, operational, and contractual differences associated with each project and highlights some operational and managerial lessons learned during the MAWS project which may be applied to other DOE vitrification projects.

INTRODUCTION

Historically, vitrification's acceptance as a solution to stabilizing nuclear waste has been limited to high level programs because of the costs associated with fully remote operations and chemical additives required to produce a stable waste form. These high level waste glasses characteristically contain small fractions of waste and large fractions of additives. Where the overriding concern is stabilization, as it is with high level nuclear waste, the costs associated with this relatively inefficient process are acceptable. In comparison, the sheer volume of the low level nuclear and hazardous waste in the DOE complex makes the costs associated with the high level approach of "additive" vitrification impractical, especially in times of decreasing federal agency budgets.

The MAWS project at Fernald was initiated to demonstrate that one of the limiting aspects of vitrification for low level wastes, additive costs, could be overcome through an innovative blending of existing site waste streams where the glass forming potential of various wastes is exploited. For GTS Duratek, this project included the installation, startup, and operation of the DuraMelterTM 300 system which is comprised of feed, melter (operating nominally at 1100oC), and off-gas sub-systems. The blending theory increased the waste fraction of the final glass product to an excess of eighty percent, thus dramatically reducing the costs not only for purchased additives, but also the variable costs for operations and disposal. In addition to the minimum additive savings, further economies were realized through the large volume reduction typical of vitrification. The other element of the program which increased efficiency was the integration of an aggressive pre-treatment of the soil waste stream provided by Lockheed Environmental Services that concentrated the contaminants in a vitrifiable soil fraction and returned a large percentage of the initial waste stream back to the site as clean soil.

MAWS is the synergistic use of multiple remediation technologies and waste stream combinations to produce the smallest amount of final vitrified waste form practical thereby significantly reducing the life-cycle cost of the process. GTS Duratek believes it is a concept that has significant potential for other sites within the DOE. That complex-wide potential is currently being quantified at the Catholic University of America's Vitreous State Laboratory through a separate contract from Argonne National Laboratory.

In contrast to MAWS, the CRU 4 Pilot Plant program was initiated to remediate a single identified waste stream of concern to the stakeholders and regulators. The silo wastes at Fernald contain large amounts of sulfates, heavy metals, and radioactive isotopes emanating Radon which make higher temperature melting desirable. Not only are the melter design assumptions different for the silo waste, GTS Duratek's scope is also different for this project with the company currently contracted to provide only the melter and glass handling system with a limited startup period following construction. Operation of the Pilot Plant will be the responsibility of the site management contractor, the Fernald Environmental Restoration Management Corporation (FERMCO). The higher design temperatures specified for this melter introduced many engineering and materials challenges that had to be solved. The differences between the two melter systems are highlighted in the following paragraphs.

TECHNICAL DIFFERENCES

The MAWS DuraMelterTM 300 System

As mentioned above, the DuraMelterTM 300 system at Fernald consists of a feed system, melter, and off-gas sub-systems. The feed system for the melter includes two 4,000 gallon feed tanks that are independently mixed by both propeller mixing (located at the top of the feed tank) and recirculation pumping at a rate of about 85 gallons per minute. For the recirculation train, feed is removed from a port at the bottom of the feed tank and returned to the top of the feed tank. These two sources of mixing action decrease settling in the tank and allows one of the mixing sources to be removed from the system for maintenance, if necessary. A small fraction of the feed is drawn off the recirculation line by the main feed pump which pumps the feed slurry into the melter. The slurry is fed into the melter through a water cooled feed tube at a rate of about 600-800 ml/minute.

The feed tanks have been scaled up from a 55-gallon drum for the laboratory version, the DuraMelterTM 100 to two 4,000 gallon tanks for the DuraMelterTM 300. Each tank provides sufficient feed for 8 to 10 days of operation enabling one tank to be prepared while the second supports processing. The challenges encountered include recirculating an abrasive slurry, settling in the feed lines, and batching-up such large volumes of slurry.(1)

The DuraMelterTM 300 is sealed, joule-heated melter operating at a nominal temperature of 1100oC and is equipped with a glass forming gem machine installed under the discharge chamber. Gems resemble flattened marbles and are about 0.5" in diameter. The gem machine cuts the discharged molten glass stream with a gear-like cam and deposits the glass on a cooling disc. The DuraGemsTM rotate about 270 degrees on the cooling disc where they are then scrapped off the disc and fall into a 35-gallon sealed drum. The purpose for the gem machine is to provide for rapid cooling of the discharged glass. This is essential for the glass to cool quickly due to the high concentrations of fluoride, found in the pit wastes, which crystallize when allowed to cool slowly (bulk discharged). This was demonstrated in a fluoride run that was performed in early January. The glass that was discharged directly into the 35-gallon drum crystallized and the glass that was discharged into the gem machine produced glass DuraGemsTM which showed no evidence of crystallization.

Several campaigns were performed on the DuraMelterTM 300. The first slurry feeding of the melter began in September 1993. The feed composition was a borosilicate recipe that did not require the full use of the off-gas treatment system. This campaign was the first shakedown run. During the campaign, the first production DuraGemsTM were made. After the run, modifications to the system were made, including modifying the feed system, gem machine, and off-gas system. The first campaign using the off-gas treatment system occurred in January 1994. During that run, a fluoride containing feed, similar to the radioactive composition without the uranium or thorium, was fed into the melter. This glass was bulk discharged during compositional turnover; fluoride gems were produced after 72 hours of continuous feeding.

The results of the first fluoride run were informative and impressive. Two objectives of the run were to 1) provide FERMCO with information to perform a safety assessment on the melter system and 2) to perform a shakedown with the operation of the full off-gas system. The run was 75 hours long with continuous feeding for the entire time. There were no major complications during the run. The off-gas system operated well within the design specifications. Feeding was maintained at a rate between 600-800 ml/min (0.16-0.21 gal/min). The cold cap coverage was about 85-95%

throughout the run and was maintained by controlling the feed rate, bubbling rate, and glass pool temperature. The quantity of fluoride retained in the glass was the highest ever for any DuraMelterTM run: 76.6% of the fluoride fed into the melter was retained in the glass. At steady state conditions, this number is expected to be about 74%.

A significant factor contributing to the high fluoride retention was the constant cold cap of 85-95%. Data gathered during an earlier DuraMelterTM 10 run showed that the larger cold cap helped to maintain the fluoride in the glass. The fluoride composition was about 97% turned over from the initial borosilicate composition after 57 hours of continuous operation.

The glass pool temperature was maintained at about 1090C with the plenum temperature at about 630C. The latter temperature is controlled by the lid heaters but is also affected by the size of the cold cap. The off-gas system which scrubs the acid gases and traps particulates also reduces the temperature of the gas stream from the melter. For example, the off-gas entering the quencher was approximately 240oC while the air entering the scrubber was reduced in temperature to about 185oC. The moist air exiting the scrubber was about 38C.

Analysis of the composition of the quencher and scrubber solutions was performed on samples taken throughout the run. Once the quencher solution reaches saturation with respect to fluoride, the remaining 26% fluoride can be recovered as sodium fluoride and recycled into the subsequent feed batch. After 20 hours into the run, the concentration of fluoride averaged 0.7 molar in the quencher and 0.12 molar in the scrubber.

During the period of August through November 1994 the melter successfully processed over 14,000 liters of actual high fluoride, low level radioactive and hazardous mixed waste from Pit 5 and 3,300 kilograms of uranium-contaminated soil from the site in four radioactive campaigns. The analytical results from the radioactive campaigns are not yet available.

Part of the proof of the MAWS concept is in the results of the leach testing of the glass and of the emissions from the melter during processing of radioactive wastes. The Toxicity Characteristic Leaching Procedure (TCLP) results from processing actual FEMP wastes on the laboratory located DuraMelterTM 100 show that the eight (8) RCRA metals were well below the EPA Limit (Table I).

Retained in the glass are 99.8% of the lead, 99.1% of the barium, and 99.8% of the uranium and thorium. Chromium detected in the off-gas system is largely due to the chromium in the refractory bricks and Inconel used in the construction of the melter. Over 70% of the chromium is retained in the glass and all but 0.06% is captured for recycling into the feed. Emissions measured during the radioactive campaign on the DuraMelterTM 100 show that the concentration of the RCRA metals, fluoride, uranium and thorium are below 25 ppb and most are less than 1 ppb (Table II).

The fluorine was measured to be less than 25 ppb; for comparison, the OSHA limit is 3 ppm. The analysis of samples from the DuraMelterTM 300 radioactive campaigns is expected to yield similar results.

The CRU-4 Pilot Plant Melter and Gem Machine

The scope for the CRU 4 Pilot Plant program is limited for GTS Duratek to designing and delivering a melter and gem machine, supervising the construction, and providing startup testing oversight. This melter will be a compliment to the balance of the Pilot Plant design which is currently under construction at the Fernald site and will provide the operating contractor with relevant data requisite for full production scale facility design.

Nominally, the DuraMelterTM 1000-HT is capable of producing one ton of glass per day, using a similar patented bubbling/agitation device as the MAWS DuraMelterTM 300. The primary difference between the design of these two melters is temperature of operation. The smaller unit processes glass at a nominal temperature of 1100oC, while the larger unit is rated at 1350oC.

The DuraMelterTM 1000-HT has been specifically developed to meet the design requirements for the K-65 silo wastes. Glass formulation tests (2) have recommended a design temperature for processing of 1350oC. This requirement coupled with the complex chemistry of the silo wastes has necessitated a novel design approach to joule heating the waste glass bath. GTS Duratek has developed a composite electrode consisting of three materials: a high temperature liquid, a refractory metal, and a refractory ceramic. Combined, these materials permit a conventional joule heated

melter electrode arrangement, which allows the aggressive glass chemistry to contact only suitable materials.
The glass discharged from this melter will be channeled to a DuraGemTM machine, which will convert the glass stream into gems similar to those produced in the MAWS system.

CONTRACTUAL DIFFERENCES

The distinctions between MAWS and the CRU 4 Pilot Plant program extend to the contractual mechanisms employed as well. The MAWS program evolved out of a Program Research and Development Activity (PRDA) sponsored by DOE's Office of Technology Development (OTD) (EM-50) and administered by the Argonne National Laboratory. When the project moved from the PRDA stage to the demonstration stage, it was natural and logical for ANL to continue the overall program management. This was accomplished through a series of three contracts with GTS Duratek for Phases I and II of the project with Fernald designated as the host site.
Phase I covered the laboratory work at the VSL and the construction and initial startup of the site located DuraMelterTM 300 system. Phase II covered the remaining pre-radioactive testing and the processing of actual site wastes from Pit 5 and the soil concentrates provided by the Lockheed soil washing system. The Phase I contract was fixed price and the two contracts that comprised Phase II were Cost Plus Fixed Fee. Both Phase I and Phase II were jointly funded by OTD and Environmental Restoration (EM-40). The CRU-4 Pilot Plant program contract, on the other hand, is strictly a fixed price contract between GTS Duratek and FERMCO for design and delivery of a melter and gem machine with ancillary requirements for construction and startup oversight.
The obvious complexity of the MAWS contractual framework, which involved project management from EM-50, EM-40, DOE Fernald, Argonne, FERMCO, Lockheed, The Catholic University of America, and GTS Duratek, developed as the project developed and represented the real needs of the project at the time. However, as the technology integrator, GTS Duratek found this framework to be very complex and somewhat inefficient simply because of the number of different decision makers involved. Project management of the CRU 4 Pilot Plant program in contrast, is completely contained within two organizations, GTS Duratek and FERMCO. Technological issues aside, the managerial logistics for this project are much simpler.

LESSONS LEARNED FROM THE MAWS PROJECT

One of the objectives of a demonstration project is to identify the strengths and weaknesses of the process. As would be expected in a full-scope demonstration project such as MAWS, many lessons were learned. With several months elapsed since the radioactive campaigns, two items stand out, one operational and one contractual or managerial.

Operations

One of the objectives of the MAWS demonstration was to achieve the maximum waste loading (waste as a percentage of the total volume) in the final glass product because every kilogram of additives not used reduces the cost for chemicals, processing, and disposal. Laboratory results using actual waste showed that waste loadings of greater than 95% could be achieved. These tests were conducted for short periods (1-3 days in duration) on a system that while functionally identical was simpler in mechanical configuration. One of the unique characteristics of the Fernald pit waste is a fairly high concentration of magnesium fluoride. While this constituent presents significant challenges in the off-gas system, it also is attractive because the fluoride acts as a glass fluxing agent thereby permitting processing at reduced temperatures. The Fernald MAWS recipe counts on the fluoride and its loss through volatilization contributes to crystalline formations in the glass. This migration of the fluoride into the off-gas occurs almost exclusively during idling periods when feed to the melter is stopped and the cold cap dissolves. During the first radioactive campaign, for which the feed stock was actually 97 wt% waste, equipment maintenance requirements necessitated prolonged idling periods resulting in some crystal formations in the discharge chamber. The "down time" required to clean these deposits added significantly to the cost of operations. The lesson to be learned is that there is a clear trade-off between waste loading and operational flexibility where a volatile waste constituent is relied upon for acceptable glass formation. In hindsight, a somewhat reduced waste loading could have provided the needed operational margin at slightly increased cost for chemicals and prevented the need to shut down the system to remove the crystalline deposits

and thereby expend significant funds for idle operator labor.
Contractual/Managerial
As discussed above, the contractual and project management mechanisms which developed for the MAWS program were relatively complex whereas those same mechanisms for the CRU-4 Pilot Plant program are relatively simple. While there is clearly a difference is scope for the two projects which, in part, explains the difference in management approach, to the greatest extent possible "simple is better." Other technology projects in their formative stages would be well served to take the time necessary to simplify the management structure of those projects as much as is reasonably practical. In the long run, the time spent will be well worth the cost.
CONCLUSION
Two vendor programs for the vitrification of Fernald wastes have been reviewed. Each of these programs has been contrasted from a technical and contractual perspective. One of these focused on the MAWS process aimed at minimizing the costs of vitrification. The second centers on the process equipment which completes the pilot process plant for the remediation of K-65 silo (CRU-4) wastes. Through vitrification, GTS Duratek is able to take Fernald wastes, in a variety of forms, and convert it into a stable product, safe for long term disposal.

ABSTRACT
Between 1950 and 1972, over 65,000 m3 of transuranic mixed waste was buried in shallow pits and trenches in the Subsurface Disposal Area at the Idaho National Engineering Laboratory,s (INEL's) Radioactive Waste Management Complex. Commingled with this waste is up to 283,000 m3 of fill soil. The pits and trenches were constructed similarly to municipal landfills with both stacked and randomly dumped waste forms such as barrels and boxes. The main contaminants are micron-sized particles of plutonium and americium oxides, chlorides, and hydroxides. Retrieval, treatment, and disposal is one of the options being considered for the waste. This report describes the results of a field demonstration conducted to evaluate technologies for excavating and transporting buried transuranic wastes at the INEL and other hazardous or radioactive waste sites throughout the Department of Energy complex.
The full-scale demonstration, conducted at RAHCO International,s facilities in Spokane, Washington, in the summer of 1994 evaluated equipment performance and techniques for digging, dumping, and transporting buried waste. Three technologies were evaluated in the demonstration: an innovative end effector for dust-free

dumping, a telerobotic transport vehicle to convey retrieved waste from the digface, and a remotely operated excavator to deploy the innovative end effector and perform waste retrieval operations. Data were gathered and analyzed to evaluate retrieval performance parameters such as retrieval rates, transportation rates, human factors design, and the equipment,s capability to control airborne contamination spread.

INTRODUCTION

From 1950 to 1972 over 65,000 m3 of transuranic (TRU) waste was disposed at the Subsurface Disposal Area (SDA) in shallow land-filled pits and trenches at the Idaho National Engineering Laboratory,s (INEL,s) Radioactive Waste Management Complex (RWMC) (1). These wastes consist of barrels, boxes, and large objects contaminated with TRU and organic materials. The primary hazards associated with these wastes are plutonium and americium compounds and organic solvents from weapons production activities at the Rocky Flats Plant. These wastes were placed in pits and trenches and covered with an average of 1 to 2 m of soil as a cap to seal the pit or trench. It is probable that during storage many of the waste containers may have lost their integrity, and the TRU materials may have leached into the surrounding soil.

In 1989, the RWMC became an Environmental Protection Agency (EPA) Superfund site. Current U.S. Department of Energy (DOE) plans to remediate the site include removing the wastes from these pits and trenches for further processing. Because of the possibility of contamination spread, retrieval of buried waste must be accomplished in a manner that will minimize the generation and spread of contaminated soils and significantly reduce the risk of accident or injury to workers. The dumping of dry soil into a funnel/dumpster arrangement has been found to be the primary mechanism for dust generation during the retrieval of buried TRU waste. The primary goal of this technology development is to reduce dust generation and the potential spread of airborne contaminants during retrieval and dumping operations and to remove the workers from the hazardous area by performing operations remotely.

In addition to excavation and dumping, exhumed waste must be conveyed away from the retrieval area to a packaging area or directly to a treatment facility. A robotic conveyance system was designed to remotely convey waste from the digging area, thus removing humans from the hazardous zone.

PROJECT DESCRIPTION AND OBJECTIVE

The development, demonstration, testing, and evaluation of a system for retrieval, conveyance, and dust-free dumping of buried waste was funded by the DOE Office of Technology Development through the Buried Waste Integrated Demonstration Program. The concept and design of the system was developed for the Buried Waste Integrated Demonstration program by RAHCO International in conjunction with Spar Aerospace Ltd. and RSI Research Ltd. A full-scale, non-radioactive demonstration was conducted at RAHCO International,s facilities in Spokane, Washington, in the summer of 1994 to evaluate equipment performance and techniques for digging, dumping, and transporting buried waste.

The objective of the demonstration was to explore the effectiveness of methods and equipment to remotely retrieve and transport buried waste away from the digface and control dust generation and contamination spread while dumping retrieved waste (2). Three technologies were evaluated in the demonstration: an innovative end effector (IEE) for dust-free dumping, a telerobotic transport vehicle (TTV) to convey retrieved waste from the digface, and a remotely operated excavator (REMEX) to deploy the IEE and perform waste retrieval operations. The TTV and IEE were developed and demonstrated by RAHCO International with Spar Aerospace and RSI Research. The REMEX is an existing remotely operated robotic excavator provided by Spar and modified to accept the IEE. These systems were developed or modified in close coordination with one another to ensure a systems design approach that maximized the effectiveness of the combined technologies.

EQUIPMENT

Remotely Operated Excavator (REMEX)

Spar and RSI have modified a conventional Hitachi EX200LC excavator (see Fig. 1) for remote operation. The modifications include the use of coordinated control technology to control the remote operation of the excavator (3). The implementation of coordinated control technology has been supported by the University of British Columbia, which has developed this technology for use with heavy equipment operation. A four degree of freedom joystick that replaces the arm of the operator,s chair controls the excavator digging functions (see Fig. 1). The conventional track control foot pedals are

Figure 1. The REMEX is a conventional excavator that has been modified with a sophisticated coordinated control system. It is operated telerobotically via a four degree of freedom joystick and operator,s control station.
maintained. The primary mode of operation is from a remote control operating station that can be located up to 2,000 ft from the REMEX and is linked to the REMEX by a telemetry cable. At the remote control station, the operator controls engine shutoff, travel, and excavator digging functions. All REMEX functions that could be performed from the cab can be performed from the remote control station.
The use of coordinated control technology allows the REMEX to be operated in a dexterous and precise manner. Conventional, manually-operated excavator systems are typically operated by two joysticks, each with two degrees of freedom. Deflecting the joysticks corresponds directly to opening and closing the valves that move the excavator arm. With the new technology of coordinated motion control, the operator uses a single joystick to control the excavator arm. There is one-to-one correspondence between the motion of the master controller and motion of the bucket. For example, a deflection of the master controller in the x-direction will produce a motion of the bucket in the x-direction with respect to the operator's frame of reference, regardless of the current configuration of the excavator arm. The speed of motion of the bucket over the ground will be proportional to the deflection of the master controller in that direction.
Innovative End Effector (IEE)
The REMEX has been fitted with an IEE, as shown in Fig. 2, to reduce dust generation during digging and dumping operations. The IEE consists of three structural assemblies - an inverted thumb, an attachable/detachable integrated transfer module (ITM), and a shovel assembly - as well as the necessary actuating linkage and hydraulic cylinders. The thumb has proven to be extremely versatile, dexterous, and productive in handling the expected waste forms. The front shovel configuration with the thumb on top was chosen to increase digging efficiency and reduce dust generation when the shovel digs into the waste. The ITM acts as a detachable loading, handling, and conveyance bucket when digging, handling, and conveying 55-gal drums, dirt, and small debris. It is a rectangular, welded steel structure and holds approximately 1 m3 of soil and waste, or two 55-gal drums. The lower shovel assembly, consisting of short digging teeth, a guide skirt, an overflow opening, and a latching mechanism, has multiple functions. When used with the thumb, it can retrieve large items and guide 55-gal drums into the ITM. It also acts as a shovel to scoop dirt and debris into the ITM. To prevent the ITM from overfilling, the shovel assembly has a small overflow opening between the teeth and top of the ITM. The shovel assembly also has a flared skirt to accommodate easy attachment of an empty ITM to the shovel assembly. A latch mechanism on each side of the shovel assembly secures the ITM to the assembly.
Figure 2. The multipurpose end effector integrates innovative features with proven excavation and retrieval technology.
Telerobotic Transport Vehicle (TTV)
The remote conveyance system (Fig. 3) was designed and provided by RAHCO International and Spar Aerospace. It consists of a track-mounted TTV, remote operator control station, and waste transport container (WTC). The TTV transports the loaded/unloaded transport containers and ITMs. The TTV is fully integrated with the end effector/waste-handling system to provide a waste conveyance solution that eliminates dust generation during conveyance operations. The TTV is designed as a multiple function vehicle. First, it conveys the empty WTCs and ITMs from the storage area to the excavation site. Second, it serves as a transfer station at the excavation site by a) supporting the transport container, b) opening, closing, and locking the container lid, and c) providing a staging platform for the empty ITM. Third, it conveys full containers and ITMs from the excavation location to the dumping/unloading location.
Fig. 3. The TTV mechanical subsystems consist of a track assembly, main frame, diesel power plant, hydraulics system, and ITM cradle. The WTC carries the ITMs and can be used to transport large objects. All of the controls necessary to operate the TTV in any operating mode are provided by the TTV operator,s control station. Co-locating the TTV control station and the REMEX control station allows for close coordination between the operators and greatly facilitates communications.
A main frame connects the tracks and supports the loads. One track is mounted rigidly to the frame while the second track is connected by horizontal pivot pin.

This minimizes racking of the frame as the TTV travels over irregular terrain. The TTV is propelled by a set of hydraulic motor-powered crawler tracks. The tracks provide stability on slopes and excellent maneuverability. Employing skid steering, the TTV can turn 360 degrees on its own center on a 4.5-m-wide path.
The 4,100-kg capacity WTC receives retrieved waste in the form of filled ITMs, 1.25 x 1.25 x 2.4-m boxes and many other expected, irregularly shaped, large waste items. After receiving the waste items directly or in an ITM, the container is closed and automatically sealed and locked to contain any dust generated during conveyance. The WTC is a steel structure approximately 1.5-m wide, 1.5-m high, and 2.8-m long, weighing approximately 1,270 kg empty. The lid structure is opened by a lift mechanism to provide frontal access, allowing easy placement of the ITM or other waste items by the operator. A pocket, located in the bottom of the container, is configured and sized to provide an easy target for the operator and self-aligns the pocket and the ITM during loading. Dust seals, located on all sealing surfaces, are provided to contain the dust generated during conveyance. A spring-loaded, latching mechanism engages the lift bar on the lid to lock and secure the lid during handling, preventing inadvertent opening of the container.
In operation, the IEE selectively retrieves the expected waste forms and places the collected waste in the WTC. For large waste items, the IEE places the item directly onto the container floor. For dirt, debris, and 55-gal drums, the excavator scoops the materials into the ITM, swings the filled ITM over the transport container, and lowers the ITM into the container pocket where it is detached. An alternate retrieval method is to detach the ITM, use the IEE to place objects into the ITM, and reattach the ITM to the IEE for placement in the WTC. An empty ITM, staged on the TTV, is then attached to the IEE and swung back to the digface (see Fig. 4). Simultaneously, the container lid is closed, securing the filled ITM in the container. The ITM is then carried by the TTV to a storage area receiving station where the filled container and enclosed ITM are off-loaded. An empty ITM and an empty container are loaded onto the TTV. The TTV then travels back to the digface.
Figure 4. A filled ITM is shown being placed inside the WTC on the TTV. After releasing the ITM, the lid on the TTV is closed and the TTV is repositioned to allow the REMEX to pick up the empty ITM staged on the back of the TTV. The REMEX continues retrieval operations while the TTV transports the waste to a processing or storage facility.
Spar Aerospace provided guidance and control systems for the TTV, consisting of the TTV control system, operator control station, and three radio frequency (RF) links between the TTV control system. The TTV control system has three separate microprocessor controllers to provide dedicated track control, waste container operation/control, and selected control of the forward and rear-mounted vehicle camera/pan and tilt units. Each microcontroller has a resident INTEL 80C196K microprocessor running proprietary software and shares a common RF link to the operator control station. The TTV also has onboard sensing systems to provide track speed transduction, a rate gyro for heading and noise filtering around the speed transducers, waste-handling logic function switches, and a vehicle acoustic ranging system array (VARSA).
The video system, comprised of forward and rear-mounted camera/pan and tilt units, gives the remote operator visibility in forward and reverse directions. The video system is used for steering control and tracking of specially designed acousto-video targets. The targets provide the TTV operator vision tracking to the REMEX to allow execution of the 90-degree turn required to align the transport container with the REMEX and receiving station.
Three vehicle control modes are provided: 1) open loop track control, 2) telerobotic control, and 3) waste container operation. In open loop track control (Mode 1), the tracks are operated from the vehicle-mounted manual control (pendant) or from the remote operator's joystick if the normal telerobotic control function either fails or is not required. Telerobotic control (Mode 2) provides resolved control of tracks through a single joystick at the remote operator's station. The joystick commands provide proportional forward/reverse and left/right directional control. The microprocessor at the operator's station resolves joystick commands into track speed commands that are sent by the RF link to the vehicle track microcontroller. The track microcontroller integrates the track speed commands with speed transducer and rate gyro feedback to control the tracks. Waste container operation (Mode 3) provides for loading and unloading while the TTV is stationary. Operator commands

from the remote control panel initiate individual control functions such as lid unlatch, open/close, and latch. The onboard control system also monitors limit switches to ensure each function has also been completed.
For teleoperated control, the TTV is operated from the remote operator control station. The control station consists of a microprocessor, control panel, RF modem, video monitor/controller, and graphical overlay controller (see Fig. 3). Operation of the TTV can be carried out using Modes 1 and 2 at the remote operator's station or independently at the TTV itself using a pendant mounted controller. An emergency stop button is also provided on the TTV and on the remote control station.
For this demonstration, the operator controlled the vehicle in the telerobotic Mode 2 using the single joystick for travel control and the forward or rearward cameras for visibility. As the TTV approached the REMEX, the operator tracked to an acousto-video target set on free-standing targets. Within 9 m of the REMEX, the VARSA was able to transduce range to the target and attitude. A graphical overlay was displayed on the operator's control station monitor. The overlay provided the operator with an image to align with the target. Boundary conditions on the overlay provide the operator with alignment and approximate ranging data, confirming the data provided by VARSA that was displayed on the panel. From this, the operator determined the distance and attitude of the vehicle with respect to the targets. Once the TTV reached a designated point near the REMEX, the operator commanded the TTV to pivot 90 degrees and align to a second free-standing target. This positioned the TTV perpendicular to the REMEX so the ITM could be placed in the transport container. The TTV was then moved to place the empty ITM at the correct location for attachment to the REMEX using the IEE. Then the TTV returned to the receiving station where the vehicle was docked to a single, free-standing, acousto-video target to unload the filled WTC.

DEMONSTRATION RESULTS

The 1994 demonstration was divided into two phases. Phase 1 consisted of a full-scale test to dig and dump dry, INEL soils mixed with simulated waste to assess the ability of the IEE to control dust generation and the potential spread of contamination during dumping operations. Phase 1 of the demonstration was performed inside a building where conditions could be sufficiently controlled to simulate a retrieval environment. Dust and rare earth tracer spread data were collected using air monitors. The demonstration included both digging and dumping operations; however, the primary objective was to test the ability of the system to reduce the generation and spread of dust during the dumping operation. Phase 2 consisted of a full-scale retrieval of simulated buried waste using the TTV, IEE, and REMEX. The purposes of Phase 2 were to test the capabilities of the TTV and to assess the ability of the IEE, TTV, and REMEX to effectively handle, transfer, and transport the waste from the digface as an integrated system.
Results from the Phase 1 tests show the IEE to be a very effective and reliable system for retrieving and transporting buried waste through the excavating process. The IEE is rugged and well suited for digging heterogeneous buried waste. Retrieval rates of 60 m3/day (80 yd3/day) or more can easily be achieved. The IEE was very effective at handling the various waste forms present in the demonstration. In particular, the flexibility of being able to release the ITM and work with the IEE thumb to pick up objects and place them into the ITM or to move items around on the digface added to the ability of the system to handle a large variety of waste forms. The IEE and thumb were found to be dexterous and capable of handling waste forms ranging from 55-gal drums to loose paper and soil. The overall system integration of the REMEX, IEE, ITM, and WTC was excellent and added to the smooth and successful completion of the Phase 1 demonstration.
The process of using the IEE resulted in dust spread that was two orders of magnitude below the test goal. The transfer of the ITM from the excavator to the transfer point was accomplished with virtually no visible dust or tracer spread as expected. The Phase 1 demonstration successfully proved that the concept of eliminating the dumping at the digface is a viable, immensely practical approach to limiting potential contamination spread during buried waste retrieval. Controlling the dust generation at the source of digging combined with the IEE,s inherently dust-free dumping operation should result in substantially greater than 98% reduction in dust spread over cases without regard for contamination control. Following transport to a processing facility, the ITMs may be dumped in a glovebox environment where contamination control systems are more easily implemented.

The Phase 2 test combined the REMEX, TTV, and ITM system to demonstrate the integrated systems approach of the design in a full-scale retrieval. The TTV and IEE were designed as a system for enhanced performance. The spring bed on the TTV assisted with easy alignment and transfer of empty ITMs from the TTV to the REMEX, while the tapered recess in the WTC assisted with alignment during depositing full ITMs. The systems approach provided for smooth and easy integration between the TTV, IEE, and REMEX.

The throughput data show that the system had a calculated production rate of 34.75 m3/day during the demonstration. With only slight modifications, a single TTV/REMEX system with multiple ITMs would easily achieve 60-100 m3/day and multiple TTVs could greatly increase throughput rates. Lack of sufficient horsepower on the TTV was the single factor that most limited throughput during this demonstration; this is also one of the easiest items to correct.

The capability of the system to handle the various waste forms is excellent. The IEE and TTV integrated well and there was virtually no spillage when loading and transporting the waste. Operator procedures and approaches such as detaching the ITM to see the digface and placing objects directly into the ITM were facilitated by the systems flexibility and enhanced the IEE,s ability to handle waste forms and reduce dust generation during retrieval operations. The IEE and thumb were extremely effective in handling and transporting the large objects from the digface. This operation was completed without any drops or slippage of the large objects.

Piloting the TTV was impaired by the lack of adequate horsepower and uneven power application to the tracks. Work arounds through equipment modifications and modified piloting methods were used to successfully complete the demonstration. The primary effect of this was that the vehicle speed had to be reduced significantly to maintain sufficient horsepower output to easily maneuver. Other than persistent minor engine problems, TTV reliability was excellent.

The TTV control system functioned well throughout the tests. Telemetry tests showed that the control system range easily met the 150-m goal. The wireless video worked well and provided a clear video signal to the TTV operator, although there was some interference from the antenna mast in specific orientations and range was limited to less than 75 m. The RF emergency stop malfunctioned and repeatedly shut the TTV engine down, so one relay was bypassed to continue the demonstration. Ultrasonic sensors mounted on the TTV provided information to the TTV operator to dock at the targets. Some crosstalk between two ultrasonic sensors gave erroneous readings to the operator. These readings were far enough from the actual readings so that the two could be easily distinguished.

The data collected for the maneuverability tests show that the TTV can repeat its placement to the targets within the specified 30 radial cm 77% of the time. Crosstalk between ultrasonic sensors contributed to the less-than-expected results. A minor software change would easily eliminate sensor crosstalk, but was not readily field implementable. The TTV had no significant problems negotiating the terrain or the 10-degree sloped hill after the horsepower output was tuned.

The equipment used for this demonstration was designed to investigate concepts for retrieval, dust-free dumping, and conveyance of buried waste. Prototype hardware and low-cost components were adapted to facilitate an inexpensive, short schedule, proof-of-concept demonstration. The hardware concept and design approach is to support a TRU environment retrieval; however, due to cost and schedule constraints, no attempt was made to provide fully industrialized equipment. There were no aspects of the equipment design that would make it difficult or prevent it from being upgraded to operate in a TRU buried waste retrieval environment.

FUTURE DEVELOPMENT AND DEMONSTRATION ACTIVITIES

The systems developed in FY-94 will be enhanced in FY-95 in preparation for a follow-on demonstration. During the summer of 1995, the Buried Waste Integrated Demonstration (BWID) program will perform an integrated field demonstration at the INEL. The integrated tests will be performed on a simulated buried waste pit. The scope of the demonstration includes the characterization, retrieval, and removal of the simulated waste from the site. Primary equipment for the retrieval and removal will include the REMEX with IEE, a remotely-controlled gantry crane deploying a cooperative telerobotic retrieval system that will deploy digface characterization, multiple manipulators and soil vacuum systems, and an upgraded TTV. These devices will be used to remove overburden soil, place waste material in transport containers, and convey waste from the dig site. All aspects of this process will be

operated remotely from a control station housed in a separate building.
The FY-95 demonstration calls for removal of a limited portion of a buried waste pit known as a hot spot. Removal of the hot spot without disturbing the surrounding waste requires that the excavation be accomplished from and above grade position. This requires that the IEE design (including ITM and the WTC) be modified from its current front shovel configuration to a backhoe configuration. This will allow the REMEX to operate from the above-grade position and dig down into the waste while maintaining the functionality and dust-free dumping capability of the current IEE design.
The REMEX will be modified to accept the backhoe configured IEE and an adaptive tuning system to maintain dynamic stability with varying end effector loads will be implemented. Other upgrades such as a stereo vision system, ruggedized sensors, and addition of coordinated control of the thumb will be added to enhance the REMEX performance and improve the human-machine interface.
From its inception, the conveyance vehicle was intended to be capable of semi-autonomous operations. The TTV developed in FY-94 was the first step toward this capability. It was designed to prove the hardware and operational concepts for buried waste conveyance and to demonstrate integration with the IEE and REMEX. The second step to be taken in FY-95 is to upgrade the control system to provide this capability. The TTV control system will be upgraded to a self-guided transport vehicle (SGTV). The SGTV will use a state-of-the-art video tracking system along with mission planning software to preplan and then semi-autonomously perform the conveyance operations. This will greatly enhance the operational flexibility of the system and relieve the operator of the highly demanding task of piloting the vehicle in a teleoperated mode. Other system upgrades such as an improved engine, hydraulic system, and collision avoidance detection will be deployed on the SGTV.
SUMMARY
The IEE proved that dust-free dumping is an efficient, effective means for reducing contamination spread during retrieval operations. The IEE design can provide the same capability as standard end effectors for retrieval operations without the inherent problem of contamination caused by a dusty dumping process. The integrated systems design approach for the development of the REMEX, IEE, and TTV provides an effective solution for remote retrieval and conveyance of buried waste. This demonstration successfully showed that buried waste retrieval can be performed remotely at low cost, at reasonable throughput rates, and with greatly improved safety for the worker and environment.
The data obtained in this demonstration will eventually be used by Environmental Restoration during the feasibility study for parts of the RWMC and, possibly, by additional programs in other locations. The data will also be used by Environmental Restoration to project additional technology needs for BWID out-year planning.
The DOE Office of Technology Development is developing and demonstrating technology to allow remote retrieval of buried waste. The BWID program is leading this effort and is planning for a retrieval demonstration to be held in the summer of 1995. The demonstration will use three primary retrieval components: a remote excavator, a robotic gantry crane, and an autonomous waste conveyance vehicle. Each of these systems has had development and demonstration activities in the past, and will be further developed for inclusion in the 1995 demonstration.

REHABILITATION OF THE SOIL USING THE MOBILE ROBOT VIRGILE

Rodolphe Gelin
CEA/DTA/CEREM/DPSA/STR

Fontenay aux Roses, France

ABSTRACT
For three years, the Robotics and Teleoperation Service of the CEA (the French Atomic Energy Commission) has been working on VIRGILE. This teleoperated vehicle is based on a four wheel drive Mercedes vehicle. It is adapted to be totally controlled by its embedded computer. The steering wheel, the throttle, the gearbox and the brakes are connected to the input/output boards of the VME computer. In a distant control room, the operator is able to drive the Mercedes using a joystick connected to an other VME computer. A Sun workstation controls two screens. On the first screen, the dashboard of the vehicle is displayed. On the second one, a top view represents the motions of the robot. The whole software is written in ADA language. The embedded computer and the fix one are connected together by a radio link relaying a 39400 b/s serial link. Furthermore, the pilot can see the environment of the robot on three video screens displaying pictures from the four embedded cameras.
The first application developed with VIRGILE is a part of the RESSAC project. The aim of this project is to rehabilitate the soil after a contamination due to a nuclear incident. The principle of the project is to pick up the grass on the soil, considering that the roots of the grass keeps the contamination at the surface of the ground. VIRGILE takes place in this scenario when there is no grass on the floor. Just after the incident, it can be teleoperated to sow grass of which roots will retain the contamination.
Two huge ramps has been installed at the rear of VIRGILE. On these ramps, sprays spreads the suitable liquid. The operator can control on the top-view interface that the whole area has been treated. The embedded computer is able to control the motion of the robot during short transmission interruptions. As soon as the transmission problem persists, the computer stops the vehicle.
The performed tests has been very satisfactory. The VIRGILE system is reliable and the vehicle itself is easy to control. If the dimensions of the vehicle will probably allow to efficiently protect the embedded computer against radiations, the problem of the safety of the transmission could be critical. But the power of the embedded computer will be used to increase the autonomy of the vehicle and therefore to decrease the need of high quality transmission. VIRGILE will be ready for the RESSAC project.

INTRODUCTION
The RESSAC project (French acronym for Soils and Surface Rehabilitation after Accident) has been initiated by IPSN (Nuclear Protection and Safety Institute). The aim of this project is to rehabilitate the soil after a contamination due to a nuclear incident. The principle of the rehabilitation is to pick up the grass on the soil, considering that the roots of the grass keeps the contamination at the surface of the soil. When there is no grass on the ground, a first step would be to sow a "fast growing" lawn of which roots will retain the contamination.
In order to efficiently and rapidly act after the contamination, the use of teleoperated vehicles is recommended. The work of STR (Teleoperation and Robotics Service) of CEA was to demonstrate the feasibility of a teleoperated vehicle able to perform the sowing task.
A first phase in the STR work was to realize the interface between a standard vehicle and an embedded computer. Then the embedded computer just had to communicate with a remote control station. During the second phase, the system performances have been evaluated in terms of ergonomy and driving accuracy. One of the most important criteria was the easiness in performing a systematic sowing task.

PRESENTATION OF THE SYSTEM
For the RESSAC project, STR has developed VIRGILE. This unmanned vehicle is based on a four wheel drive Mercedes. An operator can totally control VIRGILE from a remote control station.

The Vehicle
The used vehicle is a 300GD Mercedes. It is 5 m long and 1,70 m wide. The engine is a diesel one. The gear box is automatic and the steering is powered. These features have made the adaptations easier. The gear lever is controlled by a hydraulic jack. A small hydraulic motor is able to drive the steering wheel. The length of the vehicle allowed an hydraulic power plant, two extra batteries, an analog controller and a VME computer to be embedded.
Four fixed video cameras has been installed inside the vehicle to transmit pictures

of the vehicle environment to the operator. Three radio transmitters and one receiver link the vehicle to the remote control station.
During teleoperation phases, the embedded computer receives commands through the radio. It interprets the commands and sends them to the analog controller that controls the hydraulic actuators of the steering wheel, the throttle, the brakes and the gear lever.
VIRGILE can also be controlled in a usual way. Pressing a button on the dashboard gives the control back to an embedded pilot.
Fig.1 The VIRGILE Robot
The Remote Control Station
The remote control station includes three video monitors, deux computer screens, a SUN workstation, a real time computer, three radio receivers and one radio transmitter. On a desk in front of the screens, a joystick and four buttons are the input devices of the system for the operator.
A keyboard and a track ball are also available for operations on the computer.
The remote control station stays on castors. It can be easily moved into a van and be used in any suitable place.
The Radio Link
A full duplex radio link allows the connection between the computer of the remote control station and the embedded one. This link carries a RS422 serial link at 39400 b/s.
Two video pictures are sent from the vehicle to the control station by two transmitters developed by CEA/LETI.
The Sowing Tool
To perform the sowing task, a tool has been fixed at the rear of the vehicle. In order to avoid driving problems due to a trailer, the two six meter ramps have been fixed directly on the chassis of the vehicle. The length of the ramps has been chosen in such way that a U-turn allows the ramps to cover continuously a surface. A wheel is fixed at the end of each ramp. And the ramps are articulated on the chassis in order to deal with a non perfectly flat field. Shrouds from front and from rear keep the ramps perpendicular to the vehicle.
A compressed air bottle provides pressure in the container of product to be sowed. The sowing is controlled by two electrovalves connected to the embedded computer.
Fig. 2 Top View of the Sowing Tool
THE FUNCTIONS OF THE SYSTEM
The Driving
The pilot in the remote control station can control the direction and the speed of the vehicle using the joystick. He drives according to the video pictures displayed on the three video screens.
He can select the drive, rear or neutral position of the gear by pressing the buttons at the top of the joystick. Pushing the joystick controls the acceleration, pulling the joystick controls the braking. When VIRGILE reverses, the rear camera is selected and displayed on the main video screen and the the direction commands are flipped. So the pilot has the same feeling in driving backwards as in driving forwards.
On the left hand computer screen a dashboard is represented. On the main window, the driver can check the speed, the rolling and pitching angles of the vehicle, the selected gear position. On other pop-up windows, the state and the control of the devices (lights, windscreen wipers, sowing tool, horn...) are available. In the upper left area of the screen, warning messages are displayed and an emergency window automatically pops up in case of serious problem: loss of transmission, motion with the handbrake locked or with an opened door for instance.
The Mission following
On the right hand computer screen a top view shows the global trajectory of the robot. A graphic toolkit allows the operator to draw some landmarks as buildings, roads or trees. A planned trajectory can also be represented on the screen. So the pilot can check he is driving on the planned trajectory. If a map of the environment was available, it could be represented on this screen.
It is also possible to draw the surface covered by the ramps behind the vehicle. The operator can check that the vehicle has sowed every where on the field.
THE TESTS
The Evaluation Site
The tests have been performed at CEA center of Saclay in the south of Paris. The

movements of VIRGILE took place on a more or less rectangular shaped field. The field is 200 meters long and 40 meters wide. The ground is horizontal but irregular. A 50 cm high bump allows to test the articulation principle of the ramps and the measurement of the rolling and pitching angles. The ground is partly grassy.
Fig. 3 the Sowing Tool Mechanism
The Test Courses
The operators have freely driven on the field trying short turns and high speed straight lines. The performances have been particularly evaluated during three kinds of courses:
- Slow slaloms: the speed is about 5 km/h. The gates are 2.5 meters wide. Two consecutive gates are in opposite corners of a 5 meters square.
- Fast slaloms: the speed is about 15 km/h. The gates are 4 meters wide. Two consecutive gates are in opposite corners of a 10 meters square.
- Systematic covering: the vehicle covers the field making 20 meters long straight lines 12 meter apart.
The Pilots
Four pilots have regularly driven VIRGILE. Three of them were engineers working on the project. The fourth was a mechanics technician not particularly involved in the project. The latest pilot has tested the performances of the vehicle on the three courses described above.
THE RESULTS
Ergonomy
After set up and configuration, driving the vehicle seemed very easy to the operator. Thanks to the human factor specialist's advice and after some corrections during the tests, it is possible to drive VIRGILE with just one hand. Handling the joystick, the operator can control the gear box by pressing buttons of the top of the joystick with his thumb. The automatic selection of the rear camera makes the driving easier: the driver does not need to let the joystick to select the suitable camera.
Flipping the direction controls when the vehicle drive backwards is surprising for the driver during the first few seconds. One can thinks it is because of the operator is used to drive cars and instinctively turns the steering wheel on the right for going backwards left. But after the first hesitation, the new driving way is comfortable. Maybe too comfortable and sometimes the operator even forget he his driving backwards.
We have noticed that the operator does not look very often at the computer screens. Actually he is concentrated on the video screens and does not loose time in looking at computer screens. As long as everything is fine, he actually does not have to. The main information he could need from the computer screen is the actual speed of the engine. Looking the video screens does not provide a good estimation of the speed. It could be useful to provide speed information either by mixing numeric information on the video screens or by using a sound feed-back of what happens inside the car.
Reliability
The weakest point is the transmission system. During the three days of intensive evaluation we had many contact losses between the vehicle and the remote control station. Of course these control losses are handled by the computers. When the embedded computer has not received information for a second, it stops VIRGILE waiting for a communication improvement. Fortunately the radio link comes back after a couple of seconds but if it had not been the case, the vehicle would have been definitely lost. We have used standard radio system for the VIRGILE system but for a real application it will be necessary to use high performance transmission system. Because the loss of the control radio link is detected and handled by the computers, this problem is not too serious. On the other hand the loss of the video transmission link is much more serious. When the operator drives at 40 km/h, he does not like to loose the visual control of his trajectory. Today, the embedded computer is not able to detect video link problems, so the operator has to brake the vehicle by himself when he does not see precisely enough where he is driving. The transmission system of the video pictures has to be even more highly efficient than the control transmission system.
We have not been faced to the problem of radiation but we know that it is something we would have to handle before real application of such a system. After a nuclear incident, the radiation level could disturb the working of computers and cameras.

