ABSTRACT

Rod cluster control assemblies, part length control assemblies, burnable poison rod assemblies, flow restriction rods and incore instrumentation from 2 Westinghouse PWR's (350 MW(e)) and 1 Siemens Kraftwerk-Union PWR (965 MW(e)) as well as control rod assemblies, poison curtains, fuel channels and incore instrumentation from 2 General Electric BWR's (355 MW(e)) and (1030 MW(e)), expected with the neutrons sources to be discharged as waste over the 40 years of reactor operation, have been characterized for activities and materials for disposal projects. Packaging has been assumed 5 years after discharge from reactor. Comparisons with experimental results and further with operational and decommissioning waste are made and discussed.

INTRODUCTION

For the general licensing application made mid 1994 for the Swiss repository for short-lived radioactive waste (LLW + ILW), as well as for making projections for the repository for long-lived ILW and HLW, all the radioactive waste expected to arise in Switzerland up to the year 2040 have been characterized for activities, materials and properties up to the level of the conditioned waste package. This model inventory for disposal projects is based on waste sorts represented by average waste packages and their yearly production (1).

The wastes expected to arise from PWR (1.6 GW(e)) and BWR (1.3 GW(e)) nuclear power plants assumed to be in operation over 40 years were categorized into:

Operational waste (resins, concentrates, etc.)
Decommissioning waste
Reprocessing waste (vitrified residues, hulls, etc.) and
Non-fuel exchangeable reactor core components (rod cluster control assemblies, fuel channels, incore instrumentation, etc.).

The non-fuel exchangeable reactor core components discharged as waste have been kept separate from the decommissioning waste because they arise earlier (but with a significant fraction at the time of decommissioning). This paper presents this waste category which has not generally been addressed or reported by the radioactive waste community.

Other wastes included in the model inventory arise from medicine, industry and research. In particular, the decommissioning waste of a 600 MeV, 1.5 mA proton accelerator complex assumed to be shut down after 40 years of operation in 2036 have also been considered as the waste activity and volume are of the order of those of a 1GW(e) NPP (2).

DESCRIPTION OF THE NON-FUEL EXCHANGEABLE REACTOR CORE COMPONENTS

The types of components and the components themselves are specific to each reactor design. The raw wastes expected to arise, determined from an examination of the components on a reactor by reactor basis, are:

TABLE

The components are replaced after some years of operation when they become mechanically defective or when their operating life has ended. To estimate the numbers of components, discharged over 40 years in the framework of a model inventory, assumptions on the average operation time of the component types have to be made. To estimate the activities of the components further assumptions on the irradiation histories have to be made.

The raw wastes are materials which have been activated by the high neutron flux of the core, and in some cases, contaminated by crud deposits (components exposed to the reactor coolant water). The materials are stainless steels (structural materials), zircaloy (fuel channels), neutron absorbing materials (boron carbide (B4C), Ag-In-Cd alloys, hafnium, borosilicate glass, borated steels) and finally aluminum oxide (Al2O3) (filling material). The primary and secondary neutron sources contain, beside stainless steel, Al2O3 and boron glass, the material that generates the neutrons i.e. Cf-252 and Be/Sb-124.

RAW WASTE CHARACTERIZATION

The activation calculations have been made using the ORIGEN2 code including a cooling time of 5 years. The application of this code for these components is deficient with respect to the following points:

The neutron flux and cross sections used within the code do not take into account

for certain elements the large depression in the thermal neutron flux caused by the neutron absorbing materials (Note: for the fuel channels the calculation is correct for the metal but not for the uranium impurities within the metal because uranium is considered by the code as being in the fuel where the epithermal neutron flux is more depressed).

The code does not consider all the neutron reactions occurring from the isotopes of the elements constituting the n-absorbing materials and the metallic impurities. For instance the calculated tritium activity in the control rod boron carbide is much too low (B-10(n,t)Li-8 and secondary Li-7(n,nt)He-4 are not considered); the Be-10 (t = 1.6 106 y) activity calculated for the reaction B-10(n,p)Be-10 could be 2 orders of magnitude too low because the cross section for fast neutrons is not considered. For such cases involving disposal safety relevant radionuclide separate "hand calculations" were carried out to supplement the code.

It is expected that the development of applicable ORIGEN2 cross section libraries or other codes for radionuclide characterization of some core materials will be undertaken in the future on an international level as and when the necessity arises to specify these wastes for disposal. Such a development has just started for the reactor decommissioning wastes (3) and could include the exchangeable non-fuel core components.

The ORIGEN activity calculations have been carried out with the material compositions being specified down to the level of the major impurities. In addition, it was possible to correct for the remaining minor metal impurities in this inventory by using the results of work carried out elsewhere (4). In this work the impurities in the steels of several reactors were measured and activation calculations carried out for decommissioning waste studies. As the same type of steels are used in the components considered in the Swiss inventory, these results were added to the relevant component inventories following normalization to appropriate activities (Ni-59, etc.) arising from the main steel components with correction for different irradiation times.

Finally the crud activities were estimated by choosing an estimate for the value of the Co-60 activity per m2 (for instance 0.05 Ci/m2 for the BWR control blades after 5 years cooling) and using correlation factors for the other nuclides. For this estimation, confidential data made available to Nagra as well as data contained in Ref. 5 were used.

COMPARISON OF THIS WORK WITH OTHER EXPERIMENTAL RESULTS

Two recently published U.S. reports on the experimental characterization of reactor internals present activity results for the following components:

- PWR Westinghouse RCCA (6)
- PWR Westinghouse PLCA (6)
- BWR General Electric CRA (6)
- BWR classified CRA (7).

Comparison of the 12 activities (of interest for disposal in the USA) given in these references with the values calculated for the Swiss model inventory shows general agreement. To illustrate this 2 comparisons are shown in Table I.

TABLE I

Examination of the ratios of the activities for the PWR RCCA show that the components of the model inventory are 4 times more highly activated (long lived Ni-59, Ni-63) and have a shorter cooling time (short lived Mn-54 and Fe-55 have decayed less). More specifically it can be seen that the calculated Ag-108m and Ag-110m activities from the neutron absorbing alloy are only 50 % higher than the measured values when corrected for the higher activation.

Examination of the ratios of the activities for the BWR CRA show that the activation is the same (Ni-59, Ni-63) but the cooling assumed for the model inventory is longer (Mn-54, Fe-55 have decayed more). The discrepancy for C-14 is probably due to either the theoretical calculation or to conditions (classified CRA) not specified in Ref. 7. The crud activities (Sr-90, Tc-99, I-129, Pu-241 and Cm-242) are consistently, slightly higher than the measured activities.

CONDITIONING AND PACKAGING

Some particular types of components (poison curtains, fuel channels and incore instrumentation) that have been already discharged have been size reduced and conditioned with cement in 200 l drums. For the other components a conditioning and packaging study (8) was carried out by Nagra to define provisional waste packages

(i.e. number of components of a given type, cement quantity, internal shielding and container). The concept of a large container (18.9 and 20.2 m3) was used for the rod cluster control assemblies and the control rod assemblies. Some smaller thick-walled metallic containers (0.7 and 1.3m3), that were already available on the market, were assumed for the rest of the components types. A summary of the waste packages is given in Table II.

TABLE II

RESULTS

The detailed results of the characterization of the waste packages of the non-fuel exchangeable reactor core components (activities and material composition of the components, conditioning materials, waste package properties) can be found in the database of Ref. 1. In this paper, we present some overall results and some comparisons with the other better known waste categories (operational and decommissioning).

Figures 1 and 2 show for one of the PWR reactors and for one of the BWR reactors the activities of their packaged components expected to arise over 40 years. The activities 5 years after discharge from each reactor are summed without consideration of decay between the package production times and end of production. The grand total activities are compared with the activities of the operational and decommissioning wastes (defined 2 years after arising or NPP shut-down). The corresponding total waste package volumes of these 3 waste categories are also given. (Note: The total waste package volumes of the individual reactor core components haven been given in Table II).

Fig. 1.

Fig. 2.

The waste package volume of the reactor core components conditioned after 5 years cooling is 115 m3 / GW(e) for both PWR'S and about 1700 m3 / GW(e) for each BWR. They represent about 8 % of the PWR and 34 % of the BWR operational waste volumes. The representative percentages of the decommissioning waste are 0,4 % for old design and 1,5 % for recent design of PWR plants and 12 % for BWR plants.

Although the mass and volume of the exchangeable reactor core components discharged as waste are relatively small, their total activities lie between the activities of the operational and decommissioning waste as can be seen in Figs. 1 and 2. For all the reactors the total activity is found to be 20 times lower than the total decommissioning waste activity but 10 times higher the operational waste activity. Some radionuclide activity concentrations may exceed the waste acceptance criteria for subsurface disposal. The activities of the following long lived nuclides are greater than those of the decommissioning waste (all reactors considered together):

H-3 (12.3 y), Be-10 (1.6 10 6 y), Zr-93 (1.5 10 6 y), Ag-108 m (127 y), Cd-113 m (14.1 y), Sn-121 m (55 y), Sn-126 (1.0 105 y).

The calculated activities of the neutron sources from all reactors 5 years after discharge show the following features of interest:

- the long lived activities from the stainless steel (Ni-59, Ni-63, Nb-94) are 100 time lower than for all other reactor core components
- the H-3 activity (1 1015 Bq) is of the same order of magnitude than the activity of all other reactor core components (3 1014 Bq)
- the Cf-252 (2.6 y) activity is estimated to be 4 1010 Bq.

CONCLUSIONS

The non-fuel exchangeable reactor core components from the 5 Swiss nuclear power plants expected to be discharged as waste and packaged for disposal have been characterized for disposal projects. For such an objective, simplifications and assumptions have been made as it is not possible or relevant to consider the different irradiation histories of each of the individual components. However, as many as possible nuclide activities have been estimated and especially for the disposal safety relevant nuclides. For the first time the main features of this waste category are presented and then compared with other NPP waste categories. The radioactive waste community has almost not addressed these wastes because they are normally associated with the decommissioning waste (whereas a large fraction of them arise earlier), because they are advantageously stored for cooling before packaging due to their relative low mass and because of a lack of practical experience in characterization and packaging for most of them.

For effective packaging and disposal of individual components, the activity characterization could require significant effort if some activity concentrations

are around the limits of relatively cheap disposal. This explains the first recent U.S. publications on the experimental characterization of some real component activities based on the use of computer codes with dose rate, -rays or sample measurements. The applicability of these calculational codes (cross-sections and neutron fluxes) would certainly have to be improved especially for out-of-core materials as well as for neutron absorbing materials and their surrounding metals with respect to specific repository waste acceptance criteria and disposal route.

TRIBAL EXPERIENCES WITH THE MRS PROCESS: A CASE STUDY OF THE FORT McDERMITT PAIUTE-SHOSHONE TRIBE

Ernestine Coble

University of California, Berkeley
Council of Energy Resource Tribes Fellow

ABSTRACT

In their efforts to find a voluntary host for a Monitored Retrievable Storage facility for spent nuclear fuel rods, the Department of Energy and the Office of the U.S. Nuclear Waste Negotiator entered into negotiations with a number of Indian tribes and states. Tribal governments and communities have had significantly different experiences with the MRS process than the states. One of the tribes most interested in hosting the MRS is the Fort McDermitt Pauite - Shoshone Tribe of northern Nevada. This small and isolated tribe has received little national attention, yet the Fort McDermitt story demonstrates the variety of political and social challenges a project like the MRS poses for tribal governments and communities, and illustrates as well some of the institutional barriers to, and requirements for, successful cooperation between the Department of Energy and Indian tribes. For example, once the tribal government decided to pursue the MRS, it became, to a degree, linked to the rising and falling fortunes of the Nuclear Waste Negotiator's Office. Understanding tribal experiences is important, both for the development of more effective waste management and disposal policies, and for achieving broader goals of equity in hazardous waste management. Hazardous waste policies, in particular, must come to reflect a better understanding of this type of

linkage, in order to become meaningful and acceptable to communities beyond the beltway.

BACKGROUND

In 1987, congressional amendments to the Nuclear Waste Policy Act authorized the creation of a single Monitored Retrievable Storage (MRS) facility, which would temporarily store spent nuclear fuel while a permanent repository was developed. Towards this end, Congress established the Office of the Nuclear Waste Negotiator, and empowered the Negotiator to work with the states and Indian tribes in order to find a willing host for the MRS. The Negotiator was given considerable leeway in developing a package of benefits for the potential host, including substantial financial incentives and a variety of public programs, such as health care, education, employment, and infrastructure development, as well as problem-solving assistance. There were several anticipated phases of negotiations: Phase I involved a $100,000 grant to study the potential of siting an MRS on state or tribal lands; Phase IIa involved an additional $200,000 for further study; and Phase IIb involved additional funding for site assessment and other expanded study, as well as entry into a contractual relationship between the parties. The moneys in Phase I and IIa were essentially "no strings attached" -- the tribe or state was free to use the funds however it wished, as long as the general goal of increasing knowledge about the MRS was pursued.

The financial incentives of siting an MRS were, obviously, considerable. In addition to the millions of dollars a year the federal government would pay the host for the facility, potential employment from construction through operation for the planned 30 year life-span of the MRS, as well as public assistance programs, would likely bring new economic prosperity to an entire community. In the balance against these economic incentives, however, were a host of very substantial public concerns and fears. Whether or not the public's fear of things nuclear is "rational", it is very real, and shapes public response to programs such as the MRS. As a result of public opposition, the Nuclear Waste Negotiator was able to find only a few states willing to discuss hosting an MRS, and only 15 Indian tribes. Of those 15 tribes, only 4 tribes proceeded, or wished to proceed, to Phase IIa. None of these negotiations have been successful, in the sense that none has resulted in the identification of a feasible MRS site. Although no MRS site has been found through negotiations with state governments, either, tribal governments and communities have had experiences with the MRS process that differ significantly from the states' experiences.

This paper will tell the story of one such tribe, the Fort McDermitt Paiute-Shoshone Tribe, whose reservation straddles the Oregon-Nevada border. The tribal government applied for and completed Phase I and IIa of the MRS process, and wished to proceed further, when the opposition of the Oregon Governor and the cessation of Congressional funding for the Nuclear Waste Negotiator's Office brought their participation in the MRS process to a halt. This small and isolated tribe has received little national attention, yet the story it has to tell is both common and unique, and demonstrates quite well the variety of political and social challenges a project like the MRS poses for tribal governments and communities. In addition, the Fort McDermitt story illustrates some of the institutional barriers to, and requirements for, successful cooperation between the Department of Energy and Indian tribes. The Fort McDermitt story is a cautionary tale, and demonstrates the internal political ramifications federal policies can have for tribal governments. Once the tribal government decided to pursue the MRS, it became, to a degree, linked to the rising and falling fortunes of the Negotiator's Office. Hazardous waste policies, in particular, must come to reflect a better understanding of this type of linkage, in order to become effective in the world beyond the beltway.

THE FORT McDERMITT CONTEXT

The Fort McDermitt Paiute-Shoshone Tribe is a small, isolated and extremely resource-poor community located on a rugged 34,650 acres of trust land on the Nevada-Oregon border. The tribe has approximately 800 members, about half of whom live on the reservation. Most of the tribal lands are leased, and so most of the tribe's growing population lives along a seven mile stretch of the Quinn River Valley, three miles south of the town of McDermitt in the Nevada portion of the reservation. The tribe has no on-going economic enterprises, other than its hayland leases, and most members of the community are dependent on government programs and subsidies. The median age on the reservation is 23 years, and an unemployment rate of around 70% plagues the tribe. Per capita income on the reservation is about

$3,000., and 70% of residents live below established poverty levels.
Services the tribal government is able to provide its members are limited, and include a Head Start facility in a decrepit old building with a leaky roof, a small and understaffed Indian Health Service clinic, and law enforcement provided by a Bureau of Indian Affairs officer who refuses to live on the reservation itself, and so lives in the town of McDermitt. The tribe has no mutual assistance agreements with the town, county or state law enforcement agencies, and these entities often refuse to assist the tribe, even in crisis situations. The housing and health care facilities on the reservation are sub-standard. The closest full-service Indian Health Service hospital is over 200 miles away, and the closest hospital of any kind is 70 miles away.
The lack of economic development on the reservation does not mean that the tribe does not prioritize development. There have been a series of failed enterprises, and there is continual dialogue within the community about what might be appropriate further development. Development efforts are hampered by the remote location of the tribe, its lack of financial and natural resources, and the relatively low educational and skill levels of many tribal members. Nonetheless, the tribe is currently considering a range of potential ventures, including the building of a dam and reservoir for tourist trade, a casino and truck stop along U.S. Highway 95, and the siting of a federal Monitored Retrievable Storage facility on the tribe's Oregon lands.
THE MRS PROCESS
According to tribal officials, Fort McDermitt paid little attention to the Office of the Nuclear Negotiator's first contact, inviting the tribe to apply for funds to study the possibility of hosting an MRS. Instead, when the tribe ran short of funds to pay for some major plumbing repairs, rather than go unpaid, the plumber suggested they contact a consultant friend of his about applying for a federal study grant he'd heard of. Although the tribe had been previously unsuccessful at obtaining federal grants, primarily because no audits of its existing programs had been conducted for years, the tribal council decided to apply for a Phase I study grant. In this round-about manner, Fort McDermitt itself initiated communication with the Negotiator's Office -- perhaps a harbinger of things to come.
The tribe's Phase I application was approved in July of 1992, but initial funding did not begin until the following October, after the tribe had hired an MRS project officer and spent weeks following a paper trail through the Department of Energy. The tribe spent the Phase I grant on hiring the tribal MRS project officer, setting up an MRS office, taking members of the tribal council on tours of related facilities, and holding one large public meeting. Phase IIa funding was spent on taking 36 more tribal members on three more tours, holding several more public meetings, continuing support for the MRS project office and officer, and meetings with county and state officials. Unlike some other tribes, who essentially used all their funds to hire outside consultants, Fort McDermitt attempted to manage its own way through the MRS process, with only part-time guidance from its Washington, D.C. attorney.
Difficulties began almost immediately, on several fronts at once. As one tribal official said, the Negotiator's Office gave the tribe its money, and very little else -- no direction, few suggestions, little concrete advice. By becoming involved with the MRS issue, Fort McDermitt opened a Pandora's box it was ill-prepared to cope with, from the sincere questions of its members to the vocal opposition of neighboring county and state entities, from the arrival of anti-nuclear activists, media and other interested parties on the quiet reservation to a degree of public scrutiny unlike anything the tribe had ever experienced.
On the domestic front, tribal members were uncertain, confused and even frightened about the notion of storing hazardous waste on the reservation. The money and the jobs sounded enticing, particularly in the economic context of Fort McDermitt. But nuclear waste is a unique issue, one which has a special capacity to raise specters and fears of the unknown, and at Fort McDermitt, tribal officials were hardly reassuring figures. Politics at Fort McDermitt are characterized by a high level of mistrust and conflict, and members were as likely to see the MRS as another opportunity for government corruption as they were to view it as a beneficial public project. Questions of corruption aside, however, tribal officials were limited in their ability to provide clear and complete information to tribal members. Their knowledge of the issue was too clearly based on the same Department of Energy

publications that were available to tribal members, and members frequently had to wait for the MRS project officer to relay their question to the Negotiator's Office -- a process that was not confidence-inspiring.

Compounding the difficulties of internal dialogue was the degree of external attention focused on the tribe. Greenpeace and other environmental groups were present at the first community meeting, and worked hard over the following months to organize opposition to the MRS, from within the tribe and from neighboring communities. Opponents of the MRS raised environmental, health and safety issues, questioned the degree of public trust and confidence in the tribal and federal governments, and posed ethical questions regarding the appropriateness of hosting an MRS, given the traditional connection of Indians and the earth. Officials of the surrounding counties questioned the capacity of the tribal government to manage a project as complex as the MRS, (despite the fact that the MRS would be managed by DOE, rather than the tribe), and local townspeople made disparaging remarks about the level of alcoholism on the reservation, and their resulting fears about allowing the tribe to become involved in anything so potentially dangerous -- and lucrative -- as the MRS. The press and other media capitalized on the more sensational aspects of the debate, and rarely managed to produce complete or objective articles and stories. When the Governor of Oregon announced her opposition to the MRS, even her carefully-worded letter to the tribal council betrayed a less than complete understanding of the MRS project, process and safeguards.

FLAWS IN THE PROCESS

Clearly, the decision to become involved in the MRS process was an independent decision made by tribal officials, and they alone are responsible for choosing this course. However, they did have reasonable expectations of assistance from the Negotiator's Office and the Department of Energy. Throughout this trying period, however, tribal officials found themselves with an unexpected and damaging lack of support. The MRS project officer recalls that her first job was to figure out what to do: "They handed out the money, and then sat back and just left us be. I couldn't believe it -- here's $100,000, with no direction, nothing." After the first community meeting, it was over a year before any federal officials involved in the MRS project returned to the reservation -- they sent lots of written materials, but in a place like Fort McDermitt, government pamphlets have a limited usefulness. Tribal officials were on their own to face the storm of external opposition, to educate and inform their members and other concerned parties, to discover and develop effective ways of conducting their public dialogue and assessing the feasibility of hosting the MRS. Despite the Negotiator's wide latitude in offering assistance to the tribe should it decide to host the MRS, during the crucial public discussion phase, the MRS project officer remembers "begging" the Negotiator's Office for some sort of media training, and receiving no assistance whatsoever. Compounding the lack of non-financial assistance, the tribe found itself caught in the institutional tug-of-war between the Negotiator's Office, the Department of Energy, and Congress. Although the Negotiator's Office was empowered to promise funding to MRS applicants, the actual moneys were distributed by DOE. This bifurcated process put the tribe in the position of receiving promises from the Negotiator, but having to establish an entirely different set of working relations with DOE in order to have those promises fulfilled. Fort McDermitt is not a tribe with extensive political experience or sophistication, and overcoming the institutional barriers commonplace to the federal government was a severe drain on its resources.

To further complicate the picture, Congress itself began to take a closer look at the MRS issue. Important members of Congress were reaching the conclusion that the MRS was politically unfeasible, and possibly an inefficient, unnecessary and/or dangerous obstacle in the path of the development of a permanent repository. This new attitude in Congress forced the Negotiator's Office to begin fighting for its very survival -- leaving it with less and less time and financial resources to devote to its previously primary task of negotiating with potential hosts.

More and more time elapsed between contacts with Fort McDermitt, more and more uncertainty developed within the relation between the tribe and the Negotiator's Office, and more and more tribal members and opponents of the MRS interpreted this uncertainty and delay as a sign that things were not going well. Tribal officials' inability to provide concrete answers was seen by some as further evidence of inability or untrustworthiness and opponents capitalized on this attitude. When

funding did not arrive as planned, some tribal members believed, (or were encouraged by MRS opponents to believe), that tribal officials had embezzled the money, rather than accept explanations that Washington was delaying. When tribal officials expressed uncertainty in their discussions with county and state officials, this was interpreted as their own lack of knowledge or inability to make decisions, rather than as a direct reflection of the unstable position of the Negotiator's Office. Some tribal members, those who had voiced their misgivings of the federal government at the start, now blamed the tribal government for having gotten involved with the feds at all.

In short, the public perception of the legitimacy of tribal government actions became linked with the rising and falling fortunes and attentiveness of the Negotiator's Office. Worse yet, this linkage was seen by many as the fault of tribal officials, rather than a result of inattentiveness, or error on the part of the Negotiator's Office.

CONCLUSIONS

To be sure, the Nuclear Waste Negotiator's mandate was not to hold the hands of interested tribes, and, indeed, too close a connection between the tribal government and the Negotiator's Office might have appeared to compromise the political autonomy of the tribe's decision. The decision to host an MRS was, however, supposed to be an informed decision, a public decision, a political decision based on concrete information as well as extensive debate and dialogue. All parties concerned knew that any discussion of hazardous waste disposal was likely to be complicated by public fears and concerns, sensational press coverage, and difficult decisions about acceptable risks and benefits. The process of simply handing tribes $100,000. to study an MRS led to a number of tribes in turn handing the money to various consultants -- leaving the tribe no richer in knowledge than it began, and certainly no more likely to host an MRS.

At Fort McDermitt, tribal officials made a concerted effort to engage in a serious investigation of the feasibility of an MRS on tribal lands. In this effort, they received unconscionably little assistance from the Negotiator's Office or the DOE. As a result, the tribal government was left on its own to determine how to conduct its investigation, an intrinsically inefficient process of reinventing the wheel over and over again, as well as a potentially politically devastating experience. When the Negotiator's Office began its dealings with Fort McDermitt, it could have made some effort to determine the resources and capacities of the tribal government, and figured out suggestions for proceeding that were contextually appropriate. It could have offered media training, or recommended some other entity for the purpose. It could have prioritized consistent communication with tribal officials, and made itself more available as a resource to tribal members and officials. It could have brokered the relationship between DOE and the tribe, rather than allowing a bifurcated funding process to confuse tribal officials and drain tribal resources. It could have used its own resources to help ensure that the debate which buzzed around Fort McDermitt included all the pertinent facts and information, rather than allow it to be permeated with basic misunderstandings of the MRS and MRS process. Instead, the Negotiator's Office engaged Fort McDermitt in the MRS issue, promising funding and assistance, and then left tribal officials largely on their own to face a situation more complex than any of them could have anticipated. Despite the fact that Congress has halted further funding for the search for a willing MRS host, and despite the fact that the opposition of the Oregon Governor to an MRS on Fort McDermitt's Oregon lands is the equivalent of a political death-knell to the project, controversy around the MRS issue continues to swirl at Fort McDermitt. Months after the cessation of funding, a consortium of environmental groups held an anti-MRS conference in the town of Fort McDermitt, bringing in MRS opponents from other tribes who managed to resurrect tribal members' concerns about mismanagement of their MRS funds and the trustworthiness of their tribal officials. Independent media types are still arriving on the reservation, pursuing leads about corrupt tribal officials and naive tribal members.

Whether or not Fort McDermitt ever hosts an MRS, the conflict and mistrust that have followed from the tribal council's decision to simply study the issue will linger in the tribe's political arena for years to come. Certainly, tribal officials bear the responsibility for the outcome of their own choices. Just as certainly, however, the Office of the Nuclear Waste Negotiator, the Department of Energy, and Congress bear the responsibility for the creation and pursuit of a public policy which failed

utterly to take into account the unique aspects, resources and vulnerabilities of tribal contexts. The MRS policy, as pursued by these entities, also failed to take into account the dilemmas of hazardous waste disposal as a public issue, an issue surrounded by complex public fears and concerns, and one which requires very careful planning for public participation and responsiveness. Because of these failings, there is no feasible MRS site today. Just as importantly, the government of a small, isolated and impoverished tribe has lost a significant portion of its most valuable resource, public trust and confidence -- as has the federal government.

Session 36-A--Panel Discussion: Alternative Technologies for the Stabilization of DOE Spent Nuclear Fuels and Other Reactor Irradiated Materials
Co-chairs: Chris Whipple, ICF Kaiser;
Dieter A. Knecht, Lockheed Idaho Technologies Co.
36-A-Panel
A panel discussion was held to present a wide range of perspectives on alternative technologies for stabilizing DOE spent nuclear fuel and other irradiated materials. Panelists included Jim Werner, Director of Strategic Planning and Analysis; Jim Gallagher, Executive Vice President of Westinghouse; Marilyn Meigs of BNFL; Brian Costner, Director of Energy Research Foundation; and Alan Hoskins, manager of INEL Spent Nuclear Fuels Program of Lockheed Idaho Technologies Co. and co-chairs included Dieter Knecht of Lockheed Idaho and Chris Whipple of ICF Kaiser and chair of the National Academy of Sciences Board on Radioactive Waste Management. Each panelist gave a 5-minute presentation, followed by audience questions and answers for the rest of the session.
In the panelist presentations, Jim Werner introduced the topic concept and provided a brief overview of technical options, including processing the fuel, without separation of fissile materials, as a means of stabilizing some of the fuels. Jim Gallagher presented the progress at Hanford and path forward, including providing a more rational regulatory structure to modify overlapping regulations, using the NEPA process with input from all stakeholders, and proceeding with the engineering and management talent to achieve the desired results. Marilyn Meigs offered an option based on BNFL's experience with processing of metallic Magnox fuel, which has similar characteristics to N-reactor fuel. Brian Costner gave reasons why reprocessing should not be the "default" option and offered a path forward in which decisions should be based on the following criteria: to resolve the health and safety risks, resolve the technical issues with long-term storage and final waste form, and re-evaluate the costs of the options rather than using creation of jobs and the old self-regulation as a basis. Alan Hoskins provided the wide range of characteristics of DOE spent nuclear fuels and technical options currently under consideration. Questions and comments were lively and covered a wide range of perspectives, ranging from technical questions concerning acceptability of minimal fuel treatment to policy of overall repository viability and timing. There were strong views both against and for reprocessing, but there seemed to be some agreement that the presumption in favor of reprocessing that existed in the "old" days was no longer considered to be valid. As an indication of the success of the panel discussion, the chair of the State of New Mexico Environmental Evaluation Group expressed his thanks that an open, free discussion on this topic was held.

Martin Marietta Energy Systems
ABSTRACT
The Mixed Waste Integrated Program was established to plan, manage, and integrate the U.S. Department of Energy's mixed waste programs for research, development, demonstration, testing, and evaluation of innovative treatment technologies. The current status of the program is described including activities in process systems

integration, regulatory interfacing, and development activities in the waste destruction and stabilization technical area.

INTRODUCTION TO MIXED WASTE INTEGRATED PROGRAM TECHNOLOGY DEMONSTRATIONS

The Mixed Waste Integrated Program (MWIP) has coordinated technology development and demonstrations throughout the U.S. Department of Energy (DOE) and in private industry as needed to generate design data to improve mixed waste treatment processes. The MWIP has endeavored to meet the following objectives:

Conduct pilot-scale demonstrations of mixed waste treatment systems, treating actual waste within three years. Cumulatively, these pilot-scale demonstrations will be capable of treating a minimum of 90% of the current mixed low-level waste inventory.