There is still some work for making VIRGILE as reliable in this kind of environment as in a "pure" one.

Performance

In terms of accuracy in driving, operators have been astonished at the efficiency of the system. Of course the fix cameras inside the vehicle does not allow the operator to anticipate the needed motions but the speed of the steering wheel control makes up for this problem. With a short wrist movement on the joystick, the operator is able to turn the wheels as far as using more than one steering wheel turn. During the slaloms, very few gates has been touched.

The systematic covering task does not raise any particular problem except checking ramps for collision. It will be necessary to use two more cameras checking for the trajectory of the ramps.

CONCLUSION

Today VIRGILE works in accordance with the specifications. The main limitations before performing a real rehabilitation mission are the transmission reliability and the resistance to radiations. If dedicated sub-systems are used, these limitations will be suppressed.

In order to make the vehicle easier to be driven, the future developments will concern the autonomy of the vehicle and mainly improvements of the remote control station.

The autonomy can be used to perform systematic covering tasks. The operator will just check that everything is going fine. Autonomy can also be useful to solve transmission loss. The vehicle could come back autonomously to get the radio contact back.

Experiment shows that, as soon as the environment becomes highly unstructured, the operator does not have enough information to drive efficiently. But it is also shows that he already can not deal with all the available information. We have to find a new way of driving teleoperated vehicles, of giving information to the operator in order to make an unmanned vehicle even easier to drive than a usual car.

We can not wish that soil rehabilitation task becomes an every day task but we have to be ready to perform it as efficiently as an every day task.

ABSTRACT

A mobile robotic inspection system is being developed for remote ultrasonic examination of the double wall waste storage tanks at Hanford. Performance testing of the system includes demonstrating robot mobility within the tank annulus, evaluating the accuracy of the vision based navigation process, and verifying ultrasonic and video system performance. This paper briefly describes the system and presents a summary of the plan for performance testing of the ultrasonic testing system. Performance test results will be presented at the conference.

INTRODUCTION

Raytheon Service Company and RedZone Robotics have been contracted by Westinghouse Hanford Company to develop a system for inspection of the double shell waste storage tanks at the Department of Energy Hanford Site. The system must be able to perform Ultrasonic Testing (UT) and over 100% of the primary and secondary tank walls and

the primary tank knuckle as well as over a small percentage of the tank bottom which is accessible via air slots under the tank The system must also be capable of executing a specified initial inspection sequence in a 36 hour period, including cleaning, visual verification of surface preparation and ultrasonic inspection.
The Double Shell Tank Inspection system consists of a Mobile Control Center, Deployment Module, Cable Management Assembly, Robotic Mechanism, Ultrasonic Testing (UT) System, Visual Testing (VT) System, Robot Control System, Pneumatic Distribution System and Electrical Distribution System. An artists rendition of the system is shown in Fig. 1. A rigorous testing program is necessary to ensure that operations in the actual tank farm are smooth and trouble free and that the system will meet the requirements of the intended application. This paper focuses on performance testing of the Ultrasonic Testing system.
Fig. 1. Double Shell ank Inspection System.
TEST FACILITY
Complete and safe testing of the system requires a dedicated test facility. A full scale, partial section of a double-shell tank has been constructed in RedZone Robotics' Pittsburgh facility. The mockup is approximately 35 feet long and 12 feet nigh, constructed of three courses of four by eight foot sheets of rolled steel. A section of the mockup includes simulated haunch and knuckle regions, along with air slots. A platform mounted above the tank section represents ground level, and is used for deployment of the system through a riser. Westinghouse Hanford Company has constructed a similar, but somewhat larger facility at the Hartford site for testing and training. The performance test will be conducted at the RedZone facility.
ROBOT MECHANISM
The robotic mechanism supports deployment of the UT and VT systems. The mechanism consists of a cable management assembly, a storage enclosure, a mobile vehicle called the scan carriage and a cleaning system to prepare the tank surface for inspection. To the extent possible, the scan carriage is constructed of materials that can withstand a total radiation dose up to 1 x 106 Reds. Electronics are kept to a bare minimum, and no on-board electronics me used for components needed for recovery. An artists rendition of the scan carriage is shown in Fig. 2.
Fig. 2. Scan Carriage.
Scan Carriage
The scan carriage vehicle is a walking platform that carries cleaning and inspection hardware between the wails of the annulus of the waste tanks. The vehicle supports inspection of the primary and secondary tank wails and the floor of the primary tank via the air slots. From any location, a rectangular scan area of 64 in. nigh by 22 in. wide can be accessed. In order to inspect the secondary tank wall, the scan carriage must be relieved and rotated 180 degrees. The scan carriage is able to negotiate obstacles (air supply pipes) that are up to 15 in. from the primary tank wall, and 15 in. from the secondary tank wall. A separate tool package is used to access the air slots under the tank. The vehicle is sized to fit through a 24 in. access riser. The scan carriage vehicle navigates with the aid of an industrial machine vision system which tracks weld seams and identifies weld intersections using edge detection and line fitting algorithms,
The performance of the scan carriage will be tested by executing a series of maneuvers, including deployment. negotiation of obstacles, carrying out cleaning and inspection tasks and fail safe recovery.
Cleaning System
Effective ultrasonic examination requires that the weld, the heat-affected zone and surrounding area be free of excessive rest build-up, scale and debris. To meet this requirement, each inspection tool is outfitted with a maneuverable cleaning head. Each cleaning system consists of a cleaning head, power sources (air and electric) and attachment hardware for the corresponding payload delivery device. The cleaning system removes loose material from the base metal, but leaves tightly adhering mill scale.
An application based test will be used to demonstrate the performance of these tools. In operation, the cleaning tools are used to prepare the surface for inspection. So, the test will start with realistic surface conditions. The robot will clean the surface, and a UT inspection will be performed. Success is demonstrated by good ultrasonic coupling.
Visual Testing System
Preparation of the tank surface for ultrasonic inspection is verified by the Visual

Testing system. Additional functions of the VT system are to monitor cleaning and ultrasonic operations, and to provide video image feedback to the robot navigation system and the operator. The VT functions are performed by four cameras, one (mounted on a pan and tilt on the scan carriage) to provide a view of the general area around the scan carriage, one to perform wall inspection, one to perform air slot inspection and one (deployed through a 3 or 4 inch tank riser) to provide an overview of the scan carriage as it enters, leaves and moves within the annulus.

DESCRIPTION OF THE ULTRASONIC TESTING SYSTEM

The UT examination is designed to determine tank wall thickness, and detect and size corrosion induced pitting and cracking. The P-Scan Ultrasonic testing system, manufactured by the Force Institute in Denmark, will be used for data collection and analysis. The multi-channel data acquisition capabilities of the P-Scan system allow for simultaneous and continuous acquisition of data from four transducers. There are two transducer array modules in die DSTI system.

Tank Wall Transducer Array Module

The tank wall transducer array module contains transducers oriented at a variety of angles, using various wave modes, and frequencies to provide detection and sizing of planar reflectors and wall thickness measurements within the specified examination volume. The module can be moved to and from the weld centerline and along the weld axis. It is also capable of +180 degree rotation to provide maximization of echoes for detection, discrimination, and sizing of indications in the specified examination area regardless of their orientation to the weld centerline.

The scan pattern begins at the uppermost point of the examination area and proceeds down the tank wall, following the shortest or most convenient combination of vertical and horizontal welds. Scanning will be from both sides of die weld where access allows. Scan motion is provided by the Scan Carriage. The nominal scanning speed is 3 inches per second.

Knuckle and Air Slot Transducer Array Module

The knuckle and air slot transducer away is capable of movement in a straight line beginning at the upper most examination point of the knuckle and extending 24" into die air slot. Data is also obtained while retracting die head from the air slot. Due to the restricted area in the air slot, indexing of the transducer array module is not possible. Required examination volume coverage is provided by the orientation of the transducers within the module. The nominal scanning speed is 3 inches per second. The knuckle and slot UT transducer module mounts to the scan carriage on die output of one of the payload reels mounted on die secondary slide of the y-member. Vertical and horizontal motion are provided by the scan carriage.

UT SYSTEM PERFORMANCE TESTING

The flaw detection and sizing methodology for planar flaws evolves from techniques proven in the nuclear power industry for the detection and sizing of intergranular stress corrosion cracking. These techniques provide accuracy meeting the specification, but are dependent on surface condition. Testing of the UT System will verify the accuracy of these techniques by examining test plates with known flaws under expected operating conditions. The mockup tank surface will be heated to test the effect of heating of the couplant on UT scanning. Testing of the VT system will be conducted to confirm the ability of the system to provide the required supper for ultrasonic testing and the robot navigation and tele-operation functions. A dusty environment will be created inside the mockup annulus to confirm the ability of the VT system to function under realistic conditions.

The UT system performance test is to be conducted in a manner that simulates the way in which examination is conducted in the field and shall be performed in accordance with a written procedure provided by the contractor.

Performance Demonstration Samples

Performance demonstration specimens shall be fabricated from the same DST wall material or equivalent materials and shall have surface condition representative of the general condition of the DST scanning surface. Performance demonstration specimens shall have sufficient area to minimize spurious reflections and shall include thickness, pitting, and crack samples. The ultrasonic reflectors will be distributed to cover the through-wall thickness (t) in a minimum range from 0.25t to 1.0t

Performance demonstration specimens shall be divided into grading units. A grading unit is deemed as a minimum of 3-inches of continuous vertical or horizontal length. If a grading unit is designed to be flawed, then one (1) inch of unflawed material

must exist on either side of the grading unit The specific segment of length used in one grading unit may not be used in another grading unit.
Orientation of the cracks shall be either perpendicular or parallel to the major axis of the performance demonstration specimen. Flawed and unflawed grading units shall be randomly mixed. Performance demonstration specimens shall be embedded in the primary tank wall with their sound entry surface facing the annulus; sound entry surface of the samples shall be flush with the surrounding wall surface; exposed back surface of the samples shall be masked. The same performance demonstration specimens may be used for both detection and through-wall sizing.
Calibration
An initial calibration shall be performed and documented at the start of the performance test. The examination methodology requires multiple calibrations corresponding to 25F temperature increments. To verify the function of the temperature detectors in the UT modules at least two widely different readings shall be taken at location where the temperature can be independently measured. The high reading should be about 200 10F.
Examination Procedure
All ultrasonic indications which exceed 20% reference shall be investigated to determine their maximum amplitude. All ultrasonic indications which exceed 50% reference shall be recorded on the indication report form. Any indication determined to be originating from a surface connected planar flaw shall be tagged and reported, regardless of amplitude.
Wall thickness measurements less than 87.5% of specified original wall thickness will be tagged and reported. Stress corrosion cracks greater than 0.5 in. in length will be tagged and reported. Corrosion pitting greater than 0.35 times specified original wall thickness in depth will be tagged and reported.
For reportable indications, date shall indicate the location, area extent, and maximum amplitude for each indication. For thin areas, the reported date shall summarize the thickness measurement results.
Reports
An Indication Report Form shall be prepared for each Performance Test Plate. Location, orientation and size of cracks shall be reported on the Indication Report Form and marked on the P-Scan printouts.A detailed Tank Inspection Report shall also be prepared summarizing findings during the entire performance test.
All P-Scan examination date shall be printed in hard copy form identifying any areas with shear wave amplitudes exceeding 50% reference. The report shall note the maximum amplitude location in the X and Y axis, and the global robot coordinates. Any area that exhibits ultrasonic echoes exceeding 50% reference, hat which are determined to be geometric in nature, shall have a brief written statement outlining the basis for the conclusion. Any area determined to contain planar oriented flaws shall be identified on the hard copy printout and in a written report describing the techniques utilized and basis for the conclusion.
Performance Criteria
To complete the detection performance test successfully, the system must perform in accordance with Table I.
N- 1 crack depth from a total of N shall be reported. A depth result on one (1) crack is allowed to be left blank. If depth of all N cracks is reported, the fast N consecutive samples will be evaluated. A false call is defined as calling an uncracked grading unit cracked. A crack parallel to the major axis direction is detected successfully if a minimum of .50% of its actual length has been reported. An allowance of 0.5 inch is permitted in one direction or the other from the actual crack location.
All detected flaws shall be sized to the following requirements:
a. For circumferential flaws the minimum detected flaw shall be t in length +/- 0.5 inches and 0.5t in depth +/- 0.050 inch;
b. For longitudinal flaws the minimum detected flaw shall be 12 inches in length +/- 0.5 inches and 0.2t in depth +/- 0.050 inch;
c. For Pitting the minimum detectable pit shall be 0.7t in diameter and 0.35t in depth +/0.02 inch. The following criteria apply to depth sizing and wall thickness measurement:
 d. Each successfully reported depth-sizing measurement shall be within +/- 0.050 inch of the true depth.
 e. Wall thickness measurement shall be accurate to within +/- 0.0025 inch.

Timing Documentation
The time required for data acquisition, analysis and reporting on each sample shall be documented. The following tasks must be performed during this time:
a. Repositioning the scan carriage within one performance demonstration specimen.
b. Scanning one performance demonstration specimen for reflectors oriented perpendicularly and parallel to the major axis. This activity will consist of some number of complete scans.
c. Data analysis and generation of required documentation.
The following items are not included in the acquisition time:
d. Initial UT system calibration or calibration check.
e. Positioning scan carriage at the scan start on the performance demonstration specimens.
PROJECT STATUS
The fabrication of the Double Shell Tank Inspection System is complete and testing will have been completed by the time this paper is presented. Results of performance testing will be presented at the conference. Tank inspection operations are expected to begin in June 1995.

ABSTRACT
A mobile robot system called the Stored Waste Autonomous Mobile Inspector (SWAMI) is under development by the Savannah River Technology Center (SRTC) Robotics Group of Westinghouse Savannah River Company (WSRC) to perform mandated inspections of waste drums stored in warehouse facilities. The system will reduce personnel exposure to potential hazards and create accurate, high-quality documentation to ensure regulatory compliance and enhance waste management operations. Development work is coordinated among several Department of Energy (DOE), academic, and commercial entities in accordance with DOE's technology transfer initiative. The prototype system, SWAMI I, was demonstrated at Savannah River Site (SRS) in November, 1993. SWAMI II is now under development for field trials at the Fernald site.
INTRODUCTION
Thousands of drums of radioactive, hazardous, and mixed waste are currently stored at DOE sites throughout the United States. These drums are stored in warehouse-like facilities on an interim basis, pending final disposition. Recent emphasis on anticipated decommissioning of facilities indicates that many more drums of waste will be generated, requiring additional storage. Federal and state regulations dictate that hazardous waste covered by the Resource Conservation and Recovery Act (RCRA) be inspected periodically for container degradation and to verify inventories. All known DOE waste storage facilities are currently inspected manually. A system to perform robotic inspection of waste drums is under development by the SRTC Robotics Group of WSRC. The robotic system is the Stored Waste Autonomous Mobile Inspector (SWAMI).
The DOE Office of Technology Development (OTD) is directing this effort through the Robotics Technology Development Program (RTDP) and through Morgantown Energy Technical Center (METC). In accordance with DOE's technology transfer initiative, development work is coordinated among several DOE, academic, and commercial entities. Along with WSRC, participants include the Lawrence Livermore National Laboratory (LLNL), the University of Michigan, the University of South Carolina, the Georgia Institute of Technology, Martin Marietta Astronautics Division, and Fernald Environmental Restoration Management Corporation (FERMCO).
OBJECTIVES AND BENEFITS
Program objectives fall into several categories: reducing personnel hazards, increasing cost effectiveness, improving inspection data quality, and providing

additional information to enhance waste management operations.
Manual inspections of waste drums require personnel to be in close proximity to waste materials for extended periods of time, creating a potential for exposure to hazardous or radioactive materials. Robotic inspections will drastically reduce personnel exposure to these hazards. Significant cost savings can also be realized by reducing the personnel time required for inspections.
Since facilities of this type are typically capable of storing thousands of waste drums at a time, manual inspection is extremely tedious, and significant variations in inspection quality can be expected. Additional inconsistencies are introduced by the variations in the competence and experience level of inspectors. Robotic inspection of waste containers will not exhibit the degradation of quality or the variability associated with human performance in highly repetitive tasks.
High-quality, consistent inspection data will contribute directly to prevention of waste containment failures. The vehicle's sensor mast will also allow SWAMI to inspect the topmost level of drums (up to four drums high) as competently as the first level, a feat not easily achieved with manual inspections.
SWAMI also provides additional information not currently available with manual inspections. During the inspection, SWAMI will store images of each drum and data associated with it, including geometric data, the drum's location, bar code number, and a time stamp. After downloading, this information can be accessed directly through the site database for inventory verification, drum condition trending and other operations support. SWAMI will also conduct a rigorous survey of the facility floor for potential radioactive contamination. Performing a radiation survey during every inspection serves two functions: it provides an early alert to a radioactive spill, and also prevents the vehicle from unwittingly picking up the contamination and tracking it throughout the facility, as might conceivably occur during a manual inspection.
PROGRAM
The project is divided into four phases: prototype development and demonstration (SWAMI I), system development (SWAMI II), demonstration and testing of SWAMI II at Fernald, and transfer of technology to industry. Prototype development was initiated in 1992 and culminated in a series of SWAMI I demonstrations during the RTDP Robotics for Mixed Waste Operations Demonstration at Savannah River Site in November 1993 (See Fig. 1.). SWAMI II is currently being developed, and will incorporate lessons learned during prototype development, include several features not found on SWAMI I, and address Fernald-specific requirements. SWAMI II is currently scheduled to begin approximately 17 weeks of field demonstrations and testing at Fernald in June of 1995. Following the demonstration, an offering of SWAMI II technology will be made to industry through the SRS Technology Transfer Department.
Fig. 1. SWAMI I at the November, 1993 RTDP Robotics for Mixed Waste Operations Demonstration.
Since technology transfer to industry is a fundamental program objective, developing a system that performs its function in a cost-effective manner is of major import. Development strategy is to utilize known commercial technologies, then apply and integrate them in an innovative way. Vehicle subsystems are being developed independently and then integrated on the vehicle platform. This modularization of subsystems is also reflected in the system software.
PROJECT CONSTRAINTS
Although the parameters used for developing the vehicle are a composite of the general features of existing and planned storage facilities at the target sites, SWAMI II will initially be deployed at the Fernald Site for testing and demonstrations. As a result, Fernald waste storage specifications are predominately being used to configure SWAMI II. Waste storage facilities at Fernald are a combination of previously existing process facilities and dedicated storage facilities. Although other containers are present in relatively small numbers, SWAMI II will be targeted to inspect 55- and 85-gallon drums. These containers are stacked on pallets up to four levels high. Each drum is bar coded with a unique number for identification. Bar code label placement is relatively uniform. Aisles are a minimum of 0.91 m (36 in.) wide, many of which allow vehicle access from only one end, requiring
SWAMI II to back out of aisles. Storage facilities typically do not have temperature control. Several storage facilities have a drum capacity of approximately 12,000 drums.

SWAMI I DESCRIPTION

The SWAMI I systems fall into four general groups: the operator computer, the vehicle supervisory computer, the base vehicle, and vehicle subsystems. There are four main vehicle subsystems: image capture/compression/storage, bar code scanners, the radiation monitor, and the position determination system.

Operator Computer

The operator computer uses two programs to interact with SWAMI I: the SWAMI Operator Interface and RADMAP. Both were developed by SRTC. The SWAMI Operator Interface provides remote vehicle controls, an inspection interface, and a configuration interface. RADMAP provides a facility map on the operator screen with the vehicle's current position and status indicated with an icon. Radiation data can also be plotted as it is received from SWAMI I, or at a later time. Other information, such as alarms, can also be displayed. RADMAP has been submitted for copyright by SRTC and will be available for technology transfer. The operator computer communicates with the vehicle supervisory computer over a spread spectrum radio ethernet.

Vehicle Supervisory Computer

The vehicle supervisory computer consists of three microcomputers on a half-height VME backplane and other peripherals, including a LAN board, and digital and serial interfaces. It communicates with the operator computer over a spread-spectrum radio ethernet, and commands the base vehicle and onboard subsystems through RS-232 and RS-485 (multidrop) serial ports. The vehicle supervisory computer software was developed by the University of South Carolina. SWAMI I is the first commercial mobile robot to utilize GENeral Interface for Supervisor And Subsystems (GENISAS) software from the Generic Intelligent System Control (GISC) library created by the OTD Robotics Program. "GENISAS is a GISC-Kit package that provides general communication software interface capabilities (such as command processing and event handling) between the supervisory control system and subsystems." (1)

Base Vehicle

The base vehicle is a modified Transitions Research Corporation (TRC) HelpMate. Several modifications, such as pallet-sensing ultrasound transducers and vehicle software enhancements, were added by TRC. Other modifications were made by SRTC, including the addition and integration of subsystems. The vehicle is equipped with several systems to perform navigation, collision avoidance and collision recovery. Basic navigation is performed by dead reckoning, using encoders on the drive wheels and a gyroscope. An ultrasonic array faces forward and to each side of the vehicle. These sensors register physical features and update navigation. Collision avoidance is also accomplished using these sensors. Additional ultrasound transducer "blossoms" are mounted on the front bumper to register off of drum pallets. A forward-looking structured light system provides additional collision avoidance capability. Should a collision occur, pressure-sensitive strips located around the vehicle's periphery and compliant bumpers with deflection sensors are used to detect the impact location to aid in recovery. Emergency stop switches are also provided. The vehicle's 0.71 m (28 in.) overall width will allow it to successfully navigate within the 0.91 m (36 in.) wide aisles at Fernald.

Image Capture/Compression/Storage

The SWAMI I image capture/compression/storage system uses fixed-mount CCD color video cameras and light strobes for each drum level and aisle side. The strobes provide consistent lighting levels for image capture while minimizing power consumption. A PC-DOS (486/33 MHz) computer performs the actual image collection functions. At a command from the vehicle supervisory computer, the image system captures the digital drum images, compresses them, and attaches other data to the compressed file, including each drum's bar code number, drum location and a time stamp. The entire file is then stored to an onboard optical disk. Image capture and compression functions are performed on commercially available PC-DOS boards.

Bar Code Scanners

Fixed-mount rastering bar code scanners read the unique bar code number on each drum. A separate scanner is used for each drum level and aisle side. The scanners use a 670 nm visible laser diode light source, which is eye-safe. Since the bar codes are oriented "picket fence" style, the laser scans horizontally. A raster feature indexes the horizontal laser line vertically, creating a "scan window." This window allows the scanner to read bar codes whose location and orientation are not precisely controlled. The simple raster feature avoids the complexity, expense, weight, and power requirements of omnidirectional units. The scanners collectively

communicate with the vehicle supervisory computer through a single RS-485 multidrop port.

Radiation Monitor

The radiation subsystem monitors the floor for potential alpha and beta-gamma radioactive contamination as SWAMI I performs its inspection. The system uses gas proportional detectors, located in front of the vehicle, to detect contamination before the vehicle passes over it. Onboard P-10 gas cylinders are required to continuously purge the detectors. The system is the same as that used on SIMON, another SRTC mobile robot. SIMON has demonstrated that robotic surveys are superior to manual surveys in detecting low levels of radioactive contamination. As SWAMI I performs the inspection, data from the radiation subsystem is sent to the operator interface computer in real time over the radio ethernet and displayed on RADMAP.

Position Determination

Due to the large area SWAMI I must navigate within, accumulated errors in the base vehicle's dead reckoning navigation system will become significant. The position determination subsystem updates the vehicle's dead-reckoned position and maintains the vehicle's odometry within acceptable accuracy. Accuracy is required not only for vehicle navigation, but also so that drum images are taken from the proper vehicle position. The system uses a 360-degree scanning laser to read bar coded retroreflective fiducials placed on the facility walls. This information is then used to periodically refine the HelpMate's dead-reckoned position.

SWAMI II DEVELOPMENT

The SWAMI II system to be tested at Fernald will utilize the same base vehicle as SWAMI I, but will differ in several aspects from the prototype already demonstrated. Additional subsystems will enhance SWAMI II's ability to perform a comprehensive inspection and reduce the operator workload. Several changes are also being made to address Fernald's specific site requirements.

Geometric Inspection

A significant addition to SWAMI II will be a geometric inspection subsystem, which uses structured light to detect drum dents and blisters. Since the storage facilities at Fernald typically experience significant turnover, damage to drums (such as dents) from handling operations can occur. Another potential failure mode is corrosion of drums from the inside. This type of failure is difficult to detect visually, until it is manifested by a blister on the drum's exterior. The geometric inspection system will detect these blisters to identify an imminent containment failure. It utilizes two arrays of laser line generators and CCD cameras to obtain range-to-surface data.

Waste storage drums at Fernald are painted glossy black, a surface which makes geometric inspection with structured light difficult. Structured light systems rely on a diffuse reflection of the laser line for detection by the camera. The curved glossy black drum surfaces absorb some of the light, and reflect most of the remaining light specularly. As a consequence, very little of the impinging laser light is visible to the imaging cameras. To obtain an adequate return from the projected laser line under these conditions (while remaining in the Class II eyesafe laser realm), the orientation, laser intensity and standoff distance of the sensor package must be maintained as the sensor passes each drum.

In order to provide the required geometry, inspection platforms will be built so as to position two arrays of laser line projectors to generate two contiguous horizontal laser lines on the drum (See Fig. 2.). Two laser lines are required to fully inspect each drum's visible surface, since the cameras' view of each laser line will be periodically blocked at the top or bottom of each drum. An interlaced array of CCD cameras will sequentially capture the laser line image as the inspection array moves vertically, parallel to the drum axis. Data from the geometric inspection will be transmitted to the operator computer during the inspection mission for subsequent computer analysis.

Drum Locating

Since the structured light system requires its lasers and cameras to be aimed accurately relative to the drum axis, a drum locating subsystem will use ultrasound sensors to locate each drum during the inspection. One pair of ultrasounds mounted on the vehicle will locate the bottom most drum to position the vehicle for inspection of a drum column. As the inspection array moves vertically and transitions to subsequent drum levels in the column, another set of sensors mounted on the inspection array will provide drum location information so that variations in

drum location within the column can be accommodated.

Rust Spot/Streak Analysis

As drums are inspected, SWAMI II will also capture and transmit color drum images to the operator computer. In order to achieve the required resolution, each drum will require several piecemeal images to be taken. The operator computer will then perform an image analysis for rust spots and streaks, and will present only those drum images which indicate a potentially unacceptable corrosion condition to the operator. Drum images and associated data will be archived in a mass storage medium accessible to the operator and other site organizations. A prototype for the rust analysis system was developed by Martin Marietta Astronautics. Lawrence Livermore National Laboratory is developing the rust analysis subsystem for SWAMI II.

Site Database Interface

Fernald is implementing a Sitewide Waste Information Forecasting and Tracking System (SWIFTS). SWAMI II will interface with SWIFTS to obtain current information on the waste container inventory in the facility to be inspected, including each container's size and location within the facility. After an inspection, SWAMI II will report back to the database any discrepancies between the expected and discovered inventory. Drum images, geometric inspection data and other SWAMI II file data can also be accessed via the SWAMI II database.

Autonomous Backing

Since many of Fernald's aisles allow vehicle access from only one end, the base vehicle will be modified to allow autonomous backing with sensors to prevent collisions. Although the HelpMate is capable of backing to recover from a collision, its path planning software does not accommodate following a path while backing. Furthermore, the HelpMate's sensor array is configured for forward motion. The University of Michigan is developing an independent ultrasound subsystem which will use its own sensor array to navigate and control the base vehicle drive system during backing. It will also detect objects in its path to prevent collisions.

Scintillation Type Radiation Monitor

Scintillation-type radiation detectors are being implemented for SWAMI II. SWAMI I uses gas proportional detectors, which must be purged with P-10 gas before and during operation. Scintillation detectors do not require P-10 gas, so the onboard space requirements and mass of gas cylinders are eliminated. Lengthy preinspection purge times and gas management equipment are also eliminated. The computer and detector system is being developed by National Nuclear Corporation (NNC).

Position Determination

SWAMI II will also feature a position determination system being developed by the Georgia Institute of Technology. The system utilizes two CCD cameras mounted on a pan unit with strobes to illuminate retroreflective fiducials placed on the facility walls. Each fiducial has a pattern which the system uses to calculate both the direction and range to the target. The availability of range data will enable the system to calculate SWAMI II's position and orientation more accurately than the system used on SWAMI I. The Georgia Tech system also compares well with the SWAMI I system with respect to operating range: approximately 200 feet versus 100 feet.

SUMMARY

The SWAMI system will provide a safe, cost-effective and comprehensive method to perform mandated inspections of waste drums and obtain useful data for facility and waste management. Because it does not rely on extensive facility modifications, SWAMI will be able to be deployed in a specific facility with a minimum investment of time and capital. By automatically culling out those drums whose condition is acceptable, facility personnel can allocate more time to investigation and disposition of suspect drums.

ABSTRACT

In previously published work (Waste Management '94), the authors presented an analytic model which was developed to assist in performing site-specific assessments of both physical, and regulatory and institutional information in support of decision-making with regard to developing civilian, at-reactor SNF storage facilities (Reactor-Specific Interface, Storage, Modal Operations, and Regulatory Considerations Model).

This paper describes a Stakeholders and Issues Model which was developed as an outgrowth of the authors' previous work, and which represents an extension and expansion of the regulatory and institutional data base developed as part of the prior model. The paper focuses on the identification and characterization of parties (Stakeholders) that have historically intervened, and/or have been granted the right to intervene, in judicial, administrative, or legislative proceedings relating to the at-reactor storage and transportation of civilian SNF. The paper describes a process of documentation and characterization of Stakeholders, issues, and Stakeholder positions relevant to civilian SNF management over time. We conclude that such a process of data collection and characterization may be a useful tool to support waste management issues identification and resolution activities.

THE ROLE OF STAKEHOLDERS IN NUCLEAR WASTE MANAGEMENT

Spent fuel and high-level radioactive waste (HLW) storage and transportation activities have historically engendered heated controversy, political reaction, and extensive litigation. The debate over such activities has involved several Federal and private sector shipping campaigns and related actions, and many Stakeholders, interrelated issues, and conflicting objectives over a substantial period of time. The experience of both responsible Federal agencies and private sector owners/shippers of SNF and HLW derived from such campaigns and such actions has consistently demonstrated that Stakeholders play a significant role, both directly and indirectly, in shaping public policy with regard to the management and transportation of these materials. Stakeholder activities, including exercise of applicable regulatory authority; intervention in Federal, State and local judicial, regulatory, and administrative proceedings; utilization of existing Stakeholder outreach/participation mechanisms and other public forums; and other demonstrations of interest have been, and will continue to be, an essential and intricate part of the process involved in identifying, shaping, prioritizing, and resolving issues relevant to the storage and transportation of SNF and HLW.

This important public policy role of Stakeholders was explicitly acknowledged in the drafting of the Nuclear Waste Policy Act of 1982, as amended (NWPA). In enacting NWPA, Congress recognized that spent fuel and high-level waste management and transportation had become important subjects of public concern, and that public and private sector participation in the planning and development of the nuclear waste management system was essential to promote better understanding and to foster public confidence in the safety of the program. As a consequence, provisions of NWPA went to unusual lengths to specify rights and to provide mechanisms and funding for

affected governments to oversee and participate in the program, and to provide extensive opportunities for public participation in, and comment on, the program.

DEVELOPMENT OF A MODEL TO TRACK STAKEHOLDERS AND STAKEHOLDER CONCERNS AND POSITIONS

Conflict over spent fuel and radioactive waste management activities has been extensive and often very complex. There have been a significant number of administrative and judicial "events" related to spent fuel and high-level radioactive waste transportation and other activities, and a correspondingly large number of identifiable Stakeholders and interrelated issues. We have found that the volume of such information and other factors make analysis and utilization of such information in decision-making and issues resolution processes difficult. These other factors which we have identified include:

Complexity of interests across events. Stakeholders may often have an interest in, and be active regarding, more than one relevant activity (e.g., transportation; storage; disposal) or program (e.g., commercial spent fuel management; Defense Complex site cleanup; foreign research reactor spent fuel acceptance). An identification of these various involvements may be necessary to understanding underlying or overall Stakeholders concerns.

Diversity and scope of Stakeholder representation. Coalitions of organizations are often formed to engage in relevant intervention activities. Also, we have found that the identification of national-level Stakeholder organizations with relevant interests/concerns may result from the investigation of regional/local members which they support. Such national organizations include the Union of Concerned Scientists, which has provided technical support to the administrative intervenors in proposed Calvert Cliffs (MD) and Point Beach (WI) at-reactor storage activities.

Interrelationship of issues. Issues relevant to the transportation of SNF and HLW may appear to be different from issues raised relevant to related activities (e.g. storage) or programs (e.g. Defense Complex site cleanup). However, such issues are often interrelated, as resolution of a storage issue may require or impact resolution of a transportation issue. A historical example is the suit brought by the NY Energy Research and Development Authority (May, 1982) for the return to certain utilities of spent fuel stored in West Valley, NY: this litigation triggered additional intervention by the proposed transit and receiving States.

Given the complexities involved, and the historically important role of Stakeholders in identifying, shaping, and prioritizing issues relevant to SNF and HLW management, the authors perceived a strong need for an analytic tool with which to identify and track Stakeholders and relevant issues and positions in a comprehensive and systematic manner.

The Stakeholders/Issues Data Base Model was therefore conceived and developed by the authors to assist in the identification, characterization, tracking, and correlation of Stakeholders, issues, and Stakeholder positions across relevant events and time ("relevant events" are defined as documentable judicial, administrative, and/or legislative proceedings). The authors believe that the Model can be used as a tool to aid in decision-making and in facilitating issues resolution by providing both historic and current information regarding Stakeholders and Stakeholder concerns and positions over a wide range of SNF and HLW management activities.

DESCRIPTION OF STAKEHOLDERS AND ISSUES MODEL AND COMPONENTS

The Stakeholders/Issues Model focuses identification, characterization, tracking, and correlation of Stakeholders, issues, and Stakeholder positions utilizing documented participation in particular events (defined in the preceding paragraph) relevant to the management and transportation of SNF and HLW. The Model's key components are Event Modules which record and organize, by event, data considered by the authors to be essential to Stakeholder characterization across relevant events and time.

The Event Modules consist of two sub-components of important data: 1) Stakeholder identification and characterization and 2) Issue identification and characterization. The Stakeholder identification and characterization sub-component includes important information regarding a Stakeholder's organization, size, membership/constituency, etc. (as relevant) for each Stakeholder participant in the specific event. The Issue identification and characterization sub-component identifies the specific issues raised by each participating Stakeholder in order to characterize the relationships among the identified issues (e.g., nature, frequency, constituency, etc.).

The Stakeholders/Issues Model, with its component Event Modules and sub-components

and their relationships, is depicted in Fig. 1. Event Modules are separately categorized for use in Stakeholders/Issues analyses relevant to specific types of activities. For example, Fig. 1 depicts three separate categories of Event Modules: 1) at-reactor (ISFSI) licensing and deployment events, 2) transportation campaign events, and 3) EIS-related events. A comparison of Stakeholders and of issues can be developed among these events.

The data contained in the Event Modules has been developed from several sources, including literature searches and reviews (e.g., relevant judicial, regulatory, and administrative case files and published reports regarding the specific events), supplemented by direct surveys, interviews, and correspondence with party participants in the events.

The Model can be utilized to provide outputs of information identifying, characterizing, tracking, and correlating relevant events, Stakeholders, and issues in a variety of ways. The next Section of this paper provides some examples (a "walk through") of the potential outputs of the information from the Model.

CHARACTERIZATION OF WASTE MANAGEMENT EVENTS, STAKEHOLDERS, AND ISSUES

We have mentioned that this paper focuses on relevant judicial, administrative, and legislative proceedings or "events". By way of illustration, Table I presents a description of selected, at-reactor storage (ISFSI) licensing and deployment events for which documentation of Stakeholder participation is available and for which Stakeholder participation may be characterized through the use of the Model.

The above-cited efforts to license and deploy ISFSI technologies have generated significant public interest from diverse geographic areas, economic segments, and political/ideological positions from around the country. Table II characterizes 100 participants or Stakeholders in the six selected ISFSI events (note that a Stakeholder has been counted once for each of the presented events in which it has participated). The data indicates the diversity and number of governmental and private entities which hold that their jurisdiction, geographic area, or economic segment may be directly affected by the deployment of proposed at-reactor storage technologies. As a further example of this diversity, Table III depicts the specific organizations which are included on Table II in the category of Regional, State, and Local Energy and Environmental Concerns.

As a means of further characterizing Stakeholders, the Data Base Model enables us to compare Stakeholders across events in order to gain a perspective of the relationships (if any) among the issues associated with the different aspects of SNF and HLW management (storage, transportation, disposal). The model currently focuses on storage and transportation. Table IV presents examples of Stakeholders which have historically taken positions in both at-reactor storage events and transportation campaigns, i.e., events.

One of the findings of this correlation of data is that Stakeholders can be identified which have historically played a role in different aspects of SNF management (this finding is discussed again below with particular reference to transportation issues). This appears to result from the fact that certain SNF storage facilities have generated (or have been perceived as having the potential for generating) intense transportation activities. By way of contrast, the current public debate over at-reactor storage includes the issue of "permanency", i.e., the issue of whether it is feasible to expect dry-stored SNF to be removed to a centralized storage location (MRS) or to a disposal site in the near-term.

Transportation Issues

Table IV also depicts examples of the variety of intervention activities in which State, local, and non-governmental transportation Stakeholders have historically engaged, which have included (but have not been limited to): the attempted promulgation of regulations restricting (e.g. requiring special permits) or banning (effectively re-routing) SNF shipments; the attempted imposition on the shipments of State environmental requirements (i.e., State of Wisconsin, spill prevention and clean-up plan, 1985) and of NEPA requirements (twice successful, e.g. Sierra Club in 1988 and State of Idaho in 1989); and formally requesting that the U.S. Nuclear Regulatory Commission (NRC) impose extra-regulatory transportation safety/safeguard measures on the shipments (State of Illinois, 1983). Transportation Stakeholder activities have also included convening Public Hearings and other attempts (e.g. petitioning NRC) to participate in SNF transportation decisions and activities.

The transportation issues represented by these Stakeholder activities, as interpreted by the authors with reference to the campaign Data Base, fall into six

categories which are depicted on Table V; Table V also depicts the percentage of Stakeholders which have raised an issue. As noted on the Table, the available data may be biased toward those issues for which SNF transportation Stakeholders perceive a judicial, administrative, or legislative recourse. In this regard, we note that many such Stakeholder actions have included making various petitions to NRC which have been denied, and imposing route-related transport restrictions which have been preempted by the Federal Hazardous Materials Transportation Act (HMTA).

Earlier in this paper we demonstrated that certain Stakeholders have played a role in both SNF storage and transportation events. As depicted on Table V, our analysis of transportation issues confirms the earlier-described finding: one frequently recurring transportation issue has historically been whether or not the transportation campaign has been necessary and/or desirable, as compared to continued, in-place SNF storage. This controversy appears likely to escalate: as the National debate over at-reactor vs. centralized storage continues, it can be expected to be perceived as directly impacting additional Stakeholders.

CONCLUSIONS

Stakeholders have played, and will continue to play, an important role in the identification, shaping, prioritizing, and resolution of issues relevant to the management of high-level radioactive materials. Stakeholders are both numerous and diverse, and represent multiple segments of the U.S. population.

The Stakeholders and Issues Model developed by the authors appears to be a useful tool to assist in the identification and tracking of Stakeholders, issues, and Stakeholder positions relevant to the transportation and storage of high-level radioactive materials across relevant events and over time. This capability appears to be useful to aid in decision-making and in facilitating issues resolution by providing both historic and current information regarding Stakeholders and Stakeholder concerns and positions over a wide range of high-level radioactive waste management activities.

ABSTRACT

Remediation of the Department Of Energy (DOE) Fernald site located north of Cincinnati will generate large quantities of low-level radwaste. This volume includes approximately 1,050,000 tons of material to be removed from eight waste pits comprising Operable Unit 1 (OU-1). The remedial alternative selected includes waste material excavation, drying and transportation by rail to a burial site in the arid west for disposal.

Rail transportation was selected not only because rail transportation is safer than truck transportation, but also because of the sheer magnitude of the project and the availability of bulk rail car unloading facilities at a representative disposal site. Based upon current waste quantity estimates as presented in the Feasibility Study for OU1, a fully-loaded 47-car unit train would depart the Fernald site weekly for five years.

This paper illustrates the steps taken to obtain agency and public acceptance of the Record of Decision for the remedy which hinged on rail transportation. A preliminary, but detailed, rail transportation plan was prepared for the project to support a series of CERCLA public meetings conducted in late 1994. Some of the major issues addressed in the plan included the following:

1. Scope of project leading to selection of rail transportation
2. Waste classification

3. Rail Company overview
4. Train configuration and rail car selection
5. Routing
6. Safety
7. Prior Notification Requirements
8. Emergency Response

A series of three public meetings identified a number of issues of prime concern to Fernald stakeholders. Following resolution of these issues during the public comment period, a Record of Decision (ROD) approving implementation of the rail transportation strategy was approved pending incorporation of EPA and State of Ohio comments on December 22, 1994.

INTRODUCTION

The Fernald Environmental Management Project (FEMP), formerly the Feed Materials Production Center (FMPC), is a Department of Energy (DOE) site which produced high-quality uranium for military defense beginning in 1951. Production at the FEMP was halted in July 1989. Later that year, the facility was placed on the National Priorities List (NPL) and designated as a Superfund site under CERCLA. The Fernald Environmental Restoration Management Corporation (FERMCO) assumed cleanup responsibilities from Westinghouse Environmental Management Company of Ohio (WEMCO) in December 1992 as the DOE's first environmental restoration management contractor (ERMC). The site is now being remediated under terms of a Consent Agreement with the U.S. Environmental Protection Agency (USEPA) and a Stipulated Amendment to the Consent Decree with the State of Ohio.

Remediation of Operable Unit 1, one of the five Fernald CERCLA Operable Units, will generate over 780,000 cubic yards of material from Waste Pits 1 through 6, a clearwell and a burnpit. The waste material in these pits were generated by chemical and metallurgical processes associated with the Fernald production mission and included slags, sludges, precipitates and filter cakes. The CERCLA Feasibility Study for Operable Unit 1 identified excavation, drying and waste transportation by rail to a permitted commercial disposal facility (such as the site owned by Envirocare of Utah, Inc.) located in the arid west as the recommended leading remedial alternative.

Although Fernald has rail access and currently uses rail transportation for coal delivery, the magnitude of the project made it clear that local Fernald stakeholders would have considerable interest in all aspects of rail movement of waste. To support this anticipated level of public interest, two public meetings were scheduled prior to actual presentation of the Operable Unit One Proposed Plan in a formal public meeting as required by CERCLA. Specifically, these meetings included a rail transportation workshop on August 9, 1994, and an "Availability Session" a week later between the public and CSX railroad, the initiating rail carrier. The meetings were successful in not only communicating Fernald transportation plans but also in obtaining stakeholder input into detailed transportation plans to be developed during implementation of the project.

These meetings were themselves preceded in early 1994 by a series of interactions in the form of workshops focused on the progress of the Remedial Investigation/Feasibility Study (RI/FS) and targeted individual communications and meetings with key stakeholders. At these workshops and meetings, DOE provided a definition of the evolving scope of the cleanup and reviewed critical issues. This early work allowed DOE to ascertain many of the specific issues of concern well in advance of the transportation focused meetings held in August. More importantly, the advance work enabled DOE to identify which stakeholders required more detailed information and which issues would be their focus of concern.

THE RAIL TRANSPORTATION OPTION

The formal presentations delivered to the public beginning in August, 1994 covered the overall rail transportation plan and addressed specific concerns that had surfaced during earlier dialogue with the public in numerous forums. The presentations were outlined as follows, with the following objectives:♀

Scope of the Project

It was pointed out that over 1,000,000 tons of material would require transportation to the Envirocare site located over 1900 miles from Fernald. To illustrate the magnitude of the project, an illustration was prepared showing the anticipated volume of material in the Rose Bowl football playing field (including end zones) stacked to a height of 122 yards.

PURPOSE
The intent was to indicate that the magnitude of the project was so great that transportation by truck could not be considered a reasonable alternative to rail transportation from the perspective of local traffic and project risk management.
Waste Classification
It was pointed out that the Operable Unit 1 material was classified as Class A waste, lowest on the scale including Class A, Class B, Class C, Greater than Class C and high level waste. It was also pointed out that the material was classified as Hazard Class 7 under DOT hazardous material transportation requirements.
PURPOSE
The intent was to illustrate that the material to be transported was relatively innocuous as compared to other nuclear material routinely transported by railroad and that standard procedures existed within DOT to transport the material.
Rail Company Overview
Information was presented on safety records, quantities of material transported, revenues, etc. for both CSX and Union Pacific, the two railroads involved in the movement.
PURPOSE
The purpose was to illustrate that two of the country's largest and most reputable rail transporters would be involved in the project. These companies have adequate infrastructure and hazardous material transportation experience to handle the project.
Train Configuration and Rail Car Selection
It was stated that in order to complete the project within the conceptually proposed five-year window presented in the Feasibility Study, a 47-car unit train would leave the Fernald site every eight or nine days. In essence, three separate trains would cycle continuously between Fernald and the Envirocare site. It was emphasized that the unit train concept was adopted based on stakeholder desire to minimize risk and maximize control over waste shipments.
The project would involve almost 11,000 car loads of material and 230 train trips. One hundred ton gondola cars were presented as the rail car of choice because of their efficiency in transporting bulk material and compatibility with existing off-loading facilities. The material would be wrapped in a flexible membrane within the gondola car and the rail car itself would have a hard cover attached.
PURPOSE
The presentation of the three unit train concept was intended to make the scope of the project very clear and understandable. The numerous car control and transit time advantages of unit trains over regularly-scheduled freight service were emphasized. Gondola cars were presented as being a proven vehicle for this type of service. The flexible membrane and hard covers illustrated the intent to go beyond normal DOT transportation requirements.
Routing
Local, regional and national routing plans were presented using detailed maps for each portion of the movement. The anticipated number of Fernald shipment carloads were then compared to the number of carloads of hazardous material passing through Cincinnati annually.
PURPOSE
The intent was to pull no punches and explain exactly where trains would be passing. Each individual was able to assess the impact these movements would have on their personal circumstances. The communities where Operable Unit 1 project personnel reside were clearly labeled on the local and regional maps.
The comparison of Fernald shipments to other hazardous shipments passing through Cincinnati were intended to illustrate that the impact of Fernald shipments would be minimal and, moreover, that emergency response controls were clearly in place.
Safety
The safety statistics of transportation between rail and truck were compared.
PURPOSE
The logistic of transportation between rail and truck were compared from their perspective of community traffic impact. It was graphically illustrated that one 47-car unit train could transport waste equivalent to that contained in 219 truck shipments. Statistics, from the Association of America Railroads, were used to demonstrate that shipment of hazardous waste is safer per ton mile than by truck.
Prior Notification Requirements

Legal requirements for prior notification to communities along the rail transportation route were presented.
PURPOSE
It was pointed out that, although there were no legal requirements for prior notification, Fernald had plans to go beyond these requirements with total openness with both local stakeholders and transited states.
Emergency Response
The six levels of rail emergency response available in the event of an emergency were presented in detail including:
- train crew
- railroad emergency response organization/emergency response subcontractors
- local authorities - on scene commander
- state emergency response organizations
- DOE regional radiological assistance teams
- Fernald emergency response organization
PURPOSE
The exhaustive presentation illustrated that the infrastructure to handle rail emergencies is 1) substantial and 2) already in place.
MAJOR ISSUES
Attendance at the rail transportation workshop held on August 9, 1994 indicated that local stakeholders had an intense interest in Fernald rail transportation issues. Although lively discussion occurred in virtually every aspect of the project, three issues elicited the most vocal response at the meeting and subsequent public comments.
Use of Shandon Switchyard
The Shandon Switchyard is a small switchyard located west of Fernald adjacent to DOE property. In order to reduce the amount of new rail infrastructure to be constructed on the Fernald site for rail car staging and storage, the Shandon Switchyard was considered for this purpose. Through community involvement, discussions with rail companies and field observations by DOE and FERMCO, it was determined that upgrades would be required for the Shandon Switchyard. These upgrades would require track replacement and lighting and security installation at minimum before use of the Shandon Switchyard could be implemented.
In general, the public reaction to the use of the switchyard was negative for a number of reasons, including: 1) potential spread of contamination and 2) stakeholder fears that safeguards and controls at the offsite Shandon Switchyard location would be difficult to administer thus subjecting the yard to intrusion.
A subsequent detailed evaluation of the cost associated with the use of Shandon Switchyard for storage of either only empty, or both empty and filled cars was performed. This study compared the use of the Shandon Switchyard with on-site rail upgrades indicating that the expected cost savings associated with the use of Shandon Switchyard did not justify pursuit of this option, particularly in view of public opposition. As a result, current plans are to construct the rail upgrades necessary to accommodate rail car storage and staging within the current perimeter of the Fernald site.
Fernald-Cottage Grove Branch Line
The Fernald plant and several local businesses access national rail service via the 24 mile "Fernald Branch Line" connecting Fernald to the CSXT main line in Cottage Grove, Indiana. The branch line has received little use in recent years. As a result, repairs and upgrades to the branch line have been minimal. The branch line has five trestles and 24 road crossings. Substantial upgrades would be required to the branch line before Fernald unit train shipments could be initiated.
Local stakeholder concerns over the condition of this branch line focused on the condition of the track, the trestles (one of which is almost 900 feet long) and the absence of protected road crossings. There was much discussion over the jurisdiction of road crossings (the State DOT rather than DOE or CSX). The public was reassured that the branch line would meet all applicable Federal Railroad Administration requirements before initiating Fernald rail shipments. The public clearly indicated a desire to remain involved in the development of the rail transportation plan.
Relationship with CSX
The lack of use of the Fernald Branch Line in recent years resulted in minimal branch line maintenance. As a result, many landowners with property along the Fernald Branch line developed considerable animosity against CSX over issues such as

track conditions, drainage, shrub cutting, fencing, etc. It was clear to DOE that these concerns would have to be addressed. As a result, an "availability session" was scheduled one week after the rail transportation workshop to permit local stakeholders to meet with CSX to voice their concerns. CSX sent two representatives to represent the company at the meeting. Some frustration was vented by the public and CSX realized that they needed to re-establish themselves as a good corporate citizen and ensure that the branch line was maintained properly.

THE RESULT

On August 23, 1994, the official proposed plan for the remediation of Fernald Operable Unit One was presented to the public. It was clear that the earlier rail transportation workshop and CSX availability session did much to address the public concerns over rail transportation. Comments received by DOE during the subsequent public comment period indicated that the public supported the rail transportation option. An aggressive campaign of community involvement lead to the acceptance of this new waste transportation option, a robust program of rail shipments from the Fernald site. On December 22, 1994, the Record of Decision for the remediation of Operable Unit One was approved by the USEPA.

ABSTRACT

The U.S. Department of Energy (DOE) has performed a global scoping of packaging and transportation needs. The assessment will allow DOE to prepare for changes in its transportation requirements in the future. This needs assessment, which was initiated in mid-August 1994 and completed in December 1994, provides a global look at the types and quantities of materials DOE will be required to package and transport from 1995 through 2030.

The results of the assessment indicate that DOE can expect a rapid increase in the shipment of radioactive and other hazardous materials during the late 1990s and on into the first decades of the 21st century. From a waste management standpoint, a significant increase in DOE-related packaging and transportation activities is expected as extensive remediation is undertaken at various DOE sites. For example, some 1400 facilities are expected to be transferred to DOE EM for decommissioning, decontamination, or other similar actions. As this occurs, the quantities of hazardous materials destined for long-term storage and/or disposal are expected to grow significantly. DOE must be prepared to accommodate these shipping needs relative to human resources, packaging, systems interfacing, logistics, regulatory compliance, training, and operations. The results of the needs assessment are expected to be used by DOE planners and managers to guide future efforts to most cost-effectively accomplish this changing mission.

Summary results of the Transportation Needs Assessment are outlined, presenting the findings in terms of both the projected growth of shipping patterns and the

resulting identified human resource, software, and hardware needs and their associated costs that DOE needs to prepare to satisfy in the future.

INTRODUCTION

The U.S. Department of Energy (DOE) has performed a global scoping of packaging and transportation needs. The assessment, which was initiated in mid-August 1994 and completed in December, 1994, will allow DOE to prepare for changes in its transportation requirements in the future. It provides a rational basis for DOE to plan, schedule, budget, and staff its support for future transportation.

This assessment is different from previous efforts in that it focused, to the extent possible, on projected, quantified shipping needs based on forecasts of inventories of materials which will ultimately require transport by the Department. In addition, experts provided inputs to the assessment on the growing needs throughout DOE resulting from changes in regulations, in DOE's mission, and in the sociopolitical structure of the country. Through the assessment, DOE's transportation needs have been identified for a time period extending from the present through the first three decades of the 21st century.

The needs assessment was accomplished in three phases that identified and assessed the following:

- the packaging, shipping, resource utilization, and method of managing packaging and transportation activities as they currently occur within DOE;
- the inventory of materials which DOE will need to transport on into the next century, as well as scenarios which project when, from where, and to where these materials will need to be transported;
- requirements (i.e., needs) and expected changes for DOE to accomplish the necessary transport safely and economically, based upon the current situation and the projections.

This paper summarizes some of the findings from the needs assessment. Included are summary discussions of the assessment's background, scope, and data sources. The projections of quantities of commodities to be shipped by DOE over the next few decades are summarized. A brief summary of some of the projected transportation requirements is then provided. Finally, an estimate of costs associated with satisfying these requirements is discussed.

BACKGROUND

The DOE has historically shipped various forms of materials into, out of, and between its sites. Data from the Shipment Mobility/Accountability Collection (SMAC) database for 1993 were used to establish a basis for comparing current packaging and shipping activities with projections for the future.

Exclusive of the large number of shipments arising from the Uranium Mill Tailing Remedial Action (UMTRA) program, which are handled separately in this assessment, most of the shipments made by DOE in 1993 were general commodities shipped by air or by motor freight in less-than-truckload (LTL) quantities. These shipments involved various types of

- general commodities (nonradioactive, nonhazardous materials shipment): 590,516 shipments comprising 95% of the shipments made by DOE;
- radioactive materials: 18,434 shipments comprising 3% of the shipments made by DOE; and
- hazardous nonradioactive materials: 14,735 shipments comprising 2% of the shipments made by DOE.

These data show that (in addition to some 200,000 UMTRA shipments) DOE was responsible for over 620,000 shipments in 1993, with a gross weight of approximately 495,000 metric tons. Though this is a small fraction of the 500 billion total commercial shipments made each year in the United States, it is comparable to the number of shipments made by large private U.S. companies, such as Dupont or Johnson & Johnson.

The needs assessment considered current and future projected numbers of shipments by commodity category and whether they were shipped

- inbound (from outside the DOE complex to a DOE site);
- intersite (shipment between two DOE sites); or
- outbound (to a site outside the DOE complex).

In 1993, 46% of shipments were inbound, 48% were outbound, and 6% were intersite.

SCOPE OF THE ASSESSMENT

The Transportation Needs Assessment report addressed, where possible, all significant domestic DOE transportation requirements for hazardous (both radioactive

and nonradioactive) and nonhazardous materials, including selected international shipments of radioisotopes and spent fuel. This included materials shipped by various DOE programs which are not shipped using the Transportation Safeguards System. The study contrasts the current system with future needs to the extent possible.

Relative costs and benefits of meeting future needs through changes in DOE's method of doing business are assessed within needs categories only. Data and study resources were insufficient to conduct a rigorous cost-benefit analysis.

SOURCES OF DATA FOR THE ASSESSMENT

In addition to using the SMAC database to establish current shipping requirements, future shipping needs were projected using the materials inventory data in the newly developed Baseline Inventory Report (BIR) and other individual sources as required. For example, specific program contacts provided inputs on laboratory samples (radioactive, mixed or hazardous), cesium and strontium capsules, high-enriched and low-enriched uranium, plutonium, and depleted uranium.

Disposition scenarios were selected by the team using DOE program sources such as Programmatic Environmental Impact Statements (PEISs) and other "official" sources. Underlying assumptions are stated.

The results of a survey of human resources utilized by DOE transportation activities, which was conducted by DOE in November 1994, were used to define the level of labor resources currently required by the Department to accomplish its mission and to serve as a basis for future projections of human resource requirements under different operating scenarios.

PROJECTIONS OF COMMODITIES TO BE SHIPPED

The assessment considered the following categories of materials:

1. General Commodities;
2. NonRadioactive Hazardous Commodities;
3. Miscellaneous Radioactive Commodities;
4. High-level Radioactive Waste;
5. Spent Nuclear Fuel;
6. Low-level, Mixed, and Transuranic Waste;
7. Contaminated Soil and Debris; and
8. Special Case Radioactive Materials.

Details concerning projected shipping rates for categories 6 through 8 will be provided in this paper, although all categories were included in the global shipment requirements and cost estimates which are discussed.

Since the sources of data for projecting quantities of materials to be shipped in the future generally provided only inventory and generation rate data, it was necessary for the study team to develop or assume site treatment processes and disposition paths based on information derived from other sources. For example, for several special cases, projections (scenarios) were developed based on data provided by experts in each field. These special cases included analytical laboratory samples, cesium capsules, highly enriched uranium, low-enriched and natural uranium, plutonium, and depleted uranium hexafluoride. The resulting projections therefore include estimates of the time period in which these materials will be shipped and whether the shipments will be inbound, outbound, intersite, and/or intrasite; however, these projections do not infer, in any way, that decisions have been made on any Federal actions, they are simply estimates of what could happen.

For the nonradioactive hazardous materials and miscellaneous radioactive commodities (e.g., instruments, medical isotopes, and radioactive materials, limited quantity), the 1993 SMAC annual shipping quantities were assumed to remain constant over the assessment time horizon.

The projections were developed in terms of the units generally used to quantify amounts of each commodity: for example, cubic meters of contaminated soil, low-level waste (LLW), mixed waste, or transuranic (TRU) waste; metric tons of initial heavy metal (MTIHM) of spent nuclear fuel (SNF); number of items such as high-level waste (HLW) canisters or special form capsules of radionuclides; or metric tons of hazardous materials or general commodities.

Table I summarizes the specific projections developed for the commodities in categories 6 through 8. This summary includes projections of total quantities shipped, type of shipment, and time period of shipments. The basic commodity categories and key underlying assumptions are as follows:

Commodity Category 6: Low-level, Mixed, and TRU Waste These materials will be

collected, treated and consolidated, and shipped for final disposition. Uncertainties for low-level and mixed waste are the selection of treatment, storage, and disposal sites and the degree of centralization of these activities. Uncertainties for TRU waste are the opening date and acceptance rate for the Waste Isolation Pilot Plant (WIPP).

Commodity Category 7: Contaminated Soil and Debris Treatment and disposition is already under way for contaminated soil and debris at UMTRA sites and for other DOE environmental remediation activities. Uncertainties include the total volume of materials and reduction in transportation requirements resulting from in situ treatment. Much of this transportation demand will be to move these materials for relatively short distances to consolidate contaminated material for final disposal. The underlying assumptions for the projections are that only 6% and 8% of the total non-UMTRA contaminated soil and debris is transported intersite and intrasite, respectively. Amounts will vary from site to site depending upon the nature of the contamination, characteristics of the soils, and the site's management capability.

Commodity Category 8: Special Case Radioactive This broad category includes the following:

- analytical samples ranging from no or low radioactivity to highly radioactive materials from HLW tanks and other sources;
- cesium capsules which are currently being returned to Hanford;
- uranium ranging from highly enriched to natural that will likely be transported to the Oak Ridge Y-12 site for permanent storage;
- plutonium, for which numerous disposition options are currently under evaluation by DOE (an option based on mixed oxide fuel production and use in commercial reactors was selected for this study); and
- depleted UF6, which was assumed to be primarily converted to U3O8 LLW at a commercial facility and returned to a DOE site for final disposition.

PROJECTED TRANSPORTATION REQUIREMENTS

Shipments of radioactive and other hazardous materials, primarily waste from site cleanup activity, will create the primary increase in transportation demand, particularly for intersite and intrasite transportation. With two exceptions, it is anticipated that DOE will generally meet major new transportation requirements by packaging the commodities and shipping them on fully loaded legal weight trucks (LWT) or rail cars. The exceptions are as follows: 1) no-, low-, or medium-radioactivity laboratory samples, and 2) radioactive isotopes which will generally be shipped in individual packages either by motor freight in LTL quantities or by air.

During the needs assessment, once the commodity quantity projections were developed, the number of truck and rail car loads of commodities requiring shipment and the individual packaging requirements were then projected.

It was not possible to specifically address the shipment of individual packages by LTL motor freight or air carriers. These shipments are currently a significant quantity and are expected to remain relatively constant over the next few years. Table II provides an abbreviated summary of the projected shipment history, in terms of combined full truck load and rail car load shipments (per year), for three aggregated categories of radioactive materials.

The low radioactivity materials were placed into two categories: UMTRA wastes, and non-UMTRA wastes. Most projected LWT shipments are intersite and intrasite or other short-haul shipments for UMTRA and other contaminated soil. These shipping projections are based upon the assumption that DOE will only ship approximately 50% of the UMTRA wastes and will ship only about 14% of the other contaminated soils and debris. If the amounts of UMTRA or non-UMTRA materials requiring transport were to increase, there would be a commensurate increase in the number of shipments required.

In the non-UMTRA low radioactive category, the outbound transport of depleted UF6, the intersite transport of LEU and LLW, and the inbound transport of depleted U3O8 accounts for most of the projected rail shipments. These shipments are projected to grow from a current level of less than 5000 shipments in 1993 and to peak at over 73,000 per year in the early 21st century. This is more than a factor of 12 growth in the numbers of these types of shipments.

Note that the estimated number of UMTRA shipments, which are typically only for a distance of a few miles. These shipments account for more than 200,000 shipments per year in the early to mid-1990s. The number of UMTRA shipments is projected to

decline to one-third that value in about 2010.
The number of truck/rail car loads of high/medium-radioactive commodities is projected to grow from 21 in 1993 to over 1,500 per year by the beginning of the next century. In the near-term (next 5 years), high-radioactivity laboratory samples, and SNF from naval, DOE, and university reactors are the primary sources of this projected growth. The LWT transport of TRU waste to WIPP in 2000 is projected to require 1000 truck shipments per year until 2020. From 2010 on, rail transport of HLW canisters and commercial reactor SNF to a repository is projected to be an increasing source of transportation demand, especially when compared to the single rail car shipment of HLW waste which occurred in 1993. Sources of other, smaller shipments are cesium capsules and highly enriched uranium. This projected annual volume of high- and medium-radioactive material shipments represents a major change which DOE needs to be prepared to address.

PROJECTED TRAVEL DISTANCE

The travel distance for all full rail car and truck load shipments was projected to increase in a fashion similar to the increases shown for number of shipments. It was projected that the total travel distance will rise from 10 million miles per year (excluding UMTRA) in 1993 to over 37 million in the early 21st century. The estimate that over half of the new shipments will be intrasite limits the increases in travel mileage. Should more materials move off of DOE sites, these estimates will be low.

PROJECTED HUMAN RESOURCE NEEDS

It was quickly determined that one of the major costs associated with DOE's packaging and transportation activities is the cost of human resources. Part of the needs assessment therefore focused on defining the current and project human resource requirements and the costs associated with them.
Following a brief review of some of the DOE's field offices and the contractors associated with the field offices, it was estimated that approximately 3200 full-time equivalent (FTE) staff are currently required to operate the current DOE transportation system. This number consists of approximately 800 managerial and administrative personnel and an estimated 2400 FTE hourly personnel performing shipping, receiving, and local transportation functions. The assessment team estimated that three times as many additional hourly personnel perform other DOE transportation activities, and these figures were the basis for projecting human resource needs into the future. In turn, these estimated resources were then used to estimate costs.

PROJECTED OTHER NEEDS

Other needs were quantified in the packaging and carrier area, including the need for over 1.7 million 55-gallon steel drums per year for packaging low-level, mixed, and TRU waste for shipping in the early 21st century. Also, there will be a need for over 150 reusable shipping casks for spent nuclear fuel, canisters of high-level waste, and TRU shipments.
Added transportation requirements for various radioactive materials and wastes will require the full-time, continuous availability of the equivalent of at least 750 rail cars and truck trailers.

PROJECTED COSTS AND COST SAVINGS

The data which have been only briefly summarized here were combined with packaging and infrastructure data to provide a "top-level," rough order of magnitude (ROM) projection of costs for accomplishing DOE's shipping mission. All cost figures were provided in FY 1995 constant dollars.

"Base Case" System Costs

Through 2030, it was estimated that under the current method of performing packaging and transportation activities, DOE will spend on the order of $30 billion to meet its projected shipping needs if it continues to operate in its current fashion. These costs include all identified human resource, packaging, carrier, and vehicle and site maintenance infrastructure costs. Table III summarizes these estimates for 1993 with projections at 10-year intervals starting in 2000. As noted above, the costs are only rough approximations because of the "broad brush" nature of this assessment and limited data availability. In particular, the DOE does not currently collect the cost and activity data needed to precisely quantify its costs or project its transportation resource needs.
It is felt that these projections establish a starting point for defining future funding needs and for assessing potential areas for significant cost savings. Costs estimates shown are those associated with the actual packaging of materials for

shipment and the performance of the shipment activities. These costs are borne by the individual DOE sites and programs.

Improving Transportation System Costs

The ROM cost analysis was used to identify potential areas for cost reductions and to approximately quantify such cost reductions. The cost analysis for an improved system often used the best judgement of experienced personnel to establish potential cost savings that would arise in each area associated with an integrated systems approach. An integrated systems approach to transportation resource management was assumed for estimating these cost savings. In this assumed approach the primary emphasis was on developing tools and methodologies and implementing them within the DOE complex in a manner such that:

personnel could become more efficient in performing their tasks (improved productivity);

greater efficiencies would result from aggregating shipments, improved utilization of carriers and improved carrier-service procurements;

packaging costs would be reduced through consolidating procurements and standardizing package designs across the DOE complex;

better tariffs would be available through negotiations and by taking advantage of multiple-site shipments; and

more efficient use would be made of equipment, facility, and other hardware-related resources.

It was estimated that if these steps were taken, an improved system could result which would have the potential for significant cost savings as illustrated in Table IV. Such steps should not only reduce costs, but might also enhance effectiveness and safety. However, it must be stressed that an integrated approach to transportation and the assumed development of the needed tools and methodologies and their implementation in the field, or a similar approach to enhanced efficiency, must be realized if these cost savings are to be achieved.

Potential Cost Savings

The data presented in Tables III and IV show specifically that, based upon the ROM cost estimates performed, the DOE's packaging and transportation costs might be reduced by about $7 billion through 2030. The cost reductions were assumed to be achieved through the application of an integrated systems approach to transportation resource management. The analyses summarized in these two tables illustrate that human resource costs may be expected to drive overall DOE transportation costs over the next few decades. This is illustrated in Table V, which shows that human resource costs account for just under $20 billion (65%) of the estimated $30 billion in total transportation costs for the base case. Of the $7 billion savings in the improved system case, $5 billion is due to more efficient utilization of human resources. These savings result from elimination of redundant functions and continuous upgrade of various tools and staff training.

CONCLUSION

Based upon the Transportation Needs Assessment, which has been briefly summarized in this paper, DOE is facing orders of magnitude increases in shipping rates of some radioactive and other hazardous materials by the 21st century. Total transportation costs over the period from 1993 to 2030 may reach $30 billion. However, there are a number of measures offering the potential for significant cost reductions. It was estimated as much as $7 billion might be saved over that time period. This estimated cost reduction is based upon a ROM assessment, assuming that an integrated systems approach to transportation resource management is implemented. This approach emphasizes developing tools and methodologies and implementing them within the DOE complex to enhance the field's capabilities and efficiencies. It was noted in the study that achieving these savings will require DOE to make near-term investments to accomplish these goals.

13-4

DEVELOPMENT OF AN OPTIMIZED PACKAGE FOR LOW AND MEDIUM LEVEL RADIOACTIVE WASTE

Dr. Manfred SAPPOK
SIEMPELKAMP GIESSEREI GMBH & CO., Krefeld/Germany

ABSTRACT

The paper reports on the development of an optimised package for the final repository KONRAD in Germany. The basic idea of this concept is to produce a container by using radioactively contaminated steel scrap coming from dismantling.

In a second step, highly radioactive waste is inserted into this container and finally, in a third step, residual space between the scrap and the container walls is filled by pouring in radioactively contaminated liquid steel.
This method optimizes the package volume and saves space in the final repository.
The project is sponsored by the Commission of the European Communities.

THE MELTING PROCESS FOR RADIOACTIVELY CONTAMINATED STEEL SCRAP AT CARLA PLANT IN GERMANY

Melting of radioactively contaminated steel scrap is commonly known as a practicable, ecological and economic way for treating metallic material coming from the dismantling of nuclear power plants and installations.
This process, resulting from parallel developments in Great Britain and Germany in the early eighties, is practiced today in Sweden, France, the United States and Japan as well. Further to the melting process, a method for the re-use of this steel for the production of components to be used within nuclear facilities was developed in Germany. Especially the production of packages for transport and storage of radioactive material led to satisfying solutions. A complete survey about the melting process, regarding all items from licensing to re-use, from legislation to melt materials, is given in the Report of the European Commission on the "Technical seminar on melting and recycling of metallic waste materials from decommissioning of nuclear installations" (5).
Thus, several thousands of tons of steel scrap have been recycled, especially in the production of casks for radioactive waste. While the ecological concept was convincing from the early beginning, it was the economic aspect which brought the melting process to the leading position in radioactive metal waste treatment.

PACKAGING CONCEPT IN A MONOLITH CONTAINER

As mentioned above, during the past few years, the production of waste packages re-using radioactive material became the preferable way - not only in Germany. It was the task of the companies GNS (Gesellschaft fr Nuklear Service mbH) and SIEMPELKAMP FOUNDRY to optimize the material quantity to be brought to the final repository, with special regard to the costs of this disposal.
Figure 1 shows the concept of the Monolith container, it illustrates the procedure in detail, as being performed in Germany. The package for final repository is produced in three steps:

Production of the Container for the Final Repository

Coming from the nuclear power plant, steel scrap with a specific activity below 200 Bq/g is melted and a package is produced suitable for transport and storage of radioactive material. The relevant demands will be discussed later. In our special project, the dimensions are as follows:

length	2,000	mm
width	1,600	mm
height	850	mm
wall thickness	150	mm
total weight	10.8	tons

Filling the Container

The monolith container produced by using low level radioactive material is transported to the nuclear power plant, where medium- or high-level radioactive material is loaded into the container. The lid is put on top of the container which is qualified as an IP2-container.

Producing the Monolith

The container is then brought back to the foundry, where radioactive steel is melted. Following the existing license for the melting shop, the specific activity may not exceed 200 Bq/g. Through special openings in the container lid, the residual space between the high-active waste components in the container is filled with liquid steel, which again is in the level of low radioactive material. The container is placed right in front of the furnace and liquid steel is poured through the openings in the lid, filling the entire container to form a solid iron block.

Going to the Final Repository

The cask is now an optimum size for final disposal; the outer geometry is suitable as demanded and no empty space wastes the volume of the final repository.

REGULATIONS TO BE OBSERVED IN GERMANY

Two types of regulations influence the design of this package:
- demands on the physical integrity of the package
- limits for activity content.

Figure 2 gives a survey of the different demands on the integrity of the package. Basically, for the transport, the IAEA Safety Series are the regulations which are in correspondence with the German GGVS (Ordinance on Transport of Dangerous Goods). For the three transports (from foundry to nuclear power plant, back to the foundry and then to the final repository or intermediate storage) industrial package Type II was chosen as package design.
For the production of the package itself, radioactive material was used. Thus the transport from the foundry to the nuclear power plants has to be done under observance of the regulations, which means that a drop test from a height of 30 cm has to be carried out as well as a water spray test and a drop of a bar of 1 kg in weight from a height of 1 m onto the package.
There are no additional demands on the integrity of the package coming from the intermediate storage Gorleben. In addition to the IAEA Safety Series, the conditions for final repository KONRAD are higher, even for Type IP II packages. KONRAD repository defines two categories (Classes I and II) with lower demands put on Class I containers. In this case, a drop test from a height of 80 cm without losing the integrity must be fulfilled. In addition, in a fire test of one hours' duration at a temperature of 800C, a loss of activity below 1 Mol of the contents of the package is allowed at maximum (see Fig. 3).
The second point of interest are the activity levels to be filled into the package following the different demands of the regulations.
According to IAEA Safety Series, the maximum allowed contamination of the outside surface of the package is 10 Bq/cm. This demand is easily fulfilled by cleaning the package before transport.
The second demand, from German GGVS conditions, is that the maximum allowed surface contamination of the material being packed into the package must be below 8 x 105 Bq/cm for b- and g-emitters and below 8 x 104 Bq/cm for a-emitters. The specific activity to be filled into the package must be below 2 x 10-3 A2/g. As to be shown later, this leads to a maximum allowed activity concentration of 8 x 108 Bq Co60 per package and approx. 106 Bq Fe55. Experience shows that these two nuclides are the most important and the only ones to be considered.
For the intermediate storage Gorleben, only the Co60-content limits the maximum allowed activity concentration in the package. In this particular case, the maximum allowed total activity is 9.25 x 1011 Bq Co60.
Finally, KONRAD conditions show the highest allowed activity level which is at 5.5 x 1012 Bq Co60. The limits for Fe55 are several orders of magnitude higher and lead to no restrictions.
In addition to that, the dose rate at the surface of the package must be below 2 mSv/h in average and 10 mSv/h as maximum value. The maximum allowed dose rate at a distance of 2 m must be below 0.1 mSv/h.
One final limiting condition for the packages is given by its maximum manageable weight, which in the final repository KONRAD is 20 tons. This means that the weight of the package plus the material to be inserted and the material to fill the space between inserted material may amount to a maximum weight of 20 tons.
The table below gives an idea of the different masses the final monolith container consists of. The weight of the package with a wall thickness of 150 mm is 10,850 kg. For the production of this cask, radioactive material in a range of 40% is used which leads to a sink of 4,340 kg radioactive material.

- Weight of package 10,850 kg
- incl. radioactive material (</= 200 Bq/g) used for production (40 %) 4,340 kg
- Material to be filled in (HAW) (20 % filling factor) 1,840 kg
- Material to be poured to fill residual space (</= 200 BQ/g) 7,310 kg

Total allowed mass per package 20,000 kg
The container with a volume of 1.18 m can take up 1,840 kg of high-active waste, representing a filling factor of 20%. This figure is the result of several tests carried out before.
80% of the volume of 1.18 m are residual space between the radioactive waste components and can be filled up with liquid steel in the foundry. This leads to 7,310 kg.
As you can see, the design of the package was chosen to come to a weight of 20 t in

total, which is acceptable for the final repository KONRAD mine.

COSTS FOR DIFFERENT WAYS OF DISPOSAL

Besides all ecological considerations, the economic factor actually defines the way to final storage. The costs of three different possibilities of final storage for radioactively contaminated steel scrap have been compared:

-Conventional package

In this case, material is packed into 200-l-drums, which are in turn loaded into a final storage container.This package is brought to the final repository.

-Supercompaction

The radioactive material is supercompacted; the pellets are put into final storage containers and then taken to the final repository.

-Monolith container

The radioactively contaminated metal scrap is treated as described above and the solid block is taken to final repository.

Figure 4 shows a cost comparison between the three different methods. Basis for the cost estimates are experiences gained at SIEMPELKAMP foundry, further cost factors were taken from the report of Teunckens et.al. "Economic Aspect of Melting and/or Recycling of Waste Metals from Decommissioning" (5, p. 309).

The basis for this cost comparison was the total weight of a monolith container, i.e. 20 tons. To come to comparable quantities of metal scrap to be treated, this quantity was reduced by the non-contaminated material used for the production of the final storage container.

Nevertheless, the volume of 2.5 cm to be stored in the final repository was maintained.

The density of unconditioned scrap being filled loosely into 200-l-drums is approx. 20%, a representative figure derived from the treatment of several thousands of tons in Germany.

For supercompaction, an average density of 3.5 tons/cm should be an optimistic value for this disposal method.

After packing the unconditioned metal scrap into 200-l-drums, these have to be packed into a final repository container, following the conditions of the German KONRAD mine. In this case, approx. 60% of the container volume are not being used.

It was assumed that - before being taken to the final repository - the waste material will be kept in an intermediate storage for 5 years. This leads to additional, considerable costs.

The costs for final repository in Germany today were calculated with a figure of 10,000 $/cm. This is the actual fee for final repository Morsleben, which is presently in operation, and it is made up of 8,500 $ repository costs and 1,500 $ documentation. The same figure is presently being discussed for the final repository KONRAD, but this price will be subject to development until KONRAD will open its doors.

The comparison shows that - including the costs for final repository - the Monolith container has an advantage of approx. 50 % versus unconditioned packaging and an advantage of approx. 30 % compared to supercompaction. When final repository costs are not considered, the advantage goes down to 15 % compared to untreated scrap and remains at approx. 25 % compared with supercompaction.

In any case, regarding the safety aspects, it is of advantage to have a solid block going to the final repository.

STATE OF THE PROJECT AND FURTHER PROCEDURE

This project is carried out by the project partners KRB Gundremmingen, EWN Greifswald, GNS Essen and SIEMPELKAMP Krefeld. A delay in the project was caused by the fact that this container has to pass a license procedure at the German authorities BfS (Bundesamt fr Strahlenschutz = Federal Agency for Radiation Protection) and BAM (Bundesamt fr Materialforschung und -prfung = Federal Agency for Materials Research and Testing).

The delay of one year is particularly due to the fact that the dimension of the Monolith container is not proposed in the preliminary final storage conditions as they exist right now. Approval has recently been given to continue with the development of this container, the license is expected to be granted in early summer this year.

In parallel to this licensing procedure, one prototype container was cast and tested with non-radioactive material.

A hot test container has been produced and is on its way from the foundry to KRB

Gundremmingen. In Gundremmingen, the container will be charged with high active waste coming from the reactor vessel of KRB plant. The container will be filled and tested. As soon as the results show that it works as demanded, four other containers will be produced and filled with the rest of the reactor pressure vessel - the highly active part in the central area.
It is envisaged to conclude the project by mid-1996.

ABSTRACT
The U.S. Department of Energy (DOE) is considering a policy to manage spent nuclear fuel (SNF) from certain foreign research reactors (FRRs). The policy, described fully in the Implementation Plan(1) would involve shipment of up to approximately 840 casks from locations overseas and in Canada, via truck or rail, to one or more DOE facilities, and could involve the shipment of SNF between DOE sites. This paper provides an overview of the transportation risk analysis performed for the Environmental Impact Statement (EIS) associated with this policy. Alternatives that involve the shipments of lesser amounts of fuel, and/or shipment of other materials (i.e., target material, vitrified waste) are also being analyzed.
The interim storage site or sites for the fuel will be determined under the Programmatic SNF Management and Idaho National Engineering Laboratory (INEL) Environmental Restoration and Waste Management Programs EIS (known as the SNF&INEL EIS), which will identify a preferred alternative from effectively 12 possible alternatives (1 of 5 DOE sites or 1 of 7 different site pairs) as the ultimate interim storage site. However, eight of the SNF&INEL EIS alternatives involve sites not immediately ready to receive fuel at the onset of this policy. Therefore, for each of these alternatives, a two-phased approach involving the use of sites currently capable of receiving SNF [the Savannah River Site (SRS) and INEL] is analyzed. Analysis has been performed for splitting the fuel between these two sites at least four different ways and for varying numbers of inter-site shipments. Additional complexity is added by the current approach of using about 10 different seaports.
The collective population risk, maximally exposed individual (MEI) risk, accident

risk, and nonradiological risk assessments were performed using established methodologies and codes. The risk associated with the policy varies by more than an order of magnitude, depending on which alternative is chosen under the SNF&INEL EIS, which site(s) are selected for short-term storage under this EIS, and whether truck or rail shipments are used.

INTRODUCTION

A draft EIS showing the potential environmental effects resulting from adoption of a proposed policy for management of SNF from FRRs is being prepared. The purpose of the proposed policy is to support nuclear nonproliferation objectives of the United States. Only spent fuel which contains uranium enriched in the United States would be accepted under this policy.

Environmental and human health effects of alternatives are analyzed. If the proposed policy is adopted and implemented, then spent fuel generated in FRRs could be imported to the United States and either: 1) be transported by ship to seaports in the United States, unloaded, and then transported by truck or rail to an interim storage site; or 2) arrive at the Canadian side of the United States-Canada border in an approved conveyance (truck or rail), and then be transported in that conveyance to an interim storage site.

The unique difficulty in preparing this analysis is that the scope of the policy involves the shipping of numerous types of SNF in at least 8 different casks from any of 10 or more ports to any of 5 DOE sites. This results in a potential for thousands of risk parameters for origin-destination pairs. For the purposes of analysis, the material was binned into representative groups, and the number of shipments of material corresponding to each group was estimated for each alternative.

This paper provides an overview of the approach that will be used in the FRR SNF EIS to assess the risks from the transportation of fuel. In additions, the most important assumptions and input parameters are discussed for analysis. A number of simplifying assumptions were necessary to make this analysis manageable and useful to the readers. Wherever possible, the methodology used is identical to that used in the SNF&INEL EIS(2) and described by Monette et al.(3).

APPROACH

The policy would involve transporting FRR SNF from the ports of entry (both marine ports and Canadian border crossings) to DOE sites, and could involve transporting FRR SNF between DOE sites. The proposed acceptance of FRR SNF is subject to the selection of a management site made in the SNF&INEL EIS(2). Regarding FRR SNF transportation, there are 12 distinct decisions that could be made from the SNF&INEL EIS(2). This decision is expected to identify the use of one or more of five candidate sites and seven distinct combinations of sites.

Certain assumptions are required in order to simply and consistently describe the manner in which FRR SNF is transported to the sites. First, the shipments were divided into East Coast and West Coast shipments, depending on the country of origin. SNF shipments from Europe, Africa, the Middle East, and parts of South and Central America were designated as East Coast shipments, and all others were designated as West Coast shipments. Shipments from Canada were assumed to enter the United States from either an eastern or western point of entry, depending on the Canadian point of origin. Under these assumptions, if all SNF identified is returned to the United States, the East Coast would receive approximately five-eighths of the cask shipments and the West Coast would receive approximately one-quarter of the cask shipments. Approximately one-eighth of the shipments would come from Canada into the eastern United States.

Eight of the alternatives involve sites that could not be ready to accept SNF at the onset of the FRR SNF program. Therefore, a two-phased approach is assumed using one or both of the sites that are ready to accept SNF (SRS and INEL) as a near-term storage location. Phase 1 is defined, for the purposes of analyzing transportation, as the period of time in which shipments of FRR SNF are transported to a near-term storage site. For analytical purposes, Phase 1 is assumed to last from the beginning of 1996 to the beginning of 2006.