Transfer technologies to industry for commercial use and application to DOE sites and identify opportunities to retrofit existing projects with more effective technologies.

Demonstrate and validate commercialized technologies to contribute to world leadership of U.S. industry in environmental science and technology.

Typically, experiments conducted to develop technology are based on a single-unit operation and use surrogate wastes, although in certain cases an actual waste stream may be used. Confidence in the performance of emerging technologies is gained through demonstration of complete systems on actual wastes. The confidence of waste management customers in system performance increases the likelihood that an emerging technology will be implemented to treat DOE mixed waste. MWIP demonstrations are geared toward combining several unit operations using actual waste streams and are typically conducted at a DOE site (see Fig. 1). Demonstrations in progress are the fixed hearth plasma arc furnace system, being demonstrated at Argonne National Laboratory-West with technical oversight from the Idaho National Engineering Laboratory, and a vitrification system, being demonstrated at Oak Ridge National Laboratory, with technical oversight from the Savannah River Site.

The MWIP recognizes that technology development must address each unit operation as part of a treatment system to ensure that all treatment system elements are compatible and that the resulting system is an improvement over the alternatives. The fixed hearth plasma demonstration consists of several principal investigators whose combined work ensures that development efforts result in a technically successful integrated process system. The Program coordinates oversight of each project and interacts with representatives of the site that is hosting the project demonstration. The Program is critical in moving unit operations from the development stage of an integrated system to the demonstration stage, while ensuring that results are directed toward resolving key problems.

Both the plasma and the vitrification demonstrations have significant involvement from the private sector, including universities. In FY94, 48% of funding was directed to private industry, and 16% of funding was directed to universities. Therefore, the goal of obtaining industrial and academic involvement in project success has been met.

This paper summarizes activities associated with the development of the plasma hearth process (PHP), as well as other MWIP activities undertaken by the Waste Destruction and Stabilization (WD/S) technical area. Detailed reports on the technical progress of many MWIP-supported development activities are presented separately in this conference.

PROCESS SYSTEMS INTEGRATION THROUGH THE TECHNOLOGY RESOURCE TEAM

A technology management process, depicted in Fig. 2, was published in "A New Approach to Environmental Research and Technology Development at the U.S. Department of EnergyAction Plan," January 25, 1994. It provides the framework for identifying technology needs and developing effective, acceptable technology solutions. Integral to the design of this technology management process is teaming: the successful integration of the needs of potential technology users, suppliers of technology-based solutions, and stakeholders.

The Technology Resource Team (TRT) was established as the technology resource arm of the Mixed Waste Focus Area, and the MWIP has contributed to its success. The team fosters improved communications and coordination among customers and the research and development community to overcome obstacles to progress in solving mixed waste problems and to achieve the goals of the department's new approach to technology development. Members take a proactive approach in providing technical information (e.g., life-cycle cost and performance data), technical assistance, and tools (e.g.,

decision-making tools and design guidance) for the evaluation and selection of technologies and treatment systems. Members work closely with customers to address and resolve issues associated with the evaluation and selection of mixed waste technologies, treatment systems, and facilities. The TRT has supplied technical experts to help accomplish the following:

- Communicate technology development activities, capabilities, and benefits to customers
- Define DOE complex and site needs data from the Mixed Waste Inventory Report, Conceptual Site Treatment Plans, Draft Site Treatment Plans, Preliminary Site Treatment Plans and through site interactions
- Evaluate the results from the development and demonstration activities
- Establish consensus with regard to engineering systems and analysis tools
- Assist in the selecting, recommending, and implementing emerging technologies to comply with the Federal Facility Compliance Act (FFCA) at sites requiring them.

REGULATORY INTERFACES

A strategic objective stated in the "Mixed Waste Characterization, Treatment, and Disposal Focus Area Strategic Plan for Technology Development," April 4, 1994, is as follows: "Gain regulatory acceptance of new technology . . . through early involvement by the regulators . . . as indicated through achieving permitting of developed technologies."

Interagency contacts by which this objective can be achieved have been developed. The key in gaining acceptance of new technology is to involve stakeholder, regulators, and end-users in the technology development process. To this end, the MWIP and the National Technical Working Group (NTWG) have developed a proposal to exercise a DOE/U.S. Environmental Protection Agency (EPA) Interagency Agreement. The proposal includes the following tasks:

- Develop a permit roadmap for emerging mixed waste technologies
- Prepare waste analysis plans for nonincineration processes (characterize waste to treat)
- Develop a trial burn test plan
- Implement a technology review and exchanges.

Furthermore, the Office of Technology Development has identified a federal employee to facilitate regulatory and stakeholder interaction, including the National and Western Governors' Associations. A Draft Site Implementation Plan outlines actions necessary to obtain permits for the fixed hearth plasma demonstration to be conducted in Idaho. These activities provide consistency for stakeholder involvement.

PLASMA HEARTH PROCESS DEVELOPMENT ACTIVITIES

One of the technical areas in which technology development is required is the WD/S area. In past years this technical area sought, evaluated, and supported selected waste treatment technologies for application across the DOE complex. Recently the support has been focused on demonstration and development of the PHP and the associated technical and programmatic concerns.

The PHP is being developed as an waste treatment technology that can accept nearly all of DOE's solid mixed waste and convert the waste to melted slag and metal. This medium- or large-capacity system is capable of addressing a major waste treatment issue for the DOE. Recent estimates of the amount of DOE waste that can be accepted by a PHP system exceed 150,000 cubic meters. Figure 3 provides a "block diagram" of the PHP process. Included with the block diagram is an indication of the related design issues associated with each processing step represented by the block and the currently funded Technical Task Plans (TTP). The following discussion summarizes those issues and the related TTPs.

The DOE waste from current operations, waste retrieved from past activities, anticipated environmental restoration, and anticipated decontamination and decommissioning wastes all require characterization prior to treatment to ensure compatibility with the process and compliance with applicable permits. The PHP is capable of accepting drummed waste without shredding and with few process-imposed limits on the waste constituents. Because the process accepts a wide variety of wastes, MWIP is supporting an enhanced waste-package characterization technique in the PNFA process. The goal of the characterization process is reduction in the hazards of manual waste characterization. The status of this characterization program is being reported separately by P. Lange (1) in the conference.

Additionally, the MWIP is participating in the joint EPA/DOE NTWG to address

regulatory issues related to waste characterization requirements and their impact on DOE thermal treatment systems. Typically, Resource Conservation and Recovery Act permits for thermal treatment systems require complete waste characterization to ensure compliance with the permit conditions. The NTWG is discussing the need for this complete characterization of mixed waste for PHP processing. Relaxation of the characterization requirements could reduce operating costs and reduce risks associated with handling and manual sampling for characterization.

The next block in Fig. 1 represents the PHP primary chamber. The PHP can accept whole drums of solid and sludge wastes. This has been demonstrated by the processing of three MWIP specified wastes in FY94. Organic sludges, inorganic sludges, and heterogeneous debris were successfully processed, resulting in a slag phases that pass the EPA's toxicity characteristic leaching procedure. These tests convincingly demonstrated that the process can accept combustibles and noncombustibles with nothing more than automatic control system correction of the air flows. These tests and other significant test program results are reported by R. Geimer (2) in this conference.

The PHP testing continues to refine the designs and confirm operability using a nonradioactive pilot plant, a nonradioactive bench-scale system, and a planned radioactive bench-scale system. Three design issues being studied are melt/slag removal, radionuclide partitioning, and refractory selection for improved crucible lifetime. These design studies are reported by R. Geimer (2), R.L. Gillins and S.D. Poling (3), C. Dwight et al. (4), and A.L. Keilpinski et al. (5) at this conference. A separate program is evaluating plasma torch design improvements, using thin-plate cooling as a means of extending plasma torch lifetime.

The PHP uses a secondary combustion chamber (SCC), or afterburner, for complete oxidation of organics in the gas phase. This is represented by the third block in Fig. 1. Designs of secondary combustion chambers are well-developed and not expected to be a problem. An alternative SCC design is being designed for the bench-scale radioactive pilot plant to demonstrate an nonincineration alterative. The use of a plasma-heated (nonfossil fuel) SCC is reported by R. Geimer (2).

The DOE expects that PHP gaseous emissions will meet all regulatory requirements, because commercially available off-gas treatment systems have been demonstrated for numerous thermal treatment systems. Alternatively, the DOE is considering a minimum emission system demonstration using the PHP as a testing platform. The controlled emissions program was begun in FY94 with an identification of the options available:

Off-gases monitored on-line for process shutdown in excursions

Off-gases monitored on-line with automatic diversion to either holdup systems or additional treatment systems

Off-gases captured, monitored, and released after acceptable test results.

The preferred processes to meet the objectives of these options have been identified, and design studies are underway at DOE's Western Environmental Technology Office in Butte, Montana.

To meet the monitoring requirements of the controlled emission demonstrations, as well as to address a common stakeholder concern, the MWIP is supporting development of two-stack monitoring systems for on-line detection of off-gas pollutants. R. Gritzo (6) reports on an alpha detector that is being developed for real-time monitoring of airborne alpha emissions, and D. Otteson et al. (7) report on the use of tuneable diode lasers for continuous monitoring of volatile organic compounds. Both activities are reported elsewhere in this conference.

The current PHP design minimizes secondary wet wastes using an off-gas cleanup system that first removes all particulates in a baghouse, followed by processing through high-efficiency particulate air filters and removal of the acid gases in a wet scrub system. Spent scrubber solutions are expected to be a problem in the DOE's treatment systems, and MWIP has supported an innovative immobilization technology: chemically bonded phosphate ceramic waste forms. This activity is reported by D. Singh and A. Wagh (8) and A. Wagh et al. (9) in this conference. Polymer solidification of waste is being investigated by J. Heiser et al. (10), and polyethylene encapsulation demonstration is described by P. Kalb et al. (11). E. Franz et al. (12) have developed proposed performance criteria to be met by these waste forms.

STEAM REFORMING

The MWIP steam-reforming program has been restrained due to funding limitations in for this fiscal year. Testing has recently been resumed for the demonstration of

selected MWIP wastes. These wastes have been selected from a specified list of defined surrogates developed under MWIP funding. In FY94, only program planning activities were accomplished. The status is summarized by L. Bustard et al. (13) in another paper in this conference.

TECHNICAL SUPPORT ACTIVITIES

The WD/S technical area participated in several activities supporting DOE Headquarters (DOE-HQ) and field offices this year. Most significant is the support of DOE-HQ in the review of the site treatment plans being developed by field offices in compliance with the FFCA. The WD/S technical area reviewed several conceptual-site treatment plans, two-draft site treatment plans, and two proposed-site treatment plans. These reviews provided a technical review for DOE-HQ and identified potential applications for innovative technologies. The WD/S technical area also supported three field office activities, with senior technical review of proposed designs for waste treatment systems.

A recent development in the MWIP is the interest in alternatives to thermal treatment. In response, MWIP is developing a Technical Area Status Report to summarize low-temperature waste destruction processes available or under development. This report identifies numerous alternatives available for gaseous or aqueous wastes, but limited alternatives were identified on solid waste oxidation using low temperature processes. K. Dickerson and C. Brown (14) report on an incineration alternative in this conference.

CONCLUSION

The MWIP has been supporting numerous research, development, and demonstration activities focused on treatment of the DOE's mixed low-level waste problems. The PHP has shown good promise of being capable of treating a wide spectrum of the DOE's waste. The MWIP has developed a complex, interrelated program of TTPs addressing waste characterization, waste treatment, secondary waste treatment, waste minimization, and process monitoring designed/developed to bring the PHP process to a successful and rapid demonstration. Successful demonstration, scheduled for early FY96, will substantially address stakeholder concerns over the DOE's current inability to treat mixed waste.

ABSTRACT
The Plasma Hearth Process (PHP) demonstration project is one of the key technology projects in the Department of Energy (DOE) Office of Technology Development (OTD) Mixed Waste Integrated Program (MWIP), with potential application in the treatment of a wide variety of DOE mixed wastes. The ultimate goal of the project is a comprehensive field-scale demonstration of the PHP system for treatment of actual DOE waste. The field-scale demonstration is currently targeting alpha-contaminated low-level waste now in storage at the INEL.
Initial project activities during testing and development of the PHP have been and continue to be conducted on a nonradioactive basis. A relatively simple near full-scale batch operated PHP system was designed and constructed for Phase I proof-of-principle testing. Testing has been conducted on a wide range of simulated DOE waste types representative of a large fraction of the mixed waste now in inventory. Most recent testing for the MWIP has involved the testing of waste matrices having been spiked with hazardous constituents (organics and heavy metals) and surrogates for radioactive materials. Extensive sampling of the products and the offgas from the process was conducted. Destruction of principal organic hazardous constituents (1,2-dichlorobenzene and naphthalene) was found to range from 99.996% to >99.9999%. Heavy metals spiked into the feeds were consistently far below Toxicity Characteristic Leaching Procedure (TCLP) limits in the vitrified product. Data from the analysis of stack emissions were compared to EPA requirements, and particulate and metal emissions were well below emission limits.
Additional testing has been conducted on pilot-scale hardware to evaluate the performance of materials in the processing zone and the mechanics of material handling. Several types of high temperature refractories have been evaluated, and some found to perform much more reliably in the aggressive processing zone. Several methods for handling materials have been explored, particularly in the separation of molten products of steel and slag, and their subsequent removal from the processing chamber. Based on these tests, design of a fully integrated pilot-scale PHP and air pollution control system capable of continuous operation is currently in progress.

INTRODUCTION

The Plasma Hearth Process (PHP) is recognized as one of the more promising solutions to DOE's mixed waste treatment needs, with potential application in the treatment of a wide variety of DOE mixed wastes. The PHP development project is one of the key technology projects in the Department of Energy (DOE) Office of Technology Development (OTD) Mixed Waste Integrated Program (MWIP). This ultimate goal of this project is a successful demonstration with a field-scale PHP system for treatment of actual DOE mixed wastes. The field-scale demonstration is currently targeted for treatment of 55-gallon drums of alpha contaminated low-level waste now in storage at the Idaho National Engineering Laboratory (INEL).
The PHP is a high temperature vitrification process using a plasma arc torch in a

refractory lined chamber to destroy organics and stabilize the residuals in a nonleaching, vitrified waste form. Plasma arc technology is an innovative technology that has exhibited commercial success, primarily in its use for production of high purity alloys and other specialty metals. This project involves the adaptation of existing, well understood, and commercially available technology. The key characteristics of the PHP include: 1) extremely high temperature operation that completely destroys organics; 2) creation of a very stable, leach resistant final product; 3) the ability to accept a very wide range of waste types without pretreatment; 4) the ability to treat waste without removing it from the container; 5) generation of separate slag and metallic phases, allowing segregation and possible reuse of the metal; and 6) the preference of many radionuclides (especially actinides) to migrate to the stable slag phase. A more complete description of the PHP concept, its inherent operating characteristics, and its benefits is available in previous references (1-4).

Table I outlines the various PHP test systems that will be used for the technology development project. The terms "pilot-scale," "bench-scale," and "field-scale" are relative to this PHP project. Phase I involved batch tests using a proof-of-principle (POP) system. Phase I is now completed, and the results of these tests are the principal subject of this paper. Successes during this initial battery of tests led to the establishment of the multi-phase PHP development project. Phase II, recently initiated, is divided between nonradioactive pilot-scale (NPS) testing and radioactive bench-scale (RBS) testing. The radioactive field-scale (RFS) PHP system represents Phase III of the PHP development project, the final field-demonstration of the treatment of INEL alpha-contaminated low-level waste.

TABLE I

In addition to the above PHP systems, a nonradioactive bench-scale (NBS) PHP system is available for testing and research in the demonstration project. This system, commercially funded and operated, is located in the Science Applications International Corporation (SAIC) Science and Technology Applications Research (STAR) Center. The STAR Center system supports all phases of the demonstration project. It is used for short-term, small-scale tests where a design or operating issue can be resolved quickly and cost-effectively. Figure 1 presents a photo of the NBS hardware at the STAR Center.

Fig. 1.

The NPS, while designated as a pilot-scale, is essentially a full-scale system. The NPS will demonstrate continuous processing of 55-gal drums containing nonradioactive surrogate waste materials. Hardware and system operability and conformance to environmental criteria will be the focus of the NPS testing. RBS testing, using a PHP approximately 1/10th of the scale of the NPS, will include radioactive materials to assess the fate and partitioning of radionuclides within the process. The RFS will be essentially the same size as the NPS. Upon a successful field demonstration, the RFS will be considered for conversion to a fully operational treatment system for DOE mixed wastes.

Initial project activities during testing and development of the PHP have been and continue to be conducted on a nonradioactive basis. The nonradioactive testing segment of the project has two major goals which will aid the implementation of the field demonstration: to provide development and confirmation of the functionality of the PHP hardware; and to ensure that the process will produce results that are acceptable from a regulatory and safety standpoint. The culmination of the nonradioactive development effort is the NPS system. With the NPS, PHP development and implementation will proceed rapidly, and with reduced implementation risk because it will operate at near-field demonstration rates.

The remainder of the paper consists of three sections. The first section summarizes the results of nonradioactive testing using the POP system. The second section focuses on advanced concept tests using both the POP and NBS systems. The third section incorporates these results into the ongoing design effort for the NPS system.

PROOF-OF-PRINCIPLE RESULTS

A relatively simple, batch-mode PHP system was constructed in 1991 to test the PHP concept of waste treatment. Figure 2 presents a schematic diagram of this proof-of-principle system. Figure 3 is a photo of the POP primary melter hardware.

Fig. 2.

Fig. 3.

Three test campaigns (1-4) have been conducted with the POP system. Listed in Table II, the simulated wastes types tested represent a large fraction of the current DOE mixed waste inventory. Of the three campaigns, the MWIP tests included the most diverse waste types and the most extensive sampling and analysis. The results from the previous two campaigns were consistent with corresponding data from the MWIP tests; thus, the following discussion highlights the MWIP test results.

TABLE II

Table III summarizes key results from the MWIP tests. Each test involved processing two 30-gal drums of material. The test approach included processing the drums at an approximate rate of one per hour. Actual processing times varied from 44 to 81 minutes per drum, which translate into the feed rates listed in Table III. No attempt was made to find the a maximum feed rate for the different waste types; the feed rate could have been accelerated in most cases.

TABLE III

The only particulate emission control device employed with the POP system was a conventional baghouse. Tests with all feeds listed in Table II included stack sampling for particulate matter. Emissions were consistently below the proposed regulatory limit of 0.015 gr/dscf; MWIP data are shown in Table III.

The two organic sludge tests included determination of destruction and removal efficiency (DRE) for two POHCs. The concentration of each POHC in the organic sludge was 3.5% by weight. Table III includes the DRE results. Test 6 involved a process upset (temporary shutdown of the plasma torch) caused by an electrical short. While this upset apparently decreased the DRE for naphthalene compared to the previous test, the DRE still exceeded regulatory requirement of 99.99%.

Throughout the PHP development project the vitrified product (slag) consistently has been highly leach resistant, even though no effort has been made to optimize the product composition. The feed for the MWIP tests included spiking each of the RCRA metals cadmium, chromium, lead, and nickel to 0.1% in the waste. The resulting slags passed TCLP even though their RCRA metal concentrations were sufficiently high to flunk the TCLP had they not been leach resistant. In several cases, the resulting slag was more crystalline than glassy (due to a lack of glass forming constituents in the feed material), but still demonstrated a high degree of leach resistance. Table III includes TCLP results for the spiked metals (nickel is not a criteria metal for TCLP).

The integrity of the slag matrix from four of the six MWIP tests was evaluated using the Product Consistency Test (PCT). DOE scientists developed the PCT for assessing vitrified high level waste (5). Table IV presents the PCT results in comparison to published data (5,6). All slags with the exception of heterogeneous debris slag from Test 3 showed similar or superior leach resistance for the common analytes (Si and Na) with respect to the benchmark EA Glass. Even the more crystalline PHP slags compared favorably with engineered glasses for which the PCT is normally applied. Given that optimization of waste form performance was not an objective of the MWIP tests, the leach resistance performance of the slags is encouraging.

TABLE IV

Of particular note is the extremely low leachability of the cerium from the slags. Cerium (a plutonium surrogate) was spiked into the wastes at a concentration of 0.3%. The cerium consistently partitioned (94% to >98%) to the slag product. This result is desirable, as the radionuclide can be expected to be bound within a demonstrably stable matrix. Another 1% to 2% partitioned to the metal product that is recovered separately from the slag. The less volatile RCRA metals also favored the slag phase, although nickel has a significant propensity for the metal product. The volatile metals were captured to a high degree with the baghouse dust. Stack emissions were compared to Clean Air Act Tier II requirements and found to be well within emission limitations (4).

DESIGN SUPPORT STUDIES

The next step in the (nonradioactive) PHP development is to transition from a batch-operated process to a continuous process. Therefore, studies to support the design of a pilot-scale system with continuous capability have been a recent focus of the program. These tests allow various design concepts to be tested in either the POP or NBS systems to examine their efficacy. Based on actual test results, these design concepts are incorporated into the design, modified and re-evaluated, or discarded. The majority of the tests have focused on two areas: slag/metal separation and materials of construction.

Slag/Metal Separation and Removal

In the crucible, the molten slag and metal phases are naturally immiscible and the metal phase collects at the bottom of the crucible because it is much denser than the slag. The current PHP design approach is to recover the slag and metal phases separately in order to present DOE with an opportunity to recycle the metal while further reducing the volume of material requiring disposal.

Product removal was evaluated systematically in a series of focused tests; SAIC utilized both the POP system and the NBS system for this work. First, isolation of the molten metal phase from the slag phase by means of an underflow weir was evaluated. Once isolated in a collection area adjacent to the crucible, the metal would be relatively easy to remove by pouring. The challenge was to keep the metal molten as it passed through the underflow weir. The successful approach included high temperature, thermally conductive materials to keep the vicinity of the weir hotter than the freezing point of the metal. The hydrostatic head of the slag resting on the metal caused the metal layer on the other side of the weir to rise above the height of the metal layer in the crucible. Removal of the slag phase by tilt pouring was the next operation demonstrated. Here, the challenge was to remove the slag by tilting the crucible to pour off the slag while still maintaining isolation of the metal separated via the underflow weir. The POP system was used for these tests.

The NBS system was used to evaluate simultaneous separation and removal of the slag and metal from the crucible. Again, an underflow weir was used to separate metal from slag. Both molten streams were poured into collection vessels by continuous overflow instead of by tilt pouring. A small amount of metal "short-circuited" to the slag overflow spout and was found in the slag collection vessel. This confirmed the advantages of tilt pouring over continuous overflow for slag and metal removal.

Materials of Construction

Areas in the PHP where materials of construction are an important issue are: the crucible which contains the molten slag and metal, and the ground path that carries the plasma current from the molten bath out to electrical ground. Several types of high temperature refractories have been evaluated for the aggressive processing zone in the crucible. Alumina-chromia, magnesia-chromia, high alumina, magnesia, magnesia/carbon, and silicon carbide refractories were tested. A variety of grades and forms (brick, castable and rammable) of these materials were included in the evaluation. Alumina-chromia and magnesia-chromia (in brick form) are the best performers in the corrosive environment created by contact with the slag. All the materials tested held up well in contact with the molten steel phase under nominal waste feeds. However, certain waste feeds high in water content or other oxidizers caused failure of silicon carbide refractories whether in contact with the slag or the metal. Materials of construction tests have been conducted on both the POP and NBS systems.

Although water-cooled steel typically served as the ground path, tests in the NBS have shown that magnesia/carbon refractories are conductive enough to serve as a ground path. This enables water-cooling to be minimized, if not eliminated.

NONRADIOACTIVE PILOT-SCALE SYSTEM DESIGN ACTIVITIES

Successful product removal concepts and promising refractory materials identified from the design support studies are being incorporated into the design of the NPS. The NPS will demonstrate continuous PHP operation while treating whole 55-gal drums of nonradioactive waste materials. Thus, the NPS will include waste feed and product removal systems that will allow continuous operation. The design basis for the NPS is 1,000 lb/hr of a defined nominal heterogeneous feed. As with the MWIP tests, NPS test parameters will include destruction of RCRA organics and partitioning of RCRA metals and surrogate radionuclides. Unlike the POP system used for the MWIP tests, the NPS system will include a more comprehensive air pollution control system (APCS). Design of the NPS is nearing completion, and fabrication and installation will be undertaken in the spring of 1995. A summary of the current design is provided below.

PHP Hardware

The waste feed system will be a horizontal, water-cooled cylinder with an air-lock for loading the drums to be treated, and variable speed hydraulics for ram-feeding the drums into the plasma chamber. As with the current feeding approach, the drums will be fed axially. A constant flow of purge gas will protect the feed system from convective heat transfer from the plasma chamber. The NPS will utilize the same 1.2

MW plasma torch that was used for the POP system; however, because the NPS design will optimize the energy density of the plasma chamber and will include greater thermal insulation, the maximum NPS processing rate will be significantly higher than that of the POP system. The plasma chamber will be a vertical cylinder with a domed cap. The inner surface will be refractory lined, while the shell will be water-cooled. The plasma torch penetrates the domed cap to reach the crucible, which will be mounted to the bottom of the chamber. The torch will have a computer controlled three-axis-of-motion positioner with a manual override. Removal of the molten phases from the crucible will be accomplished by tilting the entire crucible one direction to pour the slag and the other direction to pour the metal. Two separate vessels will be positioned in a melt collection chamber located below the crucible. These vessels will be a 55-gal (or smaller) drum for the slag and a reusable cast iron pig mold for the metal. Figure 4 presents a sketch of the NPS primary melter hardware.

Air Pollution Control System

The offgas from the plasma chamber will pass through a gas-fired secondary combustion chamber before entering the APCS. The first APCS unit will be an evaporative cooler, which will use a water spray to rapidly quench the gas exiting the secondary combustion chamber to 400F. The quenched offgas will pass through a baghouse and then a HEPA bank to remove essentially all of the particulate matter. The filtered offgas will then be quenched to saturation to remove acid gases using an integrated quench/packed bed scrubber. At the scrubber exit will be a mist eliminator followed by an electric reheater. The reheater will heat the saturated gas to above its dew point so that the gas will be dry when it passes through the induced draft fan and stack.

CONCLUSIONS

The PHP has proven to be very promising as a robust, effective technology for solving the bulk of the DOE mixed waste problem. The proof-of-principle tests demonstrated the broad applicability of the PHP to safely treat diverse waste matrices. The design support studies have shown that the PHP can be made to operate continuously. Based on these successful tests, the PHP development project is proceeding with the design of new systems that will address questions regarding continuous service with wastes that include radioactive hazards. Continuous service is primarily being addressed with the NPS system. Radioactive service is primarily being addressed with the RBS. The experience gleaned from testing with these two systems will be incorporated into the design of the RFS, for which permitting efforts have begun.

RADIOACTIVE DEMONSTRATION OF THE PLASMA HEARTH PROCESS ON SPIKED AND ACTUAL LOW-LEVEL MIXED WASTE*

R. L. Gillins
S. D. Poling
Science Applications International Corporation
545 Shoup Avenue
Idaho Falls, ID 83402
ABSTRACT
The Plasma Hearth Process (PHP) is an innovative thermal treatment technology being developed to demonstrate its effectiveness as a treatment process for the large quantities of radioactive mixed waste currently stored at a number of U. S. Department of Energy (DOE) sites. PHP technology development is sponsored by the Department of Energy's Office of Technology Development (OTD) and will be demonstrated for the OTD's Mixed Waste Focus Area, which is evaluating waste treatment technologies for a wide range of mixed waste types and forms. The ultimate goal of this project is to demonstrate the PHP technology by treating actual DOE radioactive mixed wastes using a field-scale unit (i.e., production size) to be constructed at Argonne National Laboratory-West (ANL-W) on the Idaho National Engineering Laboratory (INEL). The PHP technology will progress to a field-scale status through a systematic development of PHP test units (i.e., bench-scale, pilot-scale) and well defined test objectives for the units. The hardware development and testing for the PHP technology have been separated into the categories of "non-radioactive" and "radioactive." This paper describes the radioactive demonstration portion of the PHP project.
PLASMA HEARTH PROCESS DESCRIPTION
The term "plasma" refers to a highly-ionized electrically conductive gas. Plasmas can be generated by a variety of techniques, over a wide range of pressures and energy levels. The type of plasma produced in the PHP application is a dc arc-generated thermal plasma and is created by a device known as a "plasma torch." The plasma torch used in the PHP technology development project operates in the transferred arc mode. Figure 1 contains a conceptual diagram of the PHP system. Basically, the transferred arc torch uses a flow of gas to stabilize an electrical discharge (arc) between a high voltage electrode (inside the torch) and a molten pool of waste (maintained at ground potential). Because of the very high resistance to electrical current flow through a gas, electrical energy is converted to heat. Plasma gas temperatures are estimated to reach as high as 10,000oC. Even more energy is converted to heat as the electrical current passes through the melt, creating a Joule-heating effect in the molten pool.
Fig. 1.
The resulting molten products can form two phases. Operating the plasma hearth in an oxidizing (oxygen rich) mode produces a high integrity, leach-resistant slag. Operating the plasma hearth in a reducing (oxygen deficient) mode produces the slag and an additional reduced metal phase. These two phases segregate naturally due to density differences and could be recovered separately.
The PHP technology applies chiefly to solid or sludge wastes where a stabilized byproduct is required for disposal. The technology is ideally suited for heterogeneous solid wastes of nearly any category that are difficult to treat by conventional thermal technologies. One of the key advantages of the PHP technology is its ability to process a wide variety of waste materials with only minimal regard to physical or chemical nature. This minimizes the number of different treatment processes that would otherwise be needed to treat a variety of wastes. Whole drums of waste, including heterogeneous matrices, may be fed into the process chamber, minimizing pretreatment characterization, sorting, sizing, and other handling and potential exposure to toxic and radioactive contaminants. The application for which it is currently being developed is DOE solid mixed wastes, both low-level and transuranic. These wastes are found at most DOE sites and many have no identified treatment option.
The primary functional units of the PHP system are the feed system, plasma chamber, slag/metal removal system, secondary combustion chamber, and air pollution control system. Processing begins as complete drums of waste are fed to the fixed hearth plasma chamber, where heat from the plasma torch initiates a variety of chemical and physical changes. Complex organic compounds break down into noncomplex gases that are drawn from the chamber, while the remaining inorganic material melts and separates into two phases: slag and metal. The drum and inorganic materials are "drip melted" slowly into a crucible, and the molten materials are poured into waste

containers by a simple hearth tilting mechanism to avoid tap hole plugging problems. Actinides and oxidized heavy metals migrate to the slag phase which, after being removed, cools and solidifies into a glass-like, or vitrified, material. This high-integrity final waste form, similar to that selected for high-level radioactive wastes, has repeatedly shown the ability to meet or exceed disposal requirements instituted by the Resource Conservation and Recovery Act (RCRA).