The amount of fuel that would arrive in Phase 1 and Phase 2 cannot be precisely determined at this time. In order to proceed with the risk analysis, it is necessary to make assumptions based on the available information. The split between Phase 1 and Phase 2 depends on the rate at which casks are received and the time the Phase 2 site(s) is ready to receive fuel. For calculational purposes, the casks are assumed

to arrive at a uniform rate.
Since the SNF&INEL EIS(2) does not select a specific site or sites, the disposition of FRR SNF during Phase 1 is analyzed in this EIS. Logically, Phase 1 could entail anyone of four options: 1) splitting FRR SNF by fuel type (TRIGA, which stands for Training, Research, and Isotope reactors built by General Atomic, to INEL and aluminum-based to SRS), 2) splitting the SNF geographically by port of entry, 3) transporting all SNF to INEL, or 4) transporting all SNF to SRS. Not all Phase 1 strategies are consistent with all Phase 2 strategies.
Phase 2 would begin when the Oak Ridge Reservation (ORR), Hanford Site (HS), or Nevada Test Site (NTS) could be ready to receive fuel from ports and, when applicable, from a DOE site being used for near-term storage. In all cases, Phase 2 would be dependent on the decision of the SNF&INEL EIS(2) alternative. During Phase 2, all FRR SNF arriving at ports of entry would be transported to the appropriate site. Additionally, intersite shipments from the near-term storage site could also be arriving at the SNF&INEL EIS selected site(s).
In order to maximize the calculated impacts of accidents, a highly conservative approach was used to estimate the radionuclide content of the casks. The FRR SNFs were grouped into three classes and four fuel categories for the determination of bounding radionuclide inventories. This division was created to provide a conservative representation of radionuclide inventories and to provide a means for identifying the type of transportation casks to be used for estimating the number of shipments.
The selected fuel types for the determination of bounding radionuclide inventories are:
1. Special: aluminum-based fuels that do not fit the TRIGA or Materials Test Reactor (MTR) description.
    1a. Single-Element Reactors: SNF from research reactors that operate with one element (e.g., RHF of France).
    1b. NRU-Type SNF: SNF from Canadian Research Laboratories' research reactors (e.g., NRU and NRX) and from South Korean research reactors.
2. MTR SNF.
3. TRIGA SNF.
The ORIGEN2(4) code was used to calculate the radionuclide inventory in each SNF type, based on fuel burn-up, initial inventory, and minimum decay time. It was determined that, for calculational purposes, the use of IU-04 (Pegase) transportation cask maximizes the radioactive inventory and requires the shortest cooling period (a maximum of 1 year). All shipments were assumed to fit to one of the above selected fuel types at it's maximum radionuclide inventory for calculations of overland transportation accident risks.
It is important to note that the radionuclide inventories identified here are for calculation purposes only. In reality, the majority of the SNFs would have much lower radionuclide inventories than the bounding inventories listed here. The final assumption, and the assumption most important to risk, is that the casks will have an external dose rate that equals the regulatory limit for transportation vehicles. Calculations show that this dose rate limit (10 millirem per hour at any point 2 meters from the vehicle, per 49 CFR 173.441) could theoretically be achieved in a few casks; but in general, most casks will exhibit much lower radiation fields.
Incident-Free Risk Assessment Methodology
For each representative route, the incident-free risk was estimated for the population along that route. Incident-free analysis included both the affects of the radiation field associated with the cask and the emissions associated with the truck or rail vehicle used. Additionally, the hypothetical MEI was determined for each implementation approach.
Collective Population Risk: The RADTRAN 4(4) computer code was used to consider all major groups of potentially exposed persons. The RADTRAN 4 risk calculations for incident-free highway and rail transportation include exposures of the following population groups:
  Persons along the route (off-link population): Collective doses are calculated for all persons living or working within 800 m (0.5 mi) on each side of a transportation route. The total number of persons within the 1.6 km (1 mi) corridor is calculated separately for each route considered in the assessment.
  Persons sharing the route (on-link population): Collective doses are calculated for persons in all vehicles sharing the transportation route. This group would

include persons traveling in the same or opposite direction as the shipment, as well as persons in vehicles passing the shipment.

Persons at stops: Collective doses are calculated for people who may be exposed while a shipment is stopped en route. For truck transportation, this would include refueling stops, food stops, and rest stops. For rail transportation, stops are assumed to occur for classification purposes.

Crew Members: Collective doses are calculated for truck and rail transportation crew members.

The doses calculated for the first three population groups are added together to yield the collective dose to the general public. The dose calculated for the fourth group represents the collective dose to workers. The RADTRAN 4 incident-free dose models are not intended to be used for estimating specific risks to individuals. The RADTRAN 4 incident-free dose calculations are based on expressing the dose rate as a function of distance from a point source(5). Associated with the calculation of incident-free doses for each exposed population group are parameters such as the radiation field strength, source-receptor distance, exposure time, vehicle speed, stop time, traffic density, and route characteristics such as population density. The RADTRAN 4 code user's manual contains derivations of the equations and descriptions of these parameters(5).

The collective incident-free risks are calculated for each specific alternative as follows. Each alternative is first defined as a set of origin and destination pairs. Representative highway and rail routes are determined for each unique pair of DOE sites and ports. For each pair, RADTRAN 4 is used to calculate the collective risks to workers and the public for a single shipment based on representative radiological and physical properties of the SNF. These estimates for a single shipment are referred to as per-shipment risk factors. The number of shipments transported across each linkage is then determined for both truck and rail modes. The collective risks for an alternative are calculated by multiplying the number of shipments by the appropriate per-shipment risk factor.

MEI Risk: In addition to the incident-free collective population risk assessment, the risk to MEIs has been estimated for a number of hypothetical exposure events using RISKIND(6). The receptors include transportation crew members, inspectors, and members of the public exposed during traffic delays, while working at a service station, or living near a port of entry or DOE site.

The dose to each MEI considered is calculated with RISKIND for a given distance, duration, and frequency of exposure specific to that receptor. The exposure scenarios are not meant to be exhaustive, but were selected to provide a realistic range of potential exposure situations.

The RISKIND external dose model considers direct external exposure and exposure from radiation scattered from the ground and air. RISKIND is used to calculate the dose as a function of distance (mrem/hr for stationary exposures and mrem/event for moving shipments) from an SNF shipment based on the dimensions of the shipment. The code models the shipment as a cylindrical volume source, and the calculated dose includes contributions from buildup, cloudshine, and groundshine. As a conservative measure, potential shielding between the cask and the receptor is not considered.

Nonradiological Risk (Vehicle-Related): Vehicle-related health risks resulting from incident-free transport may be associated with the generation of air pollutants by transport vehicles during SNF shipment, and are independent of the radioactive nature of the shipment. The health end point assessed under incident-free transport conditions is the excess latent mortality due to inhalation of vehicle exhaust emissions. Risk factors for pollutant inhalation in terms of latent mortality have been generated(7). These risks are 1x10-7 mortality/km (1.6x10-7/mi) and 1.3x10-7 mortality/km (2.1x10-7/mi) of truck and rail travel in urban areas, respectively. The risk factors are based on regression analyses of the effects of sulfur dioxide and particulate releases from diesel exhaust on mortality rates.

Accident Assessment Methodology

To provide an assessment of SNF transportation accident impacts, two types of analyses were performed. First, an accident risk assessment was performed that takes into account the probabilities and consequences of a spectrum of accident severities using methodology developed by the NRC(8). The accident risk assessment used route-specific information for accident rates and population densities. For the spectrum of accidents considered in the analysis, accident consequences in terms of collective dose to the population within 80 km (50 mi) were multiplied by the

accident probabilities to yield dose risk. Second, to represent the maximum reasonably foreseeable impacts to individuals and populations should an accident occur, radiological consequences were calculated for an accident of maximum credible severity in each population zone.

Accident Risk Assessment: The accident risk assessment is treated probabilistically in RADTRAN 4. Accident risk is defined as the product of the accident consequence (dose) and the probability of the accident occurring. In this respect, the RADTRAN 4 code estimates the collective accident risk to populations by considering a spectrum of transportation accidents.

The RADTRAN 4 calculation of collective accident risk employs models that quantify the range of potential accident severities and the responses of transport packages (i.e., casks) to accident environments. The accident severity spectrum is divided into the same accident severity categories as were used in the SNF&INEL EIS(2). The models take into account the transportation mode and the type of packaging being considered. The accident rates, definition of accident severity categories, and release fractions used in this analysis are discussed further in a previous section.

For accidents involving the release of radioactive material, RADTRAN 4 assumes the material is dispersed in the environment according to standard Gaussian diffusion models. For the risk assessment, default atmospheric dispersion data were used representing an instantaneous ground-level release and a small diameter source cloud(5). The calculation of collective population dose following the release and dispersal of radioactive material includes the following exposure pathways:

- external exposure to the passing radioactive cloud,
- external exposure to contaminated ground,
- internal exposure from inhalation of airborne contaminants, and
- internal exposure from the ingestion of contaminated food.

For the ingestion pathway, state-specific food transfer factors, which relate the amount of radioactive material ingested by people to the amount deposited on the ground, were derived in accordance with the methods described by NRC Guide 1.109(9). Radiation doses are calculated using standard dose conversion factors in DOE EH-0070(10) and DOE EH-0071(11).

The collective accident risk for each alternative is determined in a manner similar to that described for incident-free collective risks. Accident risks are first calculated for each unique origin and destination pair ("per-shipment" risk factors) and then summed over all pairs to estimate the total risk for the alternative. The accident risk assessment uses site- and SNF-type-specific radiological and physical characteristics. In addition, the assessment uses route-specific population density information and accident rates derived for individual States.

Accident Consequence Assessment: The RISKIND code is used to provide a detailed assessment of the consequences of the most severe transportation accidents. The accident consequence assessment is intended to provide an estimate of the maximum potential impact posed by a severe transportation accident involving SNF.

RISKIND was used for the accident consequence assessment for two reasons. First, the code has the ability to model the complex atmospheric dispersion present in severe accident environments. The atmospheric dispersion is modeled as an instantaneous release using standard Gaussian puff methods. In addition, because severe accidents routinely involve fires, modeling of the potential radiological consequences takes into account physical phenomena resulting from the fire, such as buoyant plume rise. Second, RISKIND can be used to estimate the dose to MEIs in the vicinity of an accident. The location of the MEI is determined by RISKIND based on the atmospheric conditions assumed at the time of the accident and thermal characteristics of the release.

The consequences of the most severe accidents are calculated for both local populations and MEIs. The population dose includes the population within 80 km (50 mi) of the accident site. The exposure pathways considered are similar to those discussed above for the accident risk assessment. Although post-accident remedial activities (e.g., immediate evacuation of the public or cleanup of dispersed radioactive material) would reduce the consequences of an accident, these activities were not given credit in the dose calculations.

Because it is impossible to predict the exact location of a severe transportation accident, separate accident consequences are calculated for accidents occurring in rural, suburban, and urban population density zones. Moreover, to address the effects of the atmospheric conditions existing at the time of an accident, two

different atmospheric conditions are considered. The first case assumes neutral atmospheric conditions, and the second, stable conditions.
Release Fractions Used in Accident Assessment: Radiological consequences are calculated by assigning cask release fractions to each accident severity category. The release fraction is defined as the fraction of the radioactive material in a cask that could be released from the package in a given severity of accident. Release fractions take into account all mechanisms necessary to create a release of radioactive material from a damaged cask to the environment. Release fractions vary according to the SNF type and the physical and chemical characteristics of specific radionuclides within the SNF. For instance, most solid radionuclides are difficult to release in particulate form and are therefore relatively non-dispersible. Conversely, gaseous radionuclides are relatively easy to release in the likely event that the cask and SNF elements are compromised in an accident.
Two sets of release fractions were used in the assessment depending on the SNF type, consistent with the SNF&INEL EIS(2). Release fractions developed for MTR SNF were used for aluminum-clad fuels including BR-2, RHF, and NRU SNF; release fractions for TRIGA were used for the PRR-1 SNF.
For high-level waste (HLW) shipments, the modal study results are not applicable because of differences between SNF and HLW. Therefore, more conservative release fractions from NUREG 0170 are used for HLW accident analysis. Similarly, the NUREG 0170 scheme also is applicable for shipments of target material.
The values indicate that in the most severe accidents, 100 percent of the material is released from the cask -- a highly conservative assumption for most solid waste forms and somewhat conservative for a powder or cake-like material. The accident assessment also utilizes the fraction of the release that is aerosolized and the fraction of the aerosol that is respirable. The values for HLW and target material (assumed to behave as a loose powdered material) were taken from the recommendations provided in RADTRAN 4. These values are shown in Table I.
Therefore, the maximum total respirable release fraction for the most severe accidents is 5x10-8 for HLW shipments, and 0.005 for shipments of target material. The values shown above have been used in the accident calculations for shipments of target material and vitrified material for the FRR SNF EIS.
Nonradiological Accident Risk Assessment: The nonradiological accident risk refers to the potential occurrence of transportation accidents that directly result in fatalities not related to the shipment cargo. This risk represents fatalities from mechanical causes. Nonradiological accident risks are calculated for each alternative by multiplying the total distance traveled in each State by the appropriate State fatality rate. In all cases, the nonradiological accident risks are calculated using round-trip shipment distances.
Modeling Approach
Several of the SNF&INEL EIS(2) alternatives involve consolidation of all SNF to INEL and/or the SRS and, therefore, are single-phase programs that would require no additional shipments. However, many of the possible options require the use of HS, NTS, and/or ORR, and thus would require intersite shipments. The number of intersite shipments is calculated based on the assumption that the equivalent of 10 seagoing FRR casks will fit into a single rail cask that would travel between DOE sites. Similarly, it is assumed that the contents of four FRR casks would fit into a single truck cask for intersite shipment. This assumption is based on a review of the capacities of candidate casks and of alternatives for managing the fuel during Phase 1. These assumptions, which are neither definitely conservative nor non-conservative, are considered to be reasonable and realistic. The number of intersite shipments for SNF&INEL EIS(2) alternatives that would require two-phased approaches varies between none and almost 200. The variation is caused by the large number of unique combinations of Phase 1 and Phase 2 approaches depending on the specific management sites selected. Additionally, the variation is affected by the assumption that larger truck and rail casks would be used for intersite shipments. Since the fuel may actually arrive at a variety of ports, average shipment risk factors were calculated for East Coast ports to each DOE site, and an average shipment risk factor for West Coast ports to each DOE site. An advantage of this calculation is that it does not require that a specific port be selected for analysis purposes. This approach provides a reasonable model of the average or expected affect of the FRR SNF acceptance policy might on the public. This approach is conservative since the dose rates and curie content of the fuel used for the

analyses were selected to be conservative, but, as realistic as possible since it is impossible to predict the distribution of shipments among the capable ports.
The upper and lower bound risk estimates for the FRR SNF policy were also calculated. The upper bound assumes that an acceptable port with the highest per-shipment risk factors is used for all shipments, and the lower bound risk estimates assumes an acceptable port with the lowest per shipment risk factors is used. In general, the highest risk factors result from the longest shipments, and the smallest risk factors from the shortest shipments.

RESULTS

Displaying the calculational results requires far more pages than could reasonably be included in this paper and even challenges a reasonable sized EIS Appendix. Figure 1 shows the format used in the EIS to report the impacts. The figure shows, for an SNF&INEL EIS single alternative, the ranges of risk estimates for carrying out the activities. The sizes and relative positions of the ranges are similar for each SNF&INEL EIS alternative. Since it is not within the scope of this EIS to compare programmatic alternatives, no attempt was made to graphically show more than one programmatic alternative on a single figure.
Figure 1 shows that the risk associated with crew radiation exposure, public radiation exposure and traffic accidents are within the same order of magnitude for truck shipments. The risk associated with vehicle emissions is about an order of magnitude lower, and the risk associated with radiological accidents is about three orders of magnitude lower. This is driven by the conservative assumption that all shipments are at the maximum regulatory limit. If dose rate based on past practice were to be used, the radiation exposures for the crew and public would be an order of magnitude lower and the traffic accident risk would be the highest risk associated with the policy.
Fig. 1. Typical Range of Estimated Fatalities for a SNF&INEL EIS Alternative
For truck shipments, the largest contributors to the collective population dose were found to be, in decreasing order of importance: 1) incident-free dose to members of the public at stops, 2) incident-free dose to transportation crew members, 3) incident-free dose to members of the public sharing the route (on-link dose), 4) incident-free dose to members of the public residing along the route (off-link dose), and 5) accident dose risk to members of the public. Approximately 80 percent of the estimated public dose was incurred at stops, 15 percent by the on-link population, and 5 percent by the off-link population. In general, the accident contribution to the total risk was negligible compared with the incident-free risk.
For rail shipments, the largest contributors to the collective population dose were found to be, in decreasing order of importance: 1) incident-free dose to transportation crew members, 2) incident-free dose to members of the public residing along the route (off-link dose), 3) incident-free dose to members of the public at stops, 4) incident-free dose to members of the public sharing the route (on-link dose), and 5) accident dose risk to members of the public. Approximately 70 percent of the estimated public dose was incurred by the off-link population, 25 percent by the population at stops, and 5 percent by the on-link population. As with truck shipments, the accident contribution to the total risk in general was negligible compared with the incident-free risk, even when the SNF type is selected to maximize the accident risk results.
Comparing truck risks to rail risks, Fig. 1 shows that crew radiation risks are lower when SNF is shipped by rail. This is reasonable since the train operating crew is further from the cask than the truck drivers. Vehicle emission risk is somewhat higher when SNF is shipped by rail because of the conservative assumption of one dedicated train for each cask. A railroad diesel engine emits more pollutants per trip than a large truck engine. Traffic accident and radiological accident risks are estimated to be lower for rail transport than for truck because of the lower accident rates, on a per-mile basis, for trains.
The single largest contributor to the collective population doses calculated with RADTRAN was found to be the dose to members of the public at truck stops. Currently, RADTRAN uses a simple point-source approximation for truck-stop exposures and assumes that the total stop time for a shipment is proportional to the shipment distance. It uses a similar model for rail stops, and includes a distance-independent stop time for inspections. The parameters used in the stop model were based on a survey of a very limited number of radioactive material shipments that examined a variety of shipment types in different areas of the

country(12). It was assumed that stops occur as a function of distance, with a truck stop rate of 0.011 h/km and a rail stop rate of 0.033 h/km. It was further assumed that at each stop, an average of 50 people are exposed at a distance of 20 m. The population dose is directly proportional to the external shipment dose rate and the number of people exposed, and inversely proportional to the square of the distance. The stop rate assumed results in an hour of stop time per 100 km (62 miles) of travel. The identical assumptions were used in the SNF&INEL EIS(2).

CONCLUSIONS

The transportation risk assessment conducted for the FRR SNF EIS provides a comprehensive and flexible approach that can be applied SNF shipments of all types. The approach is consistent with the SNF&INEL EIS(2) and previous transportation risk assessments. The flexibility associated with the tabulation of a large number of per-shipment risk factors gives the public and decision makers the information needed to evaluate the alternatives presented in the EIS. The results of the transportation risk assessment can be used to evaluate the relative impacts of the various alternatives in the Programmatic EIS.

The conservatism of the approach is necessary for the National Environmental Policy Act and decision-making requirements. The two major areas of conservatism are caused by the use of the regulatory limit as the dose estimate and the use of RADTRAN's default stop model. The affect of the use of the regulatory limit is uniform throughout the analysis, and can only result in the overestimation of incident-free effects. Since the use of a more central estimate of radiation dose would not change the conclusion that the incident-free risk is higher than the accident risk, this assumption is considered acceptable.

The conservative estimate of the stop times, especially for truck transportation, may cause inaccurate representation of the relative risks of truck and rail transportation. Informal discussions with shippers of SNF indicate that the stop models are very conservative, however, no published data analysis exists to support this premise. There is no evidence of a possibility that either stop model is nonconservative. Therefore, until a more exhaustive data analysis of shipping practices is carried out, the analysis was performed with the best available data.

ABSTRACT
The RADTRAN computer code for transportation risk analysis, which has been under continuous development at Sandia National Laboratories since 1977, has evolved from a purely research tool into a publicly available system with a variety of applications. This expansion of the user community has substantially increased the need to make the system easier to use without decreasing its capabilities or the quality of output. A large set of modifiable RADTRAN input files has been available via TRANSNET for several years. One approach to assisting the user involves adding annotations/information to each of these files. A second approach is providing additional help in building new/modifying old input files.
Keeping the proposed information/annotation files separate from but closely coupled to the modifiable input files within the TRANSNET shell system allows the modifiable input files to remain as regular input files while providing rapid, automatic access to useful information about the analysis. In this way, the sample input files remain intact as regular RADTRAN input files and any files generated using associated on-line menus or editors may be readily converted into new input files. A single sample file is selected and used as an example to illustrate the prototype help features.

INTRODUCTION
The RADTRAN computer code for transportation risk analysis (1,2,3,4), which has been under continuous development and application at Sandia National Laboratories (SNL) since 1977 and is now available in the fourth release (RADTRAN 4), has evolved from a tool for research and internal applications into a publicly available system used by many with less than professional expertise in risk analysis. RADTRAN 4 and related codes comprise a computational system that is publicly available on TRANSNET (5), the SNL node on the Internet that provides access to the RADTRAN code system. The expansion of the RADTRAN user community has been paralleled by increased usage of the code system on TRANSNET. The system includes a user-friendly, menu-driven, "front-end" that guides the user in the creation and editing of RADTRAN 4 input files. Since the inception of the TRANSNET system (5), SNL has maintained a telephone help capability for RADTRAN users. Users who have problems, questions, or need project-specific data are able to speak directly to a RADTRAN code developer. From this direct user interaction, two of the authors of this paper noted certain types of problems were being repeatedly encountered. Some problems could be traced to ambiguous wording in the menus or documentation or unrealistic expectations regarding capabilities and/or flexibilities of the code system, but a few problems were intrinsic to the code. For example, a user discovered that a logical error occurred when zero was entered as the population density for a route segment. The code was modified because this was a circumstance other users were likely to encounter (large areas of the United States have zero population density). At first, such difficulties were corrected as they arose on
an ad hoc basis. Any alterations made in the code were posted on the RADTRAN revision-history bulletin board on TRANSNET. As the computational system became more complex and the user community became larger and less experienced, this approach no longer sufficed.
SNL has employed several strategies to address user needs. Workshops have been held,

most recently at the International High-Level Radioactive Waste Management Conference in Las Vegas. Recognizing the value of user feedback to SNL's efforts to continue improving both the user friendliness and the technical value of the RADTRAN system, in 1994 SNL initiated a new strategy of convening formal RADTRAN user meetings. Two SNL-sponsored meetings of RADTRAN users were held in 1994. At the first of these, the scope was limited to the RADTRAN 4 code system; notices were mailed to all individuals in the United States who either had current user passwords or who had requested executable tapes of RADTRAN 4 for use with their own mainframe computers. The second meeting had a broader scope, covering both the RADTRAN system and other codes and databases available on TRANSNET. At these meetings, users were presented with an outline of planned modifications/improvements and asked for feedback and suggestions for improvement. Reports of these meetings will be available this year.

The results of these meetings were positive and constructive. The suggestions for improvements addressed everything from highly specific single-parameter comments to such broad concepts as addition of a graphical user interface (GUI) and incorporation of a geographical information system (GIS). There were several criticisms of the existing input/file/generating menus on TRANSNET. These ranged from the general to the particular. One general criticism was that several common, inadvertent key-press combinations cause the user to exit without having saved any part of the file being developed. This has been corrected on the current operating system. An example of a particular comment deals with a default dispersability category (DISP=1). It cannot be modified by the user, but the menu screens do not explain this.

While GUI development may be appropriate for the long term, the simpler matter of making it easier for a user to construct a RADTRAN input file can be implemented with available technology within the existing computational environment. Because RADTRAN requires large amounts of input data (like all risk codes) and many new users are relatively inexperienced, it seemed more reasonable to help develop the users' understanding of what is needed for suitable input than to devote resources to development of a GUI that might look like a home-computer game but not really assist the user. As long as it continues to be one of the world's most powerful tools for serious risk analysis, little purpose is served by slick packaging before basic user needs are addressed.

The current RADTRAN computational system includes a collection of approximately 15 Transportation Technology Center (TTC) file sets derived from actual risk analyses performed by SNL for the DOE. These files were placed on the system primarily to make them accessible to critics and activists opposing U.S. Department of Energy (DOE) environmental assessments (EAs) and environmental impact statements (EISs) that the analyses supported. This step was taken in response to activists' criticisms that DOE/SNL risk analyses contained "hidden assumptions" that could not be reviewed by anyone who did not have access to a mainframe computer. Placing the input files on the system thus performs a public quality assurance and review function in that it allows anyone with Internet access or a personal computer (PC) and a modem to obtain the raw input files, to run RADTRAN, and to satisfy themselves that the results reported in the documents they support are indeed the actual RADTRAN outputs.

The current menu system also allows users to modify (edit) these files. Thus, critics are able to satisfy themselves as to the effect on the result of changing "assumptions." The latter capability was soon seen to be useful to serious analysts as well, because it can be used to modify a few parameters and thereby quickly analyze similar but not identical problems. However, as currently structured, the TTC files are "pure" input files and contain little information to help a beginning user identify the sources of the data. Little need was seen for such a user interface at first, because the source information was contained in the EAs and EISs that the input files were developed to support. However, the files soon were being used as "starting points" by persons who had no interest in the original problem but who did have a similar problem to analyze. Both the lack of explanatory information and the fact that the input files cannot be easily modified without consulting the RADTRAN 4 User Guide (4) were cited as non-user friendly features of the current system during the user feedback meetings. Therefore, a first step toward increased user friendliness is the association of background information with each TTC file.

BACKGROUND INFORMATION FOR TTC FILES

Much potentially helpful background information could be associated with each input file. For example, a user might be interested in knowing why a particular input file was generated. Other types of information the user might find helpful include general conclusions resulting from the RADTRAN run and the types of related analyses that are possible using simple modifications (with the modifications described in detail) of a particular file.

ON-LINE USER GUIDE

An on-line user guide also was recommended by some users. This would consist of making the text of the published User Guide (4) available on the TRANSNET system. This option has the drawback of not being accessible while the user is building or modifying an input file. For that reason, enhancing the file-generating menus with additional information is believed to be a more beneficial option. This option is discussed in the following section.

AVAILABLE RADTRAN INPUT FILES

Figure 1 shows the list of RADTRAN TTC file sets currently available to the TRANSNET user. One set of files (FOREIGN RESEARCH REACTOR SPENT FUEL) has been selected to illustrate the proposed user assistance. These files were developed to analyze transport of foreign research reactor spent fuel by several modes (6). Figure 2 shows the second step in file selection with the present current RADTRAN menus. The first line on this sample screen is "Enter a Category Number -> 15." This means that the user selected number 15 from the list in Fig. 1. The screen shows the full title of the citation and gives all the files available under Category 15. The last line in the table is "Enter subcategory number you wish to use (1-6) -> 1," which means that the Highway Routes subcategory was selected. Figure 3 shows the last line of Fig. 2 and then shows the titles of all the input files available for research reactor spent fuel analysis by highway (truck) mode in this file set. In the example, File Number 1 has been selected. Table I a,b shows the sample input file, ASTRAXT. As the figure shows, it is "pure" computer input and does not contain much information helpful to an inexperienced user.

NEW HELP FILES

Figures 4 and 5 are examples of background information associated with a particular TTC file; in this example, the ASTRAXT file. It tells something about the nature of the problem that was to be solved, why it was important, and gives detailed information about specific input parameters used in the analysis. Figure 6 summarizes the results of running this particular TTC file for both the first route-segment (3.2 km) and the total route and shows the types of outputs that may be obtained from RADTRAN. Note that probability and consequences as well as risk are given.

SPREADSHEET FOR BUILDING AN INPUT FILE

Several users have commented that in its current form, the RADTRAN menu system does not contain sufficient help for a beginner who isn't familiar with the User Guide (4). The Appendix, p. 1, p. 4. p. 6, p.7, p.10, p. 12, shows some of the help statements for a prototype enhanced menu system; information is given for each line in a RADTRAN input file. This experimental system now exists as a PC-based spreadsheet. The few default values remaining in RADTRAN, such as those for atmospheric dispersion, are listed under the appropriate keywords. Emphasis has been placed on identifying which input values are required for route-specific analysis and which are not. In addition, the user is frequently reminded about the necessity of making the sizes of the various data arrays consistent. Failure to enter the proper number of values in certain arrays is a common beginner's error. Isotope data may be automatically entered from RADTRAN's internal isotope database by use of an alphanumeric identifier. The spreadsheet lists all available isotopes and their identifiers but does not display the contents of the database itself. A complete data list for each isotope used can be obtained by running a full output of RADTRAN.

SUMMARY

This paper has discussed approaches for responding to user comments about ease of use of the RADTRAN system. The first approach to assist users involves adding annotations/information to the modifiable RADTRAN input files on TRANSNET. The second approach provides additional help in building new/modifying old input files.

ABSTRACT

The U.S. Department of Energy (DOE) is developing route selection guidance for its unclassified Highway Route Controlled Quantity (HRCQ) shipments of radioactive material (primarily spent nuclear fuel, high-level radioactive waste, and certain large source radioisotopes). This guidance will provide DOE with a consistent means for routing HRCQ by highway and rail shipments and will allow shipment support planning activities on the part of DOE Traffic Managers, state and local officials, emergency response agencies, and other stakeholders. The major concerns that will be addressed in this guidance will be risk reduction, both radiological and nonradiological, and operational efficiency.
10 Currently, only highway shipments have specific US Department of Transportation (DOT) regulations that apply to selection of routes. Rail movements have no US DOT routing regulations. A consistent method of routing HRCQ shipments will provide all of DOE with a dependable, reproducible, and defensible way to ship. It will also provide the affected parties with the ability to effectively prepare for the shipments. This methodology will be developed with the assistance of the Transportation External Coordination Working Group and other stakeholder groups; transportation and shipping experts; and DOE traffic management personnel.
This paper outlines the regulatory framework within which DOE currently makes HRCQ shipments, the rationale for the route selection guidance, the steps that are being taken to develop the route selection guidance, and an initial set of guidance criteria and methodology that are being used as a basis for discussion.

INTRODUCTION

The U.S. Department of Energy (DOE) is developing route selection guidance for its unclassified Highway Route Controlled Quantity (HRCQ) shipments of radioactive material (primarily spent nuclear fuel, high-level radioactive waste, and certain large source radioisotopes). This paper outlines the regulatory framework within which DOE currently makes HRCQ shipments, the rationale for the route selection guidance, the steps that are being taken to develop the route selection guidance, and an initial set of guidance criteria and methodology that are being used as a basis for discussion.

REGULATORY BACKGROUND

Regulatory Background - Highway

Department of Transportation

In 1978, the Department of Transportation (DOT) initiated a rulemaking to establish a set of routing regulations for HRCQ shipments. The resulting regulations, often referred to by its docket number, HM-164, were developed based on extensive analysis and public input to provide a framework for minimizing risk. These regulations provide a framework for selecting routes for such shipments. The regulations require, among other things, that shipments be made along "preferred routes" (generally, these are interstate highways or state-designated alternatives) chosen to "to reduce time in transit" over the preferred route segment of the trip. The requirement to reduce time in transit does not always lead to an unequivocal choice of one route. For short trips between sites that are serviced by a limited number of interstate highways, the regulations will generally lead to a clear choice of one route. As the distance of the shipment increases, and the complexity of the interstate system between the origin and the destination sites increases, the choice of a single route based upon reduced time in transit may become more problematic. Through the years, Docket HM-164 has been re-opened several times to further refine and clarify the route selection regulations. HM-164C established some very specific requirements for choosing the pickup and/or delivery route to and from the preferred highway to be used. These requirements cause the analyst to evaluate the route selection in two steps. Paragraph 397.101(c)(2) in 49 CFR specifies that for pickup and delivery not over a preferred route, "the route selected must be the shortest distance route from the pickup location to the nearest preferred route entry location, and the shortest distance route to the delivery location from the nearest preferred route exit location (italics added)." Deviation from the shortest pickup and delivery route is authorized if such deviation:

1. Is chosen based on minimizing radiological risk, and
2. Does not exceed the shortest distance route by more than 25 miles, and does not exceed 5 times the length of the shortest distance route.

This means that if the shortest route to an interstate highway is three miles, then an alternate route could be used, if it does not exceed 15 miles (5 times the shortest route) and it can be shown to reduce radiological risk. If it is ten miles to the nearest interstate highway, an alternate route can be used if it does not exceed 35 miles (shortest distance + 25 miles) and can be shown to reduce radiological risk. The purpose of HM-164C is to minimize the amount of travel on secondary roads, which are considered higher risk roads.

The effect of these additional regulations is that route selection must be addressed for two different parts of the trip - (1) pickup and delivery routes and (2) preferred routes.

Nuclear Regulatory Commission

Transportation of spent nuclear fuel by highway does require advanced route approval by the Nuclear Regulatory Commission (NRC) and advanced notification to NRC of each shipment. NRC also requires advance written notification to States in which the shipment will travel, and requires that the written notification must include: (1) a listing of the highway routes to be used within the State, (2) the estimated date and time of departure from the point of origin of the shipment, (3) the estimated date and time of entry into each State, and (4) an appropriate statement that the schedule information must be protected as safeguards information. A change in arrival time greater than six hours requires notification to the State.

Department of Energy

DOE Order 5632.11, Physical Protection of Unclassified Irradiated Reactor Fuel In Transit, 9-15-92, provides direction on procedures for transporting a specific type of HRCQ shipments, irradiated reactor fuel. This Order specifies that such material shall be packaged and transported in accordance with DOE Orders 1540.1A, 1540.2, and 5480.3. On the subject of highway route selection, it says,

3. Motor carriers shall ensure that the transport vehicle operates over preferred routes selected to reduce time in transit except that an interstate bypass or beltway around a city shall be used when available. A preferred route consists of either or both:

a) An interstate highway system.

b) A State-designated route selected by a State routing agency according to Department of Transportation (DOT) guidelines and filed with that Department (49 CFR 177.835). [sic]

Regulatory Background - Railroad
Department of Transportation
There are currently no DOT rail route selection regulations for shipment of radioactive material.
Nuclear Regulatory Commission
Transportation of spent nuclear fuel by rail does require advanced route approval by the Nuclear Regulatory Commission (NRC) and advanced notification to NRC of each shipment. NRC also requires advance written notification to States in which the shipment will travel, and requires that the written notification must include: 1) a listing of the rail routes to be used within the State, 2) the estimated date and time of departure from the point of origin of the shipment, 3) the estimated date and time of entry into each State, and 4) an appropriate statement that the schedule information must be protected as safeguards information. A change in arrival time greater than six hours requires notification to the State.
Department of Energy
A memorandum outlining recommended practices for routing rail shipments of unclassified spent nuclear fuel (SNF) and high-level waste (HLW) made by DOE was issued in a memo by Lawrence H. Harmon, Transportation Management Division, Office of Defense Waste and Transportation Management, Defense Programs on 29 August 1988. The title of the memo was Current Recommended Practice For DOE Rail Routing Of Unclassified Spent Nuclear Fuel (SNF) and High Level Waste (HLW).
"Rail shipments of unclassified SNF and HLW are the responsibility of the traffic manager of the field office having program authority for its transport. Actual routes selected will be a joint effort among the DOE, its contractors, and the origin and destination carriers.
Because of the sensitivity of routing SNF and HLW through population centers, it is necessary for DOE, its contractors, and its carriers to consider additional specific route selection criteria prior to route finalization:
1. Minimize time, distance, number of carriers, and interchange points in transit.
2. Maximize the use of best track class considering that maximum safe speeds for each track class is regulated by the Federal Railroad Administration.
3. Apply lowest through rates and accessorial charges consistent with service requirements.
4. Obtain computer run from ORNL's "INTERLINE" (rail routing model) of the final alternate rail routes being considered--retain as part of the permanent route selection record.
5. Coordinate final route selection with Transportation Management Division (DP-121).
STEPS TO DEVELOP A ROUTE SELECTION GUIDANCE DOCUMENT
DOE is proposing a nine-step strategy for developing and implementing route selection guidance for HRCQ shipments. The first step in the process was to develop a strategy and have it reviewed by DOE's stakeholders. A parallel effort involved working with various transportation elements within the department, to develop draft discussion papers addressing issues associated with, and potential approaches to, route selection for each mode of transport. These draft documents served to stimulate discussion, comment, and institutional interaction. Based on feedback on the strategy and discussion papers, a draft guidance will be developed and distributed for DOE internal review. After review and revision at DOE, the document will be available to stakeholders and the general public for comment. Notice of this availability will be through the Federal Register. DOE will address all comments received in the review process. After final internal review and revisions at DOE, the guidance will be published and implemented.
METHODOLOGIES
A major part of the routing discussion papers included preliminary proposed methodologies for highway and rail. These preliminary methodologies were developed, not as a DOE position, but rather as a "springboard" for stimulating public input and discussion.
The proposed route selection methodologies use criteria that are widely accepted as being effective at reducing the risk associated with transportation of radioactive materials. The criteria were chosen based on 1) effectiveness at discriminating among routes, 2) relative contribution to various types of risk, and 3) availability of the required data.
The route selection methodologies synthesize input from a number of different

sources. The methodologies represent a simple approach to route selection, based on the premise that the best way to estimate and compare the total risk associated with shipments of radioactive materials over specific routes should be simple and straightforward. The methodologies do not measure risk in absolute terms. A number of simplifying assumptions are made in analyzing routes that preclude the process from developing specific risk measures, but still allow the comparison of relative risk associated with competing routes.

Work is currently underway to define specific values for time and population variables in the route selection methodologies. Values for these variables may change with each campaign based of differing requirements.

Highway Route Selection Methodology

The two major parameters used in the highway methodology are time in transit and population density. Other parameters that have been proposed by different groups include truck accident rates, potential property exposure, transit of environmentally sensitive areas, transit of culturally sensitive areas, emergency response time, proximity of difficult to evacuate populations (e.g. schools, prisons, hospitals, stadiums, shopping centers, etc.), transit of bridges and/or tunnels, inclement weather, and time of day considerations.

The proposed highway route selection methodology includes two independent, but related, efforts -selection of pick-up and delivery routes and selection of the preferred route to be used. Pick-up and delivery route selection is based on straightforward compliance with the provisions of 49 CFR 397.101(c)(2). This also determines the preferred route (i.e. interstate highway or state designated route) entry and/or exit points that are to be used. The selection of the actual preferred route to be traversed is based upon a process by which multiple routes are run through successive filters to eliminate routes that could be considered less desirable. The HM-164 regulations provide the first filter. The designated entry and exit points for the preferred route segment are chosen and the shortest distance pickup and delivery routes to those points are determined. The process then proceeds along two separate paths.

Pickup and Delivery Route Segment

1. Select proper origin and destination points for shipments.

2. From the origin point, choose the shortest route to the nearest preferred route entrance (in most cases this will be the nearest interstate highway). From the destination point, choose the shortest route from the nearest preferred route exit. A highway routing model can be used to determine the shortest route.*

3. Coordinate with State Departments of Transportation (or equivalent agencies) to verify that the shortest distance pickup and delivery routes are capable of handling the transport vehicles. This evaluation would consist of a review of clearances (height and width), weight limits (bridges), and local ordinances. If the selected pickup or delivery route is not acceptable, then select another route that meets the regulatory constraints.

4. Coordinate with local communities through which the pickup and delivery routes pass and provide an opportunity for local community comment and interaction on the final local route selection.

Preferred Route Segment

1. Generate a "base" HM-164 route between the chosen preferred route entry and exit points. This base route should be compliant with Federal regulations at 49 CFR 397.101 and .103 by using only preferred routes (either interstate highways and/or routes designated by States), using city by-passes when available, and should require the minimum transit time between the entry and exit points.

2. Generate optional HM-164 compliant routes to the base route until the cumulative travel time is XX percent greater than the base route.* The routes that are generated make up the feasible routes from which to select the shipment route. If no optional routes are within XX percent of the base route, choose the base route for shipment.

3. Calculate the total population along each of the optional and the base routes (a band of XX miles can be used). Eliminate all routes not within XX percent of the total population of the route with the minimum population. If only one route remains, choose that route for the shipment.

4. If more than one route still remains, determine the number of miles traversed through urbanized areas and the total population of the urbanized areas within a band XX miles wide. Divide this urban population by the number of miles traversing

urban areas to determine the potential population exposed along the transport corridor in urbanized areas. Select the route with the lowest urban population density value.
5. Write a report to document the process by which the final route was selected.
Railroad Route Selection Methodology
The two major parameters used in the rail methodology are impedance values and population density. Impedance values represent a combination of time, distance, and cost to transfer from one system to another. Other parameters that have been proposed by different groups include time in transit, cost of shipment, track class, grade crossings, accident rates measured by type of track, location, or carrier, potential property exposure, transit through environmentally sensitive areas, transit through culturally sensitive areas, proximity of difficult to evacuate populations (e.g. schools, prisons, hospitals, stadiums, shopping centers, etc.), and class of railroad company.
Rail shipments can move as general commerce, dedicated trains, or special trains. Rail shipments that move as general commerce, normally move over a maximum distance on the rail company that initiates the shipment. In this way, the originating rail company maximizes its profit. Dedicated trains carry only one commodity from origin to destination, stopping to refuel, to change crews, and if more than one carrier is required, to change locomotives. Dedicated trains tend to be used to transport large volumes of raw materials, such as coal. Layover time at railyards is kept at a minimum, reducing overall travel time considerably compared with general commerce train service. Special trains are dedicated trains with their own locomotive and crews. Certain restrictions can also be put on special trains including speed limits, stopping when meeting other trains, crew numbers, etc. The specific routes and other conditions that will be met by dedicated or special trains are negotiated through a contract between the shipper and the railroad.
The first step in route selection relates to determination of the type of rail service to be used - general commerce or dedicated (or special) train. Criteria for this determination will be based upon level of service required, institutional factors, cost, and other shipment- or campaign-specific considerations. Once the type of service has been determined, the route selection process can begin.
General Commerce
General commerce routes are selected by the rail company to coincide with normal operations. The DOE or contractor transportation manager should use available tools to confirm the reasonableness of the route chosen. Special programmatic or institutional issues may, at times, require specific route selection considerations. These should be discussed and negotiated on a case-by-case basis with the involved rail company. Issues that significantly impact route selection, may require the use of a dedicated or special train.
1. Select the origin and destination points for the rail shipment.
2. Use a rail routing model to determine a base route and feasible alternatives.* Feasible alternative routes should have an impedance value within XX percent of the impedance value of the base route.
3 Determine the population within XX miles of the track along each of the routes. Eliminate all routes not within XX population percent of the route with the minimum population.
4. Contact originating rail company to determine if the route they plan to use in general commerce is consistent with alternative routes remaining after Step 3.
5. If rail company proposes a route not remaining after Step 3, conduct a run to determine impedance and population along the proposed rail company route to determine if it is within acceptable limits of the base route.
6. Review the results with the rail company(s) to determine if a route acceptable to DOE can be negotiated.
7. If agreement cannot be reached between DOE and the rail company(s), consider use of a dedicated or special train.
8. If route selection issues can be adequately addressed within the context of general commerce operation, notify the affected states of the route that will be taken and coordinate with the states to address concerns that they have. The Federal Railroad Administration can be brought in to inspect portions of the track that are of concern.
Dedicated or Special Train
1. Select the origin and destination points for the rail shipment.

2. Use a rail route selection model, with parameters set for dedicated or special trains, to determine a base route and feasible alternatives. Select those routes with a calculated impedance within XX percent of the base route.
3. Determine the population within XX miles of the track along each of the routes. Eliminate all routes not within XX population percent of the route with the minimum population.
4. If more than one route still remains, determine the number of miles traversed through urbanized areas and the population of the urbanized areas within a band XX miles wide. Divide the population by the number of miles to determine the potential population exposed along the transport corridor in urbanized areas. Select the route with the lowest urban population density value.
5. Write a report to document the process by which the final route was selected.
6. Notify the affected States on the route that will be taken and coordinate with the States to address concerns that they may have about the route, i.e. track quality. The Federal Railroad Administration can be brought in to inspect portions of the track that are of concern.

CONCLUSION

DOE is developing rail and highway route selection guidance to be used for its unclassified HRCQ shipments. The process of developing this routing guidance involves interaction with DOE transportation management staff and affected stakeholders. DOE is developing this routing guidance to ensure a consistent set of criteria and methodology will be used in the selection of these shipping routes. A consistent route selection policy also allows DOE to plan and administer risk mitigation and public outreach programs in an effective and efficient manner.

ABSTRACT

A paper presented at Waste Management '94 described the process for selecting a preferred method (or methods) for disposal of low-level radioactive waste in New York State. Six disposal methods will be compared: above-grade concrete vaults without an additional cover, covered above-grade concrete vaults, below-grade concrete vaults, vertical shaft mines, drift mines, and augered holes. In order to make this comparison, conceptual designs were developed for each of the candidate disposal methods. While they are called conceptual designs, these designs in many cases include much greater detail than is typical of a conceptual design, to enhance public understanding of how the disposal facility will function.