Induced draft fans pull gases from the plasma chamber to a secondary combustion chamber. Once there, excess oxygen and the product gases are mixed in a very hot and turbulent environment for a sufficient residence time to complete the conversion of the gaseous organic compounds to CO2 and H2O. This secondary chamber guarantees the hazardous organics are treated completely to achieve the high destruction efficiency required by RCRA. The offgas is then scrubbed by state-of-the-art air pollution control technologies capable of removing a high degree of pollutants, producing very clean process emissions.

TECHNOLOGY DEVELOPMENT STRATEGY

The DOE OTD Mixed Waste Focus Area is sponsoring the evaluation and development of this technology by Science Applications International Corporation (SAIC) for application to DOE mixed wastes. The development process includes several PHP systems designed to address all aspects of the technology in a systematic fashion, progressing from a simple proof-of-principle unit to a field-scale prototype demonstrating full-scale operations on actual mixed waste prior to production implementation in the field. The elements of the development plan are illustrated in Fig. 2.

Fig. 2.

The first development phase, a proof-of-principle demonstration, has been completed using a simple first-generation PHP system at Retech, Inc., a manufacturer of plasma furnace systems. The tests showed that the PHP could process a variety of containerized wastes, including heterogeneous mixes, without any pretreatment. The tests also demonstrated the effectiveness of the process in destroying organics and its ability to produce a stable, leach-resistant vitrified final waste form. However, this test series did not address the behavior and fate of the actual radionuclides that will be in DOE mixed waste streams.

The second development phase features an effort to design, build, and evaluate a second-generation nonradioactive PHP pilot-scale system and to concurrently design and build a bench-scale PHP system for radioactive studies. The pilot-scale unit will be used for studying engineering/operations and evaluating advanced design concepts on surrogate waste materials. This unit will validate the operability/durability of PHP system hardware for continuous modes of operation over extended periods of time. The bench-scale system is intended to accurately simulate the behavior of radionuclides in the pilot-scale system and allow investigations of radioactive processing issues in a smaller, simpler, and less expensive unit. The relative sizes of the pilot- and bench-scale systems are compared in Fig. 3.

Fig. 3.

The bench-scale test program is structured to ensure that the plasma technology can be employed in radioactive service, and that surrogate (nonradioactive) studies on the pilot-scale unit properly model the behavior of radionuclides during treatment. These tests will demonstrate whether the PHP can successfully process radioactive wastes, especially alpha-emitters, while meeting DOE safety requirements and applicable environmental and public health regulations.

Knowledge gleaned from parallel testing of both units will be used to launch the final demonstration phase--the construction, permitting, and demonstration of a prototype field-scale PHP system for processing actual mixed waste. The field-scale system will be installed at ANL-W and will be targeted to demonstrate the treatment of 55-gallon drums of alpha-contaminated low-level mixed waste stored at the INEL. Additionally, the field-scale unit will provide full-scale verification of complete radioactive waste operations, including front-end handling through final waste form disposition. The time frame for the field-scale demonstration supports DOE commitments to various Federal Facility Compliance Agreements.

RADIOACTIVE BENCH-SCALE SYSTEM DESCRIPTION

To be located at the Transient Reactor Test (TREAT) facility of ANL-W at the INEL, the radioactive bench-scale system is configured to model the conditions of the near-full-scale nonradioactive pilot-scale PHP system currently being developed and tested at the Retech facility in Ukiah, California. The bench-scale PHP system (200

kW plasma torch compared to 1.2 MW in a full-size system) will be fabricated, assembled, and checked-out by Retech at their Ukiah facility prior to delivery to ANL-W.

The bench-scale system is a batch process, capable of feeding up to eight 1-gallon cans of waste material per test. The plasma chamber is designed to closely model the pilot-scale plasma chamber so that comparisons of radionuclide/surrogate behavior can be obtained. The Title II design of the complete bench-scale system is in progress, to be completed early in FY95. The bench-scale melter system consists of the following functional components:

- waste feed system,
- plasma chamber and crucible,
- plasma torch,
- secondary combustor, and
- air pollution control system.

Waste Feed System

A batch feeder will introduce the small waste containers into the plasma chamber. The feeder is capable of remote feeding and is oversized to allow containers of various sizes and shapes. The maximum throughput of test materials (operational feed limit) into the system is 30 lb/h.

Plasma Chamber and Crucible

The plasma chamber, commonly referred to as the melter, is a refractory-lined, double-walled, carbon steel vessel, configured as a vertical cylinder, and equipped with a closed-loop water-cooling system for chamber cooling. The top end of the cylinder has a flanged lid on which the torch is mounted and the bottom end of the cylinder has a flange-mounted hearth and crucible to collect molten material. The crucible is detachable from the removable hearth to allow batch removal of the product metal and slag.

Plasma Torch

The plasma torch is a dc transferred-arc plasma torch, model RP 75T, supplied by Retech, Inc. The torch has a hollow copper electrode and is water-cooled by a closed-loop heat exchanger. It is mounted on the lid of the primary chamber, and a three-axis-of-motion position controller controls the location of the arc inside the plasma chamber. The torch uses nitrogen as the primary plasma gas for melting, but for start-up and torch optimization other gases such as helium and argon will be used in combination with nitrogen.

Secondary Chamber

The secondary chamber is water-cooled and constructed of carbon steel lined with a refractory material. The chamber is equipped with electric heaters to maintain proper combustion and destruction temperatures. The chamber is designed to provide a minimum of two seconds residence time at a minimum of 1800oF and will be operated with a minimum oxygen content of 3% (by volume). These conditions will ensure the destruction of any gaseous organics that are released from the primary chamber. The offgas will consist primarily of CO2, N2, and H2O, with trace quantities of CO, SO2, and NOx.

Air Pollution Control System

The bench-scale system offgas will be processed and conditioned for release by an air pollution control system (APCS), which consists of the following functional components:

- evaporative cooler,
- HEPA filters (redundant),
- quencher,
- packed-bed scrubber/de-mister,
- reheater, and
- induced draft fans.

RADIOACTIVE BENCH-SCALE DEVELOPMENT STATUS

The bench-scale system is currently in the final stages of design, with a final design review scheduled for March of 1995. Upon completion of the review, fabrication of the melter system will be initiated. The procurement of major air pollution control system components, typically long-lead procurement items, is in progress so that delivery of the equipment coincides with completion of the melter system fabrication. The system will then be assembled and tested in Ukiah, California, at the Retech facility prior to delivery to ANL-W. The schedule for final installation of the system in the TREAT facility at ANL-W is aggressive, but

the system should be operational by the fall of 1995.

RADIOACTIVE BENCH-SCALE DEMONSTRATION PROJECT

The radioactive bench-scale PHP system is being designed and constructed to evaluate the treatment of actual radioactive mixed waste and to investigate the behavior of radionuclides (particularly plutonium) in the process. The bench-scale tests will investigate, in a cost-effective manner, the issues related to treating radioactive materials in the PHP before activities proceed to a more expensive full-scale demonstration. The bench- and pilot-scale units will be tested in parallel, allowing engineering development and radioactive operations to be interactively investigated.

The primary objectives of the radioactive bench-scale PHP project are:

1. to design and construct a PHP system that ensures public and facility personnel will be protected from hazards associated with the treatment of radioactive and other hazardous materials as a result of normal operations, anticipated operational occurrences, and design basis accident conditions;
2. to operate a bench-scale PHP system that accurately simulates the performance of the near-full-size pilot-scale system for surrogate/radionuclide comparisons;
3. to evaluate the behavior of radionuclides in the PHP system by means of partitioning studies, including radionuclide volatilization and deposition; and
4. to conduct treatability demonstrations on actual mixed waste to demonstrate organic destruction and to produce stable, leach-resistant final waste forms.

It is critical to the development of the PHP technology to determine the behavior and partitioning of specific radioisotopes, particularly those that are alpha-emitting. The technology can only be considered successful if it treats mixed waste without significant radiological problems, such as excessive releases of volatile radioactive species or concentration of actinide species that could result in criticality concerns. The bench-scale tests will focus on determining the relative quantities of radionuclides of interest that are retained in the slag phase or partitioned to the metal phase, and the quantity that is volatilized or otherwise transported to the offgas. The bench-scale tests will also establish the validity of the simulated waste tests conducted on the pilot-scale unit, particularly in the area of partitioning, and demonstrate that the PHP can effectively treat actual radioactive mixed waste.

The first period of bench-scale tests at ANL-W will be conducted on three categories of simulated or actual wastes:

1. simulated waste materials including surrogates for radionuclides of interest;
2. the same simulated waste materials as in (1) above, spiked with known amounts of the radionuclides of interest; and
3. actual radioactive mixed wastes.

Phase 1 Simulated Waste Tests

Simulated waste tests will be performed to checkout the system operationally and to verify the ability of the bench-scale system to model the performance of the pilot-scale system. these tests will be closely coordinated with the pilot-scale testing and will establish whether the bench-scale test results can be scaled up to full-scale. Successful demonstration of scale-up will allow correlation of the testing results between the bench-scale and pilot-scale systems. The waste materials to be tested will be a variety of simulated waste mixtures with known quantities of hazardous materials and surrogates for various radionuclides, duplicating the simulated waste mixtures to be processed through the pilot-scale system. Recipes for these simulated waste materials are based on simulation of actual mixed wastes to be processed in the bench-scale system in Phase 3.

These tests will also evaluate the partitioning of a variety of radionuclide surrogates and toxic metals in the PHP system, including stack emission rates. Partitioning refers to both the distribution of radionuclides in the three product phases (slag, metal, and offgas) and the uptake of radionuclides by the components of the system itself, such as the refractories. The methodology for evaluating radionuclide partitioning in the PHP system is as follows:

- Aspects that control the partitioning of radionuclides in the PHP system have been examined and the design of the bench-scale system conforms to the pilot-scale system in these aspects, where possible; and
- Tests with simulated waste materials, including the radionuclide surrogates cerium and cesium, run on the pilot-scale system will be reproduced on the bench-scale system.

It will be determined to what degree the radionuclide surrogates in the pilot-scale

nonradioactive system mimic the partitioning of the same surrogates in the radioactive bench-scale system. If reasonable agreement is obtained, the program will proceed to the next step of comparing radionuclide surrogates to actual radionuclides; otherwise, the bench-scale system will be reconfigured and/or operational modes adjusted until reasonable agreement between the two systems is achieved.

Although most system parameters (such as melt pool surface-to-depth ratio, refractory chemistry, melt pool temperature and chemistry, chamber size, offgas space velocity, turbulence, and power density) that affect the partitioning of radionuclides can be either matched or scaled appropriately, the complex interrelationships between design and operational parameters that affect partitioning make exact similitude impossible. An iterative approach, alternating testing and system modifications, may be required to achieve the desired level of similitude.

Phase 2 Spiked Radionuclide Waste Tests

The spiked radionuclide tests will evaluate the partitioning of actual radionuclides within the system and confirm whether surrogates for radionuclides realistically model their radioactive counterparts. The wastes materials to be tested in this phase will be the simulated waste materials from the Phase 1 tests spiked with known quantities of radionuclides. Each Phase 2 test container will be spiked with one or more of the radionuclides Pu, depleted uranium, or Cs137.

The partitioning of the spiked radionuclides will be compared to the partitioning of their respective surrogates. If the partitioning of radionuclides closely follows that of corresponding surrogates in the bench-scale system, then it can be assumed that the surrogates are valid in this application. Having previously demonstrated corresponding behavior of surrogates in the two systems during Phase 1, it can be concluded that the surrogates used in the pilot-scale system accurately simulate the behavior of radionuclides in a full-scale system. If the surrogate/radionuclide behaviors are significantly different but their behaviors can be reliably correlated, these correlations will be applied to full-scale results. Additional tests will examine the effects of varying parameters, such as radionuclide concentrations and the presence of chlorides, on radionuclide partitioning.

Phase 3 Actual Mixed Waste Tests

Testing on actual waste is intended to demonstrate that the PHP technology can easily treat a variety of mixed waste types into final waste forms that meet leachability criteria for disposal. The materials to be tested will be a variety of actual wastes from the INEL inventory of stored mixed waste. These wastes will be removed from their drums and repackaged into the smaller containers to be fed through the bench-scale system. The alpha low-level mixed waste (-LLMW) to be used in the PHP test project will be composed of Pu52-contaminated (weapons-grade plutonium) waste from the Rocky Flats Plant. It is currently stored at the INEL Radioactive Waste Management Complex. These a-LLMW waste categories include combustibles, uncemented inorganic sludges, and uncemented organic sludges. Heterogeneous solid wastes (mixed paper, metal, glass, etc.) will be obtained from low-level mixed wastes currently stored at ANL-W. These streams will be treated individually and in combinations to demonstrate the technology's relative insensitivity to variations in waste feed compositions. The effects of varying system stoichiometry on final form performance will be investigated. Finally, the effects of adding waste-form-enhancing additives will be investigated.

Test Regulatory Objectives

Emissions data will be collected during selected portions of the above-described tests to evaluate the performance of the technology with respect to regulatory requirements. Bench-scale system data will be used to support permitting of the field-scale system. The types of data to be collected include metals emission levels, radionuclide emission levels, organic destruction efficiencies, dioxin and furan generation, and NOx generation rates.

RADIOACTIVE FIELD-SCALE DEMONSTRATION PROJECT

The final activity in the PHP demonstration project will be the construction and operation of a production-sized PHP system for treating actual INEL mixed waste. This major program element will be the first step in transferring the PHP technology to the end-user. Specific mixed waste streams stored at the INEL will be selected and processed through the PHP field-scale system, which will be a complete waste treatment system from front-end waste handling through the production of a

disposable final waste form. Installed at the ANL-W TREAT facility, the unit will have a 1.2 MW torch and a throughput of up to two 55-gallon drums per hour, depending on waste characteristics.

The objectives of the field-scale demonstration are to:

verify that radioactive mixed waste can be handled in a way that is safe and complies with environmental regulations,

demonstrate the PHP's versatility in treating a wide variety of actual mixed wastes,

demonstrate the permitting and operation of a versatile DOE mixed-waste thermal treatment facility,

establish accurate life-cycle costs for the PHP, and

demonstrate the technology's readiness to be implemented complex-wide.

Due to both the aggressive project schedule and funding limitations, PHP development focuses on treating 55-gal drums of waste. Drummed waste represents over half the volume of DOE solid mixed wastes in storage. Current plans are to process up to 600 drums of mixed waste in the initial demonstration phase, in three test runs of at least 100 hours. Modifying the waste feed system or even the melter itself for receiving other waste containers, e.g. 4 x 4 x 8 ft wood boxes, will not be precluded in the field-scale design. Production treatment facilities may employ multiple feed systems connected to a single PHP, or may involve PHP units that are dedicated to nominal container types, e.g. drums, boxes, bulk (uncontainerized) solids, liquids, etc. The main thrust of the field-scale demonstration is to establish a treatment facility to begin operation on a significant fraction of the mixed waste inventory; subsequent work can address modifications to treat the remainder of the wastes.

FIELD-SCALE DEVELOPMENT STATUS

A preconceptual design of the field-scale system was completed in the first quarter of FY95. Much of the information contained in the preconceptual report was gleaned from the design activities on the full-size pilot-scale system currently underway. A conceptual design report is in work and will be issued in mid-FY95. Title design activities will follow the NEPA process, which is expected to require an environmental assessment.

NONRADIOACTIVE STAR CENTER SYSTEM DEVELOPMENT SUPPORT

An existing fixed-hearth plasma system at the SAIC Science and Technology Applications (STAR) Center in Idaho Falls has been used to investigate a variety of PHP design issues. These issues include slag/metal separation, hearth/crucible configuration development, and testing of refractory materials for wear and durability. The STAR Center system is roughly the size of the radioactive bench-scale unit and includes an early model of the same plasma torch. Hearth/crucible design, primarily of the electrical ground path, was the objective of the Radioactive Bench-Scale Design Support Studies conducted in the STAR Center. Out of this work a promising design based on a metal ground path and rammable refractory has been selected for long-duration testing. Two other viable (but less desirable) hearth/crucible configurations have also been developed. They can be used if the first choice does not meet the challenges of long duration testing. These results and the future testing planned at the STAR Center will be incorporated into the radioactive bench- and pilot-scale designs and operational philosophies.

ARGONNE-WEST FACILITY REQUIREMENTS FOR A RADIOACTIVE WASTE DEMONSTRATION*

Carla C. Dwight
Frank S. Felicione
David B. Black
R. Bruce Kelso
Grant C. McClellan
Argonne National Laboratory

ABSTRACT

At Argonne National Laboratory - West (ANL-W), near Idaho Falls, Idaho, facilities that were originally constructed to support the development of liquid-metal reactor technology are being used and/or modified to meet the environmental and waste management research needs of DOE. One example is the use of an Argonne-West facility to conduct a radioactive waste treatment demonstration through a cooperative project with Science Applications International Corporation (SAIC) and Lockheed Idaho Technologies Company. The Plasma Hearth Process (PHP) project will utilize commercially-adapted plasma arc technology to demonstrate treatment of actual mixed waste. The demonstration on radioactive waste will be conducted at Argonne's Transient Reactor Test Facility (TREAT). Utilization of an existing facility for a new and different application presents a unique set of issues in meeting applicable federal, state, and local requirements as well as the additional constraints imposed by DOE Orders and ANL-W site requirements. This paper briefly describes the PHP radioactive demonstrations relevant to the interfaces with the TREAT facility. Safety, environmental, design, and operational considerations pertinent to the PHP radioactive demonstration are specifically addressed herein. The personnel, equipment, and facility interfaces associated with a radioactive waste treatment demonstration are an important aspect of the demonstration effort. Areas requiring significant effort in preparation for the PHP Project being conducted at the TREAT facility include confinement design, waste handling features, and sampling and analysis considerations. Information about the facility in which a radioactive demonstration will be conducted, specifically Argonne's TREAT facility in the case of PHP, may be of interest to other organizations involved in developing and demonstrating technologies for mixed waste treatment.

BACKGROUND

Introduction

Argonne National Laboratory (ANL), one of the nation's largest energy research and development organizations, is operated by the University of Chicago for the U.S. Department of Energy (DOE) with sites in Illinois and Idaho. At Argonne National Laboratory - West (ANL-W), near Idaho Falls, Idaho, facilities that were originally constructed to support the development of liquid-metal reactor technology are being used and/or modified to meet the environmental and waste management research needs of DOE. One example is the use of an Argonne-West facility to conduct a radioactive waste treatment demonstration through a cooperative project with Science Applications International Corporation (SAIC) and Lockheed Idaho Technologies Company. The Plasma Hearth Process (PHP) project will utilize commercially-adapted plasma arc technology to demonstrate treatment of actual mixed waste. The demonstration with radioactive waste will be conducted at Argonne's Transient Reactor Test Facility (TREAT).

Argonne Experience

Argonne's experience began at the dawn of the nuclear age and throughout its history nuclear activities have played the central role. Argonne is a recognized leader in alpha confinement and remote operations technologies--key elements in a realistic PHP development program. At ANL-W, metric ton quantities of plutonium and uranium are a part of daily operations. Some 25,000 plutonium items in 2600 containers and 73,000 uranium items in 2140 containers exist on the site. For the past 10 years, plutonium and actinide fuel has been cast in the Experimental Fuels Laboratory. In gearing up for applying the ANL electrometallurgical process to the DOE spent fuel problems, new facilities and analysis techniques have been developed. As a result, new capabilities have been developed for process control, actinide and fission product waste streams, materials control and accountancy, criticality control, employee and public safety, and regulatory permit processing. From decades of transuranic (TRU) facility/equipment design and operations, a few simple lessons learned are now applied to all ANL-W TRU projects: 1) simplify the process, equipment, and facility to the maximum extent; 2) minimize confinement penetrations;

3) minimize moving parts, and 4) limit the energy potential. These principals are being implemented in the PHP Support Systems in TREAT, described in a subsequent section of this paper.

Plasma Hearth Process Program Description

Plasma-arc technology is an existing, commercially available processing method used primarily in the high-purity metals industry. Adaptation of this technology to treatment of mixed waste, and demonstration of this application on actual mixed waste is the focus of the PHP Project. The PHP is a high temperature vitrification technology which utilizes a plasma arc torch to melt waste material into a fixed hearth. The melted waste solidifies into separable metal and glassy-slag phases. Results of testing to date show promising results with regards to volume reduction of waste, destruction of hazardous organic constituents, stabilization of hazardous inorganic constituents in the vitrified product, and resistance to leaching from the final product. One of the greatest benefits of the PHP is the apparent flexibility to process a wide variety of waste forms without the need for pretreatment steps such as shredding or the need for additives to achieve the final product. Also, the PHP discharges much less offgas than incinerators, which are currently being scrutinized by regulators and the public. The PHP Project is funded by DOE's Office of Technology Development (EM-50), specifically the Mixed Waste Integrated Program. Programmatic aspects and results of non-radioactive PHP testing are widely published. (1,2,3)

The PHP program ultimate goal is to conduct a full-scale demonstration using actual mixed waste. To ensure success in this goal, two PHP systems will be built and tested prior to the full-scale system. A bench-scale PHP system will be constructed at the ANL-W TREAT facility to test the treatment of radioactive material containing waste forms for assessment of radiological considerations. The bench-scale system is approximately one-tenth scale of a full scale system in terms of torch power and processing rate. In parallel, a pilot-scale PHP system will be built and operated on non-rad waste to ensure system operability and reliability at a large scale as well as conformance to all environmental criteria.

Three phases of testing will be conducted in the bench-scale PHP experiments. First, simulated waste, which will include radionuclide surrogate materials like cerium, will be tested to check out the PHP systems operationally and to verify the ability of the bench-scale system to model performance of the pilot-scale system. Then, simulated waste matrices will be spiked with radionuclides, specifically plutonium, cesium, and uranium. Radionuclide concentrations in various locations throughout the PHP primary system will be measured. Finally, tests will be performed on actual waste. The actual waste streams will include inorganic sludge, organic sludge, combustibles, and a heterogeneous mixture of waste matrices. The actual waste tests are expected to demonstrate the PHP technology's relative insensitivity to variations in waste feed compositions. Also, the system will be operated to vary stoichiometry for the purpose of evaluating final waste form performance. The effects of including waste-form-enhancing additives to the feed material will also be investigated in the actual waste tests.

All of the test material to be treated in the PHP system will be packaged in small (3.8 liter) metal containers. Approximately eight containers will be processed per test. Approximately 39 tests will be processed (312 containers) in the PHP experiments, expected to be conducted over a 6- to 9-month time period. For the spiked waste tests, each container may include up to 500mg plutonium, 20g depleted uranium, and 3700 Bq of cesium-137. The radionuclides for the actual waste tests will consist of plutonium in quantities much less than the spiked tests.

TREAT History

The TREAT facility at Argonne-West was originally constructed in 1958 as an experimental, air-cooled, thermal reactor used for fuel and material testing under transient conditions. Reactor operations started in 1959, and continued for 35 years; over 2800 reactor transients have been conducted. The facility was upgraded to modern standards in 1989. The TREAT facilities existing infrastructure is being utilized to conduct the non-reactor PHP experiment. The features which make TREAT suitable for the PHP experiments include the large high bay area (35m x 21m x 23m high), double HEPA-filtered building exhaust, existing electrical and water supplies, overhead crane coverage, and truck access. TREAT support systems specific to the PHP Project are described in the following section.

PHP SUPPORT SYSTEMS IN TREAT

New support systems are being provided to the TREAT facility that will enable the PHP process equipment to be operated safely and effectively to perform the experimenters' testing and evaluation mission. Existing TREAT systems will be supplemented by additional systems for non-reactor nuclear experiments. These new systems will provide: a secondary radiological confinement to the PHP process equipment which is independent of the TREAT building; inert gases; exhaust and ventilation; communications, monitoring, alarming; process residue sampling and handling capabilities; and extended utilities and fire protection. The addition of these support systems considerably broadens the usefulness of the TREAT facility and will result in a versatile installation capable of fulfilling the facility needs to support developmental testing and evaluation of other waste processing technologies. The new support systems will be designed and installed in accordance with DOE, Environmental Protection Agency (EPA), and ANL requirements as outlined in the following sections.

General Design Requirements

Experiments in TREAT are currently constrained by the following principal requirements established by TREAT: a) Plutonium is limited to a maximum of 150 g and 1705 g biological equivalent of Pu-239 per experiment; b) Double containment is required for all test specimens containing plutonium; and c) the primary containment shall be designed to retain its integrity during all planned testing conditions, and at least one level of containment must be ensured during the maximum credible accident conditions.

Compliance to DOE Orders requires a determination of the natural-phenomena-hazard classification. DOE Order 5480.28 uses a graded approach: structures, systems, and components are assigned to one of five performance categories (PCs) in accordance with performance criteria given in DOE-STD-1021-93. Due to the low radioactive inventory involved, the PHP experiment will be classified as PC-1. Design and evaluation criteria for structures, systems, and components for earthquake, wind, and flood are based on DOE-STD-1020-94.

Specific standards to which the PHP support systems are being designed include: U. S. DOE Order, DOE-6430.1A, "General Design Criteria"; National Fire Protection Association Codes and Standards; American National Standards Institute (ANSI) N13.1, "Guide to Sampling Airborne Radioactive Materials in Nuclear Facilities"; ANSI-N317, "Performance Criteria for Instrumentation Used for In-Plant Plutonium Monitoring"; ANSI-N323, "Radiation Protection Instrumentation Test and Calibration;" U. S. DOE Order 5400.5, "Radiation Protection of the Public and the Environment"; U. S. DOE Order, 5480.5, "Safety of Nuclear Facilities"; U. S. DOE Order, 5480.11, "Radiation Protection for Occupational Workers"; International Conference of Building Officials, "Uniform Building Code"; and ANL-W "Environment Safety and Health Manual."

The PHP bench-scale experiments also require consideration of environmental requirements. A permit-to-construct will be obtained from the State of Idaho in accordance with the Clean Air Act. The EPA granted a permit for the bench-scale experiments under the National Emission Standards for Hazardous Air Pollutants. A categorical exclusion in accordance with the National Environmental Policy Act, paragraph B3.10 of Appendix B to Subpart D of 10 CFR 1021, was approved by DOE. The experiments will be conducted under a Resource Conservation and Recovery Act treatability study in accordance 40 CFR 261.4.

System Descriptions

An 11m x 14m x 7m high secondary confinement structure will be provided for backup confinement of radiological and hazardous materials during normal and abnormal operations of the PHP without reliance on the TREAT building. This structure will be located within a high-bay section of TREAT having a floor area of 735 m2, a ceiling height of 23m, and a 55,000kg bridge crane. The secondary confinement will have removable roof panels that allow equipment handling, and is designed for ease of modification, if required.

A process off-gas and ventilation system that contains the process off-gas and secondary confinement ventilation air and discharges it from the TREAT facility stack is being provided. This system includes redundant exhaust fans and HEPA filtering of the off-gas and ventilation air to reduce or limit radioactive contamination levels in the effluent gases to acceptable limits.

The ventilation system maintains a negative pressure within the secondary confinement structure relative to the TREAT building to prevent radioactive

contamination spread to other parts of the building. The system is configured such that air flow sweeps from the cleanest regions anticipated to areas within the secondary confinement having successively higher potential for contamination.
A fire protection system will provide detection and suppression of fire (by water sprinkler) within the secondary confinement and shall provide for alarms to personnel and the ANL-W fire department.
An extensive communications, monitoring, and alarm system will incorporate telephone and area-wide audio communications, monitor and record PHP secondary-confinement and process operational conditions (normal and abnormal), and provide both operator and facility alarms at preset conditions and process-parameter thresholds. This system includes extensive video equipment for monitoring and recording the process operation.
Provisions will be made for materials handling that services solid-material-entry and -discharge points. This includes logistics and equipment, as required, for the transport of waste containers to the experiment and the packaging and disposition of process wastes. A major feature is a 6m x 1.5m x 2.7m high glovebox with built-in equipment for lifting, translating, sample drilling, and weighing the PHP hearths. The glovebox will confine alpha contamination. Hearths approximately 1.22m in diameter and weighing up to 816kg will be handled within this structure. The enclosure will also be used for the extraction of representative samples from the hearth, HEPA filters, and acid-gas scrubber liquor.
Extensive radiation monitoring instrumentation will be provided to measure radiation fields and the levels of radioactive materials that are airborne or deposited on surfaces to quantify the level and type of radiation and/or airborne radioactive contamination, provide data to support operations to assess the radiological-safety conditions, and to warn personnel of abnormally high radiation fields. Radioactive emissions from the TREAT stack will be monitored by an emissions-monitoring system to quantify the level and type of radioactive effluent.
Several utility systems are being provided that enhance the usefulness of the facility. An electrical-power system connects to the existing TREAT electrical system to supply the normal- and redundant-diesel/generator power systems and distribution necessary to support the test equipment. Feeders having capacities of 600A and 400A at 480V are being provided, along with an 18kVA uninterruptible power supply.
Cooling-water systems for equipment cooling including both normal service water (12 liter/s at 290K) and a chemistry-conditioned supply of 0.3 liter/s are being provided.
An inert-gases-supply system will furnish nitrogen, helium, and argon to the PHP on process demand for torch gases, for purging the camera and view ports, and for purging the waste-feed system. Nitrogen flow may be up to 25 liter/s from a liquid nitrogen tank and vaporizer. Helium and argon flow rates up to 0.025 and 0.13 liter/s, respectively can be furnished. These flow rates could be easily increased, if needed.
A breathing-air system is being provided that furnishes breathing air to support up to 4 workers for use during suited entries into potentially contaminated areas and equipment.
All of these PHP support systems will be adequately instrumented, where practical, to monitor parameters having significant impact on the systems' operation or capabilities to provide their respective functions. Significant data will be recorded for subsequent system-performance analysis. Alarms are being provided to warn operations personnel whenever significant parameters are outside of established limits.