This paper describes the six conceptual designs. It indicates the features that are common to all six disposal methods and describes some of the major differences among the methods, including land areas required for the disposal facility, sizes of staffs, costs, volumes of materials being imported, and volumes of materials being excavated. It also lists some of the alternative design features that were considered but not used in the nominal conceptual designs.

INTRODUCTION

In response to the federal laws on low-level radioactive waste disposal, New York enacted the Low-Level Radioactive Waste Management Act in July 1986 and amended it in 1990. The Act created a Low-Level Radioactive Waste Siting Commission with responsibility for selecting both a preferred method and site for disposal of New York's low-level radioactive wastes. Under the amended Act, the Siting Commission must evaluate alternative disposal methods and select a preferred disposal method (or methods) before proceeding to select a site. The process for method evaluation and other steps in the method selection process are described in some detail in

Refs. 1 through 3. It is summarized in the following paragraphs.
Based on the input received during a public outreach program and the review of previous work by the Commission and others, the following six candidate disposal methods will be evaluated in the disposal method selection process:
- Above-grade concrete vaults without an additional cover.
- Covered above-grade concrete vaults.
- Below-grade concrete vaults.
- Vertical shaft mines.
- Drift mines.
- Augered holes.

This group of candidate disposal methods covers the full range of major conditions affecting permanent low-level radioactive waste disposal. It also includes the two alternative methods specifically mandated for consideration in the 1990 amendments to the 1986 Act: deep vertical shaft mined disposal and above-ground monitored retrievable disposal (represented by above-grade concrete vaults without an additional cover).
The Commission will evaluate the six candidate disposal methods with respect to the seven evaluation considerations listed in Table I. The relative abilities of each of the disposal methods to satisfy criteria that were formed from the evaluation considerations will be assessed. Factors for use in developing criteria and in evaluating the disposal methods are also shown in Table I. The evaluations will compare the six methods as the methods are represented by the conceptual designs briefly described here. Complete descriptions of the conceptual designs are contained in Ref. 4.

THE DESIGNS

To perform comparisons of alternative disposal methods, the Siting Commission prepared conceptual designs for the six candidate methods. Those conceptual designs were intended to meet design requirements specified in New York regulations and to be of sufficient detail to enable objective comparisons of the six methods with the aim of selecting a preferred method (or methods). In fact, it was often necessary to add more detail to the designs than is typical for a conceptual design, in order to enhance public understanding of how a disposal facility would function.

Common Features

Some features are common to all six disposal facility designs. These include features such as buildings for the receipt of waste, the placement of waste in concrete overpacks called modular disposal units (MDUs), and conduct of administrative functions. The designs were based on the receipt of a total of 5.5 million cubic feet of low-level radioactive waste over 60 years. This waste volume corresponds to the most likely or "expected" case described in Ref. 5.
For design purposes, all of the waste is expected to arrive at the disposal facility in either 55- and 85-gallon drums, 120- and 200-cubic-foot steel liners, 90-cubic-foot steel boxes, or as steel ingots that are the result of melting steam generators. It is estimated that an average of between 15 and 20 trucks a week will arrive at the disposal facility carrying waste. All of the waste except the steel ingots will be placed in rectangular MDUs of one of two sizes -- 6 feet by 6 feet by 9 feet and 8 feet by 8 feet by 9 feet. Once in place inside the MDUs, the waste packages will be grouted in place. The use of the MDUs is motivated, at least in part, by the requirement in New York regulations and Siting Commission policy that the waste be retrievable throughout the institutional control period, which is assumed to be 100 years. About 47,000 MDUs will be constructed on site: about 25,000 of the smaller size and 22,000 of the larger size.

Site Characteristics

Conceptual designs were developed for generic disposal facility sites described in Ref. 6, which provides information about the geology and hydrology of sites that are typical of the non-excluded areas in the State of New York. For the four near-surface methods (not mines), the generic site characteristics do not have a major effect on the designs, except that generally shallow groundwater conditions limit the depths to which waste can be placed below grade. Designs were prepared, to the extent necessary, for the mine disposal facilities in four geologic media: shale, salt, limestone, and igneous/metamorphic rock.

Specific Designs

Illustrations of the six conceptual designs are shown in Figs. 1 and Fig. 2. Three of the designs are based on massive concrete vaults that are subdivided into cells

by interior concrete walls. The roofs on the vaults and augered holes are tied structurally to the walls of the vaults. All of the vaults dedicated to Class B and C waste hold two layers of MDUs. The two above-grade vault designs that are dedicated to Class A waste hold three layers of MDUs, while the below-grade vaults and augered holes dedicated to Class A waste hold only two layers of MDUs. Each layer of MDUs in a vault cell contains either nine large MDUs or sixteen small MDUs. Each layer of MDUs in an augered hole contains either four large MDUs or seven small MDUs. All of the MDUs will be placed in the vaults or holes from above, using cranes.

Fig. 2. Illustration of a mined LLRW disposal facility.

The illustrations for the three vault methods are of the designs for containing Class A waste. The vaults for Class B and C waste differ slightly from those for Class A waste. The primary difference is that the Class B and C vaults are narrower, being only one disposal cell wide. All of the augered holes are the same, except that the Class B and C wastes are placed together in separate holes from the Class A waste. The vaults for disposal of Class A waste using above-grade vaults are about 475 feet long and 60 feet wide. For below-grade disposal they are about 700 feet long and 70 feet wide. For disposal of Class B and C waste in all three vault-based designs, the vaults are about 300 feet long and 30 feet wide. The augered holes are all about 26 feet in outside diameter. Holes of this size are larger than have typically been used in the past, but the large size helps keep down land area requirements for this disposal method. Use of the larger holes also reduces the amount of excavation needed and the amount of materials needed to construct the holes.

The covered above-grade vaults, below-grade vaults, and augered holes have earthen covers placed over the concrete vaults or holes. These earthen covers are 7 feet thick and consist of various layers of natural and man-made materials that serve functions such as drainage, prevention of water infiltration, prevention of animal and plant intrusion, and support of short-rooted plants at the surface.

New York regulations require that protective enclosures be placed over the disposal units (vaults and holes) while they are being filled and until they are covered. These protective enclosures are envisioned as insulated steel buildings with access for trucks carrying MDUs. The enclosures are part of the conceptual designs and are intended to protect the disposal units from weather and freezing temperatures. With the two above-grade disposal methods, the covers will not be emplaced until disposal facility closure, so some the protective enclosures will remain in place until facility closure, which could extend to as long as 60 years.

The two mine designs contain 650-foot-long Class A disposal rooms that will hold either 308 of the large MDUs stacked two high and two wide, or 612 of the small MDUs stacked two high and three wide. The disposal rooms for Class B and C waste are 600 feet long and contain 260 of the large MDUs, stacked two high and two wide. All of the MDUs for the mine methods will be placed using forklifts. The underground layout is identical for both drift and vertical shaft mine disposal methods and contains eight separate waste disposal units (panels) for Class A waste, each containing up to fourteen disposal rooms, and one waste panel for Class B and C waste containing four disposal rooms. One Class A panel and the Class B/C panel will be constructed before any waste is disposed of in the facility. As individual panels are filled, they will be temporarily closed. At the end of operations, the facility will be backfilled and seals will be constructed at strategic locations in the underground works and in the drifts or shafts.

The conceptual designs were developed to allow comparison of the inherent features of the six candidate disposal methods. The designs were not necessarily optimized and, since potential sites were not known, they will probably be changed considerably when they are developed further.

COMPARISON OF THE CONCEPTUAL DESIGNS

Table II provides information about some characteristic parameters of the conceptual designs. The parameters shown are some of those that will be used in the detailed comparison. Table II shows that the land area required for uncovered above-grade vaults and the two mine designs is approximately the same. The below-grade vaults require a little more land because, in the conceptual designs, the earthen covers over the vaults rise above the surrounding terrain and thus require a very gradual slope to prevent erosion. Covered above-grade vaults require even more land because they rise higher above the surrounding terrain. The largest land area is required by

the augered holes which, to prevent collapse of adjacent holes while new holes are being constructed, require significant spaces between holes and therefore result in larger land requirements.
The average facility staffs during operations cover a very narrow range (66 full-time staff persons to 70 full-time staff persons) for five of the six methods. The staff for the augered holes is larger because of the larger excavation, construction, and concrete work required, and because the larger land area creates greater maintenance and environmental monitoring requirements.
The estimated total lifetime costs for the below-grade vaults and the two mine methods are approximately the same. The costs for the uncovered above-grade vaults are slightly higher, primarily due to the requirement in New York regulations that protective enclosures be constructed over these vaults and kept in place until the end of the disposal facility closure. Also, in the conceptual designs it was assumed that a more expensive mix of concrete will be used for the uncovered above-grade vaults and that the walls and roofs will be thicker than for the other two vault designs. The thicker walls and roof were chosen to better withstand the effects of frequent freeze-thaw cycles. The covered above-grade vaults cost slightly more than the uncovered above-grade vaults because, while the same set of protective enclosures is needed, the cost of providing the earthen covers represents an additional expenditure for this disposal method. The largest lifetime cost is attributed to the augered holes. This is a result of much larger volumes of materials to be excavated, larger amounts of concrete to be poured, and the additional monitoring and maintenance cost associated with the larger land area required.
The volume of materials excavated on site is lowest for the uncovered above-grade vaults, representing primarily excavation to place the foundation of these vaults well below the frost line. The volume of materials excavated on site is higher for covered above-grade vaults than uncovered above-grade vaults primarily due to an assumption that some of the materials for the cover construction could be found on site. The two mine methods represent the next highest volume of materials excavated on site. This material consists primarily of the rock removed to form the accesses to the mines, rock from the excavation of the rooms where the waste will be placed, and rock from the construction of horizontal accesses to those rooms. The largest estimates of volumes of materials excavated on site are for the below-grade vaults and the augered holes. These volumes represent the earthen materials that must be removed to make room for the vaults and the holes.
In addition to materials excavated on site, large volumes of materials are expected to be imported from off the disposal facility site. Estimates of these volumes are shown in the last row of Table II. It is estimated that no material will have to be imported from off site for the mines and that only a relatively small volume of such material will be needed for the uncovered above-grade vaults, primarily to provide under-vault drainage. Below-grade vaults will require about 1 million cubic yards of material to be imported from off site, primarily to construct the earthen covers over these vaults. Covered above-grade vaults will require much more material to be imported because the volume of the covers will be much greater due to the fact that the vaults rise above the natural terrain. The augered holes will require the most material to be imported because the waste is much more spread out on the site, necessitating much larger covers.

ALTERNATIVE DESIGN FEATURES CONSIDERED

A number of alternative design features were considered for use in the conceptual designs. These features, and others, could become part of the final design for the New York low-level radioactive waste disposal facility, but were not included in the conceptual designs that will be used for the comparative evaluation. These alternatives are described very briefly below:

Disposal of some waste without using MDUs -- Some of the waste could be placed in the disposal facilities without first putting it in MDUs. This would most likely include waste that has short-lived radionuclides and lower concentrations of radionuclides. Except for the steel ingots, this alternative was not selected because of the strong emphasis in New York regulations on the ability to retrieve waste.

Use of more than one of the candidate disposal methods at a single disposal facility -- While the preferred method could involve combining more than one candidate disposal method at a single facility, the Siting Commission chose to

compare the six candidate methods first, before deciding whether combinations of methods should be considered.

Use of sand or gravel to fill spaces among the waste packages inside the MDUs -- Grout was chosen for filling around the waste packages in the MDUs because it provides structural stability, additional shielding, and chemical buffering beyond what sand or gravel would provide. Use of sand or gravel may also require more careful placement, raising the potential radiation dose to the workers who backfill around the waste packages inside the MDUs.

Loading the concrete vaults from the sides instead of from the tops -- Roofs do not have to be placed on the concrete vaults to provide a weather shield because New York regulations require the use of a separate protective enclosure over all of the disposal units when they are being filled. Therefore, there is no need for a roof on a vault while it is being filled. Side-loading makes it more difficult to reduce worker radiation doses since it is harder to keep the workers separate from the waste during emplacement.

Maintaining underground access to mines during the institutional control period for inspection and testing -- While this alternative would increase confidence in short-term postclosure performance, it would increase the cost of the mine disposal facilities, particularly for the vertical shaft mine facility.

Use of augered holes with much smaller diameters than those in the conceptual designs -- Augered holes are usually employed for disposal of waste that exhibits a high radiation dose rate external to the waste containers. It is usually a specialized method of disposal and not used for disposal of large volumes of waste. However, the comparison is being made at this time on the basis of disposing of all New York's waste for 60 years in a disposal facility using a single candidate method. It was estimated that if small-diameter holes were used there would be large increases in the land area required, excavation needed, and concrete needed compared to those required for the present conceptual design for augered holes.

Delaying backfilling and sealing of the mine underground facilities until the end of the institutional control period -- Constructing temporary seals to prevent access to the underground facility during the institutional control period and deferring backfilling and sealing until the end of that period would greatly improve the ability to retrieve the waste at a reasonably cost. However, it is inconsistent with New York regulations, which require closure to occur at the end of disposal operations.

Use of precast vault roofs -- Some proposed vault designs use precast roof slabs that would probably allow easier retrieval. However, it was felt that the monolithic vault roofs tied directly to the walls of the vault would be less likely to admit water into the vault interiors and would provide greater structurally rigidity to the vaults.

Increasing the MDU stack height from two to three (or more) MDUs in mine Class A waste disposal rooms -- This alternative would significantly decrease the size of each of the mine facilities and the associated construction costs. However, it would require a larger forklift and possibly create other logistical problems. The heaviest MDUs weigh over 40 tons.

SUMMARY

This paper briefly summarizes the designs that will be used in comparison of six candidate disposal methods for use in New York State. For further details the reader is invited to contact the New York State Low-Level Radioactive Waste Siting Commission for copies of any of the references.

DOE'S PLANNING PROCESS FOR MIXED LOW-LEVEL WASTE DISPOSAL*

ABSTRACT

A disposal planning process was established by the Department of Energy (DOE) Mixed Low-Level Waste (MLLW) Disposal Workgroup. The process, jointly developed with the States, includes three steps: site-screening, site-evaluation, and configuration study. As a result of the screening process, 28 sites have been eliminated from further consideration for MLLW disposal and 4 sites have been assigned a lower priority for evaluation. Currently 16 sites are being evaluated by the DOE for their potential strengths and weaknesses as MLLW disposal sites. The results of the evaluation will provide a general idea of the technical capability of the 16 disposal sites; the results can also be used to identify which treated MLLW streams can be disposed on-site and which should be disposed of off-site. The information will then serve as the basis for a disposal configuration study, which includes analysis of both technical as well as non-technical issues, that will lead to the ultimate decision on MLLW disposal site locations.

BACKGROUND

The Federal Facility Compliance Act (FFCAct) of 1992 requires the Secretary of Energy to develop and submit site treatment plans (STPs) for the development of both treatment capacity and technologies for treating mixed waste for each facility at which DOE stores or generates these wastes. These plans will identify how DOE will provide the necessary mixed waste capacity, including schedules for bringing new treatment facilities into operation. In collaboration with representatives from the States and the National Governors' Association (NGA), DOE has been evaluating candidate treatment options and developing these treatment plans.

Although the FFCAct does not specifically require DOE to address disposal of treated mixed waste, both DOE and the States realize that disposal issues are an integral component of treatment discussions and have representatives working on and discussing disposal issues. DOE established the FFCAct Disposal Working Group (DWG) in June 1993 to work with the States to define and develop a process for evaluating disposal options. The focus of the DWG process and discussions on disposal with the States has been to identify, from among the sites currently storing or expected to generate MLLW, sites that are suitable for further evaluation regarding their disposal capability. Sites considered to have marginal or no potential for disposal activities have been removed or postponed from further evaluation under this process. Remaining sites are being evaluated more extensively to define the technical capabilities of the sites. Ultimately, a number of sites are expected to be technically acceptable for disposal activities.

This paper describes how the disposal planning process was established, major activities from June 1993 to the present, progress to date, and the expected results from this process.

STEP 1: SCREENING PROCESS FOR POTENTIAL DISPOSAL SITES

The process adopted by the DWG for evaluating disposal options is summarized in Fig. 1. In October, 1993, DOE prepared a draft report "Framework for DOE Low-Level and Mixed Low-Level Waste Disposal: Current Overview" (DOE, 1993) describing the history and status of DOE's low-level and mixed -low-level waste disposal and also outlining a disposal planning process. The sites originally evaluated in this process were the 49 sites reported to Congress by DOE in the Mixed Waste Inventory Report (MWIR) (April 1993) as currently storing or expected to generate MLLW. In the initial step of this process, sites that were in geographic proximity were combined into a single site for consideration in subsequent steps. The following sites were combined:

Lawrence Livermore National Laboratory and Sandia National Laboratories, California;

Idaho National Engineering Laboratory and Argonne National Laboratory (West);

Sandia National Laboratories, New Mexico, and Inhalation Toxicology Research Institute; and
Oak Ridge National Laboratory, Oak Ridge K-25 Site, and Oak Ridge Y-12 Site

This grouping reduced the number of sites to 44.

The next step was the establishment of a screening process using exclusionary criteria for the 44 remaining sites. These criteria were developed by reviewing Federal and State laws regarding the siting of waste treatment, storage, and disposal facilities to determine whether any criteria existed which could be considered exclusionary minimum requirements for hosting disposal activities and which could be applied uniformly across sites. It was agreed at a joint DOE/States meeting in Tucson, Arizona, on March 3-4, 1994, that in order to be further evaluated for potential disposal activities, a site:

must not be located within a 100-year floodplain,
must not be located within 61 meters of an active fault, and
must have sufficient area to accommodate a 100-meter buffer zone.

The first criterion is derived from regulatory requirements under the Resource Conservation and Recovery Act (RCRA) and the U.S. Nuclear Regulatory Commission (NRC) which restrict the location of waste disposal facilities. The second criterion is derived from the requirements under RCRA which restrict the location of waste storage, treatment, and disposal facilities. The third criterion is derived from guidance from the U.S. Environmental Protection Agency, U.S. NRC and U.S. DOE concerning the minimum area required to properly operate such facilities.

Application of the three exclusionary criteria identified 18 sites that did not meet the criteria. The results were presented at a March 30-31, 1994, joint DOE/States meeting in Dallas, Texas. At the meeting, it was agreed that the 18 sites would be removed from further evaluation and that DOE would prepare "fact sheets" on the remaining 26 sites to provide additional site-specific information for identifying the strengths and weaknesses of the remaining sites for the purpose of disposal activities.

A predecisional draft of the report "Framework for DOE Mixed Low-Level Waste Disposal: Site Fact Sheets" (Gruebel et al., 1994) was prepared by the DOE and forwarded for comment and review on July 13, 1994, to the State representatives who had been discussing the disposal issues with DOE for further consideration as potential disposal sites. The DOE and the State representatives met on July 26-27, 1994, in Denver, Colorado, to discuss the Fact Sheet report and to consider proposals for elimination of sites from further evaluation. Prior to the meeting, the DWG had reviewed the information in the Site Fact Sheets and evaluated the 26 sites according to the following methodology:

A. The factors contained in the fact sheets were grouped into three categories:

1. Technical Considerationsfactors that represent the technical ability of a site to accommodate the waste disposal facility and minimize the risk of releases of waste constituents from the disposal facility (e.g., precipitation and evapotranspiration, tectonic and volcanic hazard potential, soil stability and topography, flooding potential, groundwater hydrology [depth to groundwater]).
2. Potential Receptor Considerationsfactors that gauge the potential magnitude of consequences in the event a disposal site ceases to function properly (e.g., population, significant groundwater resources, sensitive environment).
3. Practical Considerationsfactors that can potentially affect the development and long-term management of a disposal site (ownership, mission, MLLW storage and generation, regulatory considerations).

B. Each of the 26 sites was evaluated by the DWG according to the three categories. One of three results was assigned for each grouping: the site posed 1) a major problem, 2) a moderate problem, or 3) a minor problem. Major problems were defined as having features or attributes that make developing and operating a disposal facility extraordinarily difficult. Moderate problems were defined as significant problems that could likely be solved with additional efforts and resources. Sites designated as having minor problems were those with neither major nor moderate problems.

Based on the DWG evaluation, during the July 1994 meeting the DOE proposed to the States that 9 additional sites be eliminated from further consideration. The DOE and the States were able to agree that the following sites would be eliminated from further evaluation under this process regarding the sites' disposal capabilities:

Site State

Energy Technology Engineering Center California
General Atomics California
General Electric Vallecitos Nuclear Center California
Pinellas Plant Florida
Site A/Plot M Illinois
Additionally, DOE and the States agreed that due to its geographic proximity, the Knolls Atomic Power Laboratory at Niskayuna, New York, would be merged with the Knolls Atomic Power Laboratory at Kesselring, New York, for purposes of further analysis. The DOE and the States also agreed that the following sites, while not eliminated from further evaluation, would be given a lower priority for further evaluation:

Site	State
Weldon Spring Remedial Action Project	Missouri
Brookhaven National Laboratory	New York
Mound Plant	Ohio
Bettis Atomic Power Laboratory	Pennsylvania

Sites assigned a lower priority for further evaluation had issues that required further consideration, including whether the technical abilities of the site were adequately known, the volume of MLLW that may be generated by the site had been determined, and other arrangements for disposal of the sites' MLLW were adequate. The DOE and the States agreed to further evaluate these sites in terms of their ability to dispose of their own MLLW on-site only if no other options for disposal of their wastes could be identified through the disposal evaluation process. In no case would these sites be considered as a disposal option for wastes from other sites, and could be eliminated from further analysis should sufficient information suggest that their potential for disposal activities is too limited.

STEP 2: EVALUATION PROCESS FOR POTENTIAL DISPOSAL SITES

For the sites not eliminated from further evaluation or assigned a lower priority for evaluation, a more technically detailed analysis (performance evaluation) is being conducted to increase understanding of the strengths and weaknesses of a site's potential for disposal and to better identify what types of disposal activities could or could not occur at a site. The performance evaluation to be conducted for each of the remaining sites entails the collection of site-specific data related to the natural surroundings, geotechnical setting, groundwater and surface water characteristics, and other factors related to the disposal capabilities of each site. The sites being carried forward in this analysis are the following (Fig. 2):

Site	State
Lawrence Livermore National Laboratory, Site 300	California
Rocky Flats Environmental Technology Site	Colorado
Idaho National Engineering Laboratory	Idaho
Argonne National Laboratory	Illinois
Paducah Gaseous Diffusion Plant	Kentucky
Nevada Test Site	Nevada
Los Alamos National Laboratory	New Mexico
Sandia National Laboratories	New Mexico
Knolls Atomic Power LaboratoryKesselring	New York
West Valley Demonstration Project	New York
Fernald Environmental Management Project	Ohio
Portsmouth Gaseous Diffusion Plant	Ohio
Savannah River Site	South Carolina
Oak Ridge Reservation	Tennessee
Pantex Plant	Texas
Hanford Site	Washington

The goal of the performance evaluation analysis is to quantify and compare the limitations of 16 DOE sites for the disposal of MLLW. The objective is, therefore, to use a set of modeling assumptions of sufficient detail to capture major site-specific characteristics and yet be general enough for consistent application at all sites. The results of the performance evaluation will be represented in terms of concentrations of radionuclides in MLLW streams that a site can accept without violating the performance objectives prescribed in DOE Order 5820.2A. This information will be used to evaluate the sites and estimate the types of waste that may be disposed of at a given site. (It is important to note that although a

performance evaluation is planned for the West Valley Demonstration Project (WVDP) site, only on-site wastes will be considered because the WVDP Act prohibits the site from accepting off-site wastes). The performance evaluations of the 16 sites were initiated in August 1994, and are scheduled to be completed in June 1995. A progress report on the performance evaluation task will be issued during the PSTP process and a final report documenting the performance evaluation results will be issued in October 1995.

An important component in the performance evaluation step is the involvement of a Senior Review Panel. The Panel is established to provide independent review of the PE analysis. The panel consists of six highly reputable technical experts in various aspects of waste disposal. Five members of the panel were selected by DOE , and one member was selected by the National Governors Association. Two technical reviews have been performed to date, and two more are planned before the completion of the PE analysis.

STEP 3: CONFIGURATION STUDY

As illustrated in Fig. 1, much progress has been made in the disposal planning process. However, much work remains to be completed. The following steps outline the future activities after the performance evaluation that need to be completed in order to make an informed decision about the disposal of DOE MLLW. Coordination with the States will continue in the next steps in order to gain stakeholder input and to resolve issues at the earliest possible stage.

Develop Estimates of Waste Volumes and Radionuclide Concentrations in treated MLLW residues

Once treated methods for the MLLW waste streams are finalized through the FFCAct process, estimates of treated residue volumes and radionuclide concentrations in the treated residues will be developed for all waste streams. These estimates are needed to compare to the radionuclide concentration guidelines derived in the performance evaluation.

Compare Radionuclide Concentration in Treated Residue Estimates to Radionuclide Concentration Guidelines Derived in the Performance Evaluation

Radionuclide concentrations for each treated waste streams will be compare to those disposal values derived in the performance evaluation. Analysis will identify sites with on-site disposal capabilities and the treated waste streams they will be able to dispose on-site. Also the analysis will evaluate off-site DOE and commercial disposal capacity for those treated waste streams which cannot be disposed on-site.

Develop Sample Configuration for Disposal of Treated Residuals

Sample complex-wide configurations will be developed for the disposal of treated MLLW residuals. These configurations will take into account such technical issues as compatibility of radionuclides and capacity to handle projected residual volumes. Other types of issues will be weighed during the configuration discussions such as transportation distances and costs. Information from the DOE EM Programmatic Environmental Impact Statement (PEIS) will be included here. In addition, input from the States will be an important component in this step.

Develop a Draft Disposal System Configuration

Using the sample configurations as a basis, in coordination with NEPA requirements and with State and stakeholder input, a draft disposal system configuration will be developed. This configuration will be the basis for determining future funding and schedules for proposed disposal facilities.

INTEGRATION WITH THE STP PROCESS

The FFCAct does not require disposal to be included in the STPs; however, given the complex issues involved, DOE recognizes the importance of State input to facilitate resolution of issues related to disposal. Information on the disposal planning process is provided in the PSTP to continue to involve the States and to make them aware of DOE's continued work on this issue. A progress report describing this planning process and, in detail, the performance evaluation methodology is being prepared as part of the PSTP. Results of the performance evaluation for the 16 sites will be provided to the States when Compliance Orders are issued in October, 1995.

ABSTRACT
This study's objective is to assess means for controlling water infiltration through waste disposal unit covers in humid regions. Experimental work is being performed in large-scale lysimeters 21.34m 13.72m 3.05m (75 ft 45 ft 10 ft) at Beltsville, Maryland. Results of the assessment are applicable to disposal of low-level radioactive waste (LLW), uranium mill tailings, hazardous waste, and sanitary landfills.
Three kinds of waste disposal unit covers or barriers to water infiltration are being investigated: 1) resistive layer barrier, 2) conductive layer barrier, and 3) bioengineering management. The resistive layer barrier consists of compacted earthen material (e.g., clay). The conductive layer barrier consists of a conductive layer in conjunction with a capillary break. As long as unsaturated flow conditions are maintained, the conductive layer will wick water around the capillary break. Below-grade layered covers such as 1) and 2) will fail if there is appreciable subsidence of the cover, and remedial action for this kind of failure will be difficult. A surface cover, called bioengineering management, is meant to overcome this problem. The bioengineering management surface barrier is easily repairable if damaged by subsidence; therefore, it could be the system of choice under active subsidence conditions. The bioengineering management procedure also has been shown to be effective in dewatering saturated trenches and could be used for remedial action efforts. After cessation of subsidence, that procedure could be replaced by a resistive layer barrier or, perhaps even better, by a resistive layer barrier/conductive layer barrier system. The latter system would then give long-term effective protection against water entry into waste without institutional care.
As mentioned in the preceding paragraph, a bioengineering management cover might well be the cover of choice during the active subsidence phase of a waste disposal unit. Some maintenance is required during that period. Final closure, using geological materials, could follow cessation of subsidence. No further significant maintenance would then be required. If the geological material used is merely a clay barrier to water infiltration, the cover will be "sensitive" to imperfect construction or degradation by penetrating roots. The roots will die and decay, causing markedly increased permeability of the clay with the passage of time. A system using a conductive layer under the clay layer as a water-scavenging system will, in comparison, be "robust." Roots will still degrade the clay layer but will not degrade the scavenging layer. A root hole through the conductive layer will be analogous to a hole through a wick. It will do no significant damage. The combination of a resistive layer with a conductive (scavenging) layer underneath is thus less dependent on perfect construction techniques and will be resistant to damage by root invasion. In the absence of subsidence such a system should function effectively for millennia.
Another very useful application of the resistive layer barrier/conductive layer barrier system would be to protect an earth-mounded concrete bunker disposal unit. In that case, the barrier system would shield the concrete from exposure to flowing water. The resulting stagnant alkaline film of water would tend to protect the concrete from degradation over a long time period. Similarly, a resistive layer barrier/conductive layer barrier system could be used to protect high-level waste. If high-level waste were disposed of in fractured rock, this system could be used to divert possible fracture flow water around the waste.

INTRODUCTION

Infiltration of water into the waste is the foremost problem associated with near surface disposal of low-level radioactive waste (LLW). Up to this time, disposal unit covers have generally been constructed from soil materials. In humid areas, these soil or clay covers have generally proved less than satisfactory; often, the cover itself has served as the principal pathway for water entry into the waste (1). Water infiltrating to buried wastes, contacting the wastes, and then exiting the area can reasonably be expected to be the most important of radionuclide transport agents. Some radionuclides, such as tritium (present as tritium oxide) and those present in anionic form, will essentially move with the flow of water; others, present as multivalent cations, will move much more slowly, but all will move to a greater or lesser degree. Clearly then, it is advantageous to reduce water infiltration to buried waste to as low a level as reasonably achievable. It is the purpose of our work to examine and demonstrate various approaches for achieving that goal.

Three kinds of waste disposal unit covers or barriers are being investigated in this work:

1. Resistive Layer Barrier
2. Conductive Layer Barrier
3. Bioengineering Management

The resistive layer barrier is the well-known compacted clay layer and depends on compaction of permeable porous materials to obtain low flow rates. A simplified model is shown in Fig. 1. Flow through porous media is described by Darcy's law (2). Investigations on flow through such layers have gone on for over 100 years, so further progress in this area can be expected to be slow.

The conductive layer barrier (1) is a special case of the capillary barrier (3). Use is made of the capillary barrier phenomenon not only to increase the moisture content above an interface, but to divert water away from and around the waste. During such diversion, water is at all times at negative capillary potential or under tension. A simplified model is shown in Fig. 2.

This system consists of a porous medium underlain by a capillary break (rock layer). Infiltration barriers such as a conductive layer barrier or a clay layer barrier (or a combination thereof) must fail if subjected to substantial shearing caused by waste subsidence. Reestablishment of a layered system after subsidence failure is a difficult undertaking and is exacerbated by the increasing complexity of the layered system. The failure potential (see CAUTION) of in-ground layered systems during the subsidence period argues for development of an easily repairable surface barrier for use during that period. To that end a procedure called "bioengineering management" was developed (4). The bioengineering management technique utilizes a combination of engineered, enhanced run-off and moisture-stressed vegetation growing in an overdraft condition to control deep water percolation through disposal unit covers. An artist's conceptual drawing is shown in Fig. 3.

EXPERIMENTAL AND DEMONSTRATION

In this section we will discuss experiments being conducted in large-scale lysimeters at a humid region site in Beltsville, Maryland (see Fig. 4).

Bioengineering Management

In bioengineering management the necessary run-off is provided by features installed at or above the soil surface rather than within the profile. The procedure, described by Schulz et al. (4), was designated bioengineering management. Its principal advantage is that subsidence can easily be managed by relatively simple, inexpensive maintenance of the above-ground features rather than by difficult reconstruction of below-ground layers. It should be noted that, after a length of time sufficient so that the organics have decayed and the waste containers have completely failed, subsidence will cease and a layered system could be then installed which could last over geological time periods.

In essence, the bioengineering management technique utilizes a combination of engineered, enhanced run-off and stressed vegetation in an overdraft condition to control deep water percolation through disposal unit covers. To describe it further: if a waste burial site is selected so that incoming subsurface flow is negligible, then precipitation is the sole source of input water. In a simplified model, that water has three possible fates: 1) evapotranspiration, 2) run-off, and 3) deep percolation. Evapotranspiration has a definite limit, governed by energy input. Ideally, deep percolation should be zero, leaving only the run-off component

available for unlimited manipulation. Positive control of run-off becomes difficult with the use of compacted porous media trench caps as the sole barrier to water infiltration. The compacted material tends to become more permeable with the passage of time, due to fractures caused by waste subsidence and from the inexorable process of root growth, followed by death and decay of the roots, thus creating water channels. Evapotranspiration cannot then use all of the infiltrating water, and water percolates downward to the waste. As stated before, evapotranspiration has a theoretical maximum dictated by solar energy input to the system; only run-off remains available for nearly unlimited management. This run-off can be surface or subsurface, as long as it occurs before water reaches the waste.

Surface run-off can be managed to as high as 100 percent by means of a perfect, leak-proof roof, which is expensive and hard to guarantee. Alternatively, adequate but not total run-off can be engineered rather inexpensively by using an impermeable ground cover over part of the surface to achieve high and controlled levels of run-off. Vegetation planted between areas of impermeable cover will extend over the cover to intercept incoming solar energy to evaporate water. Roots will extend under the cover in all directions to obtain water.

Such a system can be visualized by imagining a supermarket parking lot, where trees are planted in islands, surrounded by concrete curbs, within an extensive paved area. In this case, the trees are maintained in a drought environment due to the small soil surface available for infiltration of precipitation. The paving, along with the curbing around the trees, causes run-off of most of the precipitation. Aboveground, the tree's branches and leaves extend over the parking lot and intercept incident solar energy. Beneath the surface, the roots, in a drought state, explore outward under the paving for any available water. Utilizing this concept, it should be possible, by combining engineered run-off with vegetation, to maintain the soil profile in a potential overdraft condition on a yearly basis.

Initial investigations of the bioengineering management technique were carried out in lysimeters at Maxey Flats, Kentucky. Results obtained in seasonal 1984-1985 and 1985-1986 were reported by O'Donnell et al. (5). In that work, a fescue grass crop was used with an engineered cover of stainless steel. Following seasonal 1985-1986 the grass cover was removed, a new stainless steel engineered cover was constructed and Pfitzer junipers were planted in the lysimeters. After the junipers were established, percolation data were again collected in 1988 and reported by Schulz et al. (6). The woody junipers were excellent in preventing deep percolation of water in the lysimeter.

The encouraging initial results obtained in the Maxey Flats lysimeter experiment led to the establishment of a large-scale field demonstration at Beltsville, Maryland (Fig. 4). Figure 5 is a photograph of lysimeter 1, bioengineering management, taken in December, 1994, eight years after planting of the Pfitzer junipers. Alternating panels of aluminum and fiber glass were used as the hard cover. These plots, or lysimeters, are 21.3m (70 ft) long by 12.7m (45 ft) wide, and the bottoms are 3.05m (10 ft) below grade. Figure 6 shows a side view of construction details of lysimeters 1 and 2 (bioengineering management). The only difference between the two was the initial water level in the lysimeters. The water level was 90 cm above the bottom of lysimeter 1 and 190 cm above the bottom of lysimeter 2. The water level in the lysimeter simulates the water table in a flooded disposal cell. In addition to the two bioengineered lysimeters, two reference lysimeters (3 and 4) were initially constructed. They were similar to the former, except that they were merely planted with fescue grass. No hard cover was present, but surface slopes were similar to the two bioengineered lysimeters (i.e., a slope of 1:5). Performance data for the reference lysimeters are given in Fig. 7.

The water level in the two reference plots or trenches (lysimeters 3 and 4) rose until it was near the surface. At that time, water was pumped from the lysimeters to keep them from running over. The graphs of the water tables (i.e., water levels) in the bioengineered plots (lysimeters 1 and 2) show an entirely different story, as evidenced in Fig. 8. In both cases, the water table was eliminated. It appears that the bioengineering approach could prevent water infiltration to a disposal unit. It also could be used for a remedial action in dewatering existing problem sites such as Maxey Flats.

On February 4, 1988, lysimeter 4 was pumped out to prevent overflow. It was then discontinued as a reference lysimeter and converted to a rock-surfaced, resistive-layer barrier plot. Lysimeters 1 and 2 (bioengineered) and lysimeter 3

have been continued. A summary of run-off, evapotranspiration, and pumping from those three lysimeters is given in Fig. 9.
Figure 9 shows that there was very little run-off from the grass covered plot. Most of the precipitation was disposed of, via evapotranspiration, by the fescue crop, but this was not adequate to prevent the rise of the water table. Table I gives the run-off, evapotranspiration, and deep percolation in the bioengineered plots during the past seven years. There was no deep percolation during this period. Until seasonal 1993-1994 the evapotranspiration had been rising annually, probably as a result of the greater vegetative canopy intercepting a greater percentage of the precipitation. In 1988, 1989, 1990, 1991, and 1992 the runoff percentages were 80, 74, 70, 67 and 63, respectively (7). In 1993, the run-off decreased to 61% of the precipitation. In 1994 the run-off remained the same as in 1993. During 1989, the water table was completely eliminated in both plots (Fig. 8).
In addition to rainfall, run-off, and evapotranspiration measurements discussed above, neutron probe soil moisture measurements have been made continuously to monitor soil moisture changes in all six lysimeters depicted in Fig. 4. The neutron probe measurements will indicate whether there is a gain or loss of moisture from the soil profile, or perhaps a steady-state situation where there is little or no net gain or loss of soil moisture during a year.
A steady-state situation with relatively constant moisture "dry" soil above the waste would be highly desirable with a bioengineered cover. There would then be a large safety margin to protect the waste from infiltrating water.
Neutron probe apparatus, as supplied by the manufacturer, is calibrated against moisture measurements in sand. Such calibration is of unknown accuracy when applied to soil measurements. For this reason, the probe was calibrated using the same soil as in the lysimeters. Six hundred and twenty-eight kilograms (1,400 lbs) of soil were placed in a weighing lysimeter, and measurements were made over a seven year period. Calibration data obtained using the weighing lysimeter are given in Table II. The resulting curves, depicting the factory calibration and the weighing lysimeter calibration, are given in Fig. 10. It is evident that use of the factory calibration on sand would result in a very large error in soil moisture determination.
Results of some neutron probe measurements are shown in Fig. 11 for bioengineered lysimeters 1 and 2. The data are plotted as volumetric moisture content, as a function of soil depth, on specific dates. Only nine widely spaced measurement dates are shown, for clarity. From inspection of the figure it is seen that, at the start of the experiment in July, 1987, the moisture content of the soil increased with depth until the water table was reached, then became constant. By July, 1989, the water table had been eliminated from both lysimeters, and the soil profiles were drying out. However, the soil moisture content, although much lower in the soil profile than in July, 1987, still increased with depth. This same relationship was still evident November, 1994, although the soil profile had become still drier.
Figure 12 shows the moisture content of the soil profiles in lysimeters 1 and 2 at the end of each seasonal year. Following the complete removal of the water tables during the 1987-1989 period, the soil profiles were dried out further during the ensuing years. However, an unanticipated result turned up in lysimeter 1 at the end of seasonal 1993-1994. The moisture content of the soil profile increased slightly. To shed light on that result, the moisture content in the soil profiles at four depths were plotted monthly along with monthly rainfall data (Fig. 13a, b, c, d, e, f, g, h). Here we see seasonal cyclical variations in moisture content in the soil profiles, with peak moisture concentrations occurring in the early spring, following periods of significant rainfall and minimal evapotranspiration. That cycling is both obvious and expected. What was totally unanticipated was the increase in the moisture peaks in each of the last three years in lysimeter 1. The increasing amplitudes of the moisture curves do not appear to be a result of rainfall variations, nor are they present in lysimeter 2. During the coming year we shall see if the aforementioned trends continue, and if so, we will try to determine why. Increased stemflow resulting from water funneling downward with increased plant canopy size is conceivable, but if that is the case, why do we not have increasing amplitude of the seasonal moisture curves in lysimeter 2? Although the increasing amplitude of the moisture curves for the soil profile in the spring of 1992, 1993, and 1994 in lysimeter 1 are a concern, the results to date indicate that bioengineered closure, as described in this experiment, would maintain the cover

over buried waste in a "dry" steady-state condition. This would not only prevent water from percolating down to the waste, but would do so with a large safety factor.

Fig. 13. Plot of moisture content at the 61, 122, 183 and 244 cm levels as a function of time in lysimeters 1 and 2. Bar graphs of monthly rainfall superimposed. Moisture peaks occur in springtime, following periods of low evapotranspiration and the soil profile is again dried out in following periods of high evapotranspiration. This process prevents water from accumulating in the soil profile and percolating to the waste.

Resistive Layer Barrier

As previously mentioned, on February 4, 1988, lysimeter 4 was pumped out, discontinued as a reference lysimeter, and converted to a rock-surfaced resistive-layer barrier plot. The primary reason for constructing that particular cover is the likelihood of such covers being used for uranium mill tailings. An end view of that plot or lysimeter is shown in Fig. 14. This lysimeter was completed in the fall of 1988 and data collection (measuring performance) has begun. The most important information to be gained here will be the relative weighing of the advantages and disadvantages of rock surface vs. a vegetated surface.

In addition to the UMTRA or rock-surfaced resistive-layer barrier plot, a vegetated resistive layer barrier plot was constructed. The primary purpose of this plot is for comparative measurements. Essentially, this plot is similar to the rock-surfaced plot except that topsoil replaces the rock layer, and the plot is planted with fescue grass. A diagram of this plot is given in Fig. 15.

In Fig. 9, the fate of precipitation in the UMTRA and grass-covered, clay-layer lysimeters is given. There was more than twice as much run-off from the rock-covered plot as from the grass-covered plot. Although the data show no deep percolation through the clay layers to date in either lysimeter, there is little indication as to how much safety margin has been offered. Nor is it known how consistently such near-perfect clay barriers would be installed in a routine operation. That remains a problem for future consideration.

Another concern is the possible drying out of clay barriers. If this were to happen, the clay layer would not be as efficient a barrier for preventing radon escape as planned in the UMTRA application. In addition, drying out of the clay layer could lead to cracking, leading to subsequent leakage prior to resealing by wetting. Figure 16 gives the volumetric moisture content of clay in the rock-covered (lysimeter 4) and the grass-covered (lysimeter 6) plots. In no case did the clay layer dry out significantly. On the contrary, in the UMTRA or rock-covered plot, which was devoid of vegetation, there was a slight increase in moisture content with time, suggesting that some leakage of water through the clay layer may occur in the future. Lysimeter 6 has a clay layer and a grass cover. In this case, no increase in moisture content has been observed. On the contrary, to date the moisture content of the clay layer seems to be in a rather steady state, taken over the 6 year period of measurement.

Conductive Layer Barrier

If we consider the case of water flowing downhill in an unsaturated porous medium, we have the case shown in Fig. 17. The "holes" shown in the diagram could be a rock layer, affording a capillary break or capillary discontinuity (Fig. 18). Under appropriate conditions, water everywhere in these cross-sections will be under tension, and there will be no leakage. This might then serve as an excellent means of protecting waste by conducting water around the waste. Figure 17 simulates a conducting porous medium, such as a fine sandy loam soil, lying smoothly on top of a rock layer. Problems with water flow under saturated conditions could certainly arise where a less than smooth surface ends up being constructed as depicted in Fig. 19. That is, what happens if imperfections are constructed so that "pockets" of soil extend down into the rock layer? Figure 19 represents that case. Again, there will be no leakage, provided conditions are such that the water in all parts of the conductive layer remains under tension.