CONCLUSION

The personnel, equipment, and facility interfaces associated with a radioactive waste treatment demonstration are an important aspect of the demonstration effort. Areas requiring significant effort in preparation for the PHP Project being conducted at the TREAT facility include confinement design, waste handling features, and sampling and analysis considerations. Information about the facility in which a radioactive demonstration will be conducted, specifically Argonne's TREAT facility in the case of PHP, may be of interest to other organizations involved in developing and demonstrating technologies for mixed waste treatment.

ABSTRACT

The Mixed Waste Integrated Program (MWIP) of the United States Department of Energy's Office of Technology Development is developing treatment technologies for a wide variety of materials containing mixed low-level waste, i.e., having low levels of radioactivity along with hazardous constituents. Vitrification is a promising treatment technology for many of these wastes, including contaminated soil such as that found at the Savannah River Site.

Proof-of-principle tests were performed to demonstrate the feasibility of both ex-situ and in-situ vitrification of contaminated soil by means of a plasma torch. A mixture of 89% as-excavated Savannah River Site sandy clay loam with 11% lime addition was tested. Vitrification of a mixture of this feed, in a 10" diameter crucible with a non-transferred arc plasma torch at a nominal 160 kW, was successful. The process produced homogeneous glass (albeit with local compositional variations), surrounded by a skull of incompletely reacted feed. Characterization of the resultant product durability using the Product Consistency Test (1) showed elemental leaching well below the Environmental Assessment glass (which is often used as a minimum standard of glass acceptability in high-level waste glass assessment) for both the glass and the skull regions. Future tests should include doping the soil with hazardous constituents to enable further verification of the wasteform integrity via the Toxic Characteristic Leaching Procedure (2).

In-situ operation was mimicked in the test crucible by segregating the lime additive from the soil within the crucible. Making full use of the available torch maneuvering capabilities (which would likely exceed those of a torch used in-situ) failed to produce a homogeneous melt. Therefore, intimate mechanical mixture of the additive with the soil appears crucial to the success of SRS soil vitrification, and must be included in design considerations for in-situ operation.

INTRODUCTION

The Mixed Waste Integrated Program (MWIP) of the United States Department of Energy's Office of Technology Development is funding efforts to develop treatment technologies for a wide variety of materials containing mixed low-level waste (MLLW), i.e., having low levels of radioactivity along with hazardous constituents. Vitrification is a promising treatment technology for many of these wastes, including contaminated soil. Soils with MLLW constituents are present at many sites across the Department of Energy (DOE) complex, as well as in industrial settings such as the naturally occurring radioactive material (NORM) associated with drilling operations in the oil and gas industries. High temperatures are required for soil vitrification, making plasma technology attractive for this application.

The processing requirements of one soil type may not be directly transferrable to another, due to differing morphology and chemical composition. Rather than testing a "generic" soil which might ultimately prove to have limited applicability, a representative contaminated soil material was desired for proof-of-principle testing of the plasma vitrification method. Savannah River Site (SRS) soil was used for

these tests because SRS is a large (300 square miles) DOE site where nuclear materials production and processing operations have been carried out over several decades, resulting in significant quantities of soil requiring remediation.
This paper describes the plasma vitrification tests of SRS soil which were performed at the Diagnostic Instrumentation and Analysis Laboratory (DIAL) of Mississippi State University. Both ex-situ and in-situ treatment methods are of interest; therefore, the tests were designed to demonstrate features of each.

TEST MATERIAL

At SRS, the soil most likely to be contaminated with low levels of radioactivity is that found near processing facilities. For building stability, these facilities were generally sited on a particular group of soil series. Soil excavation for construction of facilities and burial of waste resulted in mixing of diagnostic horizons to the extent that individual soil series cannot be identified. The resulting mix of material is classified, using United States Department of Agriculture (USDA) soil taxonomy, in the Great Group Udorthents. The particle size distribution for this group typically is sandy clay loam (USDA nomenclature), with an estimated breakdown of 55% quartz sand, 30% kaolinite clay particles, and 15% silt. Thus, despite the inevitable local variability in soil composition throughout the site, there is a high probability that most of the contaminated soil at SRS is quite similar in particle size distribution and mineralogy. Although a sandier soil is generally found as topsoil throughout the site, this sandy top layer would have been removed during facility construction, exposing the sandy clay loam. For the tests described herein, clean (nonradioactive) sandy clay loam was excavated from the soil pile associated with the construction of a non-radioactive site facility.
Proof-of-principle tests of sandy clay soil vitrification have been performed previously (3). From those tests, it had been determined that use of a fluxing additive was required for homogeneous vitrification, and that commercial, agricultural limestone was suitable for this purpose. Two tests had been run: one with no additive and one with 30% by volume of lime additive. Although lack of a flux additive precluded complete vitrification of the soil, too much flux was used in the second test, which resulted in precipitation of multiple crystalline phases upon cooling, again impairing product homogeneity.
Based on these findings, the feed composition for the present tests was approximately 11 weight percent agricultural dolomitic lime, (a mixture of $CaCO_3$ and $MgCO_3$, with 20% elemental Ca and 10% elemental Mg), and 89% as-received soil (i.e., with a moisture content of approximately 15% and containing small amounts of plant material, gravel, etc.).

TEST DESCRIPTION

The objective of the tests was to examine the potential for both ex-situ and in-situ treatment of contaminated soil. Processing issues for ex-situ vitrification, in which feed material is introduced into a processing vessel, include feed composition (ratio of soil to additive), feed material handling, and off-gas emissions. Ex-situ vitrification allows the use of either the transferred-arc or nontransferred-arc mode of torch operation. Transferred-arc operation may be more efficient; since heat is conducted through the melt directly, it is more likely to promote axial mixing and avoid temperature stratification.
In-situ treatment involves inserting the plasma torch into a series of boreholes at the contaminated site, withdrawing the torch as the surrounding material at a given axial location is vitrified. Any required additives would be introduced down the borehole. In-situ treatment is attractive, in that handling and transportation of contaminated material is minimized; off-gas treatment requirements may also be reduced if the soil acts as a percolation filter for off-gas. However, the feasibility of in-situ vitrification depends on the ability to achieve product quality under in-situ processing conditions. Since a fluxing agent appears to be necessary for this type of soil to vitrify, adequate mixing of the flux with the soil must be ensured. In-situ vitrification precludes the use of transferred-arc operation, since there would be no bottom attachment point for the arc when moving the melt upwards in the borehole. The increased gas flow through the torch in non-transferred arc mode might, however, increase mixing through forced convection by the gas impinging on the melt.
With these considerations in mind, two different types of tests were performed on the SRS soil:
1. The soil and lime were intimately mixed in the crucible. The torch was fixed

both radially and azimuthally.
2. The soil and lime were segregated in the crucible. The torch was manually manipulated laterally as well as axially.
The torch was run in non-transferred arc mode for all tests to permit a direct comparison of the two test types. The first test type, essentially an ex-situ demonstration, will be rerun in transferred arc mode at a later date. The second type of test was meant to mimic the in-situ processing conditions, where the flux would be introduced into the soil without intimate mixing. The second test type was repeated twice, once with only limited lateral movement, and a second time with lateral movement specifically aimed at promoting mixing between the flux and the soil.
In all tests, the torch was first run several inches above the melt for 10-15 minutes to allow the test material to soften, thus reducing blow-off, and then lowered to a distance of approximately two inches above the surface of the test material. The duration of each test was 45-60 minutes of torch operation.
The tests were performed using a nominal 250 kW plasma torch manufactured by Plasma Energy Corporation. The torch was run in non-transferred mode, using air as the working gas. In this mode, the power output fluctuated between about 130-160 kW. The airflow through the torch varied from 12-20 scfm for these tests. The torch is installed with both axial and lateral movement capabilities. A viewport equipped with video camera enabled visual observation during the test. As described below, this capability was used in one of the tests to move the torch in order to best achieve a mixed melt.
For each test, a total of 13.44 lb of feed was used (12 lb soil and 1.44 lb lime). The test material was processed in batch mode in a 10" diameter crucible which was placed inside a larger test vessel lined with refractory brick. The test vessel was sealed and under vacuum for the tests. Off-gas was monitored by a variety of techniques, including infrared, FTIR, two-color imaging, and spectroscopic pyrometry. These measurements will be reported separately.
RESULTS
Homogeneous Feed Test
The first test, with soil and lime homogeneously mixed in the crucible, produced a homogeneous, glassy material in the center of the crucible, with a 1-2 inch "skull" of incompletely reacted feed adjacent to the crucible walls and bottom. Presumably, a more powerful plasma torch, or use of the torch's lateral maneuvering capabilities, would have completely vitrified the material. To assess product quality as a function of radial distance from the torch, samples of the product were taken at three locations: 1) from the center of the melt; 2) from the transition region between glass and skull; and 3) from the skull region itself. These were examined by X-ray diffraction (XRD) and scanning electron microscopy coupled with energy dispersive X-ray spectroscopy (SEM-EDS) (Fig.1).
XRD of samples 1 and 2 (from center and transition regions, respectively) confirmed that homogenous glass was produced, with no crystalline phases observed. XRD of sample 3 (skull region) showed the presence of both quartz (the sand in the original soil) and cristobalite, with quartz predominating. Note that the transition temperature between these two phases is 1470C, which implies that temperatures in this range were experienced even in the incompletely reacted region.
SEM results of the three samples are shown in Fig. 1. All figures are at the same scale, as shown in the figures. SEM-EDS examination of sample 1 showed the presence of a number of species: Si, Fe, Ni, Cu, and Ca. The same species were identified in sample 3, with slightly higher peaks for Ca, Fe, and Ni showing some compositional variation between the glassy center and the incompletely reacted soil/lime mix in the skull region. However, SEM-EDS examination of an area in sample 2 showed the presence only of Si--none of the other species were identified except for a very minor peak for Cu. This SEM-EDS result was obtained at two locations within sample 2 which were about 1 mm apart. This implies that this area of the transition region between glass and unreacted batch is essentially pure silica glass.
The Product Consistency Test (PCT) (1), now ASTM C-1285 procedure for determining waste glass durability, was performed for the three samples, yielding leachate concentrations as shown in Table I. Note that non-zero concentrations are measured for various cations in sample 2. This implies that constituents other than silica were indeed present in this sample, contrary to the SEM-EDS indications. Therefore, we assume that sample 2's average chemical composition is similar to that of the

other samples; the SEM-EDS result can be attributed to the small scale of the SEM-EDS sample. This shows, however, that although a uniform glass product was formed in the transition region, local (microscale) variations in chemical composition resulted.

Table I shows that all three areas had releases of Si, Na, Li, and B lower than the Environmental Assessment (EA) glass which has been used as a minimum standard for durability for high level waste glass. The skull region had a significantly higher level of Ca release, however, indicating insufficient reaction between the soil and lime. The skull region also showed a slightly lower Al release than the glassy regions.

It is notable that all three samples had roughly similar release levels. That is, even the crystalline skull region material has a durability better than EA glass, as measured by the PCT. (Note that these PCT results are on a non-normalized basis, so this conclusion must be confirmed by chemically analyzing the samples and normalizing the PCT results.) The feed was not doped with any hazardous constituents, so its ability to retain such constituents could not be assessed by a direct measure such as the Toxic Characteristic Leaching Procedure (2). This should be done to verify that both the glass and the incompletely reacted material represent a viable waste form.

Segregated Feed Tests

The main focus of these tests was to explore the ability to mix the lime and soil in-situ. From visual observation during the test and of the resultant product, there was clearly a lack of mixing between the flux and soil. In the first of these tests, with relatively little lateral torch movement, the lime clearly boiled, spattering the crucible sides and vessel viewports, while the soil remained stiff. Visual examination of the crucible contents showed extreme heterogeneity in the product, with "ledges" of unreacted soil lining the sides of that portion of the crucible which contained soil (i.e., about 270 of the circumference). Even in the center of the crucible, directly below the torch, the melt extended only a short depth below the surface, and at the sides of the crucible, the glassy portion had a thickness of only about 0.25 inches.

The test was then repeated, making full use of the visual capabilites and torch movement capabilities to try to drive the lime melt into the soil and soften the soil "ledges" in order to mix them into the melt. Although some mixing was achieved by this method, visual observation during the test still showed differences between the lime and soil regions of the crucible. Post-test examination of the material confirmed that soil "ledges" were still present around the sides of the crucible, although the product appeared more homogeneous than in the previous test.

Quantitative measurements such as those performed on the homogeneous feed will be performed on the products of these tests, but are not expected to change the following conclusions based on visual observation. The first of these two tests represents the simplest configuration for in-situ operation, that is, with additive introduced in a mass down the borehole. While some torch maneuverability may be available, it will likely be limited and the torch movement will not be "tailored" to optimize the mixing operation. The second test represents an "upper bound" to the optimization of torch operation to promote mixing. Even under these conditions, a homogeneous melt could not be produced. These tests indicate that in-situ vitrification of tyis soil type would require apparatus to mix in the flux prior to treatment with th plasma torch, which will require additional design effort and feasibility testing.

CONCLUSIONS

Proof-of-principle tests were performed to demonstrate the feasibility of both ex-situ and in-situ vitrification of contaminated soil by means of a plasma torch. To represent the SRS contaminated soils, a sandy clay loam was used; a mixture of 89% as-excavated soil with 11% lime addition was tested. Crucible vitrification of this mixture was successful, producing glass (albeit with local compositional variations) without crystallization.

In-situ operation was mimicked in the test crucible by segregating the lime additive from the soil within the crucible. Making full use of the available torch maneuvering capabilities (which would likely exceed those of a torch used in-situ) failed to produce a homogeneous melt. Therefore, intimate mechanical mixture of the additive with the soil appears crucial to the success of soil vitrification, and must be included in design considerations for in-situ operation.

ACKNOWLEDGEMENTS
John Andol and the operating crew of DIAL operated the equipment for these tests. C. A. Cicero and M. K. Andrews of WSRC performed the PCT on the samples. This work was funded by the Mixed Waste Integrated Program of the Office of Technology Development, U. S. Department of Energy.

PFNA-BASED TECHNIQUES FOR CORRECTING MATRIX EFFECTS IN NON-INTRUSIVE ASSAYS OF HETEROGENEOUS WASTES
E.A. Pentaleri

Santa Clara, CA 95054
ABSTRACT
Pulsed Fast Neutron Analysis (PFNA) is a non-intrusive technique for inspecting bulk samples whose size may range from that of a suitcase to that of a commercial-cargo truck trailer. An earlier paper (1) described techniques for performing PFNA-based TRU assays on waste drums, and reasons why such measurements would yield improved accuracy, sensitivity, and throughput over existing instruments. Here we describe PFNA-based techniques for further improving the accuracy of assay results. In principle, these measurements, based mainly upon analysis of inelastic-neutron-scattering and neutron-capture gamma rays, can be performed concurrently with TRU-assay measurements. Using such techniques, a single PFNA-based inspection system would allow substantially complete non-intrusive characterization of waste containers.
INTRODUCTION
Numerous non-destructive techniques have been developed in which physical characteristics of samples are revealed upon irradiation by neutrons. These techniques may involve analysis of neutron transmission or scattering patterns, but are often based mainly on emission of secondary radiations (e.g., fission neutrons or gamma rays from capture or inelastic scattering). Many such techniques have been reliably used for decades to characterize physically small samples, but have shown inconsistent success on large items. This paper outlines some of the most serious challenges to inspecting large samples, and briefly describes PFNA-based techniques for mitigating or correcting such effects. Indeed, one should note that while the focus is upon neutron-based active inspection techniques, similar effects arise at some level for virtually all active and passive techniques based on interactions of penetrating radiation with samples.
A sample may generally be considered small if it is much smaller than the source and detector, or if its dimensions are much smaller than the distances that separate it from the source and detector. In either case, the unattenuated neutron flux and the detector's geometric efficiency may each be assumed constant over the sample volume. Often it is also possible to neglect perturbations a small sample causes to the incident radiation field and to the number of secondary radiations escaping the sample to reach a detector. Frequently, small samples can be assumed homogeneous, allowing simple corrections to be applied for such perturbations. Such assumptions may be valid even if the sample is not strictly homogeneous, as long as the scale of sample inhomogeneities is small compared to pertinent radiation mean-free-path lengths. To the extent such assumptions are valid, they constrain the possible solutions to the inverse problem and yield accurate assay results. Difficulties arise though as sample size increases and these assumptions begin to fail.
The first set of assumptions is purely geometric. Given a sufficiently well

characterized source and detector response functions, and a sufficient number of independent observations, effects related to the spatial extent of a sample can generally be treated reliably.

Arguably the most severe difficulties arise in understanding or correcting for interactions of probe neutrons with the sample itself. These interactions perturb not only the distribution of incident neutrons in the sample, but also the energy spectrum and angular correlations that may otherwise have existed between the source, sample, and detected radiations. As differential cross sections often vary strongly with neutron energy, such perturbations greatly complicate assay results. Despite these complications, it is not uncommon to assume sample homogeneity, even when such assumptions clearly be invalid. Predictably, the accuracy of results in these cases often leaves much to be desired.

OBTAINING MATRIX DISTRIBUTIONS FROM CONVENTIONAL PFNA MEASUREMENTS

As described previously (1), PFNA measurements involve interactions of essentially mono-energetic neutron pulses with a sample. With nanosecond pulse widths and ~8-MeV neutrons, time-of-flight (TOF) measurements determine interaction depths to within several centimeters. Events are usually localized in the remaining two dimensions by collimating the neutron beam. Conventional PFNA inspections are based mainly upon gamma rays from inelastic scattering of uncollided neutrons (though for very large or dense samples it is important to also consider those scattered neutrons whose energy is above the inelastic-scattering threshold).

Despite the highly penetrating nature of neutrons used for PFNA, corrections must be made for neutron removal from the uncollided beam at different depths. Fortunately, PFNA measurements yield enough information to reliably correct for such matrix effects by iteratively analyzing the observed gamma-ray signals. By constraining the corrections to match total measured neutron removal from the beam, corrections for moderate-size samples usually converge satisfactorily after a single iteration.

Conventional PFNA measurements performed in this manner allow distributions to be mapped for many elements, including C, N, O, Al, Si, and Fe, for example, and have yielded spatial resolution of ~125 cm3. These maps are uniquely detailed in their combination of spatial resolution and elemental specificity, and can be used either independently, or in conjunction with complementary techniques (e.g. computed x-ray tomography) to develop detailed models of neutron and photon transport within a sample (2). Such models can, in principle, give very good matrix corrections for both neutron and photon interactions in a sample.

Indeed, while elemental maps such as those described above certainly provide information important for developing matrix corrections, it is important to note that the list of elements mapped directly by PFNA does not include H, perhaps the single commonly occurring element that strongly affects neutron transport over the entire range of energies pertinent to existing non-intrusive techniques. Although space does not permit more than passing reference, it is simply noted here that in practice, a variation on the iterative algorithm described above yields very good maps of H distribution. Combined with maps provided directly by conventional PFNA measurements, inferred H distributions provide a very complete description of the physical system and the basis for detailed understanding of radiation transport in a sample. This information promises to be of value for both PFNA-based inspections and for correcting matrix effects in other active and passive assay systems as well.

PULSED THERMAL NEUTRON ANALYSIS (PTNA)

The prompt radiations used for PFNA inspections are observed over several tens to hundreds of nanoseconds after a neutron pulse, depending on sample depth. The pulsing frequency is chosen so no more than one pulse exists in the sample at any time. Cargo containers therefore require a pulsing frequency not more than ~5 Mhz, while pulsing rates for 208-liter waste drums can be much higher.

Although signals for PFNA measurements are induced by the uncollided pulses of essentially mono-energetic and mono-directional neutrons, various elastic and inelastic scattering processes populate lower-energy neutron groups . Neutrons in these groups have no useful angular correlation with the uncollided beam, and have reaction cross sections much different in general from those of the mono-energetic source. Because signals induced by scattered neutrons do not have the same intrinsic spatial correlation as those from the uncollided beam, PFNA inspection stations are usually designed to minimize such signals. The signals induced by scattered neutrons, can nevertheless reveal important complementary information for assaying various elements including Cl, Hg, 235U, and 239Pu, for example.

Evolving typically over millisecond time scales, the time structure of signals induced by neutrons in low-energy groups cannot be observed at the high frequencies ordinarily used for PFNA. Such measurements are possible however if the normal uniform pattern of PFNA pulsing is modulated into "macropulses" consisting of a chain of several nanosecond-wide pulses repeated at the usual interval, followed by a quiescent period up to ~1 ms. Conventional PFNA measurements can be performed during each macropulse, while concurrent Pulsed Thermal Neutron Analysis (PTNA) measurements of signals induced by lower-energy-group neutrons can be performed by analyzing signals between macropulses. Signals occurring after each macropulse are induced by neutrons whose energy spectra have progressively lower mean energy. This time-energy correlation is important, because the known variations of cross section with neutron energy (e.g., for fission and radiative capture) are the basis for matrix corrections not available otherwise.

SELF-SHIELDING CORRECTIONS IN PTNA MEASUREMENTS

Figure 1 shows MCNP simulation results of the radiative-capture gamma-ray production for different neutron-energy groups and time windows after a discrete pulse of mono-energetic neutrons. In the simulation, a 208-liter drum in an inspection cavity was irradiated by an isotropic 4.0-MeV neutron source. The drum was filled with a 150-kg homogeneous mixture of H, C, O, Al, Si, and Fe in ratios typical for mixed wastes (3). At the center of the drum was placed a 2-cm sphere containing pure CCl4, whose density was varied from 10% to 100% of normal density (1.59 g/cm3). The gamma-ray production rate has been plotted as a function of CCl4 density for each energy group and time window plotted. To more clearly illustrate the effect self-shielding has on gamma-ray production from different neutron groups, gamma-ray production rates have been normalized to those observed at the lowest density of CCl4 considered.

Fig. 1.

With a thermal-neutron cross section for Cl of ~33 b, the CCl4 suffers significant self shielding from thermal neutrons, even with CCl4 at only 25% of full density. Yet due to their smaller absorption cross section, higher-energy neutrons existing at <1 s are nearly unaffected by changes in CCl4 density. Cross sections for many elements vary inversely as neutron velocity at low energies, with strong resonances often appearing in the range up to ~1 keV. By comparing production rates of secondary radiations in different time windows with known cross section variations as a function of energy, the effective degree of self-shielding can be determined. Thermal-neutron-induced responses provide good sensitivity to small amounts of material, while systematic errors associated with self-shielding can be corrected for larger quantities of material by considering responses from higher-energy neutron groups.

An important complication to the shielding correction just described is presented by the presence of H. With mass virtually the same as that of the neutron, and a thermal-neutron elastic-scattering cross section of ~80 b, the H distribution in the sample strongly affects both the neutron energy spectrum and spatial distribution. Fortunately, the 0.33-b thermal-neutron capture cross section provides an intrinsic gauge of these effects. Because capture gamma-ray production from H occurs in exactly the same places that the probe neutrons are being moderated, these gamma-ray signals are a sensitive monitor of the local degree of moderation. In general, increasing H in the sample may either increase or decrease the total production rate for secondary radiations, but by monitoring thermal neutron capture from H itself, the degree to which this occurs can be determined. In particular, 2.2-MeV H gamma rays observed at early (e.g., <1 s) and late (e.g., > 200 ms) times reveal the net local effects of moderation and absorption. The effective degree of moderation determined from these responses can be applied as a correction to other capture gamma-ray signals measured concurrently. This is especially true for elements whose cross sections vary in the same 1/v manner as H. After correcting for the local H distribution, residual corrections may be applied for matrix absorption and self shielding effects, as described above.

CONCLUSIONS

Pulsed Fast Neutron Analysis is capable of mapping many elemental distributions. In principle, such maps provide a very complete basis for detailed predictions of neutron and photon transport. While such models can be valuable for accurately correcting matrix effects, other measurements may be performed on a PFNA platform to yield assay results relatively insensitive to moderation and self-shielding. PTNA

measurements are based on observations of secondary radiations in different time windows following a neutron pulse. By observing the time-dependent evolution of capture gamma rays from H as well as the secondary radiations from other elements of interest, differences in neutron energy spectrum and reaction cross sections make possible corrections for each of these effects in a heterogeneous matrix. By modulating the typically uniform pattern of PFNA pulses into "macropulses," PFNA measurements can be performed concurrently with such PTNA measurements, despite the much different time scales associated with the processes being measured in each case.

ABSTRACT

A full-scale integrated technology demonstration of a polyethylene encapsulation process, sponsored by the U.S. Department of Energy (DOE) Office of Technology Development, was conducted at the Environmental and Waste Technology Center at Brookhaven National Laboratory (BNL) in September 1994. Polyethylene encapsulation has been developed and tested at BNL as an alternative final waste form technology for improved treatment of low-level radioactive (LLW), hazardous and mixed wastes. A fully equipped production-scale system, capable of processing over 900 kg/hr (2,000 lb/hr), has been installed at BNL. The demonstration covered all facets of the integrated processing system including pre-treatment of aqueous wastes, precise feed metering, extrusion processing, on-line quality control monitoring, and process control.

INTRODUCTION

Following over 10 years of bench-scale research, development, and testing at BNL, the polyethylene encapsulation process was successfully demonstrated at production-scale during a Technology Demonstration sponsored by the U.S. Department of Energy's Office of Technology Development on September 13 and 15, 1994. Over 80 attendees representing DOE and the private sector participated. Figure 1 is a photograph taken during the demonstration. Simulated aqueous nitrate salt waste representing actual wastes at Rocky Flats Plant and a generic DOE mixed waste ash surrogate were processed. All aspects of the fully integrated system required for successful processing were included in the demonstration. Pre-treatment of the aqueous waste surrogate was accomplished using a vacuum dryer system marketed by VECTRA Technologies, Columbia, SC. Quality assurance monitoring of the waste and binder ratios was conducted using a transient infrared spectrometer (TIRS) developed at Ames Laboratory.

Fig. 1.

BACKGROUND

Polyethylene is a thermoplastic material with a relatively low melting point that can be processed at temperatures of 130 - 150C. Low temperature processing minimizes volatilization of hazardous constituents in waste streams and reduces the need for complicated off-gas and secondary waste treatment. Micro-encapsulation is accomplished when waste material is mixed with molten polyethylene and allowed to cool. Process development studies at BNL with polyethylene encapsulation have shown

successful process applicability to a wide range of waste types including nitrate salts and other evaporator concentrates, sludges, blowdown solutions, incinerator ash and ion exchange resins. Waste form performance has been thoroughly investigated (1,2,3) and, in general, is well above minimum requirements specified by the Nuclear Regulatory Commission (NRC) (4,5) and the Environmental Protection Agency (EPA) (6). Waste can be encapsulated with greater efficiency (i.e. more waste encapsulated per drum) and with better waste form performance using polyethylene than is possible with conventional solidification agents like cementitous materials. For example, polyethylene can incorporate up to 70 dry wt.% evaporator salt concentrates compared with a maximum of 12 dry wt.% for the best hydraulic cement formulation (7). Accounting for differences in waste form densities, polyethylene achieves at least a four-fold improvement (by weight) in the amount of waste incorporated per disposal drum.

PROCESS DESCRIPTION

The BNL polyethylene encapsulation process utilizes a versatile, industry tested, modified single-screw plastics extruder. Dry waste and polyethylene binder are continuously fed to the extruder by individual dynamic feeders. Distributive mixing within the extruder produces a homogeneous molten mixture that is extruded directly from the die into a waste container, such as a 208 liter (55 gal.) drum. The waste container is allowed to cool forming a solid monolithic waste form.

Based on bench-scale successes of the polyethylene encapsulation process with a range of waste types, scale-up to a full-scale encapsulation system that would match production capacity at a typical DOE treatment facility was planned. The BNL Demonstration and Full-Scale Test Facility encompasses a fully integrated encapsulation process including waste pre-treatment, material conveying, precise metering of feed materials, extrusion processing, and process control. Figure 2 is a photograph of the full-scale facility.

Fig. 2.

A nitrate salt solution (evaporator concentrate containing 35 wt.% dissolved solids) and a mixed waste ash were prepared and used as surrogate DOE waste streams for the demonstration. The composition of the nitrate salt waste surrogate is given in Table I. Wastes containing residual moisture require pre-treatment to bring them to dryness prior to encapsulation. Pre-treatment was accomplished using an indirect heated, stirred vacuum dryer. This technique was proven during bench-scale research and development and scale-up feasibility testing to produce free-flowing dry powders with less than 1% moisture that were amenable to extrusion.