The big question is, can conditions required to maintain the necessary soil water tension be practically maintained while using this procedure to effectively protect waste disposal units? To answer this question the apparatus schematically depicted in Fig. 20 was constructed, i.e., "a soil beam." Several miniature soil beams (Fig. 21) were constructed for use in the laboratory so that a variety of candidate conductive-layer materials could be quickly evaluated.

A number of materials were evaluated using the miniature soil beams. It was quickly established that it would be necessary to construct a resistive layer barrier above the conductive layer barrier to have a practical system. The standard was set that the resistive layer barrier have an easily achievable conductivity of not greater than 10-6 cm/sec. On this basis it was found that material such as fine sandy loam could provide an effective conductive layer barrier, that is, conduct around the waste 100% of water percolating through the resistive layer. However, the measurements showed that such materials would not provide the desired (factor of 10) safety margin.

Further investigations turned up a material, diatomaceous earth, that would fit these requirements. Measurements of tension vs. distance of flow are shown in Fig. 22.

The results of this experiment in the 137 cm (4.5 ft) long beam suggest that, as long as the flow rate is no greater than 4.2 10-4 cm/sec, the soil water will remain under tension regardless of the soil beam length. These results show that with the use of diatomaceous earth for the conductive layer and following the easily achievable standard set above for the resistive layer, it should be possible to construct a barrier that would allow no water leakage to a waste disposal unit. However, before final selection of the diatomaceous earth as the conductive layer material, we believed it to be prudent to conduct tests in a large-scale soil beam. The large beam, shown in Fig. 23, has a soil beam length of 6.4 m (21 ft). As shown in Fig. 24, a matric potential of about -15 to -20 cm of water is maintained over the entire 6.4 m length of the beam when the flow rate does not exceed 3.1 10-4 cm/sec.

The studies carried out in the large soil beam closely confirmed the data obtained in the miniature beam. Accordingly, diatomaceous earth was used as the conductive layer material in the demonstration lysimeter (lysimeter 5). It has been estimated that purchasing and shipping the diatomaceous earth to a job site any place in the United States will add about $0.50 per ft3 of disposed waste. This is over the cost of using locally obtained soil, and based on waste being 3.05 m (10 ft) deep.

After the time-consuming task of selecting the conductive layer material was accomplished, a resistive layer barrier over a conductive layer barrier was constructed in lysimeter 5. It was completed in January, 1990. A local clay from Beltsville, Maryland, the Christiana Clay, was selected as the resistive layer barrier. Testing has shown this material more than meets specifications. A cross-section of the cover system is shown in Fig. 25.

Performance of this cover is shown in Figs. 9 and 16 (lysimeter 5). Until seasonal 1993-1994 the cover system was 100% effective in preventing water movement downward through the cover. In seasonal 1993-1994, 0.13 cm (0.05 in) of water passed through the cover to the pan shown in Fig. 14. Although that amount is an extremely small percentage of the total rainfall, in theory no water should have percolated through the cover to pan. It is possible that the cover system was compromised by the instrumentation installed to measure performance. During the coming year we will try to find out if this is merely an experimental anomaly.

Further Studies of Conductive-Layer Materials

For The Beltsville study, diatomaceous earth was selected for the conductive-layer material, based both on performance and cost considerations. Based on these two considerations only, diatomaceous earth would still be the material of choice, particularly since it has a much lower bulk density than sand and is therefore less expensive to ship. However, the engineering properties of sand are better known, thus sand may be more attractive to some installers. Therefore, we have been conducting further studies with various sands. Results of studies of the unsaturated flow characteristics of four different sands are given in Fig. 26. All these sands exhibit unsaturated flow rates that are about twice that of the diatomaceous earth at any given negative matric potential. The particle size distribution of the four sands is given in Table III. The mortar sand, for example, had the narrowest particle size range, and the foundry sand had the widest particle size distribution, although the particle size distribution did not have an important effect on the flow rates reported in Fig. 26. The Nevada dune sand and the Kelso dune sands are from large eolian deposits in the Nevada and California deserts, respectively. The Kelso deposit has been mined commercially. This work on the unsaturated flow characteristics of various materials is ongoing. Hydraulic properties will be studied over a larger range of matric potentials, further deposits will be located

and investigated, and these investigations will be described in a future report.

APPLICATION

The three procedures described in the Introduction may be used singularly or in combination to protect disposal units from percolating water. The principles apply equally to above-ground or below-ground disposal. For example, a combination of covers 1) and 2), described in the Table III. Particle size distribution of the four sands used in unsaturated flow studies reported in Fig. 26.
Introduction, could be ideal for a stabilized, shallow land burial facility, whether it is above or below ground; e.g., the subsurface disposal could be in below-ground vaults, and the above-ground disposal units could be earth-mounded concrete bunkers. A combination of a resistive layer over a conductive layer in a concrete bunker or above-ground application is shown in Fig. 27. The resistive (clay) layer is the primary barrier. The small amount of water passing through the clay layer will be diverted around the concrete bunker by the conductive layer. This cover over the concrete bunker can, in theory, be 100% effective, shielding the bunker from exposure to flowing water. This would result in a film of stagnant alkaline water at the gravel/concrete interface. The presence of this high pH, stagnant water would tend to protect the concrete from degradation over a long period. A resistive layer above must leak somewhat due to the imperfections in construction when using compacted porous material (clay).
The bioengineering concept could be advantageous for either a tumulus or shallow land burial unit that would be likely to exhibit subsidence. If desired, and after subsidence has ceased, a combination of covers 1) and 2) could be constructed with geological materials to give extremely long-term isolation without further maintenance (8). Another possible application of a combination of covers 1) and 2) described in the Introduction is shown in Fig. 28. Here, high-level waste is emplaced in a tunnel excavated in rock. If a fracture were present in the rock, and fracture flow occurred, the combination of a resistive layer and a conductive layer could provide excellent isolation of the waste from flowing water. Figure 29 depicts an application where only very low flow rates need be protected against (essentially, dropwise fracture flow). Here, the system could be simplified so that only a conductive layer with a capillary break is necessary.
Fig 26.Unsaturated flow characteristics of four sands. Soil water tension at various flow rates, measured in mini-soil beam shown in Fig. 21. Tension vs. horizontal distance from discharge point. Results suggest that at rates of about 10-3 cm/sec or less, water would remain under tension at any beam length. Slope of beam is 1:5.

ACKNOWLEDGMENTS

Funding for this project was provided by the Waste Management Branch, Division of Regulatory Applications, Office of Nuclear Regulatory Research. Dr. Edward O'Donnell is the Project Manager, Dr. Frank A. Costanzi is Acting Chief of the Waste Management Branch, and Dr. Bill M. Morris is Director of the Division of Regulatory Applications.
The authors wish to express their thanks to Lester M. Fujii for his contribution to this study. Furthermore, we are indebted to the support provided this project by the University of Maryland's Experiment Station, Beltsville Unit staff, notably Peter Godwin.

WATER INFILTRATION CONTROLS AT THE WEST VALLEY LOW-LEVEL WASTE DISPOSAL AREA

P. J. Bembia
New York State Energy Research and Development Authority

ABSTRACT

The New York State Energy Research and Development Authority (NYSERDA) is implementing technologies to eliminate accumulation of leachate in low-level radioactive waste (LLRW) disposal trenches at the shut-down New York State Licensed Disposal Area near West Valley. Results to date show that installation of a slurry wall and a geomembrane cover on two trenches has stopped leachate accumulation in these trenches. Based upon this success, NYSERDA is preparing to cover the remaining trenches to reduce water infiltration into the trenches and to prevent additional leachate accumulation.

In addition, NYSERDA has initiated a pilot project to demonstrate the effectiveness of bioengineering management as a potential technique for controlling leachate accumulation in the trenches. The pilot project is being conducted on an existing LLRW shallow land burial trench.

INTRODUCTION

The New York State Energy Research and Development Authority (NYSERDA) recently installed water infiltration control technologies to remedy water management problems caused by a wet climate and a silty-clay soil, at the shut-down, commercial, Low-Level Radioactive Waste State Licensed Disposal Area (SDA) in Western New York. NYSERDA installed a slurry wall and geomembrane cover to address the immediate problem of water accumulation in two shallow burial trenches, and initiated a pilot project to assess the feasibility of a long-term bioengineering management program. This paper discusses our experiences leading to selection and implementation of these technologies, presents the results, and provides an outlook on our future applications.

The SDA occupies approximately 6.07x104 square meters of the Western New York Nuclear Service Center (Center). The Center, site of the world's first commercial nuclear fuel reprocessing plant, is located 50 kilometers south of Buffalo, New York, near the hamlet of West Valley. Nuclear Fuel Services Company, Inc. (NFS) operated and maintained the Center under a lease agreement with New York State. Currently, NYSERDA holds title to and maintains the 1.35x107 square meter Center on behalf of the people of New York State with the exception of approximately 8.09x105 square meters under exclusive use and possession of the United States Department of Energy (DOE) to perform the West Valley Demonstration Project (WVDP).

Description of the SDA

From 1963 to 1975 NFS placed approximately 6.8x104 cubic meters of packaged commercial low-level radioactive waste (LLRW) in two sets of parallel trenches referred to as the north and south areas; each containing seven trenches, numbered 1 through 7 and 8 through 14, respectively (Fig. 1). Typically the trenches are approximately 170 meters long, 6 meters deep, and vary in width from 6 meters at the bottom to 11 meters at the top, except for two specially constructed trenches. Trench 6 consists of a series of holes used for the disposal of high-specific activity wastes that required immediate shielding; and Trench 7 is a narrow, shallow trench in which the waste was encased in concrete. Wastes placed in the trenches were covered with the soil excavated during trench construction.

The trenches are constructed in the Lavery till, described as a silty-clay or clayey-silt, pebble-cobble till. It has minor amounts of small, random, discontinuous lenses of stratified sand, gravel, silt and rhythmic clay-silt laminations.(1) This area was used for disposal trenches because the high clay content and high degree of over-consolidation of the Lavery till make it virtually impermeable at depth. In-situ tests in bore holes indicate that the material has a hydraulic conductivity of about 1x10-8 centimeters per second (cm/sec). However,

samples taken from bore holes and excavations show that the upper three meters of the till is weathered as a result of desiccation. The weathered till is highly fractured and is generally more permeable than the unweathered till.

Early Water Problems and Management Activities

Because of the humid environment in the region and the very low permeability of the unweathered till, water enters the trenches by permeating through the upper weathered till or the trench covers and tends to accumulate there. Water that enters the trenches and contacts the disposed wastes is called leachate, and mobilizes the radionuclides and other waste contaminants contained in the wastes. In 1975, leachate levels rose above the original ground surface and seeped laterally through two trench caps into an adjacent brook at the north end of the SDA. NFS immediately ceased disposal operations and no waste has since been disposed of in the SDA. Following the seepage incident, NFS pumped and treated leachate from the disposal trenches. To minimize infiltration of water, NFS rehabilitated the north disposal area trench caps, incorporating a number of changes based upon experience with the southern trench cover design, which appeared to be more successful in limiting infiltration of water into the trenches.(2) However, abrupt increases in the leachate levels of Trenches 11 through 14 in the south area occurred starting in 1978. These increases were also attributed to seepage through desiccation cracks in the cover. Consequently, the covers of Trenches 11 through 14 were reworked to reduce this problem.

SITE MANAGEMENT BY NYSERDA

Monitoring and Maintenance Activities

NYSERDA assumed possession of the SDA in 1983 along with responsibility for surveillance and maintenance of the Center. During the summer of 1986, leachate levels in Trench 14 rose at a significantly faster rate than previously observed. An investigation confirmed the presence of a relatively large, permeable, stratified sand and gravel body that was projected to intersect Trench 14 near the southern end and came very close to the ground surface near the western boundary of the SDA. Historical information suggested that the sand and gravel body extended eastward beyond Trench 13 to Trench 12. A subsurface concrete barrier wall was installed immediately west of Trench 14 to block groundwater from entering the trench and to create a barrier to allow safe excavation of the sand and gravel unit, which was replaced with compacted silty-clay till from a nearby borrow area. Following this work, the Trench 14 water levels rose at a much lower, but steady rate until sudden increases in the Trench 14 leachate level occurred in late 1990 and early 1991, followed by a dramatic rise in the Trench 13 water level (Fig. 2). This occurrence repeated providing evidence for a suspected hydraulic interconnection through a sand and gravel body between Trenches 13 and 14 at the leachate elevation reached in Trench 14.

Hydrologic Investigation

In response to the initial increases in Trenches 13 and 14, NYSERDA initiated a hydrologic study to find the source and pathway of this water.(3) The study evaluated the potential for horizontal migration of groundwater into Trenches 13 and 14, as well as vertical infiltration through the cap of these trenches. A total of 28 shallow- and deep-screened piezometers were installed in logged soil bore holes south and west of these trenches. Precipitation, groundwater levels and trench water levels were monitored concurrently.

The two-year hydrologic study produced the following conclusions:

Heavy rainfalls contributed to abrupt leachate level increases in Trenches 13 and 14.

Sinkhole formation in the caps suggest that cracks in the cap serve as pathways for vertical water infiltration.

Groundwater, generally moving horizontally from west to east through the weathered till, contributed to leachate accumulation in Trench 14, while the unweathered till does not appear to contribute.

Consistently high water levels observed in the piezometers near a previously identified kettle hole deposit around the northwest end of Trench 14 indicate a possible pathway for groundwater to flow into the trench.

INFILTRATION CONTROLS

Selection of Engineering Solutions

An evaluation of alternatives to reduce or eliminate the influx of water into Trenches 13 and 14 was prepared while the hydrologic investigation was in

progress.(4) Alternative methods evaluated to minimize lateral flow included a slurry wall, soil freezing, and sheet piling; while those evaluated to limit vertical permeation included soil cover improvement, a geomembrane cover, and bioengineering management system.

Because the hydrologic study did not identify a single source for water infiltration, a combined solution consisting of a slurry wall to divert horizontal groundwater flow in combination with a geomembrane cover to obstruct the vertical seepage of precipitation through the cover was developed. The slurry wall was selected because of its natural properties, relative ease of implementation, construction cost, and absence of maintenance or operating costs. A geomembrane cover was selected because past soil cover improvement work only had limited success and bioengineering management (which has not gone beyond the research in test lysimeters) may not provide the immediate results that were needed. A very low-density polyethylene (VLDPE) geomembrane material was selected over other geomembrane materials for its combined flexibility, resistance to cold stress, resistance to tearing or stress cracking, and relative cost.

Construction

The slurry wall was aligned to run along the west (upgradient) side of Trench 14 and partially wrap around both the north and south ends (Fig. 1). The objective for the project was to cut off all desiccation cracks, fissures, or lenses of stratified coarse deposits that could transmit water to the trench. The 276-meter long slurry wall is approximately 0.9-meters wide and 9-meters deep, extending below the bottom of the lowest trench.

Slurry wall construction began in early September 1992, and was completed in three weeks. The soil excavated from the slurry trench was mixed with bentonite clay and water, then bulldozed into the trench to form a highly impermeable barrier to horizontal water flow. Mix design testing prior to construction demonstrated that adding one percent of dry bentonite to the native till would result in a barrier permeability in the area of 1 x 10-8 cm/sec. Due to the very soft consistency of the slurry wall, it was covered with soil to provide a suitable base for and to facilitate safe installation of the geomembrane cover over the top of the wall.

Surface preparation prior to installation of the geomembrane cover included stripping the grass cover from the trench caps, regrading areas to accommodate cover installation, and excavating the perimeter anchor trench for the membrane cover. The VLDPE cover extends from the center line of Trench 12 across Trenches 13 and 14 and also covers the slurry wall. It was extended to the center of Trench 12 to terminate at the crest of a slope for drainage considerations. The perimeter anchor trench is filled with stone, to also serve as a collection channel conveying precipitation runoff away from the trenches. Due to heavy rain and snow in October and November, installation of the geomembrane cover was completed in June 1993. The VLDPE cover was left exposed to limit the impact on the closure options, to allow closer monitoring for possible sinkhole formation, and to allow visual observation of the membrane for areas of possible leakage.

Results

Triaxial permeability test results of the completed slurry wall ranged from 1.1 to 2.9x10-8 cm/sec. After installation of the slurry wall, the Trench 14 water level immediately stabilized (Fig. 2). Since installation of the geomembrane cover, the water levels in Trenches 12, 13, and 14 have remained stable. Special slit trench monitoring wells, installed to monitor for groundwater mounding outside the slurry wall, have not exhibited a discernible build up. If ground water were to mound behind the wall, it could overtop the slurry wall and again provide a potential for infiltration into the trenches.

BIOENGINEERING MANAGEMENT PILOT PROJECT

Project Initiation

The purpose of the bioengineering management system is to change the humid climate conditions (where precipitation exceeds the evapotranspiration (ET) rate) to dry climate conditions (where potential ET exceeds the precipitation entering the cover soils), thus eliminating deep permeation of water through the trench cover soils into the waste. It has been demonstrated to be a successful means of controlling deep water percolation in test facility lysimeters at the U.S. Department of Agriculture's Experiment Station in Beltsville, Maryland.(6) Because it has not been previously applied to an existing disposal site, NYSERDA decided to proceed with a pilot project demonstration at the SDA. The objective of the pilot project is to

evaluate the effectiveness of this system in preventing vertical water infiltration through the trench cover soils and in dewatering the silty-clay trench cover soil, in the cool, humid, Western New York climate.

In Autumn 1993, NYSERDA installed a bioengineering management system on Trench 9 at the SDA. This trench was selected because its construction is typical of trenches at the SDA with a 2.4 meter-thick, compacted clay cover, and it has a consistent rate of water accumulation, that is believed to result from infiltration through the clay caps. Trench 9 does not appear to be influenced by groundwater or an interconnection with other trenches, making it suitable for this project.

Fiberglass panels mounted on wooden frames were placed perpendicular to the length of the trench to provide a hard cover for positive and predetermined runoff (approximately 80-90 percent of precipitation). Shallow rooted Pfitzer junipers, which are hardy in this region, were planted between the panels to provide for ET of precipitation not removed by the panels (Fig. 3).

Environmental monitoring is used to assess existing SDA environmental conditions and identify environmental changes or trends which occur in response to this pilot project. Project performance will be assessed over a five-year period by evaluating the following areas:

Ability of the system to reduce trench cover soil moisture.

The effect of the bioengineering cover on trench water levels.

Maintenance and repair needs of the junipers, fiberglass panel cover system and drainage system.

Radionuclide uptake in vegetation compared with that in grass cover systems.

Other factors affecting trench cap performance (e.g., nuisance animals, desiccation cracking, etc.).

Initial Observations

Since installation of the bioengineering management system, the junipers have done relatively well in terms of growth and appearance (i.e., color, vigor, etc.), following a set back the first winter. Rodents (e.g., mice, shrews) girdling bark and removing branches from the junipers damaged approximately 50-80 percent of the 3,000 junipers, killing approximately three percent during the first winter. Nursery professionals advised NYSERDA that the damage to similar vegetation was above normal throughout the area, likely due to the consistent heavy snow cover and the unusually cold weather experienced in the area during the winter of 1993-94. The loss of some of junipers was anticipated and, due to the initial overplanting, is not expected to affect the performance of the cover. The recovery and growth of the junipers in the first growing season indicate that the plant roots are becoming established and that the Western New York climatic conditions will not present an obstacle to plant survival.

The hard cover system required no maintenance the first year. As the junipers continue to grow and overshadow the panels, the panels will be less susceptible to weather and solar degradation.

Hypalon-lined drainage swales, along both sides of Trench 9, carry the runoff from the fiberglass panels away from the disposal trenches. The hypalon is anchored by extending stone fill for soil erosion control onto the ends of the hypalon. In Spring 1994, field inspections identified small pockets of water collecting under the hypalon at the end of the swales. Improvements to the anchorage system prevented further ponding of water under the liner.

Reducing vertical water infiltration is a fundamental objective of the bioengineering management system. From March through November, soil moisture was measured at one-foot intervals for depths from one to five feet at three locations distributed along the center line of Trench 9, in grass covered trenches, and in a membrane covered trench. Initial measurements show that moisture in the bioengineering management system trench cover soils are similar to those at the other locations. This is expected because the junipers are small and have not developed the extensive root system and foliage, which will provide the ET rate needed to reduce the soil moisture. As the junipers grow, it is expected that the Trench 9 cover soils will become drier.

Vegetation samples are collected to evaluate the potential uptake of radionuclides (carbon-14 and tritium) in plants on conventional grass covered caps, in the junipers on Trench 9 and at a control location outside the SDA. The levels of carbon-14 and tritium vary between locations and over time, not allowing any initial conclusions to be drawn.

Concentrations of radionuclides measured at the Trench 9 ambient air sampling station are consistent with levels measured at background locations one-half mile to 50 miles away.

IMPENDING ACTIVITIES

NYSERDA and DOE are jointly preparing the Environmental Impact Statement for Completion of the West Valley Demonstration Project and Closure or Long-Term Management of the Facilities at the Western New York Nuclear Service Center (EIS). The EIS will establish the basis for the approach to and schedule for long-term management of the leachate in the trenches.

However, based upon the initial success from implementation of the infiltration controls on Trenches 13 and 14, NYSERDA is preparing to install a geomembrane cover over the remaining grass covered trenches (Trenches 1 through 8, 10, 11 and the other half of 12). Even though current water infiltration rates through the grass covered, silty-clay caps are quite low, water that enters the trenches will accumulate and increase the potential for an uncontrolled release. It is likely that the accumulated leachate will eventually have to be removed and treated or solidified as part of any site closure strategy being considered in the EIS. Leachate removed from trenches will have to be managed and treated as low-level radioactive waste and possibly as RCRA mixed waste due to the potential applicability of a RCRA hazardous waste designation.

By reducing the potential for a release of leachate and reducing the generation of waste, this project is also consistent with the following regulatory and best management philosophies:

- Waste minimization
- Stabilization and source control
- Reduction of contaminant discharge to the environment

The project is intended as an interim measure until the assessment of long-term management and closure options for facilities for the SDA is complete. With an intended life of 10 years, the exposed cover is appropriate only as an interim measure. Because all closure alternatives for the SDA trenches will likely require treatment or solidification of the leachate, this interim measure is consistent with long-term management goals and closure options for the facility.

Design work has started, and installation of the geomembrane cover on the remainder of the grass covered trenches is scheduled for completion in 1995.

FINAL DISPOSAL OF LILW IN SLOVENIA - PRESENT AND FUTURE ACTIVITIES

I. Mele
A. Loose
Agency for Radwaste Management
Ljubljana, Slovenia

ABSTRACT

The siting project for low and intermediate level radioactive waste repository in Slovenia started in late eighties. In this project only surface and near surface repository type was considered. The site selection was planned to be concluded at the end of 1994. The project, which was divided into four steps, successfully

followed the plan until the last fourth step. After the third step was concluded, the public presentation of the results, i.e. five most suitable locations, provoked extremely negative public response. The fourth step of siting, that includes also field investigations, was stopped. Since the continuation of the project was not feasible, the Agency for Radwaste Management, responsible for the project, decided to investigate some other possibilities: the site selection for underground repository of low and intermediate level radioactive wastes and volunteer siting. In this paper recent siting activities as well as previous siting project are presented..

INTRODUCTION

In Republic of Slovenia, the small country with the population of about 2 millions on approximately 20.000 km2, one nuclear power plant and one small TRIGA research reactor are in operation. The nuclear power plant (Westinghouse technology, total capacity 632 MWe) was constructed as a joint venture between Republic of Slovenia and Republic of Croatia and is in commercial use since 1982.

For safe and reliable operation of NPP and research reactor the appropriate radioactive waste management is of great importance. Being aware of that problem, the first preliminary studies concerning the low and intermediate level radioactive waste repository started before the nuclear power plant went into operation but the siting project actually started in late eighties, several years after the NPP went into operation. Due to the natural characteristics of our country as well as economical and technical reasons, the project was oriented more towards surface and near surface type, than towards underground disposal.

In 1990 the time schedule for the siting project was prepared and discussed in the parliament. According to this plan the siting project was divided in four steps and planned to be concluded in 1994.

In 1990 the Guidelines with the instructions for siting of low and intermediate level waste disposal facility in Republic of Slovenia were published by the Slovenian Nuclear Safety Administration (1). Only the criteria for surface and near surface options were considered. These Guidelines, including 43 obligatory site selection criteria, represented the basis for siting project. Subsequently the Guidelines were revised by international experts (2) and in 1991 Revision 1 was published in Official gazette (3).

The siting project was initially under the responsibility of the Division for radwaste management which was founded in 1986 and organized within the NPP Krsko. In 1991 the Agency for Radwaste Management, independent on radwaste producers, was established by the Slovenian government (4) and authorized to carry out the radwaste management projects, including siting of low and intermediate level radioactive waste repository.

LILW REPOSITORY SITE SELECTION - PROJECT HISTORY

The objectives and main results of the siting project are presented in Table I. Following the Guidelines and the siting schedule, the first step was started and concluded in 1990 (5). As the result the unacceptable areas were excluded by application of the exclusion criteria. Since some of the criteria, applied in this step, were extremely severe and rigorous, only few % of whole Slovenian territory remain available for further examination. For example, only the criterion of active faults presence excluded 97 % of our total area. The siting project continued by second step which was successfully concluded in 1991. Following the comparison criteria 36 suitable locations were selected (6). After conclusion of first and second step the results were publicly announced, but except some disagreements no significant reactions were noticed.

At that time the ecological movements in Europe have influenced the formation of similar groups in Slovenia. The changes in our political, economical and social system that occurred in late eighties and early nineties encouraged groups and individuals to become publicly active. New political parties were founded, among them the green party which became politically active. On the other hand the number of opponents to peaceful use of nuclear energy was rapidly increasing. Consequently the members of the green party and ecologically oriented groups started to show increased interest for the radioactive waste management and the site selection project.

The siting project still continued according to the schedule. At that time the third step of the repository project already started. This was the step at which the Agency for Radwaste Management took over the project. The technical part of the

project, including all criteria, specified for the third step except public acceptance, was concluded in 1993 (7). As a result of this step five most suitable locations were identified. In accordance with the practice from previous steps the results were presented to the public. The presentation was unsuccessful and has provoked a strong disapproval within the local communities where the locations were identified. The Agency for Radwaste Management was blamed not to provide regular and sufficient information on the project to the public and not to present and discuss the problem with the representatives of these communities prior the public presentation of the results. The opposition in these local communities was very strong and it soon became evident, that the public acceptance criterion at these locations can not be fulfilled. The expert group, that revised the project, decided to shift the public acceptance criterion into the fourth step so that the third step was considered as concluded (8). Nevertheless, it was impossible to proceed with the siting procedure at these five locations, since the field works at locations were planned to be performed within the fourth step. The project was temporarily stopped.

SITING PROJECT - PRESENT SITUATION

More than one year after the third step of siting project was concluded, the situation in our country, regarding the public acceptance of radioactive waste repository, has not improved. Due to the negative public opinion the continuation of the siting project on five selected locations was recognized as not feasible. The construction of the repository for radioactive wastes is shifted into the next century.

As long as there is no final repository for radioactive wastes in Republic of Slovenia they are stored on locations where they are produced. There are two such locations in Slovenia: the storage for the operational wastes from nuclear power plant on Krsko site and the storage of low and intermediate level radioactive wastes from all other producers in our republic (research, industry and medicine) at Research reactor center Podgorica. On the third location near village Zavratec temporary storage for the decontamination wastes after an accident at the Oncological Institute in Ljubljana in 1961, is placed. On first two locations besides low and intermediate level wastes the spent fuel elements are stored in spent fuel pools, as well.

In Table II. the present quantities of low and intermediate level radioactive wastes as well as storing capacities for these three locations are given. From the table it can be seen that the most critical situation is in NPP Krsko, where storing capacities will soon be occupied.

In nuclear power plant by optimization of working procedures a considerable reduction in waste production was achieved over the last several years. Besides this, another effort in minimization of radioactive waste quantities by the supercompaction of wastes, is currently taking place. It is expected, that by this campaign the present volume of low and intermediate wastes in Krsko will be reduced for approximately 360 m3. Regarding the limited storing capacities at NPP site, all these activities are necessary to provide normal power plant operation until the final disposal facility will be available.

Since the present siting project is stopped and it is not expected that the continuation of this project on selected locations would be feasible in near future the Agency for Radwaste Management is looking for other possibilities to proceed with the project. According to the experience in some other countries the Agency decided to start a new project for underground disposal of low and intermediate level radioactive wastes, which is hoped to be more acceptable to the public.

As the basis for siting procedure the Guidelines with the siting criteria for underground disposal should be prepared and issued by the authorities. For this purpose the Agency for Radwaste Management started the preparation of the siting criteria. Recently, the preliminary criteria have been concluded (9, 10). When the Guidelines will be issued the siting project will start.

The new criteria for the underground repository of low and intermediate level wastes take into account most of the recommendations of international experts (2), given for the siting of surface and near surface repository, some useful experience from other countries and also our own experience. The criteria are basically divided in two main categories: general criteria and geological criteria. Most of the general criteria are the same or very similar as in the Guidelines for surface or near surface repository, so it is expected that some results of the previous siting project can be used. However, significant differences are expected in application of

seismic and active fault criteria, since these criteria appear to be less rigorous in case of underground repository. Taking into account that in first project only active fault criterion excluded 97% of the territory, even small changes in this criterion can considerably increase the area of potential locations.
From lessons given in previous project we learned that public acceptance is the crucial moment in whole siting procedure. Therefore it is planned to support this site selection project for underground repository by intensive public informing and educational campaign from the very beginning. Public acceptance will be evaluated after each step. Since it is not likely to continue with the next step of site selection unless the public acceptance is achieved, it is difficult to predict the time schedule of this project, especially because it depends also on financial sources that will be available to the project.

SITING PROJECT - FUTURE ACTIVITIES

Besides the siting project for underground repository the Agency for Radwaste Management plans also some other activities connected to the site selection. Recently the survey of the abandoned mines and some other underground facilities was concluded (11). The project continues with the study on possible use of these abandoned mines and other underground objects to store or to dispose off the radioactive wastes (12).
Other possibilities for site selection are being studied, as well. Following the foreign experience the analysis of volunteer siting has just started (13). The first study in this field should identify the most suitable approach to invite the communities to volunteer their locality to host the repository.
The volunteer siting became more feasible since the Environmental Protection Act (14) was issued in 1993. By this act the financial compensations to local communities, which would host the project of general importance, are foreseen. This possibility is now being studied to be applied in the volunteer siting project for radioactive waste repository.
Special program is being prepared also for the activities concerning public relations and educational programs. Regular opinion polling and different presentation materials like brochures and booklets are part of this program.
At the same time some other studies concerning the low and intermediate level radioactive waste management like Preparation of preliminary acceptance criteria for radioactive wastes (15), Overview of the materials suitable for engineered barriers in LILW disposal (16) as well as Transportation of low and intermediate level radioactive wastes (17), are performed. However, final reports can not be prepared before the location of the repository is known.

CONCLUSIONS

Since the siting project for surface and near surface repository in Slovenia was stopped and it is not expected to be continued in near future, the Agency for Radwaste Management, which is responsible for the site selection, decided to start a new project for underground repository. The criteria for underground repository site selection have already been prepared. It is expected that the Guidelines will soon be issued by the Slovenian Nuclear Safety Administration and the project will start.
As seismic and active fault presence criteria are different in case of site selection for underground and surface repository , it is believed that by new siting project more potential locations will be available than in first case. However, the possibility to conclude the siting project successfully , depends significantly on public relations. Therefore, the Agency decided to pay strong attention to these activities from the very beginning of new project.
At the same time the possibilities for volunteer siting for radioactive waste repository are studied . Since such approach was already successful in some countries, the Agency intends to apply it in Slovenia as well, if the results of preliminary study will be positive.
The staff of the Agency for Radwaste Management put strong efforts in realization of siting project. By new approach and better public relations it is believed that the project will be successfully realized.

ABSTRACT

Heat generation from radioactive decay and chemical degradation must be considered when implementing low-level radioactive waste (LLRW) disposal. This is particularly important when considering the management of spent radioisotope sources. Heating considerations and temperature calculations for the proposed IRUS (Intrusion Resistant Underground Structure) near-surface disposal facility are presented. Heat transfer calculations were performed using a finite element code with realistic but somewhat conservative heat transfer parameters and environmental boundary conditions. The softening-temperature of the bitumen waste-form (38oC) was found to be the factor that limits the heat generation rate in the facility. This limits the IRUS heat rate, assuming a uniform source term, to 0.34 W/m3. If a reduced general heat-limit is considered, then some higher-heat packages can be accepted with restrictions placed on their location within the facility. For most LLRW, heat generation from radioactive decay and degradation are a small fraction of the IRUS heating limits. However, heating restrictions will impact on the disposal of higher-activity radioactive sources. High activity 60Co sources will require decay-storage periods of about 70 years, and some 137Cs will need to be disposed of in facilities designed for higher-heat waste.

INTRODUCTION

Heat generation from radioactive decay and chemical degradation must be considered when implementing low-level radioactive waste (LLRW) disposal [IAEA 1985]. This is particularly important when considering the disposal of radioisotope sources. This paper summarizes heating calculations that have been performed for the proposed Intrusion Resistant Underground Structure (IRUS) disposal facility. Heat limits are

proposed for the IRUS facility, and these are compared with radioactive decay and chemical degradation heating rates expected in IRUS waste. The implications of heating considerations on managing Canada's LLRW are also discussed.

The IRUS disposal facility (Fig. 1) is based on an open-bottom concrete vault, and is designed for radioactive waste with a hazardous lifetime of less than 500 years [Hardy, et al., 1988]. The facility is expected to be filled with higher-activity LLRW from Canadian nuclear research programs and radioisotope applications. The basic design principles for IRUS are to contain the waste within the vault (i.e., restrict the release of contaminants), and isolate the waste from the environment (i.e., prevent inadvertent intrusion).

The IRUS facility is 32 m long, 22 m wide and 9 m deep, and is divided into 6 cells that provide a total useable volume of about 3900 m3. The reinforced concrete walls are arched so that when the cells are empty, the external soil pressure creates compressive stresses within the walls, reducing the need for reinforcing bars. The walls are 0.61 m thick, and the reinforced concrete roof is 1 m thick. The floor is permeable to avoid the "bathtub effect", and is composed of two buffer layers: a 0.3 m thick mixture of sand (90%) and clinoptilolite (10%), and a 0.3 m thick mixture of sand (90%) and Dochart clay (10%). The clinoptilolite and clay have the capacity to sorb many critical radionuclides from aqueous solution, and thus reduce radionuclide escape from the vault. To avoid flooding, IRUS is to be located in a free draining sand deposit with its foundations at least one meter above the highest recorded water table. Final closure of the facility will include a multilayer earthen cover system about 2 meters thick.

During the operating phase, the IRUS facility will be covered with a temporary weathershield building. The building will contain a gantry crane for transferring materials to the cells using remote attach/detach capabilities so that entry into the cells is not required. The principal waste packages will be 0.4 m3 bales of compacted waste (90% volume) and 200 litre metal drums. The bales will include fibrous materials, plastics, and small quantities of metals. Most drums will contain a bitumen waste-form produced from liquid-solidification processing or ash immobilization. Waste will occupy about 50 percent of the IRUS volume. Voids between packages and layers of waste will be backfilled with sand (90%) and clinoptilolite (10%).

FACTORS LIMITING HEATING RATE IN THE IRUS FACILITY

Factors that could limit the heat generation rate within the facility were determined, as summarized in Table I. For each factor a maximum allowable temperature or temperature gradient was determined (column 3). The melting temperature of bitumen (38C) was identified as the factor that would limit the allowable temperature, and thus the heat load, in the IRUS facility.

Concrete strength is generally not affected by temperatures less than 38C [Mittelacher, 1992]. At temperatures above 75C, decreases in strength have been measured by Carette and Malhotra [1985]. Thermal stresses due to temperature gradients in the concrete walls during the operational and post-closure phases have been considered for the temperature design load of the IRUS structure [Mok, 1989]; the largest temperature gradient of the study was assumed to be a maximum allowable temperature gradient in the concrete for this analysis (i.e., 26.7C/m). The waste-form most sensitive to increased temperatures is the bitumen used for liquid solidification. This bitumen is similar to type 80/100-150, which has a melting point in the range of 38-53C [IAEA, 1993]. Bitumen's flash point temperature is well above its melting temperature, and is not a limiting factor. Microbiological degradation of hydrocarbons in bitumen occurs at temperatures from 0 to 70C. Under the most favourable conditions of temperature, pH, and O2 availability for degradation, the maximum microbial penetration of bitumen would be of the order of 0.7 mm per 100 years [Allison, et al., 1991]; therefore, it is not expected to limit the temperature in the IRUS facility. Temperature gradients in the waste will increase tritium migration. The allowable temperature gradient for tritium migration have not been determined, but this consideration is not expected to be critical. Finally, the steel containers of the waste are not given any credit as a barrier to waste migration, so corrosion rate temperature dependence will not limit the allowable temperatures.

TEMPERATURE CALCULATIONS FOR THE IRUS FACILITY

The finite element computer code, ANSYS 5.0A, was used to perform calculations of temperature in and around the IRUS facility. Calculations were performed for a base

case with uniform heating throughout the facility, and for a case where a limited number of high-activity packages were included. Analyses of sensitivity to the various thermal conductivities, boundary conditions and location of facility with-respect-to surface and aquifer were also performed. A 2-D cross-section of the two middle cells of the repository, where the temperature would be the highest, was used as a basis for the simulation. The cross-section was simplified, as shown in Fig. 2, using the following assumptions:
Fig. 2. Sketch of the ANSYS model of the IRUS facility
All cells have the same heat load, giving plane symmetry in the centre of the inner concrete wall.
The waste was assigned a uniform thermal conductivity based on thermal conductivity of building rubble materials, fibrous materials, plastics, sand, and bitumen.
The overburden layers (gravel, cobblestone, fine sand, and top soil) and buffer layer (90% sand, 10% clinoptilolite) were assigned the thermal conductivity of sand. This is justified since the thermal conductivities of these layers are similar, and minor differences in their thermal conductivities will not significantly impact the calculated temperatures.

Thermal Conductivities

Typical values and bounding ranges were identified for the thermal conductivities required for the temperature simulations (Table II). The bounding ranges were used for sensitivity studies, and to help establish a conservative reference scenario. The walls and the roof of the IRUS facility will be constructed of high-performance reinforced concrete with limestone aggregate. The typical thermal conductivity of concrete with limestone aggregate is 1.56 W/m.K; the selected range of 1.2 to 1.8 W/m.K is slightly more conservative than the typical range. The thermal conductivities of the sand, overburden and buffer is typical of Ottawa area sand with a moisture content of 2-4%. The effect of moisture migration on thermal conductivity of sand was also considered; it was concluded that the selected range of the thermal conductivity of sand covers the effect of moisture migration satisfactorily.
The thermal conductivity of the heterogeneous waste/backfill mixture expected within IRUS has not been explicitly determined. The dry environment within the vault, coupled with the slightly elevated temperatures expected, suggest that the thermal conductivity of dry sand (0.35 W/m.K) would be a reasonable starting point. Fibrous materials and air gaps in the compacted bales may decrease this value somewhat. The thermal conductivities selected for this study cover the range of realistic values, although the "typical value" is likely to be somewhat low.

Boundary Conditions

The boundary conditions were established based on annual averages of environmental parameters. Annual averages of environmental parameters were used throughout this study, since seasonal temperature variations are insignificant two or three metres below the ground surface [Wildsmith, 1976]. Parameters such as air temperature, ground temperature, aquifer temperature, solar radiation, wind speed and ground-to-sky radiation for the Chalk River/Ottawa Valley region were considered. Since the radionuclides in the IRUS facility will be active for several decades, slightly conservative ranges of annual averages of all parameters were used, based on measured data.
Adiabatic boundary conditions were assigned at the vertical boundaries, as shown in Fig. 2. The location of the right boundary was sufficiently far away to not affect the temperatures in or around IRUS facility. At the horizontal boundaries, constant temperature boundary conditions were assigned. The ground surface temperature range was based on the sensitivity analysis of the environmental parameters; therefore, it covers the effects of all those parameters on the ground surface temperature. The effect of heating in the IRUS facility on the ground surface temperature was also examined. It was found that heat load of 2 W/m3 (which is about 5.5 times higher than the established limit) affects the ground surface temperature only by 0.2 to 0.3C.