A production-scale Liquid Volume Reduction System (RVR-200) was supplied by VECTRA Technologies, Inc., Columbia, SC. The blender/dryer portion of the RVR-200 can be seen on the right hand side of the photograph in Fig. 1. Dryer capacity is 757 liters/day (200 gal./day) equating to 408 kg (900 lbs.) dry salt/day for the nitrate salt surrogate containing 35 wt.% solids. The dryer was specially fabricated for the BNL Full-Scale Test Facility and incorporates design features to allow flexibility in testing various wastes. The liquid is charged to the vessel through a top port and discharged through a bottom 152 mm (6 in.) diameter, pneumatically operated ball valve, into a variable speed grinder to reduce particle size. The final product is emptied to 208 liter drums maintained under negative pressure to prevent powder dispersion.

Material feed is accomplished with two dry material feeders (AccuRate Model 610, Whitewater, WI) converted to a loss-in-weight (LIW) system (Merrick Industries Model 510, Lynn Haven, Fl). This system delivers accurate predetermined mix ratios of waste and binder to the extruder. The LIW control system consists of three computer controllers arranged in a feedback loop: a master controller that specifies the total feed rate and two slave controllers, one for each feeder, which calculate their respective feed rate as a fraction of the total feed rate depending on the waste/binder ratio. "Pacing" software allows the master controller to decrease the master reference feed rate if an underfed condition is sensed by either individual feeder. The master reference signal will decrease until both feeders can satisfy the lowered demand. The accuracy of a LIW system is better than 1% deviation from setpoint.

Waste and binder are dynamically fed to a 114 mm (4.5 in.) production-scale extruder (Davis-Standard, Pawcatuck, CT) with an output capacity of 900 kg/hr (2,000 lb/hr). The extruder is equipped with five electrically heated and water cooled zones and two die zones. Solid state differential thermocouple controllers maintain

temperatures to within 1C. Zone temperatures and pressures, melt temperature and pressure, current draw, and screw speed are constantly monitored.
An on-line monitor to provide real-time waste composition data for the polyethylene/waste melt as it is extruded has been developed at Ames Laboratory (8). The monitor is based on a technique known as transient infrared spectroscopy (TIRS). The monitor is installed at the end of the extruder and operates by inducing a small temperature differential on the surface of the extruded melt, reading the infrared spectra, then providing computerized analysis to convert the spectra to a waste composition. A photograph of the Ames TIRS system is shown in Fig. 3. By calibrating the monitor with spectra for known waste loadings, the instrument provides real-time data on the actual waste loading of encapsulated waste exiting the extruder. The TIRS system can be used to continuously check for any variations in the waste/binder ratio and provide on-line quality control data. If a significant variation is detected, immediate corrections can be made to the waste/binder feed ratio.
Fig. 3.
An open-loop, integrated process control and data acquisition system coordinates material feeding and extrusion processing. Process control is accomplished with computer software (LabVIEW for Windows, National Instruments, Austin TX) installed on a standard IBM compatible PC. The process control computer monitors the extruder output rate by weighing the quantity of material exiting the extruder. A low-profile scale located under the drum being filled sends a signal to the process computer via an RS-232 serial port. This signal is converted to an output rate by the process control software which, in turn, sends a 0-10 V signal to the Loss-in-Weight Master Controller as the updated total feed rate. This method allows the feed rate to match the output rate. Other process parameters, such as extruder zone temperatures and pressures, can be acquired and stored for future quality assurance.
Confirmation testing was conducted on the final waste form products from the full-scale demonstration for QA/QC monitoring and waste form performance. Core samples were taken from the final waste forms to test compressive yield strength as a measure of mechanical integrity, and for density measurements to check homogeneity of the waste and polyethylene binder. Compressive yield strength data for waste forms containing 30, 40, 50, and 60 wt% nitrate salt waste are represented graphically in Fig. 4 and range from 2150 psi to 2420 psi. Waste form density as a function of waste loading is given in Table II. Compressive strength and density results closely resemble data previously measured for laboratory-scale specimens (7).
Fig. 4.
CONCLUSION
The successfully completed production-scale technology demonstration at BNL has shown that polyethylene encapsulation is a viable new process for treatment of many problem mixed waste streams within DOE and the commercial sector. Over the past 10 years, it has progressed from proof-of-principle through bench-scale testing to production scale technology demonstration. The full-scale system at BNL's Environmental & Waste Technology Center complements a fully equipped process development and testing facility for investigating encapsulation technologies for various waste streams. Successful integration of waste pre-treatment, feed metering, extrusion processing, on-line monitoring, and process control during the production-scale demonstration provides necessary confirmation of process viability prior to "hot" testing with actual wastes. A full-scale field demonstration of a mobile polyethylene encapsulation system using actual mixed waste is currently planned. The polyethylene encapsulation process will then be ready for implementation within the DOE complex and the commercial sector.

ENCAPSULATION/SOLIDIFICATION OF TRITIATED WASTE WATER USING POLYMERS AND POLYMER IMPREGNATED CEMENTS

J. Heiser

P. Kalb
Brookhaven National Laboratory
Building 830
Upton, NY 11973

ABSTRACT

Tritium, especially in the form of tritiated water, is extremely mobile and no suitable treatment currently exists. Brookhaven National Laboratory has developed methods of stabilizing tritiated water in polymer impregnated cements (PIC) in which a porous (cement) waste form is first prepared, solidifying the waste material. The cement or concrete waste form is then impregnated with a thermosetting resin, and the resin is cured in place. The open porosity of the cement becomes filled with polymer, and, as a result, water infiltration and leach pathways are reduced. Other thermosetting polymer systems were also investigated including water extendible polyester styrene (WEP) for the stabilization of low concentration tritiated liquid waste streams. The water extendible polyesters were also used with a water absorbing starch polymer additive.

Tritium leachability from polymer impregnated or encapsulated forms relative to ordinary Portland cement (OPC) waste forms was used to determine performance. The effective diffusion coefficients (De) were calculated from the release rates. For the baseline OPC the De was 3.6x10-8 cm2/sec. De for the polymers were 3.5x10-9, 1.4x10-9, 1.2x10-9 and 9.7x10-10 cm2/sec for the PIC with a high alumina cement, the PIC with OPC, the WEP with starch polymer addition, and the plain WEP respectively. With the low activity waste, the baseline PC had reasonable performance by itself. Performance gains were 10 times for the high alumina cement-PIC, 26 times for the OPC-PIC, 30 times for the WEP/starch and 37 times for the WEP.

INTRODUCTION

During FY94 Brookhaven National Laboratory (BNL) was contracted by the Department of Energy's Office of Technology Development to perform mixed waste treatability studies using alternative polymer waste forms. Included in these studies was the encapsulation/solidification of liquid waste contaminated with low levels of tritium. Tritium, especially in the form of tritiated water, is extremely mobile and no suitable treatment currently exists.

In the mid-1960's to mid-1970's BNL developed and patented methods for tritium fixation using polymer impregnated waste forms (1). Polymer impregnated cement (PIC) waste forms are typically prepared in a two-step process. A porous waste form was first prepared, solidifying the waste material. Tritiated water was fixated as either a cement hydrate or adsorbed on a material such as silica gel incorporated in a cement matrix. The second step involved impregnating the cement or concrete waste form with a thermosetting resin, then curing the resin in place. The open porosity of the cement becomes filled with polymer, and, as a result, water infiltration and leach pathways are reduced. Tritium fixation was demonstrated by measuring laboratory leach rates in water. Full scale lysimeter testing was conducted at the Savannah River Site. Resin impregnated concretes were investigated in Japan for

waste containers and the composites thoroughly characterized (2). The method proved reasonably successful and resulted in waste forms of greatly reduced leachability and enhanced durability. Current concerns about the safe disposal to tritiated waste have lead to the re-investigation of this method as well as examining some of the newer polymers such as water extendible polyester styrene.

The tritium waste water treated in the earlier studies contained high levels of tritium (curies/L). The cost of tritium has since lead to improved recovery methods and the levels of tritium in liquid waste streams has been greatly reduced. The performance advantage of polymer impregnated cement may not be as great if the tritium source term is low. BNL investigated the use of polymer impregnated cement (PIC) for the stabilization of low concentration tritiated liquid waste streams. The waste stream used was tritiated cooling water, containing 50,000 picocuries/mL tritium, obtained from the High Flux Beam Reactor at Brookhaven National Laboratory. In addition to PIC a water extendible polyester styrene (WEP) was also investigated. Polyester resins are a commonly used family of thermosetting resins. By adding an emulsifying agent the resins can be made compatible with water. The water ends up encapsulated in tiny microcells evenly dispersed through out the polyester-styrene polymer.

FORMULATION

A PIC is made by impregnating a cement or concrete form with a liquid resin and then curing the resin in place. This fills the void space of the cement with polymer and reduces leaching pathways. Typical resin systems that can be used for the impregnation include; polyester-styrenes, methacrylates, furfuryl alcohol, etc. Several methods of curing the resins can be employed. Curing is a chemical reaction that results in the polymerization of the monomer. Polymerization can occur through gamma irradiation, at elevated temperatures using a thermally activated initiator, and at room temperature using a catalyst promoter combination. The latter two are preferred for polymer impregnation.

The polymerization of unsaturated monomers such as methacrylates and polyester-styrene is typically a chain reaction. Polymerization can be initiated by the action of a free radical on a monomer molecule, which leads to polymer chains consisting of thousands of monomer molecules. Free radicals can be formed by the decomposition of a relatively unstable material called an initiator or a catalyst. Peroxides are commonly used as initiators. The peroxide molecule splits at the O-O bond and when subjected to heat or in the presence of a promoter, forms two free radicals that have unpaired electrons and, thus, are very reactive.

Promoters can be used instead of temperature for ambient temperature curing of catalyzed monomer systems. Promoters (also called accelerators) are chemical compounds that induce the decomposition of a peroxide catalyst by breaking the O-O bond. This reaction can take place at a wide temperature range, depending on the promoter-catalyst system used.

Cure time is dependent upon temperature, promoter-catalyst combination and concentration, and admixtures (or contaminants) that may retard or enhance the set. Gel times (the time after which the resin viscosity increases rapidly and can no longer be poured or worked) were set at 3 hours for this study. Gel times can be manipulated easily by the resin manufacturer or the catalyst-promoter supplier. The reaction is exothermic and results in an autoaccelerating reaction that must be properly controlled.

Using a thermally activated initiator allows the greatest degree of freedom during the impregnation step. The waste form can be immersed in the liquid for as long as necessary to achieve full penetration of the form by the resins. Once the form is fully saturated the resin can be cured by heating the waste form. Thermally activated initiators exist that can be activated at low temperatures (~50C). With room temperature cures that require a promoter-catalyst combination the reaction begins as soon as the combination are brought together. This results in the resins having a limited "pot-life" or time that they remain at low viscosity and can still be used for impregnation. The waste form impregnation must be completed prior to the gel-time of the resin.

A methacrylate resin system was selected to fabricate the laboratory samples. Methacrylate monomers (acrylic) are a low viscosity, commonly used, family of polymers. A methacrylate resin manufactured by the 3M Company (3M 4R Concrete Restorer) was used. It is a modified high-molecular weight methacrylate (viscosity = 5-10 cps). The system consists of dicyclopentadienyl methacrylate and isooctyl

acrylate. Room temperature polymerization is accomplished using a cobalt octoate promoter (reducing agent) and cumene hydroperoxide initiator (oxidative catalyst). The resin was polymerized using a promoter-catalyst combination that yielded a 180 minute pot-life. Since the laboratory samples were small (3 to 20 cm) the impregnation time was low and samples were cured at room temperature without concern about impregnation and gel times.

The initial step in the PIC process is the preparation of the cement-based waste form. In previous BNL studies, a water to cement ratio of 0.2 was used which is below the theoretical value required to fully hydrate the cement. By using less water than required for hydration, all free tritiated water will be bound to the cement. The low water to cement ratio results in a dry paste that has to be vibrated (or tamped) into a mold. This also results in a more porous waste form that is more easily impregnated with the resin. BNL investigated ways of reducing the porosity of the initial cement form and pumpability of the cement paste. Lower porosity would result in slightly higher waste loadings and increased performance of the cement matrix in terms of leaching but would make impregnation more difficult. Increasing the pumpability or workability of the paste would result in reduced processing by eliminating the vibration compaction or tamping step. A super plasticizer was added to the paste to increase slump (more fluid) at the same water to cement ratio. The paste was molded into 10 cm diameter by 20 cm length cylinders and allowed to cure for 24 hours. The resultant waste form was apparently very low porosity, judged from microscopic inspection. A simple resin soak method of impregnation was not deemed feasible for such a low porosity matrix. To increase the depth of penetration into the sample a vacuum impregnation technique was attempted. The specimens were placed in a vacuum chamber for 6 hours to remove the air from the pore structure. Resins were then introduced, while maintaining the vacuum and the sample allowed to soak. After one hour the vacuum chamber was brought to ambient pressure, the samples were allowed to soak for an additional hour and then placed into sealed plastic containers and allowed to cure. After curing, the samples were cross-sectioned and the depth of penetration determined. The resins could only penetrate 2-3 mm into the cement matrix (see Fig. 1). The addition of pressure above ambient during the second soak phase did not increase the depth of penetration. Specimens of the higher porosity, low-slump cement which had high porosity were impregnated by placing specimen in a vat of resins for 2 hours after which they were transferred to plastic containers, sealed and allowed to cure. Cross-sectioning of these samples showed complete penetration of the resin into the sample. From these results it was apparent that the higher porosity cements had a great advantage over the lower porosity pastes during the impregnation process. All laboratory test specimens were prepared using a 0.2 water to cement ratio and no slump increasing additives.

Fig. 1.

SAMPLE PREPARATION

BNL fabricated bench scale samples of tritium encapsulated in ordinary Portland cement, PIC or WEP. Five lots of samples were prepared consisting of a baseline of portland cement, two types of PIC, and two formulations of WEP. The baseline was made by mixing tritiated water with type II Portland cement. The water-to-cement ratio was 0.35, a typical value used to make a workable cement paste. The cement paste was mixed in a conventional mixer for 2 minutes and the mix poured into a cylindrical mold and vibrated for 30 seconds. The cement was allowed to cure for thirty days before testing. The samples had average densities of 1.95 g/cm3. The final waste form contained 19,500 picocuries/cm3 (10,000 picocuries/g).

PIC samples were made by mixing tritiated water with either Portland type II cement (PC) or a high alumina cement (HAC) [Secar 80, LaFarge Corp., high calcium aluminate]. The water-to-cement ratio was 0.2 for all PIC samples. The paste was allowed to cure for 48 hours and removed from the mold. Waste forms were fabricated using the room temperature curing techniques described earlier. The resin and catalyst were premixed together prior to introducing the waste form. The sample was then immersed in the resin to allow the resin to infiltrate and fill the pore structure of the waste form. The gel time was set to be approximately three hours. The cement form was immersed for 2.5 hours, removed from the resin, replaced into the sample mold which was then capped and the final waste form was allowed to cure. All waste forms were fully impregnated, as verified by cross-section analysis of sample waste forms prepared with non-tritiated water. Waste form bulk density, before and after resin impregnation, and weight of resin absorbed during

impregnation were measured as a matter of process control. The PC-PIC samples had an average density of 1.78 g/cm3 and used 20 % (by weight) resin. The HAC-PIC samples had an average density of 1.88 g/cm3 and required 15.3 % resin for impregnation. The final waste forms contained 23,500 picocuries/cm3 (13,250 picocuries/g) for the PC based PIC and 26,300 picocuries/cm3 (14,000 picocuries/g) for the HAC based PIC.
The resin was a high molecular weight acrylic (3M4R 5742) manufactured by the 3M Company. The resin was purchased unpromoted and required the addition of a promotor (cobalt octoate) and an initiator (cumene hydroperoxide) for polymerization to occur. Once the initiator is added the polymerization reaction begins. The useful working time of the resin is about 90% of the final gel time. After this time the viscosity increases to a point that further impregnation is not possible. The gel time was set at three hours by varying the promotor/catalyst ratio. [It must be stated that the initiator and promotor are not to be added together or a violent reaction will occur. The promotor is added to the resin, thoroughly mixed and then the initiator may be added. The promotor can be added in advance, and the prepromoted resin has a shelf life of up to six months.]
There are several methods which can be employed to facilitate the impregnation of the cement paste. The simplest is to immerse the waste form in the resin at ambient pressure. This is suitable for high porosity materials or thin sections were depth of penetration is not limiting. Another way of impregnating introduces the resin to the form under vacuum. The vacuum is used to remove the air in the pore structure of the waste form which impedes resin flow into the pores. Much greater depth of penetration can be obtained this way. A final method of impregnation follows the vacuum technique but after the form is fully immersed in the resin, the system is pressurized to force the resin further into the sample. For the bench scale samples which are of limited diameter, the least complicated technique of immersion at ambient pressures was chosen.
The WEP samples were made by mixing tritiated water with an emulsifiable polyester styrene resin using a high shear mixer. The resins (Aropol WEP 662P) were obtained from Ashland Chemicals, Inc., prepromoted with cobalt and were initiated with methylethylketone peroxide. Two lots were prepared; the first lot of WEP had no additives, the second lot contained 0.2 % (by weight of WEP resin) of an absorptive starch polymer. The starch polymer was capable of absorbing 400 times its weight in water and was added as a dry powder to the WEP resin. It was hoped that the starch polymer would help hold the water more tightly in the waste form. The resin manufacturer recommends a maximum water content of 50%. For both lots the water content was 32% of the resin by weight (24% of the weight of the final waste form). The water was slowly added to the resins while the shear mixer was running. After complete addition of the water, mixing was continued for one minute, the MEKP catalyst was added and mixing continued for an additional thirty seconds. The mix was then poured into cylindrical molds and allowed to cure. Gel time of the resins was approximately five minutes. The polyester based samples had average densities of 0.99 g/cm3 for the plain WEP and 0.98 g/cm3 for the WEP containing the starch polymer. The final waste forms contained 24,500 picocuries/cm3 (24,800 picocuries/g) for the plain WEP and 24,500 picocuries/cm3 (25,000 picocuries/g) for the WEP and starch polymer.

WASTE FORM PERFORMANCE EVALUATION

Tritium leachability from polymer impregnated or encapsulated forms compared with ordinary Portland cement (OPC) waste forms was used to determine performance. Leaching of these samples was performed following the Accelerated Leach Test. This standard method, developed at BNL (3), predicts a sample leach rate provided data fits a diffusion controlled model. Samples tested were nominally 3.0 cm in diameter and 3.0 cm in length. The test involved 13 leachant changes over an 11 day period. The volume of leachate was modified from 3.0 liters to 0.5 liters to achieve reasonable count rates. Since the contaminant is tritiated water and the leachate is water there will be no concentration effects and the change in leachate volume has no effect on the test results. Specimens were suspended using monofilament fishing line approximately into the center of each solution. Duplicate samples were leached at 20C. Tritium concentrations were determined by liquid scintillation counting.
The effective diffusion coefficients (De) were calculated from the release rates (Table I). Figure 1 shows the cumulative fraction leached as a function of time for each of the solidification methods. For the baseline OPC the average De was 3.6x10-8 cm2/sec. Average De for the polymers were 3.5x10-9, 1.4x10-9, 1.2x10-9 and 9.7x10-10

cm2/sec for the PIC with HAC, the PIC with PC, the WEP with starch polymer addition, and the plain WEP respectively. With the low activity waste the baseline PC had reasonable performance by itself. Performance gains were 10 times for the HAC-PIC, 26 times for the PC-PIC, 30 times for the WEP/starch and 37 times for the WEP. The difference in leach rates of the PC-PIC and HAC-PIC is probably due to the lower polymer loading of the HAC forms. Leach rates appear to be in line with polymer content with pure polymer being lowest. The diffusion of tritium through the polymer is likely the rate determining step (diffusion occurs at a slower rate than the exchange of tritium between bound and unbound water molecules). Figure 2 graphically depicts the relationship of polymer loading to effective diffusion coefficient. As the amount of polymer in the waste form increases, and hence the wall thickness of the diffusion barrier increases, the leach rate appears to decrease.

TABLE I

Fig. 2.

Fig. 3.

CONCLUSIONS

In terms of leachability of tritium pure polymer (WEP) performed slightly better than waste forms containing 20% polymer (PIC) and much better than plain portland cement (OPC). The final choice of stabilization/solidification method will depend on the waste form performance requirements, cost and processing requirements. The processing and cost are lowest for the OPC and for low concentration waste streams the performance may be adequate. As the waste stream concentration (of tritium) increases the performance of OPC is expected to be greatly reduced. Where high performance is required the polymer systems may be more suitable. The performance differences for the WEP and PIC were not that great and as such a compromise must be made between material cost of the polymers and processing costs. Thermosetting polymer resins cost vary from $0.60/lb for common polyester-styrene resins to $6.00/lb for specialty resins. For polymer impregnation commonly available, low cost resins can be used. The cost of these should range from $0.60/lb to $1.00/lb. For the pure polymer system with aqueous waste a water extendible resin must be used and these are generally more expensive ranging from $1.50/lb to $3.00/lb. Choosing a 55 gallon drum and using the densities and formulations of the laboratory samples results in the following requirements: OPC waste forms use 662 lbs of cement; WEP waste forms use 345 lbs of polymer resin; and PC-PIC waste forms use 544 lbs of cement and 163 lbs of polymer resins. Assuming $0.05/lb for cement, $0.60/lb for resins for PIC and $1.50/lb for WEP resins results in a materials cost of $33 for OPC, $125 for PC-PIC and $517 for WEP. Processing for OPC and WEP are simple mixers; standard cement or in drum mixers for OPC and a high shear mixer for WEP. Both systems are commercially available. For the PIC a multi-step process is required; mixing and curing of the cement followed by impregnation which may require an evacuation step for 55 gallon drum scale. The additional cost (capital, maintenance, and operations) of these added steps must be considered.

PROPOSED WASTE FORM PERFORMANCE CRITERIA AND TESTING METHODS FOR LOW-LEVEL MIXED WASTE*

ABSTRACT

Proposed waste form performance criteria and testing methods were developed as guidance in judging the suitability of solidified waste as a physico-chemical

barrier to releases of radionuclides and RCRA regulated hazardous components. The criteria follow from the assumption that release of contaminants by leaching is the single most important property for judging the effectiveness of a waste form. A two-tier regimen is proposed. The first tier consists of a leach test designed to determine the net forward leach rate of the solidified waste and a leach test required by the Environmental Protection Agency (EPA). The second tier of tests is to determine if a set of stresses (i.e., radiation, freeze-thaw, wet-dry cycling) on the waste form adversely impacts its ability to retain contaminants and remain physically intact. In the absence of site-specific performance assessments (PA), two generic modeling exercises are described which were used to calculate proposed acceptable leach rates.

INTRODUCTION

The U.S. Department of Energy (DOE) is developing processes and systems for the treatment and disposal of radioactive and hazardous mixed wastes accumulated during decades of weapons production and other operations. The treatment and disposal of these wastes has to be performed in a way that minimizes exposure to operational personnel, assures the health and safety of the public, and protects the environment from the risks associated with the release of hazardous chemical and radioactive components from the waste. These wastes must be managed also according to applicable State and Federal regulations, as well as DOE orders.

There is no single set of regulations which governs the treatment and disposal of all of DOE's low-level mixed waste (LLMW), although in 40 CFR Part 268.42 the EPA has identified technology-based treatment standards for a limited number of mixed wastes. Management of the chemically hazardous component of mixed waste must meet EPA regulations in accordance with the requirements of the Solid Waste Disposal Act, as amended by RCRA in 1976, and the Hazardous and Solid Waste Amendments Act of 1984. In cases where the state's regulations are more stringent than EPA's, the state's regulations prevail, according to the Federal Facility Compliance Act of 1992 (FFCA). The management of the radioactive components of the waste is governed by the guidance in DOE Order 5820.2A, Chapter III, Management of Low-Level Waste. If the waste is to be transported, it must meet the Department of Transportation and State transportation requirements.

The first barrier to releases of contaminants after disposal in a multiple barrier system is the solidified waste form. In the past, waste form characteristics were considered to be of secondary importance to the hydrogeochemical characteristics of the disposal site. Experience gained in operating low-level waste (LLW) disposal sites has made it apparent that waste forms play an important role in isolating the radioactive and other toxic components of the waste. Degradation of waste forms in disposal has resulted in releases of the contaminants from the disposal units into the environment. Also, poorly solidified waste forms, due to chemical and mechanical instabilities, have resulted in incompletely solidified waste unsuitable for disposal, thus requiring reprocessing at additional cost.

In order to judge whether or not the waste form will retain the hazardous components, waste form performance criteria are necessary. Such criteria, related specifications and test methods will allow comparison of technologies for treatment systems, demonstrate regulatory compliance, introduce uniformity into waste form comparisons across the DOE complex, improve quality control, help predict long-term waste form performance, and generate data for input to models for site performance assessment. The criteria and testing methods proposed here provide guidance for those developing and testing waste forms.

WASTE FORM PERFORMANCE CRITERIA AND PERFORMANCE ASSESSMENT MODELS

Waste form performance criteria are meant to provide some level of assurance that the treated waste will perform as expected over a defined period of time. To establish the necessary level of performance the waste form must be viewed as part of the entire waste disposal system; including components such as the engineered structure, the container, the geochemistry of the site and its climate. After estimates have been made quantifying the various components of the disposal facility and its environment, a performance assessment (PA) model can be used to estimate the dose that would be received as a result of disposal under the assumed conditions. By varying the quantities used to describe individual functions or performance, the PA model can be used as a tool that provides, within rather broad ranges, an assessment of how the various components of the disposal system interact to alter the final dose estimate. Waste form performance, in the sense of release rates, is a major

factor in the performance of the system. While it is desirable to use PA models developed for site-specific applications to develop criteria for each site, those PAs are several years away. Meanwhile, there is an urgent need within DOE to develop generic criteria so that waste treatment processes and site designs can proceed and be tested against the criteria.

To establish leach rate guidelines for use in the waste form performance criteria (Tables I and II), two sets of PA modeling exercises were used. Each set included two generic sites, humid and arid. One set was conducted for radionuclides by IT Corp (1). for the DOE Mixed Waste Treatment Project and the other for RCRA metals by Brookhaven National Laboratory (2). Similar methods and assumptions were used. However, the regulatory criteria for the two are different. For the radiological modeling an effective dose equivalent of 25 mRem/year (DOE Order 5820.2A) is used as the pass/fail limit. For RCRA metals the limit that was chosen is a metal concentration that is 100 times the EPA drinking water standard in ground water at the bottom of the disposal trench (3).

Results from the radiological assessment indicate that the major contributors to the dose at a generic site are 238U and its daughters, 228Ra, and 99Tc. The generic PA model for a humid site uses a release rate for the waste form of 8.12 x 10-6 per year (8 parts per million per year), which yields an effective dose equivalent greater than the DOE limit. For an arid site, the same waste form release rate results in an annual effective dose equivalent that is below the DOE limit. It is the inventory, the geochemistry and the hydrology of the site that control doses over long times (>1000 years). Considering the large uncertainties of the estimated doses, and the fact that release rates measured in the laboratory test procedures are conservative since the tests expose the waste form to far more water than a disposal environment, we have chosen a maximum leach rate of 10-5 per year as a reasonable generic value for wastes containing long-lived or high toxicity radionuclides. This value is subject to change if site-specific PAs show that site characteristics will accommodate higher (or require lower) leach rates.

These results, as well as those from work at Savannah River Site (SRS) (4), indicate that the radionuclides that have the greatest impact are those with long half-lives and some of the daughters that are generated by their decay. It is evident that large quantities of U/Th wastes will result in significant long-term doses at humid sites, even for a waste form with a very low release rate. This is the result of the extremely long half-lives and the limited credit that can be claimed for the long-term performance of waste forms and engineered structures. Thus, for some radionuclides limits on inventory in the disposal facility are necessary.

The presence of long-lived radionuclides makes it clear that there needs to be an approach by which doses are attenuated, if not reduced in total, for the long-lived radionuclides. This can be achieved by requiring very low releases from the waste form. Radionuclides with shorter half-lives can be sequestered sufficiently long by the disposal facility to allow them to decay to levels at which there is little concern, assuming other features of the disposal facility perform as expected. As a result, very low leach rates only need to be required for long-lived (or high hazard) radionuclides, while short-lived radionuclides can be released at higher rates without increasing risk. This concept places emphasis on waste form quality (regarding release) where it is needed, while accepting a lower quality and, therefore, usually lower cost waste form when appropriate. This is reflected in the three levels of waste form performance in Table I. These three categories were determined by a method which includes calculation of a figure of merit (FOM) based on allowable limits of intake (ALI) (5), the half-life and a generic inventory of DOE LLW. This method is described in Ref. 2.

A similar argument can be made for non-radioactive hazardous constituents of the waste. Materials regulated under RCRA are found in an estimated 70,000 cubic meters of stored low-level mixed waste and in currently generated waste streams that have an annual generation rate of about 7700 cubic meters per year (6). From a preliminary review of the gross composition of mixed wastes (personal communication with Wayne Ross, Pacific Northwest Laboratory) approximately 2 weight % of the waste consists of lead, 1.9 weight % is chromium, 1.5 weight % is nickel, 0.02 weight % is mercury (all in one waste stream), 0.02 weight % cadmium (two waste streams) and 0.02 weight % beryllium (two waste streams). Releases of these materials must also be considered with respect to requirements in the DOE order regarding protection of public health and groundwater resources.