Effect of Voids Within the Vault

Voids may form within the vault, either through incomplete backfilling around waste or waste slumping. The effects of voids on the heat transfer characteristics were investigated. Horizontal air gaps up to 0.5 m were considered. In the ANSYS model, the closed air gap is represented as a solid material having an effective thermal

conductivity of the air gap [Holman, 1981], which includes the effects of conduction, convection and radiation. The effective thermal conductivities, found for various air gap heights for a heat load corresponding to the temperature limit of 38C in the waste, were used in the finite element simulation.
For vertical air gaps, it was found that the effective thermal conductivities were within the bounding values of the thermal conductivity of waste, and in some instances slightly higher than, therefore, their thermal effect is effectively covered by the waste thermal conductivity.
Calculations
The problem of the IRUS heating was simplified to five parameters, as listed in Table II. Temperature calculations were performed to determine the heat generation rate which produces the limiting temperature of 38C. Calculations were made for a typical case with uniform heat generation throughout the waste, and then single parameter sensitivity analyses were carried out to lower and upper bounding values. Various schemes were considered that allowed some higher-activity packages to be placed in IRUS. Such schemes must be simple to implement operationally, and they must be amenable to simulation. A suitable scheme reduces the general heat limit for waste, but allows for higher-activity packages to be placed anywhere within 1.2 m of the top or bottom of the facility. To simulate higher activity packages, some finite elements were assigned higher heating rate than others according to selected perturbation schemes (i.e., higher heating in top and bottom layers).
RESULTS
The calculated heat rate limits for IRUS that give a maximum temperature of 38C are presented below. In all cases the temperature gradients in the IRUS structure are less than 50% of the imposed 26.7C/m limit.
Heating Rate Limit with Uniform Heat Source
Calculations using the typical values for heat transfer parameters given in Table II, and assuming uniform heat generation throughout the waste, give an IRUS heat rate limit of 0.63 W/m3. Single parameter sensitivity analysis showed that the heat limit is not very sensitive to the parameters in Table II except for the kwaste. The heat load is, in most cases, in the range of 0.5 to 0.7 W/m3 except for the lower bounding value of kwaste when it is 0.35 W/m3. Analysis also showed that a 1 m increase in the distance between the IRUS facility and the aquifer or ground surface decreased the heat load by about 0.02 W/m3. Due to uncertainty in some of the parameters, and recognizing that the IRUS facility will need to maintain its performance for several centuries, the reference case was defined as having a typical thermal conductivity of waste form and conservative bounding values of all the other parameters. This conservative reference case gives an IRUS heat rate limit of 0.34 W/m3. If the waste form thermal conductivity can be better defined, then the heat limit can be adjusted using the data in Table III.
Heating Rate Limit with Higher Activity Package Perturbation
The higher activity package perturbation calculations were performed using the same reference case boundary conditions and thermal conductivities as described earlier for the uniform heating source. The calculations show that IRUS could handle a small number 0.4 m3 packages with heating rates of about 10 W/m3. If a general heat limit of 0.1 W/m3 is applied to the facility, then high-activity packages with heating rates up to 1.6 W/m3 could be placed anywhere within 1.2 m of the top or bottom of the facility.
HEATING WITHIN IRUS
Heating in LLRW occurs from radioactive decay and chemical reactions during the waste degradation process. In general, heating in LLRW is expected to be small, although some radioactive sources do produce significant power.
Radioactive Heating
In solid-LLRW, all radioactive decay energy, except neutrino energy, is deposited locally (neutrino interaction cross sections are negligible). The heat energy and corresponding Bq/Watt for some representative radionuclides in LLRW are listed in Table IV, columns 2 and 3, respectively. These values were derived from average energy released per decay provided in ICRP Publication 38 [1983].
As presented earlier in Section 4, the heat rate limit in IRUS could be implemented as either a uniform limit of 0.34 W/m3, or alternately, as a base value of 0.1 W/m3 with some higher-activity packages permitted with heating rates up to 1.6 W/m3. Radionuclide limits for these different options are presented in columns 4, 5, and 6 of Table IV. These are single nuclide limits, and a sum-of-fraction rule must be

applied to mixtures of radionuclides.
To assess the impact of heating limits on IRUS waste acceptance, the expected LLRW inventory must be considered. Preliminary inventory estimates suggest that the total activity in the IRUS vault will be about 4.0 x 1014 Bq, with 3H (1.6 x 1014 Bq), 137Cs (1.1 x 1014 Bq), and 60Co (2.1 x 1013 Bq) being the highest- activity longer-lived nuclides (Hardy et al., 1991). The total activity results in about 40 watts of radioactive heating [Chan et al., 1994], which translates to an average heating value of 0.01 W/m3. This low value suggests that a general heat limit of 0.1 W/m3 would be accep for IRUS, thus permitting a limited number of packages with heating rates up to 1.6 W/m3.
The IRUS facility could be used for the disposal of sealed radioactive sources, although heating rate and risk-based limits will exclude acceptance of some sources. Table V shows the distribution of activities for the higher-activity sealed sources currently licensed in Canada [Beriault, 1994]. Only sources with a half-life greater than three years are included in the , since shorter half-life sources can be easily stored until their heat generation rates are low. The final column in the shows the IRUS activity limit in a 0.25 m3 package, based on a heat limit of 1.6 W/m3 and assuming that the waste occupies 50% of the vault volume. Sealed sources that exceed this limit are indicated with shading in the .
The data in Table V show that only 60Co, 137Cs, and 241Am sources are above the IRUS heat limit in significant quantities. The very-high-activity 60Co sources, which represent several 100 kW of power, would need to be stored for a period of about 70 years before they qualify for disposal in IRUS. Although the 137Cs sources represent a much smaller heat source than the cobalt, their longer half-life makes decay-storage impractical. High-activity cesium sources will either have to be dismantled to distribute the heat source, or disposed in a facility that can accommodate higher-heat waste. The higher-activity americium sources are not likely to be sui for near-surface disposal (excluded by risk-based limit), and these sources will likely be disposed in a geologic facility.
Heat Generated from Biogeochemical Processes Associated with Waste Decomposition
Leaching experiments have been performed on compacted bales of LLRW to monitor their degradation. The degradation process can be related with simple redox reactions to eventually give heat generation rates. To extrapolate the leaching measurements to give an estimate of the IRUS heat generation rate, a correction factor must be applied to reflect the drier environment expected in IRUS.
Microbial degradation of organic matter in landfill sites is one of the major sources of heat. This reaction gives the theoretical yield of anaerobic degradation of cellulose [Pirt, 1978; Rees, 1980]:
1 kg $C_6H_{12}O_6$ → 0.25 kg CH_4 + 0.69 kg CO_2 + 0.056 kg dry biomass
+ 632 kJ heat (1)
The water content and the flora dictate the regime of the reaction (aerobic or anaerobic). In a closed system such as a landfill or a confined aquifer, the most energy-yielding substrates will be assimilated preferentially either until depletion, or until the concentrations of these substrates become too low to be favourable thermodynamically. The substrates are generally reduced in this approximate order: O_2, NO_3^-, Mn(IV), Fe(III), SO_4^{2-}, CO_2, N_2 [Scott and Morgan, 1990]. Several redox couples may coexist, due, in part, to the relative closeness in redox couples and heterogeneities in the reactor.
Four bales of compacted low-level wastes were sealed in separate metal boxes to monitor the decomposition process. Each box was connected to a pump in a closed loop and water was recirculated daily over the bales to keep them wet, but not flooded. Major ions, gases, dissolved organic matter (DOM), etc., were monitored periodically [Caron, 1994] on all the bales. Two complete sets of redox-sensitive parameters were used on two dates (spanning over approximately one year) for mass balance calculations. The parameters showing the most important changes are shown in Table VI (O_2, SO_4^{2-}, NO_3^- and Mn were measured but their contribution was small). They were related together with a series of redox reactions (Table VII) to determine the contribution of each reaction in that time period. The energy released is given by the enthalpy DH (negative values denote exothermic reactions).
Heat Production Calculations
The time "zero" of the experiment was set when water was added to each bale. The results of 6 are shown for only one bale as an example. The most important assumptions related to these calculations are:

the gas generation rates were linear over the duration of the experiment, based on the long bale-degradation half-life (30-2400 years)[Caron et al., 1995];

all the DOM was acetic acid, which is reasonable based on elevated levels of acetate measured in these bales, [Caron, 1994];

nitrogen was assimilated to produce ammonia, and not displaced. Ammonia was not measured, but the calculated concentration (~0.08 mole/L) is not unrealistic of landfills [Rees, 1980; Lisk, 1991; Ehrig, 1983].

Only the spontaneous reactions (noted with a negative DGr value) were used because microorganisms are unlikely to go against an energy expense for fulfilling their energy needs. Hydrogen gas was not detected, but its assimilation (reaction 4 in 7) and production are more than likely.

The total energy released to the surroundings is the sum of all the enthalpies of each of the reactions (7):

Eq. (2)

where i corresponds to reactions 1 to n, and Ci is the relative contribution of reaction i. This amounts to 1734 kJ for bale #6, which is higher than the energy released (840 kJ) from the stoichiometric reaction (1), corrected for the same amount of cellulose. The major difference between our calculation and equation (1) is the contribution of metal corrosion (reaction 1 in Table VII) and CO2 reduction to methane (reaction 4 in Table VII). Credit is not given to energy losses due to conversion to biomass.

Degradation Rates Applicable to the IRUS Environment

To estimate the heating rate expected in IRUS, the heating rates derived from the leaching tests must be corrected to reflect the dry environment expected in IRUS. Gas generation rate measurements by Torok and Haas [1992], using the same bales degrading in dry conditions, allow for a reasonable estimate of the required correction factor. Their reference gas generation rate was 0.021 l/kga. Gas generation rates in the leaching tests (Table VIII) were 5 to 60 times higher than this reference value, so the heat generation was normalized to the same rate to give corrected values.

CONCLUSIONS AND RECOMMENDATIONS

Factors that could limit the temperatures and temperature gradients in IRUS were investigated, and the melting temperature of the bitumen waste form (38C) was found to be the most restrictive. Heat transfer calculations, based on realistic, although somewhat conservative heat transfer parameters and boundary conditions, suggest that a heat rate limit of 0.34 W/m3 is appropriate for IRUS, assuming a uniform heat source throughout the facility. Alternatively, a general heat limit of 0.1 W/m3 could be applied, with heating rates up to 1.6 W/m3 within 1.2 m of the top or bottom of the facility. Assuming a 50% waste packing efficiency, the heat limits for the waste packages will be double the facility limits. For example, a general package heat limit of 0.2 w/m3 can be applied, with some high-activity packages accepted with heating rates up to 3.2 w/m3. Heat limits are sensitive to the waste form thermal conductivity. The proposed heat limits are based on a somewhat conservative waste-form thermal conductivity, and this should be reviewed once the actual IRUS inventory is known.

Heating in LLRW occurs from radioactive decay and chemical reactions during the waste degradation process. For most of the LLRW expected to be disposed of in IRUS, radioactive decay heating is expected to be about 0.01 W/m3. The IRUS facility may also be used for the disposal of sealed sources. A review of sealed sources licensed in Canada shows that most sealed sources fall within the 1.6 W/m3 heat limit noted earlier. The exceptions to this are 60Co, 137Cs, and 241Am. 60Co sources could be decay-stored for about 70 years at which time they could be economically disposed of in IRUS. On the other hand, the longer-lived 137Cs and 241Am sources will likely need to be disposed of in facilities that can accommodate higher-heat loads (e.g., fuel-disposal facility).

Heating generation from waste degradation due to biogeochemical processes has been evaluated based on leaching experiments with compacted waste bales. The results, corrected to account for the dry environment expected in IRUS, suggest that chemical heating will contribute about 0.004 W/m3, which is a small fraction of the proposed IRUS heat limits.

ACKNOWLEDGEMENTS

The valuable and continuous advice of Dr. J.T. Rogers in the heat transfer calculations is deeply appreciated.

ABSTRACT

A panel of scientists, appointed by the Board on Radioactive Waste Management of the National Academy of Sciences/National Research Council (NAS), is completing a review of the so-called "Wilshire Report" and the Ward Valley site which has been licensed by the State of California for the Southwestern Compact's regional low-level radioactive waste disposal facility. The review was requested in March 1994 by Interior Secretary Bruce Babbitt who asked the Board to evaluate certain "earth science concerns" raised in the "Wilshire Report." Completion of the Academy's evaluation has been delayed and its report is now expected in early March 1995. Academy review of a proposed project that has already been licensed by the authorized governmental agency is unique and raises a number of institutional issues. NAS review may or may not be consistent with statutory and regulatory standards adopted and implemented by federal and state governments for low-level radioactive waste disposal facilities. The delay of the project due to the review and the ultimate role of the report in the federal decision process in response to the State of California's request to purchase the Ward Valley property from the U.S. Bureau of Land Management (BLM) are also matters of public policy concern. Only when the Academy completes its review and makes its report public will we know how it has dealt with these institutional issues and with what degree of success.

INTRODUCTION

In June, and again in December 1993, three geologists employed by the U.S. Geological Survey (USGS) at its office in Menlo Park, California raised concerns about the suitability of the Ward Valley site for California's and the Southwestern Compact's proposed low-level radioactive waste disposal facility. Their document, prepared for release at a press conference held in Los Angeles on December 8, 1993, has come to be known as the "Wilshire Report" after the lead author Howard Wilshire.

The Ward Valley site is federal land under the jurisdiction of the U.S Bureau of Land Management (BLM), an agency within the Department of the Interior. The California Department of Health Services (DHS) application to the BLM to purchase 1,000 acres at Ward Valley has been pending since July, 1992. (The BLM has been fully involved on the California LLRW project with DHS since 1988 when it was clear that the California site would be on BLM land.) On March 14, 1994, Secretary of the Interior Bruce Babbitt requested the Board on Radioactive Waste Management (BRWM) of the National Academy of Sciences to evaluate earth sciences concerns in the Wilshire report and to deliver a report to him by December 1, 1994. The Secretary's request followed several actions and counter-actions taken by the Department of the Interior during the preceding fourteen months. (See section on Political Antecedents on page 3.)

BACKGROUND

Environmental documentation for the Ward Valley disposal project was issued in April 1991 by DHS and BLM as a Final Joint Environmental Impact Report and Environmental Impact Statement, and, following public hearings on the joint EIR/EIS and the draft license, the public comment period was closed in August, 1991. In September, 1993, the BLM released a Final Supplemental Environmental Impact Statement (FSEIS) which found that the "Ward Valley facility will meet or exceed all environmental health standards with no contamination of ground or surface water," confirming the findings of the earlier documentation. On September 16, 1993, the DHS issued a license to US Ecology, Inc., the company that had been designated "license designee' in late 1985. In August 1993, Secretary Babbitt requested the Governor of California to hold one more hearing, and the Governor agreed. In that request, the Secretary indicated his objective of reaching a decision on the land sale by the end of the year. On November 24, 1993, Secretary Babbitt canceled the hearing he had requested that California conduct, and put the land sale on hold. On March 14th, 1994, the Secretary requested the review by the BRWM which is the subject of this paper.

COMMITTEE COMPOSITION, TASK STATEMENT AND SCOPE OF TECHNICAL ISSUES

The "Committee to Review Specific Scientific and Technical Safety Issues Related to the Ward Valley, California, Low Level Radioactive Waste Site" appointed by the BRWM is comprised primarily of earth scientists in the disciplines of geophysics, geochemistry, tectonics, hydrology of the unsaturated zone, hydrology of fractured media, and sedimentary geology. The committee also includes a civil engineer and desert ecologist.

The Committee's Statement of Task states, in part:

"The Committee will undertake an examination of the relevant data, reports, license

application material, and other documents that address the following specific issues related to the Ward Valley, California site:
1. Potential infiltration of the repository trenches by shallow subsurface water flow, including the possible presence of tritium in the deeper soils, and interpretation of C-14 ages.
2. Potential transfer of contaminants through the unsaturated zone to the ground water.
3. Potential for hydrologic connection between the site and the Colorado River.
4. The absence of plans to monitor ground water or the unsaturated zone down-gradient from the site.
5. The potential for failure of proposed engineered flood-control devices.
6. Potential damaging effects on the desert tortoise habitat.
7. Potential interference with revegetation and reestablishment of the native vegetation.
"The objectives of the study are 1) to assess the adequacy of the site studies relative to the above enumerated issues and the validity of the conclusions concerning site performance that are the subject of debate, and 2) to determine if the enumerated concerns are valid, significant, and unresolved and, if so, to assess the potential impacts on site performance.
"The committee will comment only on the scientific and technical issues. It will not evaluate the site nor be a party to any approval process."
The committee held two public meetings in the City of Needles, California (the community nearest the Ward Valley site) on July 7-9 and August 30-September 1, 1994. The panel visited the site and listened to presentations by the DHS, US Ecology, and the Wilshire group and their respective contractors and consultants. The panel also heard public comment during "open microphone" sessions at the end of each day, with presentations generally limited to 5 minutes. The committee also invited written submissions. These public portions of the committee's work raise several policy issues related to procedure and the standard for evaluation.

POLITICAL ANTECEDENTS TO SECRETARY BABBITT'S REQUEST TO THE NAS

In January 1993, Secretary Babbitt rescinded the Ward Valley land sale to California which had been approved by former Secretary Lujan. He also rescinded Mr. Lujan's record of decision. In August, in a letter to Governor Wilson, Mr. Babbitt requested that California hold one more hearing on the adequacy of the Ward Valley site. The Secretary outlined a schedule that anticipated a decision by Interior on the land sale by the end of the year. In September, the BLM issued its FSEIS as described above. On September 16, 1993, the DHS issued its license to US Ecology, and the Governor announced that he would agree to hold the hearing requested by Mr. Babbitt. On November 24, 1993, Secretary Babbitt canceled the hearing he and Governor Wilson had agreed to hold. The Secretary's stated reasons were that California had issued a license and that the license was being challenged by a lawsuit in state court in which petitioners claimed that state law requires an "adjudicatory hearing" before a license may be granted. But Governor Wilson had personally notified Mr. Babbitt in advance that a license decision would be made, pursuant to the order of the appellate court, prior to the hearing on federal issues related to the land transfer. Secondly, the adjudicatory hearing issue had already been resolved by the state Court of Appeal. The Secretary's basis for delay was removed in February 1994 when the state trial court in Los Angeles granted a motion for summary judgment and ruled that state law requires no such hearing. This ruling was based on the Sacramento Appellate Court's ruling in May 1993. Whatever Mr. Babbitt's reasons for requesting the NAS/BRWM review, it has provided the Administration with more than a year's delay past the Secretary's original decision schedule of December 1993.

ISSUES RAISED BY THE ACADEMY'S REVIEW AND PROCEDURES

Fairness/Openness

Ward Valley opponents have charged that the appointed Ward Valley panel is not "balanced." In a July 1, 1994 letter to Dr. Bruce Alberts, President of the National Academy of Sciences, U.S. Senator Barbara Boxer (D-California), an outspoken opponent of Ward Valley since 1991, stressed the importance of the case under study, "where the issue is whether the proposed nuclear dump could radioactively contaminate the Colorado River for generations to come." Senator Boxer complained of "an apparent heavy bias in favor of those with contracts and other ties with the nuclear industry and associated institutions involved in the promotion of nuclear activities in this country." She also questioned the objectivity of panel members

who "have published on the very issues the panel is to resolve, having taking (sic) positions contrary to those of the U.S. Geological Survey (USGS) scientists whose work they are to review." Neglecting the large role assigned to Dr. Wilshire and his allies in the committee's public sessions in Needles, she complained about the agenda's "...precluding any participation by any representative of or scientist with any of the entities opposing Ward Valley." (Emphasis in the original.) Senator Boxer urged Dr. Alberts to "clean up this mess."

In his response, Dr. Alberts described the process by which the National Research Council (NRC) selects "an expert committee with the appropriate scientific and technical qualifications to investigate the issue at hand. The selection of the committee is made by the NRC Chairman after reviewing candidates suggested by internal and external sources. The NRC committee selection process also strives to balance potential biases with regard to the issues in dispute and to avoid conflicts of interest that would compromise the study." With respect to the Ward Valley panel, Dr. Alberts wrote, "Based on the completed forms and the discussion in executive session, my staff and I have confirmed that the committee as a whole is technically highly qualified, is reasonably balanced, and does not have a bias or conflict of interest that would prevent it from reaching highly-credible scientific conclusions regarding the seven technical issues in dispute." Dr. Alberts noted, "As an aside, you might be interested to know that three members of the committee, including the chairman, were recommended by environmental organizations; none of the committee members was suggested by industry or by proponents of the use of Ward Valley for low-level radioactive waste disposal."

Dr. Alberts went on to describe the limited scope of the NRC study: "...seven very specific technical issues in dispute between the USGS geologists, the State of California and Wilshire et al. As with any NRC committee, it will not address issues extraneous to its charge --however important and broad those issues may be. In planning its recent meeting, both parties to the controversy (Wilshire and associates and the State of California) were given the opportunity to choose their agenda items, and were given the amount of time they requested for each presentation. At the end of the meeting on July 9 the committee chairman asked Dr. Wilshire if he had enough time to present his case. Dr. Wilshire responded that he had."

A Ward Valley opposition group that addressed the NAS committee's meetings in Needles has complained that they were not treated fairly. The facts are otherwise and show much greater deference paid to opponents than to organizations that use radioactive materials, generate LLRW, and will be the customers for the Ward Valley disposal facility.

At a meeting of the NAS Board on Radioactive Waste Management at the Academy's Beckman Center in Irvine, California on December 15, 1994, a spokesperson for the Committee to Bridge the Gap (CBG) stated:

"We became very concerned that the panel, even as unbalanced as it was, needed to hear both sides. The site owner and the proposed site contractor were given days of time to make formal presentations. Experts from the site opponents were precluded from making any formal presentation. Not permitted at all. My group, the Federation of Scientists, others have sued the Department of Health Services and US Ecology over this issue and were, in fact, victorious. They were permitted to make formal presentations; our group was not. The public was permitted to make five-minute comments at the end of each session from a peanut gallery, but the project's opponents were not permitted formal presentations." a, b

The CBG spokesperson then described a thirty minute presentation he was allowed to make prior to the last day's meeting in Needles with members of the committee attending voluntarily an informal session at the rear of the meeting room. He characterized this as speaking from the "back of the bus."

In fact, during the two three-day meetings in Needles, the Wilshire group put on numerous witnesses including the three geologists themselves, as well as geochemists, hydrologists (the Wilshire Report authors have stated on the record that they are not hydrologists), and a biologist. In addition, a member of the Committee to Bridge the Gap Technical Review Panel, a hydrologist, made a formal presentation as a consultant to the Wilshire group. At the NAS meeting in early July, CBG was allowed thirty minutes to make a presentation on groundwater protection issues.

Despite requests to the NAS Committee by Cal Rad Forum, no privileges were extended

to waste generators comparable to those extended to opponents. A request for thirty minutes for an informal presentation was denied.
Representatives of Cal Rad Forum and other supporters of the Ward Valley project used the open microphone sessions to make short presentations refuting claims by opponents concerning the composition of the waste stream and the need for the disposal facility in the Southwestern Compact region, to rebut statements by the Wilshire group regarding the significance of assertions of connections between ground water at Ward Valley and the Colorado River, and to outline provisions of the U.S. Nuclear Regulatory Commission's regulations which have been ignored by the Wilshire group, CBG, and others who are in opposition to the Ward Valley project and to the Low-Level Radioactive Waste Policy Act. Subsequent to the public meetings in Needles, Cal Rad Forum supplemented its oral comments made during the open microphone sessions with written submissions. The NAS Ward Valley committee repeatedly invited written submissions stating that their work would be based primarily on written material. The Cal Rad spokesperson (Pasternak) indicated his group's willingness to play by whatever rules of procedure the committee established. The CBG spokesperson urged the committee to overrule its chairman regarding access to the microphone.
It should be anticipated that Ward Valley opponents will continue to attempt to discredit the composition and fairness of the committee and its procedures (witness the "peanut gallery" comment about the committee's open microphone sessions). The apparent purpose is to discredit the outcome in advance so that the issues put forth as the basis of their opposition may be kept alive. Their complaints should be taken with a pillar of salt.
STANDARD OF REVIEW
A license has been issued by the California DHS to US Ecology to construct and operate a low-level radioactive waste disposal facility at Ward Valley. The license has no practical effect until acquisition of the site by the State of California. The license was issued by the agency authorized by federal and state law to exercise regulatory oversight and was pursuant to adopted state and federal regulations. Environmental documentation published by BLM and DHS includes both a Draft Joint Environmental Impact Report/Statement and a Final Joint EIR/S by DHS and BLM to comply with both state and federal environmental laws, as well as a Final Supplemental Environmental Impact Statement issued by the BLM. The DHS has also prepared a Safety Analysis report. The license and EIR certification are now under appellate review in state court; therefore, the Academy's review is concurrent with ongoing legal processes in the state of California for which the standard of review will be the applicable laws and regulations.
The decision by the Secretary of the Interior (in which the White House apparently participated) to request a review by the BRWM is seen by many as part of an effort by the federal Administration to "second guess" California's regulatory licensing decision. Intervention by the federal government in California's low-level waste disposal program has been criticized by many including the former chairmen of the oversight committees in the Congress: Senator Bennett Johnston and Congressmen Philip Sharp, John Dingell, and Richard Lehman. Given the regulations which have guided the applicant (US Ecology) in its site characterization work and the regulatory standard of review which has guided the state of California, it is fair to ask the NAS Ward Valley panel, what standard of review will be applied? What will be the framework for the evaluation of the concerns in the Wilshire Report? Will the work of the Committee be guided by or compatible with the governing regulations which constrain and direct the State's administrative agency and courts?
View of the State of California on the Standard of Review
At the start of the Ward Valley committee's first meeting in the City of Needles on July 7, 1994, Elisabeth Brandt, Chief Counsel and Deputy Director for the Department of Health Services addressed the committee from the point of view of an attorney who is a regulator. She described how the Department, for ten years, has "worked to elevate science over emotionalism, publicrelation, and bureaucratic convenience." She stated that "Science drove our effort for two reasons." These are that "California wanted to approve a site and a facility design that the experts could honestly say would be excellent from the technical point of view" and "...the state has a profound need for a low-level radioactive waste site to support its users of radioactive materials - medical, academic, biotechnology, industrial, and power-generating." She said "The approach which California has taken to the Ward

Valley facility should be very compatible with the interest of this committee."
Deputy Director Brandt stressed the importance of making decisions and the necessity to bring regulatory review to closure. She went on to "raise one point that is of great importance to those of us who deal not in abstract questions, but in the practical realities. Misters Wilshire, Howard, and Miller have raised seven different issues. We have answers to each of these general issues which give us sufficient confidence to go forward. Still, I would be the last person to claim that definitive answers to all of the detailed issues they have raised are known today. As an academic matter, claims can always be made that additional research and new physical measurements are necessary to increase some element of scientific certainty."
"However, I believe that the issues which they claim require further physical and analytical work do not pertain directly to the safety of the proposed Ward Valley facility. They may be issues of valid research or academic interest, and addressing them may improve our understanding of this part of California. But, given our current knowledge, they are not issues that need to be answered to determine whether radionuclides from the disposal trenches will or will not endanger public health or safety or the environment." (Emphasis added.)
She urged the members of the committee to "maintain a clear mental separation between those issues that affect health and safety related to the proposed Ward Valley facility and those issues that might tempt you as scientists to want to learn more, but that either do not relate to the safety of waste disposal, or did not need to be answered to make a licensing decision."
And, describing the Department's regulatory role: "Our concern as the regulatory agency was to thoroughly answer those questions that relate directly and measurably to health, safety and protection of the environment. We requested US Ecology and its contractors to study the site to the point where they and we were satisfied that we knew everything that was necessary to a full safety assessment for the proposed facility. Then we stopped."
And finally, "In making our determination that harm would not occur, we used two guides. The requirements of the state and federal statutory and regulatory framework, and the principle, derived from this guidance, that any exposures and all environmental effects, even when they are well within specific regulatory limits, must be as low as reasonable achievable, or ALARA."
"... The NRC has established reasonable health and safety standards which we must prove we can meet. And we have proven that the Ward Valley facility can meet those standards. But it will also operate under the ALARA principle to exceed the expectation of those standards."
View of Users of Radioactive Materials (Cal Rad Forum) on the Standard of Review. The Nuclear Regulatory Commission's "Reasonable Assurance" Standard at Part 61.23
During the open microphone session at the Committee's public meeting in Needles on August 30, 1994, Dr. Pasternak presented a statement by Dr. Budnitz and himself on the standard of review from the perspective of scientists who are also former regulators.c A written statement was also submitted for the record. Drs. Budnitz and Pasternak supported the remarks of DHS Chief Counsel Brandt: "As scientists who are former regulators, we endorse the Department of Health Services" approach and urge you to relate your scientific inquiry to the regulatory standards which must be met before a license can be issued." Drs. Budnitz and Pasternak cited the "special place" which NRC's regulations occupy in the California licensing framework. "In 1983, the California Legislature directed the Department of Health Services to adopt regulations for low-level waste disposal consistent with 10 CFR 61. In 1984, the Department adopted the federal regulations by reference. These regulations establish a "reasonable assurance" standard for license review." The statement went on to provide examples of how "reasonable assurance" applies: protection of the general public from releases of radioactivity, protection of inadvertent intruders, that the radiation protection standards of Part 20 will be met, long-term stability of the disposed waste and the site to eliminate to the extent practicable the need for site maintenance following closure, meeting the technical requirements for land disposal facilities, etc.
The statement by Drs. Budnitz and Pasternak cited errors in the Wilshire analysis that display a lack of familiarity with the NRC regulations. The criticism that plans are lacking for monitoring groundwater or the unsaturated zone down-gradient from the site assumes, in effect, that regulatory monitoring requirements will not

be followed. The Wilshire Report's assertions regarding interconnections with the Colorado River also ignore regulatory requirements. The Budnitz-Pasternak statement notes:

"Another example of how regulatory guidance can inform evaluation of the proposed disposal site relates to the assertions by Wilshire, Howard, and Miller that there is potential for hydrologic connection between the site and the Colorado River. Having postulated such hydrologic connection, Wilshire, et al stop with no further evaluation of what such connection might or might not imply with respect to reasonable assurance of protection of the public health and safety. None of the geochemical and radioactive decay processes which can reduce the concentrations of radionuclides are mentioned...Radioactive decay is, of course, time dependent, and familiarity with NRC guidance could have prevented this error. NRC's comments on its regulations contain the following (Federal Register, vol. 47, page 57450, December 27, 1982.):

The Commission believes that reliance should be placed on siting requirements which will keep water away from wastes, result in low volumes of contaminated water being released, and provide a long travel time for decay. (Emphasis added.)

"Of course, no connection to the Colorado River has been established, and both the project applicant and the Department of Health Services are on record as believing that none exists. However, even if such a connection were to exist, travel times to the Colorado River by any postulated route are in the thousands of years. This is far longer that the 500-year hazardous life of Class C waste. Without an evaluation of the physical and geochemical processes such as radioactive decay and sorption that would control radionuclide migration in groundwater (in the hypothetical case that radionuclides reach groundwater), not to mention a health physics evaluation of the impact should any radionuclides ever reach the Colorado River or any other source of drinking water, a critique based on postulated interconnections is irrelevant."

OTHER UNCERTAINTIES IN THE NAS REVIEW AND ITS ULTIMATE USE

The NAS Review

Safety of disposal of low-level radioactive waste is enhanced by factors in addition to those provided by a superior site. The NRC's regulations include a waste classification system and waste form and packaging requirements, financial requirements, requirements for post-closure institutional controls, and operator qualifications. All of these enhance the ability of the disposal project to isolate the wastes safely. Given the focus of the committee's inquiry on earth science issues, how will the committee factor in these portions of the regulations? What role, if any, will health physics and risk analysis considerations have in the NAS review?

Standard of Review by the Secretary of the Interior

To date, the Secretary of the Interior has not said how he and the Administration will utilize the NAS report in their decisionmaking on the Ward Valley land sale. In our view, it is very unlikely that the NAS report will conclude that the DHS made an error in issuing a license to US Ecology to develop and operate a LLRW disposal facility at Ward Valley. Unless the report identifies significant, new safety or environmental impacts issues not addressed by the DHS, the 1,000 acre Ward Valley site should be sold without further unnecessary delay to the State of California.

BENEFITS TO DATE OF THE NAS REVIEW

The Academy review encouraged the USGS to complete work on a report on the characteristics of the unsaturated zones at the Beatty, Nevada and proposed Ward Valley, California sites sooner than might otherwise have been the case. The USGS report, "Estimates of Percolation Rates and Ages of Water in Unsaturated Sediments at Two Mojave Desert Sites, California-Nevada, " by David E. Prudic, U.S. Geological Survey, Water-Resources Investigations Report 94-4160 was completed in late August 1994. This official, peer-reviewed report on the unsaturated zones at the Beatty and Ward Valley sites concludes, on the basis of chloride profiles, that most precipitation does not penetrate the soil to a depth of more than a few meters, and that the estimated movement of water below a depth of 10 meters is of the order of only 3 to 5 centimeters per 1,000 years. These characteristics lead to the conclusion that regulated disposal of LLRW at these sites poses no threat to ground water.

As a result of the NAS study, a number of agencies have reviewed estimates of the amount of plutonium likely to be disposed at the Ward Valley site during its

thirty-year operational life. Data compiled by the Idaho National Engineering Laboratory from waste shipment manifests show that the amounts of plutonium shipped for disposal declined markedly beginning in the early 1980s. The DHS, the USNRC, and a report by the Congressional Research Service reflect a consensus that the amount of plutonium likely to be disposed at Ward Valley is several orders of magnitude less than the amount assumed for the Ward Valley performance assessment in the license application.

CONCLUSIONS

An evaluation of the "Wilshire Report" and the Ward Valley site is underway by a committee convened by the National Academy of Sciences/National Research Council Board on Radioactive Waste Management. Completion of the study report, originally expected in December 1994 is now expected in early March 1995.

Opponents of the Ward Valley project have criticized the composition of the committee and the fairness of the committee's procedures. The competence and balance of the committee has been capably defended by Dr. Bruce Alberts, President of the NAS, and a review of the committee's proceedings show far greater deference was paid to opponents of the project than to supporters in terms of time allowed for presentations and accepting witnesses for formal presentations.

The NAS review probably prompted USGS to complete work on a study of the vadose zones at Ward Valley, California and Beatty, Nevada sooner than might have been the case otherwise. The findings of this official, peer-reviewed USGS report confirm the existence of characteristics that make these arid sites suitable for safe disposal of LLRW. As a result of the NAS review, reevaluation of the amounts of plutonium likely to be disposed of at Ward Valley have been carried out by the Department of Health Services, the Congressional Research Service, and the USNRC. These reviews indicate a much smaller amount of plutonium is likely to be disposed at Ward Valley during its thirty-year operating life than assumed for the purpose of the Ward Valley performance assessment in the license application.

A license, dependent upon the land transfer for practical effect, has been issued for the proposed Ward Valley LLRW disposal project, and judicial review of the license and accompanying environmental documentation is ongoing. The standard for both administrative action and judicial review are clear; they are governed by statutes and regulations of the federal and state governments. The NAS review is concurrent with judicial review, but the standard for the NAS review is not clear. Both the California Department of Health Services and Cal Rad Forum have urged the committee and the BRWM to look to the legally adopted regulations as a framework for their review.

Upon release of the NAS report, the Secretary of the Interior should sell the land for the Ward Valley site to the State of California without further delay unless the report identifies significant new issues not addressed by the DHS in its licensing record.

Session 15 -- Hydrogeologic Considerations in the Disposal of Radioactive and Mixed Waste

AN ALTERNATIVE CONCEPTUAL MODEL FOR THE SATURATED ZONE AT YUCCA MOUNTAIN NEVADA

Linda L. Lehman
Tim P. Brown
L. Lehman & Associates, Inc.

ABSTRACT

State of Nevada funded research on water level fluctuations in the vicinity of Yucca Mountain has led to the formulation of a different and more complex conceptual model of the saturated zone hydrology than has previously been envisioned or analyzed for the site. The alternative saturated zone model posed herein requires a close coupling of thermal, tectonic and hydrologic processes in a structurally controlled domain.

INTRODUCTION

This paper summarizes separate studies funded over the past few years by the State of Nevada Nuclear Waste Project Office. These studies include the analyses of water level data from the saturated zone and computer modeling exercises of unsaturated zone hydrologic data. The results of these individual studies, together with

observations of the potentiometric surface and temperature data, led to the development of a different, more complex model of the saturated zone than presently analyzed in performance assessments.

These studies suggest that saturated zone flow around Yucca Mountain is complex and not fully understood. Evidence exists for locally focused recharge. Recharge can also be focused along fault and fracture zones in both the saturated and unsaturated zones. The data also indicate that there exist hydrologic domains bounded by faults. These domains are only loosely connected and respond to recharge and seismic disturbances differently. In addition, the seismic responses of the water table indicate significant coupling between the hydraulic system and local stress conditions.

ANALYSES

Water Level Oscillations

Analysis of water table oscillations was performed on eight water table wells in the vicinity of Yucca Mountain. The period, phase shift, amplitude of water level measurements was analyzed over a several year period. The results of this study indicated that while amplitudes were small, there were marked similarities in periods and phase shifts between wells on the west side of the mountain while wells located on the east side of the mountain show different similarities.(1) Figure 1 shows the locations of the wells studied indicating similar grouping.

The similar groups of wells line up along a direction parallel to the major north to south trending fault zones. This was the first indication that, 1) the flow field at Yucca Mountain was structurally controlled and, 2) that there were two separate, or weakly coupled flow systems. The finding of separate systems was also supported by chemistry data produced by the Desert Research Institute which indicated chemistry on the east side was quite different than water chemistry on the west. (2) The frequency of oscillations were shorter on the east side than the west, exhibiting an average of 2.4 years on the east and 2.6 years on the west. These frequencies were compared with a plot of rainfall distribution from 7 rain gauging stations in a broad region surrounding Yucca Mountain. It showed an approximate 2.5 year cycle in rainfall periodicity. This could indicate that even these deep wells at Yucca Mountain are responding to the rainfall frequency.

Effects of Earthquakes on Water Levels

As part of the DOE environmental monitoring program, the water levels in environmentally sensitive springs and nearby wells are routinely monitored. Of these springs Devil's Hole is a critical habitat for the desert pupfish, an endangered species. Devil's Hole is located about 25 miles south of Yucca Mountain near Ash Meadows adjacent to the Stewart Valley Fault which trends in a northwest to southeast direction. As a result of a series of earthquakes experienced during the summer of 1992, Devil's Hole water levels underwent changes. These earthquakes were the June 28th 7.5 magnitude earthquake centered at Landers, California, the 6.6 magnitude earthquake which occurred 3 hours later centered near Big Bear, California, and the June 29th, 5.6 magnitude earthquake centered at Little Skull Mountain, Nevada, just 23 kilometers southeast of Yucca Mountain.

The response to these earthquakes differed in the various wells located near Devil's Hole. The level in Devil's Hole showed a temporary drop, while a nearby well indicated a significant rise. This difference was puzzling, but it was noted that the location of these two monitoring points was separated by the Stewart Valley Fault and that perhaps the fault was influencing the responses. This led to examination of all the DOE water level data available in the Yucca Mountain region during the time period of the earthquakes. The water level data showed four distinct types of response to the earthquakes as follows:

- an upward temporary spike
- a rapid upward change with an apparent long-term stabilization at a higher level
- a downward temporary spike
- a rapid downward change with an apparent long-term stabilization at a lower level.

Table I

Because of potential fault control of these responses, the wells were plotted and compared with fault traces in the area. Figure 2 shows the locations of wells which experienced water level changes greater than 15 cm, and the locations of major fault zones. Increasing water levels are indicated by upward arrows and downward trends by downward pointing arrows. It can be seen that most of the wells which experienced increased water levels are closely associated with the northwest

trending shear zones. The downward trending water levels do not correlate to the shear zones but align more closely to normal faults.
The most obvious explanation for these responses might suggest that some areas experienced compressive strain, reducing effective pore volume and raising water levels, while other areas experienced tensile strain, increasing effective pore volume and lowering water levels. Alternatively, the result of nearby earthquakes and sudden changes in local stress may be to cause changes in fracture aperture where fractures are held at relatively low closure pressure. This would lead to nonlinear permeability changes in the host rock causing large scale adjustments in the hydrologic system including rapid water table elevation change, altered flow patterns, and adjustments in flow velocities. This process may be coupled with thermal flow as well so that adjustments in fracture and fault properties may affect the locations and magnitudes of local convection features. In this case the explanation for the observed water table responses might be a unique combination of effects from strain on hydraulics and thermal flow for each monitoring location. These observations have several implications. First, that the level of the water table is structurally controlled and is closely linked to the ongoing tectonics in the region. These observations may also indicate that the hydraulic conductivity field in these fault zones is transient, not steady as is currently assumed in performance assessment models. Other impacts to the flow field are local changes in hydraulic gradient and direction or diversions of the flow field. One well experienced a water level rise of 16 feet, which in flat gradient areas of the flow field could cause temporary, if not permanent changes in flow direction and velocity.
Unsaturated Zone Analyses
Analyses done as part of the INTRAVAL project included predictions of water content within deep boreholes at Yucca Mountain and calculations of potential recharge using traditional runoff techniques. These analyses have been documented in a previous paper and are not repeated here. (3) The results of these studies indicated that significant infiltration through the unsaturated zone was possible and that this infiltration may be controlled by faults and fracture zones. Models applied at INTRAVAL which simulated flow through discrete fractures (simulated as high conductivity zones), did a better job of matching water content and were more consistent with water chemistry data. These fracture controlled infiltration models also allowed for more rapid infiltration through the unsaturated zone than could be accounted for in the more traditional matrix flow models. Areas where significant infiltration occurs are limited and most likely occur along fractures and fault zones and areas of fault intersections. This focused infiltration concept also allows for very high flux rates to occur locally, rather than as a uniform distribution of rainfall. Uniform distributions were a commonly used assumption in performance assessments completed at that time.
Other Observations
The US Geological Survey has also published information relevant to this conceptual model of the saturated zone flow field. These data include the newly revised potentiometric surface data and temperature data at the water table. The potentiometric data indicate a series of embayments or potentiometric lows coincident with northwest trending shear zones running along the eastern flank of the mountain. This would indicate that water is draining into these fault zones. The temperature distribution at the water table is shown as Fig. 3. This temperature data shows a cold water plume coincident with the Ghost Dance Fault zone, which runs through the center of the repository block. An interpretation of this temperature data is that cold water is moving from the high gradient area to the north of Yucca Mountain via the Drill Hole Wash Fault or other nearby faults, into the Ghost Dance Fault. This interpretation is considerably different than the published flow models of the US Geological Survey which indicate a more uniform and generally eastward flow field across the Yucca Mountain block. (4) The water level measurements alone may not be accurate enough to show movement of a narrow fault controlled plume of cold water. It is also possible that the anisotropic effects of the fault control or dominate the flow at this location.
Additionally, published observations of the US Geological Survey show other areas where similar anomalous gradients such as those encountered at Yucca Mountain occur. (5) One anomalous gradient appears just to the north of the Ash Meadows region and coincides with a fault intersection. It was also concluded that the flow field in

the Nevada Test Site region was highly compartmentalized rather than a continuous uniform field.
Finally, Czarnecki analyzed a breach of the large hydraulic gradient as a potential scenario to be considered. (6) In his model, the resultant flow field was quite similar to the temperature plume shape, shown in Fig. 3. This more southerly flow was different than the normally modeled base case, primarily due to rock property changes and higher head gradients to the north. This same type of flow response is expected for the model proposed herein.
Alternative Saturated Zone Model
Taken together the above information resulted in a different conceptualization of the flow field than that currently being considered. The model is structurally controlled by fault or fracture zones of a self-similar fractal nature . Fracture zone intersections play a key roll in the distribution of recharge, velocity fields and pathways. The model is also dynamic rather than static, and has the potential to change rapidly due to tectonic movements.
The proposed model of flow is shown in Fig. 4. This figure shows the potentiometric surface and the proposed flow paths. It allows some water movement to occur across the mountain block from east to west, primarily via discrete northwest trending fracture zones. The Solitario Canyon Fault zone creates a resistance to eastern flow but does not prevent it. A steep hydraulic gradient exists at the location of the Solitario Canyon Fault and is equal to 35 meters of head difference over a lateral distance of about 1000 meters. Water movement across this fault probably occurs as a result of intersections with northwest trending shear zones and creates flow to the next lower level of the water table. The water table directly under Yucca Mountain is very flat.
Colder flow also enters the Yucca Mountain block from the northwest across a very steep hydraulic gradient. This gradient is equal to over 300 meters of head change across 2500 meters distance. The faults in the Drill Hole Wash region no doubt play a role in the transport of water across this hydraulic barrier. Where the Drill Hole Wash Fault or those near it intersect the northern extension of the Solitario Canyon Fault a potential breach may occur and allow the colder water north of the steep gradient to move down this fault zone and subsequently into the Ghost Dance Fault. The proposed model and the potentiometric surface also suggest that another fault zone exists just to the south of the repository footprint. This zone may also be transporting water from the Solitario Canyon side of the block toward the east. This area of the mountain has not yet been mapped in detail.
The proposed alternative model leads to many challenges for site characterization because a number of questions must be answered. Some of them include:
1.What changes to the existing site characterization program are needed to fully examine a complex, compartmentalized, and dynamic flow model containing fractal-like properties rather than a simplistic model of the flow field with statistically described parameters?
2.What are the implications to repository performance assessments or risk assessments of the following?
The flow field is dynamic and water-level changes can be expected due to tectonic events, which could lead to changes in gradients and possible local reversals or diversions in flow directions.
Velocity fields may also change with time, perhaps compression along the northwest trending shear zones causes increases in velocities, while extension along north south trending faults may cause decreases in velocity.
3.What are the effects of the large temperature differences encountered across the mountain block? Are they affecting the velocity field in a significant way?
While we cannot answer all of these questions at present, we can ask that the DOE investigate the implications of this alternative model. Any future modeling and performance assessments, to be credible, must be consistent with the hydraulic and temperature data at the very least. The emerging isotope chemistry data should also help to better define the flow field and answer some of the above questions.