Unlike assessment of doses resulting from radionuclides, a PA is not required for RCRA constituents. However, to calculate what the guidelines should be for the limit on the release rate of RCRA constituents from the waste form, a PA method similar to the one described above for radionuclides was employed (2).
Assessments of releases from an underground disposal unit using the Disposal Unit Source Term (DUST) Code (7) were made for lead (Pb), chromium (Cr), and mercury (Hg). This was one of the codes which was used by IT Corp in the PA modeling discussed above. The DUST Code is a one-dimensional code that models the transport of contaminants from waste containers to the disposal unit boundary. The parameters were chosen to match as closely as possible the conditions used in the IT Corp. PA. The effects of several parameters were examined. Of greatest interest was the effect of a waste form's fractional release rate on contaminant concentration at the base of the disposal unit and how these concentrations differed at humid and arid disposal sites. Although it is certain that the water infiltration rate affects the fractional release rate, the intent was to examine the effects of varying conditions on contaminant transport by varying one parameter at a time. A second reason for the DUST modeling exercise was to see how concentrations of Pb, Cr, and Hg (which correspond roughly to potential dose exposures for radionuclides) changed as a function of time. A value one hundred times the EPA drinking water standard for the specific RCRA metals was used as a target (at the bottom of the disposal unit) concentration.
Waste form fractional release rates from 10-8 to 10-2 were used in the calculations. From this exercise release rate targets for waste form performance were developed that are not based on regulations, but on performance needed under a set of disposal conditions. While actual allowable release rates should be determined on a site-specific basis, this process allowed the setting of an annual release rate of 10-5/yr as a numerical guideline. The modeling indicates that at this release rate the groundwater concentrations below the trench slightly exceed the target concentration. However, the modeling is highly conservative, since it did not consider factors such as sorption by the soil and solubility limits of contaminants.
PROPOSED CRITERIA AND TESTS
The modeling results show that the fractional release rate is a prime consideration in assessing long-term performance of and subsequently developing criteria for mixed waste forms. The approach to developing the criteria presented in this paper is based on the following:
Release of contaminants by leaching is the single most important parameter by which the effectiveness of a waste form is judged.
The waste form should retain the original desirable qualities of the solidification agent.
Acceptable release rates of contaminants from waste forms are defined by analysis of releases from disposal facilities through Performance Assessment modeling.
Solidified LLMW contains <100 nCi/gm of TRU
Only inorganic RCRA hazardous components are addressed here. It is assumed that organics have been removed or destroyed in a pretreatment step or are below regulatory limits.
The waste form is a monolith.
Since we believe that the rate of release of contaminants from a waste form is the single most important parameter exhibited by the solidified waste, then leachability is the primary property against which a waste form is judged and, as such, is also used to assess the impact that several types of stress can have on the solidified product. Consequently, the first tier of tests includes a leach test required by EPA and a leach test designed to determine the net forward leach rate of the solidified waste. The first tier tests should be performed first to determine acceptability. Only on passing the given specifications for the leach tests should other tests be performed. The second tier of tests is designed to determine if a set of "assaults" on the solidified waste adversely impact its ability to retain contaminants and to remain physically intact. They are meant to be representative of potentially detrimental factors (either external to the waste form or as a result of internal processes such as irradiation). Some second tier tests are not appropriate for all materials and can be omitted for certain solidified wastes. This is left to the judgment of those doing the testing. However, it is important that all materials should be tested at least once with all of the second tier tests because the history of solidification processes is replete with surprise failures. In the case where

standard tests are not available, the following is suggested. For radiation stability, if a waste form is expected to be exposed to greater than 106 R over a period of 300 years, then it should be tested by irradiation with a source of high energy gamma rays. The total exposure should be equivalent to the total exposure that the waste form will accumulate over 300 years. For testing the stability in water, the samples should be immersed in distilled water for 90 days. In the case of testing for freeze/thaw stability, the apparatus and cycling schedule of ASTM B-553 (8) should be used at temperature ranges of 60C (3C) to -20C (3C). It is recommended that once nondestructive testing (NDT) has been developed for examining waste form integrity, it should be used to supplement or replace compressive strength methods in order to reduce the time and cost involved. A compilation of the proposed criteria and tests is presented in Table II and a more detailed discussion is presented in Ref. 2.

ABSTRACT
The Environmental Protection Agency (EPA) best demonstrated available technology under the Resource Conservation and Recovery Act (RCRA) for many hazardous wastes is incineration (1). However, public pressure has caused state and federal regulators to consider tightening emission standards on incineration units. Accordingly, the U. S. Department of Energy (DOE) Environmental Management (EM) and the Office of Technology Development are exploring alternatives to incineration to address the large amounts of existing hazardous and mixed waste. Thus, the purpose of this paper is to review washing technologies as an alternative to incineration.
Soil washing is the extraction of contaminants from excavated soil by mixing the soil with water, solvents, surfactants, or chelating agents (2). Soil washing is a combination of physical and chemical treatments performed on soil in an aqueous solution. It is often used as a size segregation technique with washing of fines from coarse soil. The process removes contaminants that reside in specific grain-size domains, separates the waste stream into "cuts", and focuses on treatment appropriate to the contaminant/grain-size relationship. Usually, heavily contaminated soils are treated several times in a multistage counter-current system. The contaminated water or solution is then treated for removal of contaminants.
Early development and implementation of soil washing technology was based primarily on the use of water as the extracting solvent (3). This process is most applicable in the remediation of soils containing highly water-soluble constituents or soils containing low concentrations of silt and/or clay particles. Currently soil washing processes include extraction media ranging from alkaline mixtures of ionic and nonionic surfactants and bioremediating agents to acid extractions. Early soil washing applications were for topsoil rather than for buried and otherwise stored waste, although some buried waste and contaminants would be amenable to this approach. Additionally, washing processes may provide added benefit for treatment of debris.
INTRODUCTION
The EPA best demonstrated available technology under RCRA for many hazardous wastes is incineration (1). It has been shown to be effective in meeting the destruction and removal efficiency requirements of RCRA and the Toxic Substances Control Act. However, public pressure has caused state and federal regulators to consider tightening emission standards on incineration units. In May 1993, EPA announced a de facto moratorium on the permitting of new incinerators until new emission standards are established. Accordingly, DOE-EM and the Office of Technology Development are exploring alternatives to incineration to address the large amounts of existing hazardous and mixed waste.
Approximately 250,000 m3 of mixed low-level waste (MLLW) is currently retrievably stored within the DOE complex (4). An additional 900,000 m3 of MLLW is expected to be generated through waste operations, environmental restoration, and decontamination and decommissioning activities over the next five years (1). Treatment capacity for the majority of these wastes can be described as: 1) no proven treatment technology exists, or 2) currently available technologies need extensive modification to be capable of treating radioactive waste. The existing MLLW matrices as a percentage of the total stored mixed waste are listed in Table I (5). Although the concentrated organic material requiring destruction is not large, organic compounds may be spread throughout these matrices in low concentrations.
Soil washing is the extraction of contaminants from excavated soil by mixing the soil with water, solvents, surfactants, or chelating agents (2). Soil washing is a combination of physical and chemical treatments performed on soil in aqueous solution. It is often used as a size segregation technique with washing of fines from coarse soil. The process removes contaminants that reside in specific grain-size domains, separates the waste stream into "cuts", and focuses on treatment appropriate to the contaminant/grain-size relationship. Usually, heavily contaminated soils are treated several times in a multistage counter-current system. The contaminated water or solution is then treated for removal of contaminants.
TABLE I
Early development and implementation of soil washing technology was based primarily on the use of water as the extracting solvent (3). This process is most applicable in the remediation of soils containing highly water-soluble constituents or soils

containing low concentrations of silt and/or clay particles (usually <15% smaller than 50 m). The EPA Superfund Innovative Technology Evaluation (SITE) program now includes soil washing processes using extraction media ranging from alkaline mixtures of ionic and nonionic surfactants and bioremediating agents that act as biosurfactants (6) to acid extractions for removing heavy metals from contaminated soils and solids (7). These processes represent a significant extension of existing soil washing techniques presently being used on a wide scale in Germany and the Netherlands.

Early soil washing applications were for topsoil rather than for buried and otherwise stored waste, although some buried waste and contaminants would be amenable to this approach. For example, if the contaminant is soluble and the contaminated surfaces are accessible (removed from bags and containers), it may be possible to decontaminate the bulk of such buried waste by washing, leaching and, extraction. Additionally, washing processes may provide added benefit for treatment of debris by envoking the debris rule (see Debris Washing).

EPA (8) has the following insights on soil washing:

"Soil washing is basically a volume reduction technology that uses wash water to separate contaminated soil into two fractions: a large fraction of relatively clean, coarse soil and a smaller fraction of fine soil/sludge containing the concentrated contaminants.''

"Hydrophobic contaminants can be difficult to separate from soil particles into the aqueous washing fluid.''

Complex mixtures of contaminants in the soil make it difficult to formulate a single suitable washing fluid that will remove all the different types of contaminants from the soil.

"A high percentage of clay and silt (e.g., >>30-50%) in the soil usually indicates that soil washing will be unfavorable due to the amount of time and money required to treat this volume of contaminated soil.''

"Chelating agents, surfactants, solvents, and other additives are often difficult and expensive to recover from the spent washing fluid and then recycle in the soils washing process.''

Identification of the contaminants is important. Volatile organics may require removal in a pretreatment step or treatment of air emissions. Solubilities of contaminants is important in deciding whether wash solution additives are needed. Metal speciation is important in metal solubility.

Soil particle-size distribution and chemical analysis of the contaminants are important characterization data for soil washing.

TECHNOLOGY DESCRIPTION

Soil washing technology is commercially available through numerous vendors. A search of EPA's Vendor Information Systems for Innovative Treatment Technologies (VISITT) data base, version 3 (9), identified 19 soil washing vendors with processes in various stages, from laboratory bench-scale to full commercial scale. Each soil washing vendor uses a slightly varied process train and/or reagents for removal of contaminants (10, 11, 12, 13). As reported by the vendors, these processes are in the following stages of development: three bench-scale, two pilot-scale, and 14 full-scale. Additionally, numerous soil washing demonstrations (including solvent extraction and debris washing) have been conducted as part of the EPA SITE program (14).

Soil Washing

Soil washing is an ex-situ process that incorporates size classification and vigorous scrubbing of soil particles with water to remove heavy metals or organic contaminants. Soil washing can be and has been used as a single-stage, stand-alone technology where applicable or coupled with other on-site remediation technologies to achieve desired final contaminant levels. In some cases, water-soluble surfactants, chelating agents, acids, or bases may be used to facilitate contaminant removal. Soil washing is based on the observations that: (1) contaminants tend to concentrate in the fine and organic fractions of the soil (e.g., silt, clay, humic matter) due to physical and/or chemical adsorption; and 2) contaminants associated with the coarse soil fraction (e.g., sand, gravel) are often present as a thin surface coating that can be removed by vigorous scrubbing and attrition of the soil particle surfaces (9) (Fig. 1) (15). Many soil contaminants, both organic and inorganic, tend to chemically or physically attach to the silt and clay fractions of the soil. The silt and clay, in turn, tend to attach to coarse sand and gravel

particles. The various processes used in soil washing break the silt and clay away from the coarser fractions and scrub the coarser fractions, resulting in clean sand. Fig. 1.
Thus, the objectives of the technology are: 1) to reduce the volume of soil that require further treatment or disposal by concentrating the contaminants, 2) to transfer the contaminants to a more easily treated aqueous phase, and 3) to produce a washed soil product that meets clean-up criteria.
A "basic" soil washing treatment system (Fig. 2) includes four major sub-systems: 1) screening (soil preparation), 2) washing, 3) soil and water separation, and 4) waste water and sludge treatment and management (9,16,17). Screening is employed to remove the oversized soil fraction. The initial process is accomplished with vibrating screens and then with attrition scrubbers. Water is then added, and the resulting slurry is separated into coarse-grained sands and fine-grained materials, typically by use of hydrocyclones. Underflow from the hydrocycLones contains the coarse-grained sands that require treatment, typically by air flotation. Surfactants may be added to the sand to aid in reducing the surface tension binding the contaminant to the particles (18). This allows the contaminants to "float." They are then removed by air flotation and forwarded onto sludge management. Overflow from the hydrocyclones contains the fine-grained, contaminated material. This fraction can then be either processed by an alternative technology or dewatered and disposed of off-site. The small volume of contaminated residuals are subsequently treated by appropriate destructive or immobilizing processes such as thermal desorption, chemical extraction, biodegradation, solidification, or vitrification. Sludge management typically requires additional treatment such as polymer addition, thickening, and dewatering. Cleaned soil may be either redeposited on-site or otherwise beneficially used as backfill or industrial sand. For MLLW, if soil is treated in such a way that the waste can be considered low-level waste, then the treated soil can be disposed of at an appropriate facility (e.g., Nevada Test Site). Process water is cleaned of contaminants and recycled for further use in the system. Fig. 2.
Other variations to soil washing technology include debris washing, solvent extraction, solvent washing, and in situ soil flushing. General descriptions of debris washing and solvent extraction are presented below. Solvent degreasing was used successfully at the Oak Ridge K-25 site, but its use was stopped in order to avoid exposing the workers and the environment to the hazardous solvents. In situ soil flushing has been demonstrated and consists of water or an aqueous solution, injected into, or sprayed onto, the area of contamination and the contaminated elutriate collected and pumped to the surface for removal, recirculation, or on-site treatment and reinjection (2). During elutriation, the flushing solution mobilizes the sorbed contaminants by dissolution or emulsification. Handling and treatment of the elutriate are required, and delivery and recovery systems are needed. Medium-solubility organic compounds and soluble salts are the most likely contaminants to be treated.
Debris Washing
Sludge and debris washing technologies are similar to soil washing, but typically require additionally stages for screening, mixing, and scrubbing, as well as variations within the stages (e.g., sorting, high-pressure washing, solvent treatment). Debris is defined by EPA as a solid material exceeding a 60-mm particle size that is intended for disposal and that is: 1) a manufactured object, or 2) plant or animal matter, or 3) natural geologic material (19). Further, any mixture where the debris portion comprises the largest amount of material present by volume as determined by visual inspection is classified as debris. The Hazardous and Solid Waste Amendments to RCRA allow hazardous wastes to be land-disposed only if they are treated or can be land-disposed in units satisfying the so-called no-migration standards in RCRA section 3004. Land disposal includes any placement of hazardous waste in a landfill or other facility specified in RCRA 3004 (k). Alternative treatments are permitted for debris in lieu of waste-specific treatments. Application of these regulations to qualifying MLLW can result in the following (19):
- simplifying processing and associated characterization requirements;
- shortening the research, development, demonstration, testing, and evaluation time frame;
- reducing the cost of processing and disposal; and

reducing the potential health risks to operations personnel and the public by reducing waste treatment and handling processes.

In addition to washing technologies, alternative treatment technologies that are applicable to treatment of MLLW include: biodegradation, physical extraction (e.g., abrasive blasting, scarification, grinding, spalling, high-pressure steam and water), thermal extraction (e.g., high-temperature metals recovery, thermal desorption), chemical destruction (e.g., oxidation and reduction), thermal destruction (e.g., incineration, plasma arc), macroencapsulation, and microencapsulation (19). Debris washing technologies include: water washing, solvent washing, chemical foams and gels, acid washing caustic washing, liquid-phase solvent extraction, and vapor-phase solvent extraction. The EPAs Risk Reduction Engineering Laboratory and IT Corporation have developed an on-site metallic and masonry debris decontamination process (14, 20,21). The entire system is mounted on two 48-ft flatbed semi-trailers and can be readily transported to the site. This system can be applied to various types of debris (scrap metal, masonry, stones) contaminated with pesticides, PCBs, or metals. The net costs for on-site debris decontamination ranged from $50 to $75 per ton and the system is estimated to be able to handle from 50 to 120 tons of typical debris per day.

Solvent Extraction

Solvent extraction is potentially effective in treating contaminants by separating solids (sludges or soils) into three fractions: oil, water, and solids. As the fractions separate, contaminants are partitioned into specific phases. Typically solvent extraction employs three treatment steps: soil washing using a solvent, soil drying, and solvent regeneration (12).

First, contaminated solids, slurries, or waste waters are fed into the extractor. The extraction fluid (solvent) is circulated through the contaminated matrix to wash the soil. Liquified gas solvent may be used to extract organic compounds, oil, and grease from contaminated sludges and soils. Controlled temperature and pressure optimize the washing procedure. Typically, more than 99% of the organic compounds are separated from the feed. Following phase separation of the solvent and organic constituents, treated water is removed from the extractor, while the mixture of solvent and organic constituents passes to the separator through a valve where pressure is partially reduced. In the separator, the solvent is vaporized and recycled as fresh solvent. The organic compounds are drawn off from the separator and either reused or disposed. Hot inert gas or solvent-free gas is heated and injected into the soil to complete drying of the soil.

Extractor design is different for contaminated waste waters and solids. For waste water, a tray tower contractor is used, whereas for solids a series of extractor/decanters operating counter-currently are employed. Extraction efficiencies of 90 to 98% have been achieved on sediments containing PCBs, while laboratory experiments have yielded 99.9% removal efficiencies for volatile and semivolatile organic compounds. Estimated costs for PCB cleanup range from approximately $150 to $450 per ton of waste.

Several different solvent extraction technologies are available. For example, the Resources Conservation Company's Basic Extractive Sludge Treatment (B.E.S.T) technology utilizes triethylamine as the extraction agent (14). Triethylamine has an inverse miscibility in which it is hydrophobic above 20C and hydrophilic below 20C. This property allows the process to extract both aqueous and nonaqueous compounds by changing the temperature of the solvent, and solids can be dewatered while simultaneously extracting organic contaminants. The Low-Energy Solvent Extraction Process (LEEP) uses common organic solvents to extract and concentrate organic contaminants (14). Contaminants are removed from the soils by hydrophilic leaching solvents then concentrated by use of a hydrophobic stripping solvent. Bradtec has developed and tested a dilute, aqueous based, extraction process that combined dissolution with dilute selective solvents, contaminant recovery and solvent regeneration for treatment of radionuclide and metal contaminated soils (22). Finally, the Center for Hazardous Materials Research uses an acid extraction treatment system in the soil washing process that uses hydrochloric acid to extract contaminants from soils (14).

INPUT AND OUTPUT STREAM CHARACTERISTICS

Ex situ soil washing is applicable to soil, sediments and sludges contaminated with hazardous organic compounds, radionuclides, and toxic heavy metals (Table I). Specifically the process can be applicable for treatment of soils contaminated with

wood-preserving chemicals (e.g., PCP, creosote), organic solvents, electroplating residues (e.g., cyanides, heavy metals), paint sludges, pesticides, and petroleum and oil residues (8). Particle-size distribution is the key parameter for determining the feasibility of soil washing. Typically for soil washing to be economical, the contaminated material size distribution should not consist of more than 40% passing 45 microns or 325 mesh (9). Materials finer than this begin to reduce the amount of recovered clean soil for redeposition. In addition, the contaminated soil should contain less than 20% by volume of solid organic material such as leaves, roots, and twigs. For nonmobile treatment units, potential sites should have a minimum of 5,000 tons of material in order to justify the fixed costs of mobilization and demobilization. In situ soil washing (flushing) is most applicable to highly permeable soils. All input streams must be sorted, separated and prepared prior to soil washing (23).

TABLE II

There are four waste streams generated during soil washing: 1) contaminated fines and humic compounds from the soil washing unit, 2) waste water, 3) sludge from the soil washers, and 4) air emissions (16). Soil washing is typically considered a waste minimization, volume reduction process which reduces the original amount of material that needs to be remediated by an ultimate destruction or immobilization technology. Thus, solid output soil washing streams can be further separated into two broad categories: 1) coarse-grained cleaned material for on-site backfilling and redeposition and 2) fine-grained material requiring further treatment for regulated disposal. Discharge water may need treatment to meet discharge standards; however, this water should be recovered and reused to the maximum extent possible in the washing process. The residual solids from waste water treatment process, such as spent carbon and sludges, must be treated before disposal. Any air emissions must be collected and treated to meet regulatory standards.

TECHNOLOGY STATUS

Soil washing is an available technology that has been used as a remedial action for contaminated soils. Several soil washing demonstrations have been conducted by the EPA at Superfund sites. For buried waste that is conceptually the same as soil but more heterogeneous, soil washing is in the development stage. Doubtless, modifications will have to be made to handle buried waste and the secondary waste streams. This concept may prove effective for a given scenario but not necessarily in general. Once the concept has been accepted as effective, then details such as emptying bags and containers need to be developed. The most difficult part to develop may be proving that the treated waste is clean. The whole point of the treatment is to cleanse the bulk of the waste of contamination and to take advantage of the debris rule. A technique must be developed to ensure that the treated waste is truly free of contamination. Without such assurance, the treated waste will be disposed as if it were still contaminated, even if it is not. Finally, the wash water/leachate/extract is a secondary waste. Cleaning and recycling this secondary waste stream must also be developed if the concept proves to have merit.

Several full-scale soil washing plants with capacities of 6.5 to 30 tons/h are in operation in the Netherlands and Germany (24). Soils (165 tons) from the United States have been shipped to the full-scale facility at Moerdjik, the Netherlands, for testing (25). This plant has an annual treatment capacity of 80,000 tons. However, emphasis in Europe is on removal of semivolatile organic compounds, polyaromatic hydrocarbons, PCBs, and pesticides; none of the plants are presently removing radionuclides or heavy metals from soils. Also, most of the soils and sediments being remediated are sandy-textured (>85% being >50 m diameter).

For the specific contamination found at each individual site considering this alternative technology, further development is required. Field screening and material handling as needed in conjunction with sediment removal, and further treatment will be required following removal. Additionally, a systems tradeoff may be required to determine if the process has merit for the proposed application.

REMOVAL EFFICIENCY

Based on the various individual site characteristics, removal efficiencies are reported anywhere from 85 to 99% for organic compounds, 80 to 99% for semivolatile organic compounds, 50 to 99% for oil and grease (and other petroleum hydrocarbons), 84 to 88% for PCBs, 93 to 99% for cyanides, and 50 to 90% for heavy metals (see Fig. 3) (8,9). As a very general statement, applicable contaminants can usually be removed from coarse soil fractions (greater than 200 mesh) with relatively high

removal efficiencies (95 to 99.9%) at low to moderate cost, while fine soils, silts, and clays (<200 mesh) yield only moderate contaminant removal efficiencies (50 to 90%) at a moderate to high cost (9). Volatile organic contaminants often are easily removed from soil with a 90 to 99% efficiency. Semivolatile organic contaminants may be removed to a lesser extent with use of a surfactant (40 to 90%), while metals and pesticides, which are less soluble in water, often require acids or chelating agents for removal (8).
Fig. 3.
Bench-scale studies have been conducted evaluating the effectiveness of various extraction media on the removal of plutonium (Pu) and americium (Am) (26,27,28,29). Extraction media included (1) pH 12.5 NaOH solution, (2) a 2% HNO3, 0.2% HF, 2% pine oil, and 5% Calgon solution, and (3) 2N HCl. Soils from five DOE sites were extracted at a 1:1 soil-to-solution ratio in a rotary extractor for 6 min at 70 rpm. The extractions appeared to reduce concentrations of Pu and Am in the fractions >105 m and concentrated the radionuclides in the <105 m size fractions. Based on wide variations in the results, the authors concluded that the selection of extraction media will have to be tailored for each soil. Research funded under the Uranium in Soils Integrated Demonstration at Fernald, Ohio, indicated that soils containing 400 to 500 mg/kg uranium (soils sampled from within the Fernald production area and around a low-level waste incinerator) can be lowered to concentrations of <50 mg/kg using extraction media that are selective for uranium leaching. The best results have been obtained using an extraction medium that includes a strong reducing agent and strong complexing agents for uranium (30, 31). Carbonate leaching in combination with attrition scrubbing also appears to be a possible method for removing uranium to levels <50 mg/kg for the soil sampled within the production area (32).
COST OF TECHNOLOGY OR EQUIPMENT
A wide range of soil washing costs have been reported in the literature. For example, EPA (16) estimated the cost range for soil washing to be between $60 and $230 per ton. Trnovsky et al. (33) estimated the present worth from the estimated capital and operating and management costs for several remedial action alternatives at the Petroleum Products Corporation Superfund Site in Pembroke Park, Broward County, Florida and estimated the unit cost of soil washing to be $50 to $65/ton. Soil washing when used as a pretreatment to solidification/stabilization resulted in significant cost savings by decreasing the volume of soil that needed to be stabilized.
The following are EPA comments on soil washing costs (8): (1) treatment and disposal of contaminated residuals can be a major expense; (2) design field tests can be expected to range from as low as $100,000 to more than $500,000 (1989 costs); (3) costs for a German (Harbauer GmbH) full-scale soil washing facility are reported as, capital cost $6,000,000 (1986 dollars) for a 15 to 20 ton/h facility, O&M costs of $150/ton soil including water treatment, and sludge disposal costs of about $50/ton soil, and (4) processing costs for other less complex European soil washing operations are estimated at $73 to $110/ ton soil.
SUMMARY AND REQUIRED DEVELOPMENT
The primary advantage of soil washing is volume reduction of wastes requiring ultimate disposition. Soil washing can be cost-effective as a pre-processing step in reducing the quantity of material to be processed by another destruction and/or immobilization technology. It may also be used to transform the feed into a more homogeneous condition to augment subsequent treatment systems operations. Additionally, soil washing provides a closed system that remains unaffected by external conditions, and hazardous wastes can be excavated and treated on-site (34). Contaminants in soils containing a high fraction of silt and clay-sized particles are, typically, strongly adsorbed and are difficult to remove by soil washing. Hydrophobic contaminants generally require surfactants or organic solvents for removal from the soil, while complex contaminant mixtures in soils, as well as frequent changes in the contaminant compositions, make it difficult to design a single washing fluid that will consistently and reliably remove all of the contaminants (8).
A major need in development of soil washing technology is a clear understanding of the acceptable cleanup concentrations of contaminants. The nature of the extraction medium depends on characteristics of the organic compound, radionuclide, and/or heavy metal in the soil and the physicochemical characteristics of the soil; thus, each contaminant and soil needs to be investigated to properly assess the

probability of decontamination. Simple soil washing, using water as the extraction medium, will not suffice in cleanup of heavy-textured soils containing a variety of radionuclides, heavy metals, and organic contaminants.

A policy needs to be established about disposition of the cleaned waste (e.g., use of the debris rule where the treated waste is no longer handled and disposed of as RCRA hazardous waste), and a positive characterization technique needs to be developed to assess the cleanliness of the treated waste (i.e., quality assurance/quality control for the treatment).

Additionally, the need exists to prove in the laboratory that buried waste can be cleaned by such an approach. Although a technique may have proven effective in soil washing, the chemical and physical characteristics of buried waste may differ sufficiently from contaminated soil for the approach to also work effectively. Of course, the technique should be acceptable, as developed, for treating contaminated backfill and soil surrounding buried waste. After proving that the concept is useful, details such as removing waste from bags and containers need to be developed before field testing. To claim any benefits from the treatment, a positive test for the cleaned waste must be developed. In addition, a treatment cycle must be developed for the secondary waste stream to recycle the wash water/leachant/extractant and concentrate and to dispose the removed contaminants.

In summary, until the moratorium on permitting incinerators is resended and/or the emission standards are established washing technologies are viable alternatives to incineration. Furthermore, washing technologies may provide added benefits to the treatment of debris for mixed low-level waste through use of the debris rule.

STEAM REFORMING OF DOE COMPLEX WASTE SIMULANTS

J.E. Miller
P. B. Kuehne
Sandia National Laboratories
P.O. Box 5800
Albuquerque, NM 87185

ABSTRACT

Sandia National Laboratories has worked with Synthetica Technologies and Manufacturing and Technology Conversion International (MTCI) to demonstrate the applicability of their commercial steam reforming technologies for treating DOE low-level mixed wastes. Previously, Synthetica successfully demonstrated destruction of a Sandia formulated lab trash simulant. During November, 1994 Synthetica did not adequately process the aqueous halogenated organic liquid mixed waste simulant (MWTP-2110) formulated by the DOE Mixed Waste Integrated Program (MWIP). Testing at MTCI is ongoing and initial results appear to be favorable. Approximately 200 lbs each of the MWIP aqueous halogenated organic liquids (MWTP-2110), and absorbed aqueous and organic liquids (MWTP-3113/3114) simulants have been processed. At 1650 F, destruction efficiencies of greater than 99% were obtained for tetrachloroethylene, toluene, and 1,2 dichlorobenzene. Product gases consisted primarily of H2, CO2, CO, and CH4 and had higher heating values of up to 355 BTU/SCF. Conclusions concerning the suitability of the MTCI process for treating DOE mixed wastes will be drawn upon the completion of testing.

INTRODUCTION

Steam reforming is a process of reacting organic materials with high temperature steam to produce CO, CO2, and H2. Halocarbons also produce mineral acids (e.g., HCl). Traditionally steam reforming has been utilized as a process for producing molecular hydrogen from hydrocarbons. (1) More recently steam reforming has been developed as a non-oxidative alternative for waste destruction. (2) In the steam reforming environment, products of incomplete combustion (PICs) commonly seen in oxidizing environments such as polychlorinated dioxins and furans are not produced. Furthermore, by operating with an excess of steam, the formation of thermodynamically reformed products such as polynuclear aromatics may be greatly suppressed.

Sandia National Laboratories has worked with Synthetica Technologies and Manufacturing and Technology Conversion International (MTCI), two suppliers of steam reforming technology, to demonstrate and extend the applicability of steam reforming to DOE complex wastes. Synthetica markets a steam reforming apparatus that employs a two step process for waste destruction, gasification in a feed device at temperatures up to 1100F followed by destruction in an electrically heated high temperature reactor (2100F) known as a detoxifier. The MTCI single step process, is an intermediate temperature (1600F) fluidized bed that is heated by pulse combustion. The pulse combustor results in highly turbulent combustion mixing that significantly enhances heat transfer. The combustion gases do not mix with the feedstock or product gases. Therefore, both technologies destroy wastes in an oxygen free environment, and result in a hydrogen rich product gas.