FLUID FLOW THROUGH VERY LOW PERMEABILITY MATERIALS: A CONCERN IN THE GEOLOGICAL ISOLATION OF WASTE
Dwight E. Deal
International Technology Corporation
ABSTRACT
The geological isolation of waste usually involves the selection of sites where very low permeability materials exist, but there are few earth materials that are truly impermeable. Regulatory concerns for the containment of radioactive material extend for geologic periods of time (i.e., 10,000 years or more), and it becomes nearly impossible to "assure" the behavior of the site for such long periods of time. Experience at the Waste Isolation Pilot Plant (WIPP) shows that very slow movements of fluid can take place through materials that may, in fact, have no intrinsic permeability in their undisturbed condition. Conventional hydrologic models may not be appropriate to describe flow, may provide modeling results that could be in significant variance with reality, and may not be easy to defend during the regulatory compliance process. Additionally, the very small volumes of fluid and very slow flow rates involved are difficult to observe, measure, and quantify.
The WIPP disposal horizon is excavated 655 m below the surface in bedded salt of Permian age. Salt has some unique properties, but similar hydrologic problems can be expected in site investigations were other relatively impermeable beds occur, and especially in deep sites where significant overburden and confining pressures may be encountered. Innovative techniques developed during the investigations at the WIPP may find utility when investigating other disposal sites.
The details of flow in these very low permeability units is quite complex and difficult to quantify. Vertical drillholes yield inconsistent data, even when closely spaced, but horizontal drillholes provide consistent and comparable data sets. Flow may be constrained to a relatively few, fairly discrete, bedding planes and radial flow (as assumed in most modeling) toward an excavation or drillhole may not occur. Fluid preferentially occurs in the more argillaceous beds and is not uniformly distributed throughout the salt. The pore spaces in some units may be so small that surface tension forces become significant and Darcy's Law may have to be applied in a modified form or may not hold at all. Additionally, some previously unsuspected flow mechanism may be acting, such as compaction in the pillars driving brine out of poorly compacted clays.
Ongoing work at the WIPP is expected to continue to advance understanding of flow through very low permeability materials. The study of flow under these conditions will become increasingly important as additional waste disposal sites are designed that require assurance of their safety for geological periods of time.
WORK SUPPORTED BY THE U.S. DEPARTMENT OF ENERGY UNDER DOE CONTRACT NO. DE-AC04-86AL31950, DOE-WIPP 91-047C
The geological isolation of waste usually involves the selection of sites where very low permeability materials exist, but there are few earth materials that are truly impermeable. Regulatory concerns for the containment of radioactive material extend for geologic periods of time (a mandated 10,000 years). The study of ground water and the engineering aspects of hydrogeology have traditionally focused on ground water as a resource (1, 2). As a result, the focus has been on the conditions of flow where the quantity and quality of the water available are adequate for human

use and the materials containing the water allow it to flow (or be induced to flow) rapidly enough so that useful quantities can be produced in reasonable amounts of time.

Disposal sites are usually chosen on (or in) materials with very low permeability for which conditions of flow are less well understood. In order to predict the long term behavior of any such disposal site, we must first have experience with and an understanding of the detailed behavior of the systems acting at the disposal site. Uncertainties in the prediction of repository behavior can be significantly reduced by continued site investigations, but can never completely be eliminated. For these and other reasons, the National Research Council (3) concluded that science cannot "prove" (in an absolute sense) that a disposal site will be "safe" as defined by existing Environmental Protection Administration standards and United States Nuclear Regulatory Commission regulations.

Numerous recent studies have demonstrated that describing flow under low permeability conditions stretch the limits of our knowledge for shales (4, 5, 6), clays (7, 8), unsaturated fractured rock (including shales, clays, tuff, and basalts)(9), and evaporites (10, 11). Recent experience at the Waste Isolation Pilot Plant (WIPP) shows that very slow movements of fluid can take place through materials that may, in fact, have no intrinsic permeability in their undisturbed condition. Conventional hydrologic models may not be appropriate to describe flow (12), may provide modeling results that could be in significant variance with reality, and may not be easy to defend during the compliance process. Additionally, the very small volumes of fluid and very slow flow rates involved are difficult to observe, measure, and quantify.

The WIPP disposal horizon is excavated 655 m below the surface in bedded salt of Permian age. Considerable stratigraphic variations occur within the salt beds. Although dominantly halite, individual units range from clear halite through argillaceous halite to polyhalitic halite. Interbeds include clay seams and anhydrite beds. Water is present in several ways within the Salado Formation (11): (1) within hydrous minerals such as gypsum and clays, (2) as fluid inclusions within halite and other crystals, (3) within intergranular pores and open fractures, and (4) as intergranular moisture within poorly consolidated clays which occur within salt crystals as well as between halite, anhydrite, and other crystals.

The undisturbed clear halite units may be effectively impermeable. State-of-the-art permeability testing (13, 14) was unable to measure any permeability, indicating that if it exists at all, intrinsic permeability of the clear halite units is less than 1 x 10 -23 m2 (0.01 nanodarcy). Those halite units that contain a few percent clay are more permeable, typically less than 1 x 10-20 m2 (10 nanodarcy). The permeability of the interbedded anhydrite units are several orders of magnitude greater, typically between 1 x 10-19 and 1 x 10-18 m2.

Salt has some unique properties, including the fact that at repository depths it deforms plastically. Studies undertaken during the Brine Sampling and Evaluation Program (BSEP) at the WIPP (15, 16, 17, 18, 19, 20, 21) were directed primarily toward the environment in and directly adjacent to the underground excavations. These studies and others (22, 23, 24, 25) show that the rock immediately surrounding the excavation is altered significantly from its original state due to the influence of deformation induced by the rock excavation and the movement of salt toward the excavation. The common theme running through the BSEP investigations relates to the presence and movement of brine in rocks that saw little to no fluid migration prior to the development of deviatoric stress accompanying excavation and the permeability enhancement caused by elastic expansion and brittle deformation of the salt and anhydrite units.

A halo of deformation forms around the excavations, whether they are rectangular or circular in cross section (Fig. 1). The development of this halo of deformation around an underground excavation at the WIPP, sometimes described as the Disturbed Rock Zone, is discussed by Deal and Roggenthen (11). They point out that there are generally two parts to the deformational envelope around underground excavations in salt: an outer zone where dilatency and microfracturing occur with pore pressures above atmospheric (zone C in Fig. 1), and an inner zone characterized by macrofracturing and pore spaces where the pressures are essentially at atmospheric (zone B in Fig. 1). Some authors tend to treat the inner zone, which includes the volume of rock that has separated (decoupled) from the host rock, as simply a growing part of the excavation comprising the "Actual Opening" (26). Brine moving

toward the excavation behaves differently in these two zones, and it is important to consider both of them when discussing brine seepage into the WIPP excavations.
FIG. 1
The salt at the WIPP originated as a stratified and bedded sedimentary rock and consists of alternating sequences of halite, argillaceous halite, polyhalitic halite, clay layers, and thin anhydrite beds. As a result, there are numerous horizontal discontinuities. There are clay partings and thin (1-3 cm) clay beds, as well as beds of anhydrite ranging from a few millimeters to a meter or so in thickness. The anhydrite beds are brittle and do not deform plastically at repository depths. Typical storage rooms are 4 m (13 ft) high, and 10 m (33 ft) wide. Therefore, the deformational sequence is complicated by the effects of geometry and the stratigraphy as the disturbed envelope is driven toward a circular geometry (Fig. 2).
FIG. 2
Evidence is abundant that the excavation geometry around the openings at the WIPP is modified by these discontinuities and inhomogeneties. It includes failure of roof and floors due to heaving, separation along clay seams, and the development of macrofractures in ribs (11, 22, 25). The patterns of fracturing and deformation observed at the WIPP is shown in Fig. 3.
FIG. 3
The details of flow in these very low permeability units is quite complex and difficult to quantify. Vertical drillholes yield inconsistent data, even when closely spaced, but horizontal drillholes provide consistent and comparable data sets (21). Flow may be constrained to a relatively few, fairly discrete, bedding planes and radial flow (as assumed in most modeling) toward an excavation or drillhole may not occur (21). Fluid preferentially occurs in the more argillaceous beds and is not uniformly distributed throughout the salt (18). The pore spaces in some units may be so small that surface tension forces become significant and Darcy's Law may have to be applied in a modified form, such as the piece-wise method suggested by Deal et al. (18), or may not hold at all. Additionally, some previously unsuspected flow mechanism may be acting, such as compaction in the pillars driving brine out of poorly compacted clays (18).
A number of modeling efforts have been made in an attempt to predict seepage into the WIPP excavations. Seepage into a horizontal drillhole 7.6 cm (3 in) diameter and 46 m (150 ft) long is predicted to be on the order of 0.01 liters per day if a permeability of 1 x 10-22 m2
(0.1 nanodarcy) is used for the undisturbed salt. Three drillholes of that dimension have been monitored for over 2 years and all three accumulate fluids at seepage rates on the order of 0.01 to 0.02 liters per day.
The way in which flow rate varies with time is important. If flow rate eventually reaches a steady rate, then there may be some far-field brine that flows through the body of the undisturbed rocks to reach the repository excavations. If flow rate continues to decrease and eventually ceases (21), then there is no significant amount of brine derived from the far-field and only brine released from the disturbed rock zone due to depressurization will enter the repository excavations. Observations are presently being made at the WIPP to determine which of these conditions exist.
If no far-field flow exists and radial flow occurs in all directions toward a waste storage room, then release of brine from the disturbed rock zone around the excavations due to depressurization is estimated to produce about 150,000 liters of brine (21). This volume is on the same order of magnitude as the volume of brine (220,000 liters) necessary to corrode all the metal in the waste and waste storage drums (21). Anoxic corrosion will consume brine and produce metal oxides and hydrogen. If the volume of brine entering the repository is less than that required to completely corrode the metal, then all the brine that comes in contact with metal will be consumed.
As pointed out above, there is good evidence that the assumption of radial flow may not hold for the WIPP. The undisturbed clear halite units have such low permeability (or none at all) that flow is probably constrained and only occurs horizontally, parallel to bedding. In that case, less than one tenth of the 150,000 liters estimated above may enter the repository to react with the metal stored there. If compaction of the clays is the source of the brine rather than release of brine from the disturbed rock zone due to depressurization, then even less brine may enter the

repository.
Continued site investigations at the WIPP are defining the bounds of the brine seepage phenomena. After extensive modeling, field investigations, and experiments, some uncertainties still exist. Although the details of flow in the geologic units at the WIPP are quite complex and difficult to quantify, it is clear that only very small quantities of brine moving very slowly are involved. Although field investigations show that very little brine actually enters the excavations (see BSEP references cited previously), it is impossible to completely eliminate all uncertainty. The fact that some uncertainties remain should not be sufficient to prove that the disposal site is "unsafe." Some other criteria should be used to determine whether or not the relative risk of transporting this waste to the WIPP and disposing of it there is less (and more acceptable to society) than the risk of leaving it where it is or disposing of it in some other way.

ABSTRACT

A performance evaluation (PE) is an analysis that estimates radionuclide concentration limits for 16 potential Department of Energy (DOE) mixed low-level waste (MLLW) disposal sites based on the analysis of two environmental exposure pathways (air and water) to an off-site individual and an inadvertent-intruder exposure pathway. Sites are analyzed for their ability to attenuate concentrations of specific radionuclides that could be released from wastes in a hypothetical MLLW disposal facility. Site-specific data and knowledge are used within a generic framework that is consistent across all sites being evaluated. After estimates of waste concentrations for the three pathways are calculated, the minimum of the waste concentration values is selected as the permissible waste concentration for each radionuclide. The PE results will be used as input to the process for DOE's MLLW disposal configuration.

Preliminary comparisons of results from the PE and site-specific performance assessments indicate that the simple PE results generally agree with results of the performance assessments, even when site conditions are complex. This agreement with performance-assessment results increases confidence that similar results can be obtained at other sites that have good characterization data. In addition, the PE demonstrates a method to provide DOE decision makers with a simple, conservative, defensible, and easily understandable analysis that provides results similar to those of more complex analyses, and which can be used to aid MLLW disposal configuration plan development.

INTRODUCTION

The Federal Facility Compliance Act (FFCAct) of 1992 (1) requires DOE to work with its regulators and with members of the public to establish plans for the treatment of DOE's mixed wastes. Although the FFCAct does not specifically address disposal of treated MLLW, both DOE and the States recognize that disposal issues are an integral part of treatment discussions. The DOE established its MLLW Disposal Workgroup in June 1993 to work with the States to define and develop an evaluation process for disposal options. This joint DOE-State process has narrowed the sites for further evaluation from 49 to 16.

A PE has been developed to quantify and compare the limitations of 16 DOE sites for the disposal of MLLW. The principal goal in developing the PE is to estimate, for residues resulting from the treatment of MLLW, permissible concentrations of radionuclides that could be disposed at each site. The PE consists of simple analyses consistent with the approach used in many low-level waste (LLW) performance assessments. The objective is to use a set of modeling assumptions of sufficient detail to capture major site-specific characteristics and yet be general enough for consistent application at all sites. Additionally, the analyses must ensure that no systematic biases are introduced, the sites are analyzed consistently, and all major assumptions are clearly stated.

Although the approach is simple, every effort is made to ensure that the PE is technically adequate for the intended purpose and that the PE results reflect the strengths and weaknesses of each of the 16 sites for the disposal of MLLW. To ensure technical adequacy, the following strategy was adopted:

Use the existing knowledge, analyses, and data at each site to the extent practical;

Use well-established policies and recommendations on disposal-related issues; and

Use extensive and continuous reviews from both internal and external experts.

The PE analysts rely extensively on interactions with site personnel to utilize important research, site characterization, modeling, and other analyses that have been performed. These interactions include visits by the PE analysts to each of the sites. Based on discussions with personnel who have spent years studying their sites, the PE analyses incorporate the best documented understanding of the sites into the PE framework.

FRAMEWORK OF THE PERFORMANCE EVALUATION

The PE is solely a radiological assessment even though the waste is mixed with hazardous components that are subject to Resource Conservation and Recovery Act (RCRA) requirements (2). This approach is taken by assuming that the hazardous component of the waste is treated and the disposal facility designed per RCRA specifications. Further analysis of the performance of hazardous components currently is not required by the Environmental Protection Agency (EPA) or any state with RCRA primacy.

The PE estimates permissible concentrations of radionuclides in disposed waste using the performance objectives specified in DOE Order 5820.2A (3) as "performance measures" for the radiological assessment. Performance measures are used in the PE to relate radionuclide concentrations in disposed waste to permissible doses to individuals for three exposure pathways: ingestion of drinking water and all-pathways exposure to atmospheric releases to an individual at the performance boundary (i.e., point of compliance), and all-pathways exposure to an inadvertent intruder. All of the performance objectives in DOE Order 5820.2A could be used as performance measures in the PE. However, experience with performance assessments (4, 5) has shown that some of the performance objectives are generally more restrictive than others. Thus, the performance measures used in the PE are:

4 mrem (0.04 mSv) per year from the drinking-water pathway for releases to water;

10 mrem (0.1 mSv) per year from all pathways for atmospheric releases; and

100 mrem (1 mSv) per year from all exposure pathways for chronic exposure of inadvertent intruders.

Based on guidance for conducting performance assessments (6), calculations for the PE use a performance boundary that is located 100 m from the edge of the disposal facility, and the period for consideration is 10,000 years from the time the disposal facility is closed.

Two generic disposal facilities are considered in the PE: a RCRA-compliant, below-ground trench and a RCRA-compliant, above-ground tumulus. The size and shape of each generic facility is assumed to be the same for all sites. The generic

disposal facilities were selected to provide consistency in evaluation of the 16 sites.
The same list of radionuclides is used in the PE to enable comparisons of the 16 sites. Because the actual radionuclide inventory that might be disposed in a facility is unknown, the duration of contaminant release is also unknown. Therefore, a continuous release of radionuclides from the disposal facility is assumed. Assuming a continuous source is considered to be reasonable and conservative.
The waste form in the PE is assumed to be grouted treatment residuals. Grout, which consists primarily of hydrated Portland cement and fly ash, is often used to stabilize both wastes containing hazardous metals and residues resulting from thermal treatment. Grout is the primary waste form considered in three LLW performance assessments: Oak Ridge Solid Waste Storage Area 6 (4); Savannah River Z-Area (5); and Hanford grout (7).
For the water and atmospheric pathways, the sequential attenuation of contaminants that occurs between the waste in the disposal facility and the performance boundary is represented by "concentration reduction factors" (CRFs). The CRF approach is used so that intermediate results can be displayed to allow for comparisons of effects of the disposal facility and site on overall performance. For the water pathway, the CRFs represent concentration attenuation related to the contaminant release rate from the facility and dilution of leachate with uncontaminated groundwater. For the atmospheric pathway, the CRF represents the reduction in contaminant concentration provided by diffusion through the overlying soil and by atmospheric dispersion to the performance boundary.

METHODOLOGY

Three sets of calculationsfor the drinking-water, atmospheric, and inadvertent-intruder pathwaysform the foundation of the PE. In general, for each pathway the maximum permissible contaminant concentration at the performance boundary is determined for each radionuclide by using the performance measures and the appropriate pathway or scenario dose conversion factors (annual effective dose equivalent per unit concentration) based on EPA dose conversion factors (8). Conceptual models for environmental flow and transport are developed based on interactions with site personnel. For the water and atmospheric pathways, the concentration reduction provided by the environment is estimated using results of site analyses and data evaluation. For the intruder analyses, concentration reduction is estimated for appropriate exposure pathways for several intrusion scenarios; interactions with site personnel focus on selecting appropriate "credible" intrusion scenarios based on site-specific conditions. Once estimates of waste concentrations are calculated for the three pathways, the minimum of these values is selected as the permissible waste concentration for each radionuclide.

Water Pathway

Different hydrogeologic environments cause the water flow to vary considerably from one site to another; therefore, an acceptable conceptual model and its associated assumptions must be supported by site-specific knowledge and data. Depending on site-specific conditions, pathways to be considered may be surface water, the vadose zone, and groundwater. Once the water-flow paths are established, similar radionuclide-transport assumptions are imposed on each site to provide consistency in the PE analyses. A generic conceptual model incorporates site-specific geometry and water-flow pathways into a simple transport analysis (Fig. 1). Results are compared with available site-specific analyses to identify areas where differences exist.

FIG. 1

Site-specific data required to perform the water-pathway analysis come from site personnel either as data from site characterizations and reports or from site-selected literature. The minimum data that are required are natural infiltration rates, distance between the disposal facility and groundwater, Darcy flow rates, porosity, ambient moisture content, mixing depth in the aquifer, dry bulk density of the porous media, and solid/liquid partition coefficients of the porous media.
Two CRFs are calculated for the drinking-water pathway: one for the concentration attenuation between the disposed waste and leachate exiting the bottom of the disposal facility, source CRF; and one for the concentration attenuation between the leachate exiting the disposal facility and the water at the performance boundary, the environmental transport CRF for drinking water. The source CRF is defined as the

dimensionless ratio of the waste concentration to the resulting leachate concentration. Desorption with advecting flow is the mechanism used to describe the leaching of radionuclides from the grout, consistent with analyses in LLW performance assessments that have evaluated grouted waste forms (4, 5, 7). Because the desorption model is based on a grouted waste form, the radionuclide-specific values for the source CRF for each type of generic facility are the same for all 16 sites.

The environmental transport CRF for drinking water is defined as the ratio of the concentration of the leachate exiting the disposal facility to the resulting concentration in water at the performance boundary. The concentration attenuation represented by the transport CRF for drinking water consists of dilution due to mixing with uncontaminated groundwater and/or surface water. Effects of radioactive decay and decay product ingrowth are also included in the analysis.

Atmospheric Pathway

The conceptual model for evaluating the atmospheric pathway is derived from performance assessments for LLW disposal facilities (5, 7, 9, 10). The model is generalized for the PE and uses site-specific data for many of the parameters. Only the volatile radionuclides 3H and 14C are considered in the PE for atmospheric transport. In the model, radionuclides are transported from the disposal facility to the soil surface by vapor diffusion. When the radionuclides reach the soil surface, they are entrained in the air and are transported to an assumed receptor located at the performance boundary. Atmospheric dispersion also causes minor attenuation. Site-specific data required to perform the atmospheric pathway analysis come from site personnel either as data from site characterizations and reports or from site-selected literature. The site-specific data required for the soil diffusion calculation are the same as those required for the water pathway. Atmospheric dispersion data include probabilities of wind speed and direction and stability class.

Three CRFs are used to account for the attenuation encompassing diffusion to the ground surface, mixing in air, and dispersion in the atmosphere to the performance boundary. The CRF for diffusion in soil is conservatively modeled (i.e., large diffusion constants) in an attempt to bound releases from alternative transport mechanisms (e.g., desiccation cracks, burrowing animals, and root uptake). The CRF for diffusion in soil is defined as the ratio of the radionuclide concentration in the waste to its resulting concentration in the upper one centimeter of soil. The CRF for mixing with air is defined as the ratio of the radionuclide concentration in the upper one centimeter of soil to its resulting concentration in air at the facility boundary. The CRF for atmospheric dispersion is defined as the ratio of the concentration at the facility boundary to its resulting concentration at the performance boundary 100 m from the edge of the disposal facility. Gaussian dispersion is the concentration-attenuating mechanism used in the dispersion CRF. The effect of radioactive decay is included in the analysis.

Inadvertent Human Exposure

Standard scenarios that were developed for performance assessments of LLW disposal facilities (4, 11) are used in the PE to analyze inadvertent intrusion. These scenarios were selected based on experience indicating that the chronic agriculture (homesteader) and post-drilling scenarios are generally the most restrictive scenarios for most sites and facility designs. In some cases, however, these scenarios are tailored for site-specific conditions. The agriculture scenario includes establishment by an intruder of a permanent homestead directly above a disposal facility with the foundation of the home extending into the waste; some of the waste exhumed from the disposal facility is mixed with native soil in the intruder's vegetable garden. The post-drilling scenario considers the construction of a well for a domestic water supply by an intruder who resides permanently nearby a disposal facility; the well is drilled through the disposal facility.

Total intruder doses consist of doses from several exposure pathways (e.g., external exposure to the waste, ingestion of food or soil, and inhalation of suspended soils). Factors that are used to calculate the doses and, therefore, scenario dose conversion factors include, for example, correction factors for the amount of natural soil mixed with exhumed waste, plant to soil concentration ratios, shielding factors, and fraction of time exposed through a certain exposure pathway. Some of the factors used to calculate the scenario dose conversion factors are constant, while others may vary depending on such factors as exposure pathway and disposal

technology. The effect of radioactive decay prior to intrusion is included in the analysis.

DISCUSSION

The PE project provides estimates of the maximum permissible concentrations that can be disposed of at 16 DOE sites for 58 radionuclides based on the most constraining of three performance measures: 4 mrem (0.04 mSv) per year dose from drinking water, 10 mrem (0.1 mSv) per year dose for all pathways from atmospheric releases, and 100 mrem (1 mSv) per year dose for all pathways from inadvertent intrusion. These estimates of concentrations are based on a relatively simple analysis considering existing generic and site-specific knowledge and data.

The primary use of the PE results will be to compare the estimates of permissible concentration limits for disposal with concentration estimates for stabilized MLLW residues resulting from treatment processes. The comparison will provide indicators both of the amounts and types of waste that are acceptable for disposal at each site and of the wastes that are not acceptable for disposal at each site.

Comparison of results from the 16 sites requires that the general analysis framework be as consistent as possible, while site-specific input is required to ensure that the analyses are representative of site conditions. A simple flow and transport analysis that allows incorporation of site-specific flow conditions meets both these objectives. The project framework and results are reviewed by internal and external panels to ensure consistency of application among sites and to ensure that results and conclusions are supported by the data and analyses. Interactions with site personnel familiar with site-wide characterization efforts, environmental restoration efforts, and performance-assessment and modeling efforts ensure that the best understanding of site characteristics and data relevant to waste disposal are incorporated into the analyses.

The PE is a deterministic analysis, and a quantitative uncertainty analysis is not performed. The degree of uncertainty associated with site-specific data and conceptual models varies from site to site, depending on the current level of understanding of radionuclide transport and availability of data to support the conceptual model. Less uncertainty may exist at sites where extensive site characterization work has been done. Uncertainty is addressed qualitatively in the PE by discussing confidence in data and results based on the quality of the data source (e.g., well-documented site-specific data, site-supported literature data, or unsupported assumed data) and level of understanding of flow and transport at the site.

Care has been taken in executing the PE to avoid bias in analyses that draw comparisons between sites with vastly differing attributes (e.g., small versus large sites, western versus eastern sites, or arid versus humid sites), and efforts have been made to ensure that the results of the PE do not indicate unwarranted advantages or disadvantages for any disposal site. Sensitivity analyses are used to identify the magnitude of change in parameter values required to change the controlling pathway or scenario. For example, one sensitivity analysis will determine the increase in infiltration rate required to change the controlling pathway for a permissible radionuclide concentration from the intrusion pathway to the drinking-water pathway. Analysis results indicating that a large change in infiltration rate would be required indicates the robustness of results to the assumed value of infiltration. Similar analyses will be performed for other input values and modeling assumptions.

Preliminary comparisons of PE with performance-assessment results have shown that the results of the simple PE model generally agree with results of the performance assessments, even when site conditions are complex. No direct comparisons can be made at sites with no existing performance analyses, but, based on the comparisons with performance-assessment results, the PE results are expected to provide a reasonable representation of site conditions when good characterization data are available. Sites with little characterization data will have the greatest uncertainty in results.

CONCLUSION

While the PE cannot be used as a substitute for performance assessments, it demonstrates a method to provide DOE decision makers with a simple, conservative, defensible, and easily understandable analysis that provides results similar to those of more complex analyses. Simple representations of complex phenomena may be the only way to gain public acceptance of MLLW disposal facilities that evoke deep

concerns in a cautious, non-technical public.

ABSTRACT

A regional, three-dimensional groundwater flow model was developed to support the characterization and licensing of the Central Interstate Compact's Low-Level Radioactive Waste Disposal Facility located near the town of Butte in Boyd County, Nebraska. This model was used to simulate saturated groundwater flow in the unconsolidated sediments overlying the Pierre Shale. The model was calibrated for steady-state conditions representative of long-term average hydrologic stresses, which included recharge from precipitation, evapotranspiration from off-site wetlands, and pumping from production wells. Model results were used to confirm the recharge, groundwater levels, flow velocities and directions on-site, all of which are key to performance assessment. The most likely groundwater pathways off-site were also identified.

INTRODUCTION

The Central Interstate Compact is seeking a license from the State of Nebraska to construct and operate a low-level radioactive waste disposal facility at a site located near the town of Butte in Boyd County, Nebraska. The groundwater modeling presented here was conducted to support the characterization of the site and

demonstrate compliance with the requirements of Title 194 - Nebraska Department of Environmental Control, Chapter 5 -Technical Requirements for Facilities, Section 001.01B, which specifies that the disposal site shall be capable of being characterized, modeled, analyzed, and monitored. The capability to model the site consisted of developing a conceptual model from hydrogeologic data acquired as part of site characterization. The significant hydrogeologic features of the conceptual model were then quantified and incorporated into a numerical model. The site was deemed "modelable" when consistency between the conceptual and numerical models was achieved. Parameters that cannot be directly measured at the site, including the long-term average recharge to the saturated zone, were also determined by model calibration. This paper describes the results of this site characterization effort.

SITE DESCRIPTION AND CONCEPTUAL MODEL

The Butte site lies on a 320-acre tract of land located between Ponca Creek and the Niobrara River in central Boyd County, Nebraska. The site itself occupies 110-acres of the southwest portion of this property. Geologic boreholes, 117 in number, were used to characterize the stratigraphy and geology of the 320-acre area, which range in age from late Cretaceous to Quaternary. Overlying the late Cretaceous Pierre Shale and the Niobrara Formation is a thin (10 to 40 ft) sequence of unconsolidated sediments. These late Tertiary- to Quaternary-age deposits are divided into four stratigraphic units: surficial fines, upper sand, fine-grained sediments, and contact zone. This sequence appears to exist over most of the modeled region, except in the area adjacent to Ponca Creek where terrace sand and gravel deposits are present. Observation wells were completed in 51 boreholes at 39 locations. Hydraulic tests were conducted in open boreholes and screened observations wells to estimate the hydraulic conductivities of the various stratigraphic units. Groundwater levels have been measured on a weekly to monthly basis from late 1989 through 1994.

These site investigations have determined that the shallow groundwater flow system present in the unconsolidated deposits at the site is the principal system for subsurface migration of radionuclides. Because of the very low hydraulic conductivity of the underlying Pierre Shale, groundwater flow is restricted primarily to the shallow system. Recharge rates and the locations of recharge/discharge zones are influenced by the high potential evapotranspiration (40 to 46 in./yr) relative to the average annual precipitation (23.67 in./yr). Because the potential evapotranspiration exceeds precipitation, only a small fraction of precipitation or snowmelt that infiltrates the soil leaves the root zone and reaches the water table as recharge. In areas of topographic lows where the water table is shallow, such as off-site wetlands, evapotranspiration exceeds infiltration due to the proximity of the water table to the ground surface. Such off-site areas discharge groundwater by means of evapotranspiration.

On a regional scale, the shallow groundwater system is bounded to the south by the regional groundwater divide, to the north by Ponca Creek, to the east by Dizzy Creek, and to the west by an unnamed Ponca Creek tributary (Fig. 1). Given these boundary conditions, the regional groundwater flow is generally north-northeast from the regional divide towards the Pierre Shale outcrops exposed along the bluffs of Ponca Creek and its tributaries and the lower reaches of Dizzy Creek. Groundwater discharge occurs along these outcrops in the form of springs and seeps. Off-site wetlands, where the water table is shallow and evapotranspiration exceeds infiltration, function as groundwater sinks from which groundwater is lost to the atmosphere by evapotranspiration. These wetlands locally reverse the general north-northeast groundwater gradient. Locally, piezometric surfaces developed from observation well measurements show that groundwater flow is relatively uniform across the 110-acre site in the north-northeast direction. Once off-site, groundwater flow continues toward the wetland group located to the northeast of the 110-acre site, and to Wetland 01 in particular, which is located in the northeast portion of the 320-acre area.

MODEL DESIGN AND CALIBRATION

Modeling Strategy

A regional modeling approach was adopted that allows the areal and vertical extent of the model to be defined by natural hydrogeologic boundaries. Because the boundary conditions largely determine the flow pattern in steady-state simulations, boundary conditions were specified at defined physical and hydraulic features (e.g., outcrops, streams, regional groundwater divides). The presence of distinct saturated hydrostratigraphic units (upper sand, fine-grained sediments, contact zone) required

a three-dimensional representation. Because nuclide transport to potential receptor locations requires hundreds to thousands of years, average groundwater flow velocities and directions are of primary interest. A steady-state model was therefore used to simulate the regional groundwater flow under long-term average conditions. The computer code MODFLOW (1) was chosen to construct the numerical model. Because MODFLOW enjoys wide use, the code has had the benefit of extensive testing and verification, and the code is recommended for groundwater flow analysis by the NRC.

Finite-Difference Grid

The block-centered, finite-difference grid developed for simulation of the regional groundwater flow is shown in Fig. 1. Areally, the grid extends from the regional groundwater divide to Ponca Creek in the south-north direction and from an unnamed Ponca Creek tributary to Dizzy Creek in the west-east direction. The long axis of the grid is rotated 30 degrees from the east-west direction to minimize the total number of nodes in the rectangular, finite-difference grid and to allow alignment of the grid with the northwest-southeast trending topographic features that define off-site wetlands. The horizontal finite-difference grid resolution was chosen to be commensurate with data resolution. Within the characterized 320-acre area, a grid size of 250 by 250 ft was adopted, which allowed reasonably accurate representation of the characterized spatial variation in hydrostratigraphic unit thickness and elevation. Outside the characterized area, a coarser grid ranging in size from 250 by 500 ft to 500 by 500 ft was selected. Vertically, the finite-difference grid was resolved into four layers corresponding to represent the three hydrostratigraphic units. Layers 1 and 2 were used to represent the upper sand unit and fine-grained sediment unit, respectively. Layers 3 and 4 were used to represent the contact zone unit. Two model layers (versus a single layer) were used to represent the contact zone to allow for the possibility of groundwater flow in the contact zone under water table conditions.

Boundary Conditions

Boundary conditions were established at natural hydrogeologic boundaries defining the extent of the regional model. The Pierre Shale outcrops north and northeast of the Butte site and functions as a physical boundary along which flow from the shallow groundwater system may discharge in the form of springs or seeps. The Drain Package in MODFLOW was used to simulate this condition. If the piezometric head is above the outcrop elevation at a given location, discharge occurs in proportion to the difference between the piezometric head and outcrop elevation; otherwise, there is no discharge across this boundary. Drains were represented in the finite-difference cells falling on the Pierre Shale outcrop. Drain conditions were also imposed along the ephemeral streams bounding the eastern and western model extremities. This condition allows groundwater to discharge if the piezometric head elevation of the underlying groundwater system is greater than the streambed elevation, the discharge rate being proportional to the difference between the piezometric head and streambed elevations. No discharge occurs if piezometric head remain below the streambed elevation. The regional groundwater divide lying to the south of the Butte site forms a hydraulic boundary across which the flow is zero. This boundary was taken to be coincidental with the surface topographic divide, which itself is coincidental with the top-of-bedrock divide. Vertically, the top of the Pierre Shale forms a no-flow boundary, given its very low hydraulic conductivity. A no-flow condition was therefore specified over the base of the contact zone.

Hydrologic Stresses

Hydrologic stresses imposed in the model include groundwater recharge from precipitation, groundwater discharge by evapotranspiration, and groundwater discharge from pumping wells. The basis for assigning recharge and discharge areas and rates, and pumping rates follows.

Recharge was imposed over the entire model domain, which itself was divided into zones of normal and high recharge on the basis of surficial geology. The zone of normal recharge extended from the regional groundwater divide to the southern extent of the terrace sand and gravels lying south of Ponca Creek, while the zone of high recharge was defined by the extent of the terrace deposits. This division was made to account for the higher infiltration rates and higher saturated groundwater flow rates likely to occur in these deposits, which are much coarser than the sediments on the characterized 320-acre area. Recharge was estimated by calibration, as there

is no universally applicable method for estimation other than calibration (2). Due to the shallow depth of groundwater and high potential evapotranspiration, groundwater discharge by evapotranspiration in low lying areas is a characteristic of this region. Areas of groundwater discharge by evapotranspiration were therefore defined in the topographically low areas of wetlands. The locations and areal extents of wetlands were determined from National Wetland Inventory maps (Butte NW, Nebr.-S. Dak; Butte, Nebr.-S.Dak.). Small wetlands (i.e., smaller in area than a single finite-difference cell) were not considered as discharge areas because their contribution to the overall water balance is negligible. Evapotranspiration from wetlands was modeled using MODFLOW's Evapotranspiration Package. This routine assumes that evapotranspiration is a function of depth to the water table. When the water table is at the ground surface, the evapotranspiration rate is taken to be its maximum value, the potential evapotranspiration rate for the region (45.6 in./yr). Conversely, when the water table is at or below the extinction depth (an estimated 5 ft), evapotranspiration is zero. Between these limits, the evapotranspiration rate decreases linearly with increasing depth.

Data on the 20 pumping wells in the modeled area were obtained from a well canvass. Since only one well was metered, pumping rates for the remaining wells were estimated from the number of people, number and type of livestock, and lawn and garden irrigation demands placed on each well. These data were furnished by each well owner or user. Pumping rates were then determined using unit consumption rates appropriate for the region. To assess the accuracy of this procedure, the estimated pumping rate (0.76 gal/min) and measured pumping rate (0.49 gal/min) for Well 4, located just east of the characterized 320-acre area, may be compared. All pumping wells were assumed to extract their water from the contact zone.

Hydrostratigraphic Representation

Construction of a regional groundwater flow model required that the hydrostratigraphy defined for the characterized 320-acre area be extended to the natural hydrogeologic boundaries defined above. The hydrostratigraphy for the model domain was developed by extrapolating information developed for the characterized area, supplemented by additional geologic and hydrogeologic data available for the region. Supplemental data sources included driller's logs acquired during the well canvass, stratigraphic test hole logs and geologic maps given by Souders (3), and test pit logs and geophysical profiles for the adjacent borrow source area located on the quarter section due west of the site. These data were used to develop a geologic map depicting the top of Pierre Shale and a number of geologic profiles showing the elevations and thicknesses of the surficial fines, upper sand, fine-grained sediment, and contact zone in the model domain.

Details of the geologic interpretation are not within the scope of this paper and are reported elsewhere (4). The thicknesses of the layers shown in the profiles generally reflect the thickness and range of variability observed at the 320-acre area, modified as required by the data. The surficial fines unit, which is part of the vadose zone, was assumed to persist across the entire area as a layer about 5 ft thick on the average. The upper sand is known to account for most of the local small-scale topographic mounding on the 320-acre characterized area and was allowed to do so on the profiles; characterization data indicates this unit may be absent beneath wetlands. The fine-grained sediments unit is indicated by the data to be absent or strongly reduced in thickness across the Pierre Shale high south of the site, becoming much thicker farther south toward the Niobrara River. The contact zone was considered to range generally between 3 and 5 ft in thickness across the study region. Only the upper sand, fine-grained sediment, and contact zone were represented in the model; the surficial fines unit was excluded because this unit is not saturated by average groundwater levels.

Hydraulic Conductivity

The horizontal hydraulic conductivities of the upper sand unit and fine-grained sediment unit were assigned the geometric mean values determined by field testing on the characterized 320-acre area, i.e., 1.4x10-3 cm/sec for the upper sand and 1.5x10-5 cm/sec for the fine-grained sediment. The horizontal hydraulic conductivity for the contact zone was determined by calibration (see below) but constrained to fall within the 3.5x10-5 to 6.8x10-2 cm/sec range determined by field testing on the 320-acre area. An additional constraint required that the calibrated contact zone hydraulic conductivity be within an order of magnitude of the observed value in a finite-difference cell for which an observation exists. The vertical hydraulic

conductivity of each hydrostratigraphic unit was taken to be 1/10 the horizontal value, which is within the range commonly observed for regional model applications (2).

Model Calibration

Model calibration was achieved by adjusting the recharge and contact zone hydraulic conductivity until the modeled piezometric heads and water budget (spring flows) matched the observed record. The observed piezometric heads used for calibration were chosen to reflect long-term average groundwater levels. Within the characterized property, the observed heads were determined by time-averaging hydrographs for the contact zone wells for the 3-year period extending from 1990 through 1992. This period was selected as representative of long-term average conditions because the mean annual precipitation for these three years (26.67 in.) nearly equals the mean annual precipitation (23.67 in.). Outside the characterized property, observed heads were estimated from the static depth to groundwater obtained through the well canvass and well location and ground surface elevation estimated from USGS topographic maps (10-ft contour interval). The observed heads estimated in this manner must be regarded as approximate (5 ft) because this procedure provides a one-time versus time-averaged value and because of uncertainty in assigning elevations to the groundwater. These data were therefore given less weight in the model calibration. The spring flows referenced by US Ecology (4), which were measured in a year of below average annual precipitation, were used for calibration. Again, these data represent one-time measurements that likely underestimate the spring flows for the time-averaged period and were treated accordingly during calibration. The observed piezometric heads used for model calibration are shown in Fig. 2.

Model calibration was expedited by first constructing an equivalent, two-dimensional, areal model. Calibration parameters were then adjusted in this areal model to (1) minimize the residual errors (observed head minus modeled head) so that the mean of the residual errors was approximately zero, and (2) match approximately the total spring flow to that observed. Recharge was obtained first by matching the observed heads and head gradients across the characterized area and the observed total spring flows, using the geometric mean transmissivity of the contact zone. The model was further calibrated to better match the observed head distribution by spatially distributing the total transmissivity into zones, and then adjusting the transmissivity of each zone to more accurately reproduce the observed heads. A three-dimensional model was then constructed by distributing the calibrated total transmissivity for a given zone into transmissivities for each of the three hydrostratigraphic units. Given that the hydraulic conductivity and saturated thickness of the upper sand and fine-grained sediment are known, adjustments in transmissivity/hydraulic conductivity were made in the contact zone only. Predictions from the three-dimensional model were essentially the same as those from the calibrated two-dimensional model. Further calibration using the full three-dimensional model was unnecessary.

MODEL RESULTS

The modeled regional head distribution for the contact zone is shown in Fig. 2. Results for the contact zone showed this unit to be saturated over most of the modeled region, although the unit is likely unconfined and only partially saturated in the area between the site and the regional groundwater divide and in other areas where the top of Pierre Shale is high in elevation. Regional flow patterns inferred from the head distributions in the contact zone show groundwater generally flowing from the regional groundwater divide to the north-northeast towards the Pierre Shale outcrop and east towards Dizzy Creek. The groundwater sink created by the group of wetlands near the northeast corner of the characterized 320-acres modifies the general flow pattern, locally reversing the predominant regional gradients to the north-northeast. The head distributions in the overlying model layers were similar when saturated, with small head differences across hydrostratigraphic units. This result is consistent with well pair observations on the characterized 320-acres. The head distribution for the upper sand indicated that the upper sand is, for the most part, unsaturated under long-term average conditions. Regional groundwater flow is therefore restricted primarily to the contact zone under these conditions.

Locally, the head distribution for the contact zone are shown in Fig. 3. These results show that groundwater flow across the 110-acre site is nearly uniform in the north-northeast direction. After groundwater leaves the site, flow patterns are

controlled by the group of wetlands (around the northeast corner of the 320-acre area) from which groundwater is lost by evapotranspiration. Most of the groundwater leaving the site flows through the contact zone to Wetland 01, while the remaining fraction is captured by a pumping well just east of the characterized 320-acres (Well 4). Results of a particle tracking analysis using MODPATH (5) are illustrated in Fig. 3, assuming releases from the areal extremities of the Class A and Class B/C disposal units. The plotted pathlines show that most radionuclides originating from the cells would collect in Wetland 01. Nuclides originating from the southeast corner of the Class A unit would be captured in Well 4.

A water budget for the regional model was completed to assess the magnitudes of the inputs to and outputs from the system. On a long-term average basis, about 22 gal/min are supplied to the modeled region by recharge as determined by calibration, i.e., 0.053 in./yr normal recharge over the site and most of the modeled region, and 0.5 in./yr high recharge over the terrace sand and gravel deposits. Pumping wells discharge about 4 gal/min, drains (springs) along Dizzy Creek, the Ponca Creek tributary and the Pierre Shale outcrop discharge about 14 gal/min, and off-site wetlands discharge about 4 gal/min by evapotranspiration. The modeled spring discharge compares favorably with the observed discharges from springs 10 and 71 that total 11.2 gal/min, i.e., the modeled value is of the same magnitude but in excess of the observed value.

DISCUSSION

Based on the consistency between site characterization data, conceptual model, and numerical model, the Butte site was found to be "modelable" and in compliance with this particular site suitability requirement. Additional information obtained from the regional model included an estimate of the long-term average recharge, a quantity otherwise difficult to estimate for a shallow groundwater system in a subhumid climate and a key parameter for performance assessment. The regional model confirmed the location of the compliance point on the northern site boundary for the performance assessment of the groundwater pathway. The analysis further showed that the off-site pathways terminate in a wetland just northeast of the 110-acre site and in an adjacent pumping well.

Results from the regional model were used to support the development of a local performance assessment model that describes the leaching of radionuclides from the waste cells and their transport to a compliance point on the site boundary. These processes were represented in a two-dimensional vertical slice model located along a groundwater pathline identified by the regional model. The performance assessment modeling was conducted for a hypothetical release of radionuclides under a very conservative set of assumptions, e.g., high recharge and high water table conditions persisting indefinitely. The performance assessment model demonstrated that the dose resulting from a radionuclide release would be below the criteria established by the State of Nebraska.

A sensitivity analysis of the regional groundwater flow model described in this paper is currently underway. US Ecology and its principal subcontractor, Bechtel National, Inc., continue to work with the State of Nebraska to achieve a timely review and licensing decision on the Butte site.