Arrangements were made for each company to demonstrate their technology on mixed waste simulants formulated by the DOE Mixed Waste Integrated Program (MWIP). (3) The simulants that were tested include aqueous halogenated organic liquids (MWTP-2110), and absorbed aqueous and organic liquids (MWTP-3113/3114). The simulant compositions as employed in these tests are outlined in Table I. The formulations in Table I may differ slightly from other formulations as they were taken from a draft document. Testing was to be carried out in duplicate with 200 lbs of simulant being treated in each test. Metrics included characterization of the effluent gas and residual matter including the working fluid (condensed water).

TABLE I

SYNTHETICA TESTS

In previous tests conducted using Synthetica's drum feed evaporator and detoxifier on a Sandia devised simulant, mass reductions of about 20:1 and volume reductions of

greater than 150:1 were demonstrated. (4) Also, a simple mass balance verified the steam reforming chemistry (consumption of water and waste). The simulant chosen for these tests represented a week's worth of lab-trash generated in the SNL hot cell and consisted primarily of shredded solid carbonaceous material such as lab coats, paper towels, and plastic with about 5% by weight organic liquids. Despite a noticeable in-leakage of air, the exhaust gas was found to be well enough characterized and to contain low enough levels of pollutants that permits could be sought from local regulatory agencies. Therefore the conclusion of the tests was that steam reforming could be a practical alternative for SNL to pursue for treating its own mixed and low-level radioactive waste. Similar results were anticipated for other wastes.

The MWIP aqueous halogenated organic liquids simulant (MWTP-2110) proved to be more challenging to the Synthetica system. The amount of tetrachloroethylene and dichlorobenzene in the waste simulant was reduced as indicated in Table I in order to accommodate limitations for chlorocarbons in the detoxifier. Also, the amount of the inert vermiculite was scaled down by about 40% so that the entire volume of waste simulant could fit into a single drum. The resulting formulation with its high levels of volatile organics could not be successfully processed with the equipment currently available at Synthetica. During the attempted processing of this waste simulant, several problems were encountered.

A significant leakage of air into the system occurred as the reactor temperatures increased during startup. This problem was initially diagnosed as a ruptured burst disk. Replacement of the disk and subsequent startup of the system and commencement of the test ensued. Approximately two hours and thirty minutes into the test run, an abnormally high pressure drop across the absorber bed was observed. At the same time symptoms of a plugged condenser were observed by test personnel. As a result of these problems, the test director terminated the run to protect the equipment. Investigations conducted after the system had cooled revealed the absorber bed was plugged with soot, while the condenser was completely plugged by large crystals of what was believed to be naphthalene, and a second black tar-like substance. Investigation by Synthetica personnel into possible causes for the plugged absorber bed revealed a cracked reactor bed which allowed leakage of air into the system. Other possible explanations for the plugged bed include inadequate steam and design limitations of the current system for processing waste containing large amounts of volatile organics. Toluene and naphthalene comprised 19.5 and 5 percent of the MWTP-2110 waste simulant respectively.

Two weeks after the attempted test run, Synthetica and Sandia mutually agreed to terminate further test efforts. Sandia's decision was based on several factors including system repair time, contractual period of performance, and optimism on successful completion of other mixed-waste tests given the simulant recipes and current equipment.

Synthetica has designed new system components that when fabricated, should improve their ability to process wastes such as those proposed in these tests.

MTCI TESTS

Testing of mixed waste simulants is currently underway at MTCI. Currently, one test has been performed with each of the two feedstocks shown in Table I. Duplicate tests have yet to be performed. During the tests, the composition of the effluent gas (CO, CO2, H2, O2, N2, CH4, C2H4, C2H6, C3H6, and H2S) was measured by gas chromotography on a five minute interval. Several samples were also collected by an independent laboratory for GC/MS analysis to provide confirmation of the results. The flue gas from the pulse combustors was also periodically analyzed by a combustion analyzer. At least four solids samples were withdrawn from the reactor during each test to help evaluate mass and volume reduction and the fate of the RCRA metals and radionuclide surrogates in the simulants. At the conclusion of each test, the entire volume of bed material was removed to assist in this analysis. Samples of condensate were also taken. Temperatures were recorded at 1 minute intervals, flow rates were recorded at 20 minute intervals, and the condensate collected was measured at 10 minute intervals. During the duplicate tests, gas sampling will be performed to allow for the measurement of dioxins and furans via EPA procedure 23.

In the first test that was performed at MTCI, 195 lbs of the 3113/3114 simulant was processed at 1500-1550F. During the second test, 198 lbs of the 2110 simulant was processed at 1600-1650F. During each of these tests, silica sand was used as the bed material. Due to the large number of samples collected for analysis many of the

results from the two tests are currently unavailable. However the results that are available appear to be favorable.
Table II summarizes the destruction efficiencies obtained for many of the key organic components present in the tests. At 1550 F, the destruction efficiency of 1,2 dichlorobenzene exceeded 98% while that of naphthalene exceeded 99%. These compounds are recognized as being very thermally stable and therefore represent something of a worst case for the system. Elevating the temperature to 1650 F in the second test resulted in raising the destruction efficiency of 1,2 dichlorobenzene to greater than 99%. MTCI is currently considering the addition of a second stage, higher temperature reactor to their system in order to achieve even greater destruction efficiencies.
TABLE II
The composition of the reformer effluent gas for each test is summarized in Table III. A complete mass balance has not yet been performed. However, the primary gaseous products were H2, CO2, CO, and CH4. The large quantity of CO2 is indicative of water/gas shift chemistry rather than oxidative combustion. The H2S shown in Table III probably originates from the ion exchange resin in the simulants. The HCl formed from the chlorocarbons was collected in the scrubber downstream of the reformer. Also included in Table III are heating values for the product gas. The heating value of the gas can be utilized in the MTCI system by feeding the gas to the pulse combustion system.
TABLE III
CONCLUSIONS
The equipment available at Synthetica at the time of these tests was inadequate to process the aqueous halogenated organic liquid mixed waste simulant (MWTP-2110). Based on this outcome and other considerations further testing was not attempted. Synthetica is in the process of designing new system components that when fabricated, should improve their ability to process wastes such as those proposed in these tests.
Testing at MTCI has not been completed. However, initial results for the MWIP aqueous halogenated organic liquids (MWTP-2110) and absorbed aqueous and organic liquids (MWTP-3113/3114) simulants appear to be favorable. At 1650 F, destruction efficiencies of greater than 99% were obtained for tetrachloroethylene, toluene, and 1,2 dichlorobenzene. Product gases consisted primarily of H2, CO2, CO, and CH4 and had higher heating values of up to 355 BTU/SCF. A more complete evaluation of the suitability of the MTCI process for treating DOE mixed wastes will be possible when the remaining tests are complete and the data is analyzed. Complete mass balances including the fate of the metals and radionuclide surrogates will be available.

ABSTRACT
It is important to make the best use of the available technology to aid in the safe

and efficient disposal of wastes at the U.S. Department of Energy (DOE) sites. A relatively mature technology, waste vitrification has been found to be cost effective, environmentally sound, and well suited for a variety of radioactive waste types. Scientists began studying the technique of incorporating radioactive waste into glass during the 1950's. Experimental melters have been used since 1975 to perfect the vitrification process. Over the past 20 years, scientists and engineers at the U.S. Department of Energy's Savannah River, and Hanford sites, and at the West Valley Demonstration Project have been developing expertise to characterize waste, tailored formulations to produce durable waste glasses, and developed technologies to effectively process and vitrify these wastes. Recently the glass melter in the Defense Waste Processing Facility (DWPF) was started up at the Savannah River Site (SRS). This facility is designed to remotely process and vitrify the high-level radioactive waste currently stored at the SRS. Startup of the melter was a vital part of the facility qualification, and involved treatment of simulated waste. The qualification phase will continue until late 1995 when radioactive wastes are scheduled to be processed in the facility.

The Environmental Protection Agency has declared vitrification the "best demonstrated available technology" (BDAT) for stabilization of heavy metals and high level radioactive waste. Nine nations have either chosen, or are considering, glass as a solid waste form for their highly radioactive wastes. By choosing glass, they minimize the lengthy, costly testing required of other waste forms.

Vitrification is cost effective and can produce an extremely durable glass form, which can isolate contaminants from the environment for thousands of years. Benefits of the application of glass technology to the disposal of wastes include:

well characterized waste form stability,
extremely low release rates in environmental conditions,
excellent mechanical and thermal stability,
no combustible or pyrophoric properties,
retention of essential release properties even if disturbed or mechanically damaged during storage or disposal,
low generation of potentially respirable particles,
ability to accept high loadings of heavy metals,
ability to accommodate fluctuating waste types with negligible effect on release properties,
ability to combust limited amounts of organics (including carcinogens),
volume reduction, reducing disposal costs
total destruction of asbestos,
and scale of facility adaptable to accommodate a wide range of disposal needs.

Compliance with environmental waste disposal regulations can be very expensive. While vitrification capital costs may be somewhat higher than conventional waste solidification techniques, such as cementation, the expense is more than offset by the savings from volume reduction and reduced monitoring inherent in the more durable waste form. The high temperature in the melter also destroys organic materials, thus further reducing the regulatory burden of disposal.

In the last decade there has been increased commercial interest in waste vitrification, and a growing convergence of the traditional commercial glassmaking and metallurgical approaches to waste glass production. The metallurgical approach is characterized by extremely high operating temperatures with molten metals present, strongly reducing conditions, and products that are not dependent on variations in appearance or small volume defects. In the metallurgical tradition, the glassy phase is a waste byproduct which should be minimized, and which results from winning metals from ores, or in secondary smelting operations. In the metallurgical tradition many of the refractories used are basic and are incompatible with production of high durability glasses. For example, a basic oxygen furnace for iron production may have a slag that is saturated with lime to maximize the scavenging of sulfur and phosphorous. A refractory of CaO may function for two years in this service, but would be dissolved in one week's time if subjected to a soda-lime-silicate bottle glass at the same temperature. By comparison, commercial glasses are usually acidic melts, and efforts to minimize furnace rebuilding result in the use of durable, acidic refractories: silica, high alumina, high zirconia, or high chromium oxide refractories, which are generally not compatible with a molten metal phase. Resolution of these conflicting requirements is one of the issues being addressed.

Parallel to the metallurgical tradition is the commercial glass making tradition. Initial waste glass processes, equipment and controls were based in the commercial glass making tradition, adapted to the requirements for working with radioactive materials, and slurries and sludges. In the glass making tradition, the glass product and its forming or final characteristics are the reason for the glass making operation. Thus, glass product formulation is rigidly controlled, with raw materials selected for their uniformity in composition and physical or handling characteristics. The incorporation of regulated waste products into such operations are difficult because of the inherent variations in source material. This additional process variation, and the increased regulatory requirements have minimized use of waste materials that are not produced internally. However, recycling, environmental and litter control regulations are increasing the use of internally-generated and post-consumer recycle in the glass bottling and television / computer monitor production plants.

RADIOACTIVE WASTE TREATMENT

The Mixed Waste Integrated Program seeks to develop and demonstrate technologies which can make significant improvement on existing commercially mature treatment systems. Vitrification has the potential to treat approximately 75% of the mixed (RCRA hazardous and radioactive) wastes being stored at DOE sites. The waste glass systems that are being considered are soda-lime-silica, borosilicate, aluminosilicate, nepheline, basalt, iron enriched basalt and phosphate glass systems. Glass ceramic systems have also been considered, many of which can be potentially produced as glass and subsequently heat treated to develop crystalline phases.

The ability to vitrify waste depends upon how well the waste is characterized, and on the flexibility of the melter and of the glass formulation. Considerations are physical form of the waste, size, water and organic contents, handling characteristics, ash composition, volatile materials, and extent of remote handling required. Relatively minor mass fractions of radioactive materials can cause orders of magnitude differences in the cost of personnel protection, offgas treatment required, and the capital, operational and maintenance costs. Waste is characterized using the most advanced technologies available, and the best way to vitrify the waste products is determined. Hazardous species in almost any material can be characterized using tools that include inductively coupled plasma-atomic emission spectroscopy; inductively coupled plasma-mass spectroscopy; atomic absorption spectroscopy, ion chromatography; x-ray diffraction; and x-ray fluorescence. For radioactive elements, gamma ray spectroscopy and alpha energy spectroscopy may be combined with more traditional counting methods.

The behavior of nearly every element in the periodic table has been studied in waste glass development. SRS has used a systems approach and process models have been developed to ensure that the melt's viscosity, durability, liquidus, and other important properties can be estimated from the melter feed ingredients. For more complex problems, the product composition control system, built upon proprietary statistical process control algorithms, allows for random variations, and suggests corrective actions. As a result, a durable glass product is reliably produced, while minimizing process upsets.

Melters are being applied to the immobilization, volume reduction and stabilization of High Level Radioactive Waste (HLW) Low Level Mixed Wastes (LLMW), Transuranic (TRU), Low Level, and chemical (RCRA) wastes. LLMW and TRU types generally do not require heavy shielding to control radiation doses to operating and maintenance personnel. The low penetrating radiation levels of these wastes allow them to be treated in facilities where direct contact maintenance can obviate the expense of remote maintenance facilities. Direct contact maintenance allows the adaptation of commercially available equipment, which has been precluded by the restricted maintenance conditions in High Level Waste facilities. Thus, rather than using expensive custom melter designs, the LLMW and TRU processes can use adaptations of commercial glass making equipment. However, these wastes share many contamination and environmental release concerns with High Level Waste. Thus, they require waste-form quality, contamination control features, and production control practices similar to the High-Level Wastes. When treating LLMW the requirements for protection of the operating personnel from contact with the wastes vary dramatically, dependent upon the source and type of the waste. For example, the hazards associated with natural and low enrichment uranium are primarily those of potential heavy metal

poisoning. In contrast, the 10 - 100 nanoCurie per gram low level transuranic wastes are potential sources of ingestion of maximum permissible body burden dosages of plutonium, since they may contain small "hot spots" or particles which could become airborne and result in personnel contamination through ingestion or respiration. DOE has needed a facility where commercial pilot scale equipment could be operated on surrogate (non-radioactive) simulations of typical DOE waste streams. The DOE/Industry Center for Vitrification Research (Center) was established in 1992 at the Clemson University Department of Environmental Systems Engineering, Clemson, SC, to address that need. The Center aids in the application of vitrification technology to the immobilization of hazardous, radioactive, and mixed wastes, by combining technology and lessons learned in commercial glass making with DOE contractor experience and DOE needs. During surrogate operations the melters are checked for:
1. general operability (i.e. does the unit perform as advertised)
2. general limits of processability (e.g. operating temperature range),
3. normal and specialized maintenance requirements,
4. compatibility with waste glass formulations (i.e. materials of construction, since high temperature equipment can be rapidly destroyed by chemical attack if materials of construction are not suitable)
5. interfaces with the rest of the treatment system (pretreatment and offgas treatment requirements),
6. product conformance to regulatory requirements, and
7. as far as possible the operating economics (life cycle costs, manpower requirements, utilities, raw material costs).

The non-radioactive pilot scale testing at Clemson Univ. has been a necessary step in adapting commercial technology to DOE's needs. Efforts are now being made to make the next transition. to demonstration on actual waste at the waste generation site, using equipment suitable for production treatment of small sites. A "Transportable Vitrification System" (TVS) is being completed in FY95 by SRS for field demonstrations of vitrification at various DOE sites on contact handled wastes. The Modular system will have generic melter feed, offgas treatment and laboratory capacity. Alternative melter systems can be substituted for the original melter after initial operations, to handle variations in physical or chemical properties of the wastes. The entire system can be transported via tractor trailers to allow vitrification of a variety of hazardous waste streams at different sites. The "TVS" has become a main focal point of SRTC vitrification activities, with waste glass formulations and alternative melter configurations to deal with specific waste issues.

RADIOACTIVE WASTE TYPES SUITABLE FOR VITRIFICATION

Vitrification has been demonstrated to be capable of incinerating organic materials and incorporating the resulting ashes in a number of inorganic glass systems. Initial operations have focussed on the vitrification and volume reduction of inorganic sludges resulting from waste water treatment. The high temperature melting process destroys the chemical compounds associated with such wastes, and ties poisonous elements up into a durable matrix. It has been demonstrated that soda-lime-silicate, aluminosilicate, and borosilicate glasses bind hazardous elements.

Current wastes of the beta-gamma type that are most suitable for vitrification are SRS M Area sludges and filter papers resulting from uranium forming and cladding, and similar waste water treatment sludges from Oak Ridge, Rocky Flats Plant and Los Alamos Scientific Laboratory. The M Area sludges have been contracted for on-site vitrification treatment by Duratek Co. There is enough inventory to keep a large scale facility operating for about two years, after which the equipment will be available for treatment of other wastes. A model "Upfront" delisting petition is being prepared for SRS M-Area sludge so that these wastes can be delisted from RCRA concern, allowing them to be disposed as Low Level Waste. Again, economics plays a major role in the effective disposal of these wastes, the major justification being that delisting of the hazardous portion of these wastes will allow more efficient disposal. Vitrification is clearly justified for these wastes because it will reduce the waste volume relative to the cement waste form, and will provide an increase in waste form durability: In fact, the vitrification process won over a competitive cementation process for the M Area sludge treatment because it was able to demonstrate lower disposal volumes and costs.

Alpha emitting transuranic wastes (TRU) are comparable to High Level Waste in

biologic risk, but require smaller scale operations. In these waste types, major goals are to convert small volumes of liquid or solid flammable wastes into small waste forms that are easy to handle, but provide a high degree of contamination control (isolation). Waste glass is essentially a sealed source, which reduces the dispersibility of a wastes during accidents, and the transferability of activity by contact. The high temperature melting process combusts organics and reduces the volume of this waste category, which primarily consists of solutions, contaminated plastic, cloth and paper products. Current investigations at SRS include formulation of glasses for vitrifying surplus transuranic solutions. If the TRU solutions were declared waste, they would be considered mixed waste because of their low pH and high nitrate concentrations. Vitrification will allow the storage and subsequent shipment and use or disposal of Pu, Np, Am and Cm.

SELECTION OF WASTE STREAMS FOR VITRIFICATION DEMONSTRATIONS

Fiscal year 94 operations focussed on waste water treatment sludges from SRS, ORR, Rocky Flats and Los Alamos. Treatability studies have been conducted on SRS and ORR sludges, and surrogate pilot scale operations conducted for SRS and ORR sludges. Surrogate pilot testing for RF and LANL sludges are being completed in FY 95. This category, including pond wastes constitutes about 1/3 of the entire DOE inventory of Low Level Mixed Wastes. Initial operations of the Transportable Vitrification System will be on and Oak Ridge Reservation sludge of this type. Surrogate (non-radioactive) pilot-scale demonstrations are being completed on the Rocky Flats Plant Precipitate sludge and LANL TA-50 sludge. Correlations for X-ray Fluorescence (XRF) to Ion Coupled Plasma Emission Spectroscopy (ICP-ES) analyses will be completed, which will help to define the durable glass processing region of the CaO-Fe2O3-SiO2 ternary system, and provide a rapid composition measuring device for use in field demonstrations.

In fiscal year 95, the Savannah River Site has been tasked through MWIP to investigate vitrification technology of high mercury and high organic waste streams. The waste streams that will be investigated are as follows:

1. Mercury Contaminated Storm Sewer Sediments from ORNL
2. Ion exchange resin used at SRS and ORNL.
3. Other Waste Streams

Due to the chemical composition and physical characteristics of these waste streams, they are very strong candidates for vitrification treatment. These waste streams also represent wastes that are found throughout the DOE complexes, and thus finding a viable solution to their disposal is imperative. In this task, crucible-scale studies will be performed on surrogates of the materials to determine the optimum vitrification processing limits. Once these are determined, vitrification studies will be performed with the actual radioactive waste streams and pilot-scale studies will be performed with the surrogates.

ORNL Storm Sewer Sediments - This waste stream was selected in conjunction with ORNL. ORNL is currently investigating Hg removal processes. This waste stream appears to be amenable to both ORNL processing and our vitrification treatment. The goal is for this waste stream to be treated in the Transportable Vitrification System after the WETF sludge is treated. The analyses of this waste are currently being reviewed for accuracy. It appears that the waste is very high in silica content and contains about 20,000 ppm Hg. ORNL expects that with the Hg removal process that the Hg levels could be reduced to 30-100 ppm. As soon as a final analyses of this waste is received, crucible-scale studies will be completed. Pilot-scale studies will be completed in the melter which proves to be the most applicable from crucible-scale studies (temperature and processing limits).

Ion Exchange Resins used at SRS and ORNL - Since many sites are currently or are planning on using ion exchange resins to treat wastes, it was decided to determine if vitrification was a viable treatment method for encapsulating the resins. Two types of resins have been identified. One is a resorcinol-formaldehyde resin for Cs removal in HLW. It is being considered for use at the SRS, ORNL, and Hanford. The other resin is from reactor facility operations, where it is used to treat the storage basin water. One resin's approximate composition after removing Cs from waste is 35.5 wt% C, 7 wt% Na, 0.95 wt% Cs, 45.5 wt% O, 5.8 wt% H, and 0.07 wt% K. Data will be compiled from pilot-scale demonstrations with resins and simulated wastes. Resins from reactor operations are composed of divinylbenzene / styrene copolymer beads with the cation resin having a sulfonic acid group attached and the anion resin having a quantenary ammonium group attached. The cation resins used in

the reactor areas have hydrogen ions attached for exchange and the anions have hydroxide ions attached for exchange. The major species which are trapped on the resins are Na, Ca, K, Si, NO3-, SO4-2, and Cl-, and the resins contain Cs-137, Sr-90, and Tritium.
The optimum glass composition for ion exchange wastes will be determined, as well as the maximum waste loading. Vitrification studies with actual wastes will be performed at the SRS, with the best estimate of the typical waste loading of the resin. Pilot-scale studies will be completed in the Stir-Melter since it seems to be the most amenable to vitrification of this type of waste. It is considered a mixed waste because of the Cs that remains on the resin and because the resin is organic. Crucible-scale studies will be performed to optimize the glass composition and waste loading. A mercury waste stream containing radioactive cesium was selected in conjunction with the Environmental Protection Dept. of SRS. The waste is on the Mixed Waste Inventory Report and was also in the Draft Site Treatment Plan as being scheduled for treatment. An acceptable treatment method had not been previously determined, so the applicability of vitrification will be tested after ion exchange treatment to separate the cesium from the soluble mercury. Crucible studies will be performed with the clean resins and the spent resins to determine the optimum glass composition and processing conditions. Once this is determined, the surrogate resin will be treated on a pilot scale.
The Environmental Protection Division of SRS also asked for help with treating soils from spill remediation and toxic characteristic contaminated debris. Contamination can be the result of hazardous chemical spills, or low levels of TRU or mixed fission products. Currently, these wastes are disposed of without further processing by shallow land burial. Vitrification of these materials will bind the hazardous and radioactive species, reducing the risk of ground water contamination. This waste stream consists of soils, sand, and associated debris (rocks, wood, etc.) and associated water/liquid resulting from cleanup activities of spills and remedial actions contaminated with Toxicity Characteristic constituents and radioactive materials. This material was generated from site wide general SRS operations (Operations Waste and ER). This contact Handled waste has Am-241, Cs-137, Pu-238, and Pu-239. The contamination is dispersed through the matrix. Presence and levels of hazardous constituents will vary dramatically based on the clean up activities. Usually the containers are only hazardous for one or two of the TC constituents.
Toxic Characteristic Metal Contaminated Debris - Comprised of non-combustible debris material (metal, floor tiles, light bulbs, broken thermometers, recorders, equipment, etc.) which has one or more toxic characteristic metals and/or organics as a hazardous constituent(s). Generation is from site wide operations (transition and decommissioning and decontamination activities). Generation is expected to be 1063 m3 by 12/97, 1077 m3 by 12/98 and unknown quantities after that. The inventory is 5.6 m3. Radionuclides vary depending upon the location where the waste was generated.Cadmium, chromium, lead, mercury, and asbestos are the contaminants.
Spent Filter Cartridges and Carbon Filter Media-Filter cartridges were used in SRS fuels facilities to remove particulates, consisting of mercury salts and depleted uranium from process streams. They contain U-235 and U-238. It is also suspected that the filters contain Cr and Pb. Cylindrical filter cartridges are constructed of a PVC exterior frame surrounding a fibrous cartridge media. Ronningen-Petter filters (Dover Corp) Extended Area Bags are constructed of pleated spun-bonded polyester. The pleated filter is bonded to PVC which is molded on top and bottom. No metal is used in their construction. Mercury salt and particles of depleted uranium are the expected impurities on the cartridges. The projected generation is at a rate of about 0.6 m3 until 12/99. The current inventory is 0.8 m3. Future generation will be subject to LDR storage prohibitions. Contamination is dispersed through matrix.
SRS MELTER SYSTEMS
The range of melter technologies demonstrated, or being considered includes Joule-heated melters, induction melters, high temperature plasma torch systems, resistively heated refractory metal bushings, and microwave systems. Each system has advantages for application to specific waste streams. Tailoring technologies to particular waste steams helps to maximize effectiveness and efficiency of waste vitrification options.
Slurry Fed Melters (SFM), also known as HLW melters, Joule Heated Melters, and Ceramic Melters, have been developed in the U.S., Europe and Japan for the conversion of HLW to borosilicate glass for permanent disposal. Laboratory and pilot

scale operations have been conducted to develop equipment, glass compositions and control methods. The majority of these systems have been developed for remote operation, with essentially no maintenance over a 2 to 4 year melter life. The relatively high cost of these melters is the result of the specialized requirements of remote installation, operation, maintenance and removal. The systems were developed for vitrification of waste water treatment sludges, and are very suitable for that operation. The slurry fed melters are the result of several generations of melter development based originally on commercial, electrically heated melters, adapted to the requirements of remote, non-contact maintenance, where the only available tools for changing out melter components or entire melters are a crane with hooks and an impact wrench. Major differences between HLW Melters and Commercial Melters have been: the use of metal shells to contain glass contact refractories and thermal insulation, the development of specialized slurry feeding and glass pouring systems, and the use of nickel based alloys for electrodes carefully matched with glass composition control. The HLW style melters will be used for initial SRS LLMW treatment in the M-Area Sludge treatment. High temperature melters and stirred melters are also being demonstrated since they appear to have cost and operating advantages.

High Temperature Melters are based on commercial melter materials which permit operation at temperatures higher than those of the HLW systems. The commercial systems are also based on direct contact maintenance, allowing possible cost reductions for LLMW treatment. As in all high temperature systems, the life of the system, and a large fraction of the cost is limited by the materials of construction. Glass systems include borosilicate, aluminosilicate, calcia-aluminosilicate, basalt, and soda-lime-silicate systems. As a result of the broad range of glass compositions and refractory and electrode materials available, a major need for commercial waste glass systems is selection of composition limits, operating temperatures and materials of construction: For optimum operations these can vary from one waste to the next. A second major need in commercial glass systems is sealing of the systems to control airborne contamination during the melter feeding and glass pouring operations and demonstration of slurry feeding of wet sludges. A vendor supplied system is being investigated at Clemson Univ., and as the initial melter for the Transportable Vitrification System.

Stirred Melter The current stirred-melter was developed to combine the high production rates and high glass quality features of the Joule-heated melters with the low-cost, compact, easily maintained features of the pot melters. Melt rates in the stirred-melter are believed to be proportional to melter volume, rather than melt surface area as in conventional melters. A small scale system has been installed at Clemson University.

Similar to the continuous pot melters are the commercially available bushing melters which are used to melt high quality fiber glass. Pots for these systems are fabricated from platinum group metals, and are heated by passing current through the pot. The commercial systems are economically viable because of very low consumption rates of the platinum, and the ability to recover the platinum for reuse. SRS is considering small systems based on commercial bushings for specialized transuranic waste melting.

Induction melters have been used for about 40 years at the SRS for production melting of uranium, lithium, plutonium and aluminum alloys, for vacuum hot pressing of plutonium dioxide, and to initiate transuranic fluoride reductions. They are reliable, low cost, high throughput devices for the melting of metals which directly couple to the radio frequency fields established by the induction coils, or the material to be melted can be indirectly heated by RF coupling to the graphite or silicon carbide crucible. The metal melting systems have used graphite and silicon carbide crucibles, with magnetic stirring to assure alloy uniformity.

Graphite Electrode Arc Melters are the basis for stainless steel and ferro alloy production, as well as such diverse operations as acetylene, phosphate, and fuse-cast refractory production (zirconia, alumina and chromia). Commercial units can be as large as 50 feet in diameter with electrodes in excess of 2 meters in diameter. The electrodes for such systems require constant renewal, since the graphite reacts with the melt and with oxygen in the melter atmosphere. Methods are available for electrode feeding, including forming and graphitization of the electrodes as they are consumed. Many melters are run "cold top" in open crucibles, where the feed batch provides the furnace cover. Refractories are selected based on

the chemical system being processed, and refractory life varies dramatically dependent upon product and the amount of thermal cycling. Most of these systems operate in foundry environments, and have not required sealing of the electrodes to the furnace, or fume control during pouring. As a result, most commercial melter systems have uncontrolled air leakage around electrodes, and do not provide sufficient fume control or prevent contamination of the outside of the vessel. Combustible gasses can be formed by carbothermic reaction, pyrolysis of the treated material or by water-gas-shift reactions between carbon and water. The most extensive research of graphite electrode arc systems for DOE wastes have been conducted by INEL, and by PNL at the Massachusetts Institute of Technology (MIT). A bench scale systems is being supplied to SRTC by INEL, which will be installed in a SRS glovebox for LLMW and TRU testing. A larger pilot scale unit is being vendor supplied by the developer of the MIT unit to determine if such a unit should be considered as a replacement for the TVS when processing high metal content wastes. Plasma Arc Melting is being investigated at Mississippi State University and the Georgia Institute of Technology. Furnaces may be refractory lined, or of the cold crucible type. Refractory lined systems must have control limits to minimize glass and metal attack, and overheating by the plasma. Plasma arc torch design is a mature technology, and is available from a number of vendors, but torches require rebuilding on a monthly basis. Torch failure can result in uncontrolled coolant addition to the treatment furnace. Treatment furnaces have been offered commercially, but except for primary metals production they have been used primarily for recycle of metals or laboratory testing. SRS is following the work at other sites on equipment development, and supporting brief tests at universities to determine if SRS wastes are compatible with the emerging designs. A Russian designed hybrid plasma/induction melter is being obtained for testing at Georgia Tech., which combines cold crucible melting with plasma melting.

Cold Crucible Induction Melters Melter manufacturers in France, Russia and the United States, have developed cold crucible induction melters, where the water cooled induction coil is in direct contact with the material being melted. The steep temperature gradients produced adjacent to the induction coil cause a "skull" melting effect, where the material being produced forms its own crucible. In waste melter operations this means that the need for replacement of crucible materials is avoided, at the cost of reduced melting rate. STRC is considering such technology for future generations of High Level Waste melters, and for high salt content wastes.

Demonstrations of refractory life, control of melter pouring, control of wasteglass quality, control of combustible offgasses, control of high vapor pressure metals, control of volatilization and entrainment of radioactive materials, integration to offgas systems, and maintenance of the torch under radioactive conditions are major portions of all SRS testing.

SUMMARY

Vitrification offers many attractive waste stabilization options. Versatility of waste compositions, as well as the inherent durability of a glass waste form, have made vitrification the treatment of choice for high-level radioactive wastes. Adapting the technology to other hazardous and radioactive waste streams will provide an environmentally acceptable solution to many of the waste challenges that face DOE today.

ACKNOWLEDGEMENT

ABSTRACT

Vitrification studies with simulated Low Level Mixed Waste (LLMW) sludges were performed at the Savannah River Technology Center (SRTC). These studies focused on finding the optimum glass compositions for four simulated LLMW wastewater treatment sludges and were based on both crucible-scale and pilot-scale studies. Optimum compositions were determined based on the maximum waste loading achievable without sacrificing glass integrity.

Crucible-scale study results indicated that 45 wt% waste loading was obtainable with a Oak Ridge Reservation (ORR) West End Treatment Facility (WETF) simulated sludge when various additives were used. For a simulated Rocky Flats Plant (RFP) Precipitate sludge, durable glasses were produced with 75 wt% waste loading at higher temperatures and with 65 wt% waste loading at lower temperatures. Charcoal additions had to be used in manufacturing these glasses to deter the formation of a sulfate salt layer. Simulated Los Alamos National Laboratory (LANL) TA-50 sludge was also tested. A durable glass was produced at higher melting temperatures with 65 wt% waste loading.

Pilot-scale study results indicated that durable simulated Savannah River Site (SRS) M-Area sludge glasses could be produced with up to 90 wt% waste loading when melted in higher temperature melter systems and up to 85 wt% waste loading when melted in lower temperature melters. Pilot-scale studies were also performed using simulated ORR WETF sludge based on the crucible-scale findings. The most durable glass produced was melted in a high temperature melter system and contained 45 wt% waste loading.

INTRODUCTION

The Department of Energy (DOE) has chartered the Mixed Waste Integrated Program (MWIP) to investigate waste forms for LLMW. Vitrification of the wastes is a main focus of the MWIP investigations. To help develop the alternative waste forms, MWIP has funded the SRTC to perform vitrification studies. SRTC's vitrification effort is in conjunction with the DOE/Industrial Center for Vitrification Research (Center) located at Clemson University.

Vitrification studies in fiscal year 1994 involved both crucible-scale and pilot-scale studies with simulated wastewater treatment sludges. The simulated sludges tested included SRS M-area wastewater treatment sludge, ORR WETF sludge, RFP Precipitate sludge, and LANL TA-50 sludge.

SRS M-Area sludge has evolved from wastewater treatment of Ni plating line sludge. The sludge contains a large amount of Si from the M-Area filtration process which uses perlite as the filter aid. The Resource Conservation and Recovery Act (RCRA) metal of concern is Ni while the radioactive element of concern is U. The inventory of this sludge is about 1,100,000 gallons, and it is currently being held in storage tanks after treatment. It has been characterized by C.M. Jantzen of SRTC and a surrogate composition was developed (1). Crucible studies with both simulated and actual sludge were performed by C.M. Jantzen as part of an M-Area treatment study; however, results will not be reported in this paper since the studies were performed under a separate project scope.

ORR WETF sludge has resulted from treatment of nitrate-containing wastes by biodenitrification. The sludge contains a large amount of Ca and a small amount of organics. The RCRA metals of concern are Ba, Cd, Cr, Pb, and Ni, while U is the radioactive element of concern. The current inventory of this sludge is approximately 7,100 m3, and it is currently being stored in 500,000 gallon tanks. It was characterized by W.D. Bostick of Oak Ridge National Laboratory (ORNL), who developed a surrogate formula and recipe.(2) Ce was substituted on a molecular weight basis for uranium, so the behavior of the radioactive element could be monitored.

RFP precipitate sludge has evolved from chemical precipitation of aqueous waste from plutonium recovery operations, and thus is a transuranic (TRU) waste. The sludge is generated during chemical precipitation of radioactive elements from liquid wastes. The major constituent of this waste is Fe, but it also contains a small amount of nitrates. The RCRA metals of concern are Cr, Ni, Pb, Cd, and Ag, while the radioactive element of concern is Pu. The current inventory of this material is >3 m3, which is currently stored in 55 gallon drums. The sludge was characterized by RFP personnel and a surrogate composition was developed (3). However, W.D. Bostick of ORNL derived a different surrogate formula from this characterization and composition, so this composition was used for these crucible studies to be consistent with other MWIP sponsored programs (2).

LANL TA-50 sludge has been derived from a liquid waste processing plant that uses influent water containing about 100 mg/L total dissolved solids for decontamination, rinse down, and other processes. This wastewater is treated with ferric sulfate and precipitated lime. The wastewater is later filtered and a sludge remains. The major constituents of this sludge are Ca and Si. The RCRA metals of concern are Cr, Ni, Pb, Cd, and Ba, while the radioactive element of concern is U. The total inventory of this sludge is estimated at 270 m2, with about 139 m3 subject to Environmental Protection Agency (EPA) Land Disposal Restriction (LDR) prohibition, and it is stored in 55 gallon drums (2). Based on available analytical data, W.D. Bostick of ORNL derived a surrogate formula (2), which was used in these studies, but information was not available on the level of RCRA metals in the actual sludge, so a standard spike of 500 ppm was incorporated. For the crucible studies, Ce was used as the substitute for uranium.

The compositions of the simulated sludges used in these studies on a normalized weight percent oxide basis are given in Table I. Anions, such as nitrates and sulfates, and waters of hydration from the batch materials were not included in the tables, since they are not of concern during crucible-scale vitrification.

Crucible-scale studies were performed using these surrogates (with the exception of the SRS M-Area sludge, since they were already performed) in order to determine the types and quantities of glass forming additives to be added to each waste. The information gained is necessary to perform the pilot scale demonstrations at the Center. Eventually, simulants of all of the wastewater sludges will be vitrified in demonstrations at the Center, but, as of now, only the SRS M-Area and ORR WETF demonstrations have been completed. Only results from the glass characterizations performed for these demonstrations will be discussed here.

EXPERIMENTAL

As mentioned earlier, Bostick's surrogate recipes were used in the crucible-scale studies. The recipes were used to make approximately 500 grams of each type of waste. The wastes were blended with various glass formers in order to determine the optimum glass compositions for pilot scale testing. The amounts and types of glass formers to be used were determined from previous crucible studies performed at other DOE sites, where applicable, or were determined from expected glass making regions of ternary diagrams. The compositions to be tested on the pilot-scale were determined based on waste loadings, PCT results, and TCLP responses. The batch compositions tested for each waste type are given in Table II, along with the associated batch number and melt temperature. For the SRS M-Area studies and one of the pilot-scale ORR WETF studies (OR12P), the compositions tested at the Center are given, along with the associated melter instead of melt temperature. In Table II, hydrous borax is abbreviated as HB and diatomaceous earth is abbreviated as DE. In the studies, additives were added as listed in Table II with the exception of Na_2O which was added in the form of Na_2CO_3. Batches OR1 and OR7 were used in the pilot-scale studies at the Center in the Stir-Melter and EnVitCo melter, respectively. Charcoal had to be added to Batches RF6 and RF10 to deter the

formation of a sulfate salt layer. Batches LA4, LA5, and LA6 were tested to try to utilize the Minimum Additive Waste Stabilization (MAWS) concept. Using RFP simulated sludge as the glass additive, up to 100% waste loadings were tested.

For the crucible-scale studies, approximately 70 gram batches were made of the glass compositions shown in Table II. The batches were placed in covered high purity (99.8%) alumina crucibles and placed in a furnace at the specified melt temperatures for 4 hours. After 4 hours, the crucibles were removed from the furnace and the glasses were air quenched to room temperature. In the pilot-scale studies, the batches were continuously fed to the melters. Glass samples were taken once steady-state conditions were met. This usually occurred after three melter volumes of glass had been produced.

For all studies performed, the glasses were analyzed for chemical constituents and phase assemblage. The chemical constituent analysis was performed on the glass product using Inductively Coupled Plasma - Emission Spectroscopy (ICP-ES) and Atomic Absorption (AA) Spectrometry. Phase assemblage was characterized using X-ray Diffraction (XRD) and Scanning Electron Microscopy (SEM).

To assess the integrity of the glass, the Product Consistency Test (PCT) (4) and the Toxicity Characteristic Leaching Procedure (TCLP) (5) were also performed. The PCT is a crushed glass leach test that measures the releases of B, Si, Na, and other elements in 90C ASTM Type I water over a period of seven days and is the standard test used for determining the durability of High Level Waste (HLW) glasses (4). Each glass sample was tested in triplicate and submitted for leachate analysis, with the results averaged and normalized. The PCT results were compared against the HLW Environmental Assessment (EA) glass PCT values (6) to determine the stability of the glass in water.

While the PCT is the accepted durability test for HLW, the TCLP is recognized as the standard test method for determining the hazardous nature of a waste. For the scoping crucible-scale tests, the TCLP was performed on +100 mesh (>0.150 mm) crushed glass. In general, EPA tests are usually performed on larger size glass specimens, as was the case with the pilot-scale glasses. Thus, the crucible-scale results reported here provide a conservative estimate of the leach resistance since approximately 200 times more surface area was exposed to the leaching solution. TCLP extractions were performed on the glass, and the resulting leachates were analyzed by ICPES. The TCLP results were compared against the more restrictive of either the TCLP or RCRA Land Disposal limits.

CHEMICAL CONSTITUENTS

Table IIIA , B lists the oxide composition of all of the glasses produced in the vitrification studies (7,8,9,10,11). The batches that did not produce homogeneous glass were not analyzed, and thus are not included. As stated above, batches OR1 and OR7 were used in pilot-scale demonstrations. The pilot-scale SRS M-Area and ORR WETF glasses are designated by the "P" after the Batch ID.

PHASE ASSEMBLAGE

The phase assemblage of the glasses as determined by XRD are given in Table IV (8,10,11) XRD results are not included for the pilot-scale glasses produced at the Center. For the most part, volume percent analyses were not available, since standards for these compounds are not available at SRTC for determinations. Quantitative XRD analysis was performed on glasses OR1-OR3 because a standard was available. The largest volume percentage of crystals detected was found in the glass OR3, which was around 9%, while glasses OR1 and OR2 had less than 0.5%. The unusually high amount of crystals in glass OR3 did not seem to greatly affect the durability. SEM analysis confirmed the XRD findings.

Although quantitative results were not available for the RFP sludge glasses, a comparative analysis of the peak intensities on the XRD spectra indicated that larger quantities of crystals were present in glasses RF8 and RF9. The relative intensities of the other spectra were only slightly above background. The crystalline phases detected did not seem to significantly affect the durability results. SEM analyses could only verify the presence of the hematite (Fe_2O_3) in the glasses.

For the LANL simulated sludge glasses, the results show that at least one glass from each ternary system contained crystals. In all cases except for LA18, the glasses that contained crystals were the glasses with the highest waste loading. SEM analysis of the glasses verified the presence of crystals in LA3, LA4, LA7, LA17, and LA18 and verified that the remaining glasses were free from crystalline phases.

PCT RESULTS

The PCT data in g/L for all of the fabricated wastewater treatment sludge glasses is given in Table V (7,8,9,10,11). The normalized releases of B, Si, and Na were well below the EA accepted values (6) for all glasses with the exception of glass LA17. The RCRA metals of concern and Ce, which was used as the radioactive surrogate for some of the glasses, were only released in very small amounts. In most cases, they were near the detection limits. Some of the releases were not applicable, since they contained only trace amounts of B. Glass LA17 was the only glass tested to actually exceed the EA accepted PCT values (6), so it was considered unacceptable for further pilot-scale testing.

TCLP RESULTS

The TCLP data in mg/L for all of the wastewater treatment sludge glasses are contained in Table VI (7,8,9,10,11). As mentioned earlier, the TCLP was performed using a modified procedure for the crucible study glasses, while the TCLP for the pilot-scale glasses was performed by outside vendors on standard sample sizes. Results for the remaining RCRA metals are not included in the table since they were not included in the glass compositions.

All of the SRS M-Area pilot-scale, ORR WETF (with the exception of OR1P, OR10 and OR12P), RFP Precipitate (with the exception of RF8 and RF9), and LANL TA-50 (with the exception of LA1, LA3, LA13, and LA18) simulated sludge glasses performed better than the EPA limits.

OR1P exceeded the listed EPA limit for Ni, which is based on the RCRA disposal limits. However, new regulations which were effective December 19, 1994 raised the limit for Ni to 5.0 mg/L (12), so this glass would be considered acceptable. OR10 exceeded the EPA limit listed for Pb and Ni, which is the RCRA land disposal limit. However, the Pb release did not exceed the TCLP limit of 5.0, and Ni does not exceed the new Ni limit of 5.0 mg/L. Once again, the tests for the crucible-scale glasses were performed on very conservative particle size glasses so this consideration must be taken into account when looking at the overall quality of these glasses. OR12P exceeded the listed Ni limit, but does not exceed the new regulation Ni limit.

Glass RF8 exceeded the Cd, Ni, and Ag EPA limits and glass RF9 exceeded the Cd limit. However, the RFP Precipitate simulated sludge used to fabricate these glasses was spiked with 500 ppm of the RCRA metals, which was much higher than what was actually present in the sludge according to chemical analyses. By taking the elevated spike levels into consideration and adjusting the TCLP releases accordingly, the releases of Ag and Cd are reduced to 0.036 and 0.057, respectively, for glass RF8, and the release of Cd for RF9 is reduced to 0.012.

No information was available on the amount of Ni present in the sludge from the chemical analyses, so this value was not reduced for glass RF8. However, if the new limit is used for Ni, the glass would have passed the Ni criteria without the scaling factor being considered. These scaled results show that glasses RF8 and RF9 could possibly produce acceptable glass when the actual sludge is vitrified because of the lower amounts of RCRA metals that will be present. Also, it must be remembered that the TCLP was performed on a very conservative sample size, so the results are also very conservative.

Glasses LA1, LA3, LA13, and LA 18 exceeded the Cd limit. However, the new regulatory limits effective December 19, 1994 have raised the Cd limit to 0.19 mg/L (12), which would mean that only glass LA3 exceeded the Cd limit. These glasses will not be considered for further pilot-scale studies, since more acceptable glass compositions were found.

CONCLUSIONS

In order for glasses to be considered acceptable, they had to meet the PCT and TCLP criteria. Crystallinity in the glasses was also considered when determining a good glass, since the formation of crystals tends to decrease durability. A brief summary of the findings of all of the studies mentioned in this paper follows:

For SRS M-Area simulated sludge, up to 90% waste can be vitrified in borosilicate glass when melter systems such as the EnVitCo melter are used. Waste loadings of 85% are possible when melter systems such as the Stir-Melter are used. In both cases, hydrous borax was used as the glass forming additive.

For ORR WETF simulated sludge, crucible-scale studies showed that durable glasses consisting of 45% sludge can be vitrified at either low or high temperatures depending on the glass additives used (a combination of diatomaceous earth and hydrous borax or perlite only). The pilot-scale studies indicated that glasses

capable of passing the PCT and the new disposal limits for the TCLP can be produced at 45% or 40% waste loadings depending on the melt temperature and glass additives used.

For RFP Precipitate simulated sludge, high melting temperature glasses with waste loadings of up to 75% are possible. When only lower melting temperatures are available, waste loadings of up to 65% are possible. In both cases, a mixture of diatomaceous earth and hydrous borax were used as the glass forming additives. Crucible-scale study results indicate that 3 wt% charcoal should be added to prevent the formation of a sulfate salt layer.

For LANL TA-50 simulated sludge, a durable glass can be produced at high temperatures with 65% or 35% waste loading depending on the glass additives used (either a mixture of Al_2O_3 and SiO_2 or Na_2CO_3 and diatomaceous earth). Crucible-scale results also indicated that it was possible to produce a durable, leach-resistant glass by combining LANL and RFP simulated sludges with waste loadings of up to 100% possible. However, the reality of mixing these two waste streams is very slim since they are not located on the same site, so the composition was not recommended for further pilot-scale studies.

The fabricated glasses were plotted on associated ternary diagrams. Glasses M1P, M2P, M4P, M5P, OR1-OR3, OR1P, RF2, RF6-RF10, LA1, LA3, and LA13 fell within the known glass forming region of the borosilicate ternary system, while glasses M3P, RF4, and RF5 fell within the expected glass phase separation region. Some of these glasses (OR1-OR3 and OR1P) also fell within the suspected glass forming region of the CaO-Al_2O_3-SiO_2 ternary system, as did glasses OR7, OR7P, OR10, OR11, LA7, LA8, and LA9. Additional glasses fell within the expected glass making region of the CaO-Fe_2O_3-SiO_2 ternary system. These glasses included RF6, RF8, RF9, and LA6. Finally, glasses were also made in the known glass forming region of the Na_2O-CaO-SiO_2 ternary system. These glasses were OR12P, LA17, and LA19.

VITRIFICATION DEVELOPMENT FOR MIXED WASTES

Richard Merrill
Katherine Whittington
Richard Peters
Pacific Northwest Laboratory*
Richland, WA

ABSTRACT

Vitrification is a promising approach to waste-form immobilization. It destroys hazardous organic compounds and produces a durable and highly stable glass. Vitrification tests were performed on three surrogate wastes during fiscal year 1994: 183-H Solar Evaporation Basin waste from Hanford, bottom ash from the Oak Ridge TSCA incinerator, and saltcrete from Rocky Flats. Preliminary glass development involved melting trials followed by visual homogeneity examination, short-duration leach tests on glass specimens, and long-term leach tests on selected glasses. Viscosity and electrical conductivity measurements were taken for the most durable glass formulations. Results for the saltcrete are presented in this paper and demonstrate the applicability of vitrification technology to this mixed waste.

INTRODUCTION

The U.S. Department of Energy (DOE) is considering high-integrity waste forms to dispose of mixed low-level radioactive and hazardous waste. Vitrification is a promising waste-form option; it destroys hazardous organic compounds and produces a durable and highly stable glass. Vitrification research has been conducted through the Mixed Waste Integrated Program (MWIP) of the U.S. Department of Energy (DOE) Office of Technology Development. During fiscal year 1994, MWIP requested that Pacific Northwest Laboratory (PNL) evaluate processing limits for vitrification treatment of DOE mixed wastes. Of particular importance was the investigation of glass concentration limits for such components as halides and sulfates. PNL was the original developer of DOE vitrification technology selected for treatment of high-level waste (HLW) in the United States and other countries. The expertise and facility capabilities developed under the HLW programs are directly applicable to mixed waste vitrification development. These laboratory studies precede design of vitrification equipment and process flowsheets to permit environmentally sound treatment and disposal of mixed waste.

The waste stream considered in this study was the saltcrete waste from the Rocky Flats Plant (RFP) in Colorado. The use of large quantities of nitric acid in the RFP's production process generated a high volume waste stream primarily composed of neutralized nitrate salts. The salt solution was treated with a flocculant to help precipitate solids and radioactive material and was then processed in a clarifier. The overflow from the clarifier was sent to an evaporator and concentrated to a 35 wt% nitrate or brine salt solution. The salt solution was dried in a spray dryer and combined with cement to produce a grouted material called saltcrete. Many of the saltcrete blocks swelled and crumbled during extended outdoor storage. This work investigated vitrification of the failed saltcrete blocks.

Glass development entails directly analyzing the composition of the waste or using the best available data, and integrating that information with knowledge of glass chemistry, experience at PNL, and literature surveys to formulate canditate glass compositions. The canditate compositions are then prepared in the lab with non-radioactive chemicals and trial melts are made. The melts are inspected and characterized for leachability, homogeneity, viscosity, and electrical conductivity.

METHODOLOGY

Crucible melts containing varying amounts of simulated waste and additives (e.g., silica, boric acid, alumina, and phosphate) were prepared to define a glass composition suitable for vitrification. Initial glass compositions were based on compositions reported in the literature and previous melting experience at PNL. Additional melts were performed to refine the compositions based upon the homogeneity, viscosity, and chemical durability observed in the preceding melts.

The saltcrete waste consists primarily of portland cement, spray dried salts, and water in proportions (wt%) ranging from 55% salt, 18% cement, and 27% water to 51.3% salt, 22.2% cement, and 26.5% water. An approximate composition of the dried salts and the average portland cement composition (1) before shutdown of RFP operations are shown in Table I.

A surrogate waste was formulated from batch chemicals to match the reported composition of the saltcrete waste. Crucible melts were made with measured amounts

of surrogate waste and additives. The surrogate waste and additives were manually mixed and transferred to a fused silica, alumina, or porcelain crucible. The crucibles were placed in a furnace and held at the melt temperature (1000C to 1400C) for one to two hours. In some melts, the crucible was removed and the glass poured to permit estimation of the melt viscosity. In others, the furnace was turned off and allowed to cool slowly before the samples were removed. The cooled crucibles or poured glass buttons were then visually inspected for overall appearance, unmelted material, multiple phases, and crystalline inclusions.

A simple screening leach test provided a rapid estimate of the chemical durability of the glass formulations that were visually homogenous and had a suitable melt viscosity. The screening test resembled the EPA's Toxicity Characteristic Leaching Procedure (TCLP) in that a crushed glass sample was tumbled with the leachate. In this test, a sample of glass was crushed and sieved to a -4mm/+1mm size fraction and leached with deionized (DI) water at room temperature for 24 hours, during which time it was tumbled at 30 rpm. The mass ratio of water to sample was 10:1. The leachate concentrations were measured by inductively coupled plasma atomic emission spectroscopy (ICP-AES). Comparison of the normalized leach rate for the sample and that of standard glasses leached under the same conditions provided a comparative assessment of the samples durability.

Chloride concentrations in the final melts were analyzed by fusing the sample in Na_2CO_3 and submitting the diluted fusion for ion chromatography analysis. Matrix spike recovery of chloride by this method exceeded 90%.

RESULTS AND DISCUSSION

Glass Formulation

The primary issue associated with vitrification of the saltcrete waste is the relatively high content of salts in the waste, specifically chlorides and sulfates. Many metal chlorides have a low melting point and high vapor pressure (2) and therefore volatilize readily during glass melting. Volatilization from the melt can result in the loss from the glass of the elements and radionuclides that were to be immobilized in the vitrified waste form (3,4). Sulfates and chlorides have low solubility in typical borosilicate glass systems (<1 wt%), and when they coexist in glass, the solubility of each is even lower (5). When present in excess of their solubility limits, sulfate and chloride can form a molten salt phase on the surface of the glass with resulting processing problems (electric short-circuiting in a joule-heated melter, increased corrosion, and volatilization) and impairment of product quality (concentration of hazardous/radioactive elements into a highly leachable phase). The effort to define process limits for various problem constituents in glass included attempts to develop formulations with better retention of chloride and sulfate in the glass.

Previous work supported by the MWIP program had demonstrated the usefulness of phosphate in vitrification of wastes high in sulfate (6). The use of phosphate glass formulations promotes the decomposition and volatilization of sulfate at a low temperature, thereby avoiding the problem of secondary sulfate-phase formation. Therefore, the sulfate content of the saltcrete waste is not expected to pose a problem for phosphate glass formulations. The current work further investigated phosphate glasses as a means of increasing chloride retention in the glass melt. Phosphate glasses can be melted at low temperatures (as low as 1000C in this work), potentially reducing chloride volatility, and can accommodate large anions in the glass structure. The ability of certain phosphate glasses to retain chloride in the melt was therefore investigated in this work. Some silicate glasses were also investigated to achieve higher waste loadings and to provide a comparison to a more traditional glass for the phosphate formulations tested.

Forty-nine waste glasses were formulated and prepared for the simulated saltcrete waste. Target melt compositions and other data for several of these melts are presented in Table II. All of the formulations listed produced homogeneous, glassy melts except for SC30, which had streaks of opacity indicating phase separation or crystallization in the melt. The phosphate melts were transparent yellow, and the silicate melts were transparent green. The phosphate formulations had lower melting points and generally lower waste loading than the silicate melts.

Leach rates of the saltcrete glasses by the simple leach test previously described was comparable to that of high-level waste reference glasses leached by this same method. (ARM-1 - 0.18 g/m2; DWPF-EA - 0.32 g/m2). Leach results are expressed as the total release (grams of glass leached per square meter of surface area). Both

phosphate and silicate formulations for the saltcrete produced glasses with a durability comparable to typical high-level waste glasses. A comparison of the results from all the melts allows some general statements to be made about the glass formulations tested. Durability of the phosphate glasses appeared to be improved with increased alumina content (up to 25 wt%). Boron was observed to have a favorable effect on glass formation up to at least 6 wt% in some of the phosphate melts; however, several silicate melts with boron added to lower the melting temperature formed a separated salt phase on the surface of the melt. Analysis of this phase by X-ray florescence showed the primary components to be Na, K, Cl, and S.

Chloride retention was investigated in several melts. A low melting phosphate formulation (1000C) was spiked with increasing amounts of chloride by substituting NaCl for Na2O on an equimolar Na basis. The target chloride content of the melts was 1.6 wt% to 9.3 wt%. The products ranged from homogeneous glasses to two-phase melts. Table III presents results from this series of melts. Retention of chloride in the vitrified product ranged from about 50% to 70% after melting for one hour in an open crucible. After 24 hr uncovered in the furnace, retention of chloride in a melt with the composition of SC16 was only 15%. Chloride retention in several silicate melts (1350C) and phosphate melts at higher temperatures (1150C to 1200C) ranged from about 20% to 40% after one hour.

The above melts show that at least 2.6 wt% chloride can be retained in a homogeneous glass without visible phase separation. At 3.6 wt% chloride, opaque white streaks were present in an otherwise homogeneous, transparent yellow glass. Higher chloride concentrations led to phase separation of a molten chloride salt. The low melting temperatures of certain phosphate glass formulations appeared to improve the retention of chloride in the melt; however, significant losses still occurred and most of the chloride was lost from the melts after 24 hours uncovered at the melt temperature. Increasing chloride content of the glass generally had a negative impact on durability, largely from enhanced leaching of sodium from the glass.

CONCLUSIONS

The saltcrete waste is readily vitrified into both phosphate and silicate glasses. The resulting product is stable and substantially reduced in volume. Nevertheless, the high chloride content of these wastes poses a problem for vitrification technology due to its limited solubility in the glass matrix and high volatility from the melt. Certain glasses were shown to retain a substantial, although limited, amount of chloride. However, increased chloride concentration has a detrimental effect on glass durability and potentially on the vitrification process due to chloride volatilization. Although the low-melting temperature phosphate formulation provided significant retention of chlorides, at best only a few weight percent chloride can be contained in the glass and, even at the lower melting temperatures, chloride volatilization is a significant concern.

ABSTRACT
Treatability studies have been conducted at the laboratory-scale to evaluate vitrification of waste water sludges at the Oak Ridge Reservation (ORR). These studies are being conducted jointly by Westinghouse Savannah River Technology Center (SRTC) and Oak Ridge National Laboratory (ORNL). These studies include testing with surrogate waste formulations at both the laboratory-scale and pilot-scale, and testing with actual waste at the laboratory-scale, pilot-scale, and field-scale. ORR was chosen as the host site for the field-scale demonstration. The Y12 West End Treatment Facility (WETF) waste water treatment sludges, which are RCRA F-listed wastes, were chosen as the candidate waste stream for the first field-scale demonstration. The laboratory-scale "proof-of-principle" demonstrations reported in this study and the pilot-scale studies planned for FY95 on the WETF sludge will provide needed operating parameters for the planned field-scale demonstration. These laboratory-scale "proof-of-principle" and pilot-scale studies also provide needed data for the evaluation of the feasibility of vitrification as a stabilization option for a variety of wastes which do not currently meet RCRA/LDR (Resource Conservation and Recovery Act/Land Disposal Restrictions) requirements for storage/disposal and/or those for which treatment capacity does not presently exist.
INTRODUCTION
Technologies are being developed by the US Department of Energy' s (DOE) Nuclear Facility sites to convert low-level and mixed wastes to a solid stabilized waste form for permanent disposal. Vitrification is one of the most important and environmentally safest technologies being developed. The Environmental Protection Agency (EPA) has declared vitrification the Best Demonstrated Available Technology (BDAT) for high-level radioactive waste (1) and produced a Handbook of Vitrification Technologies for Treatment of Hazardous and Radioactive Waste (2). The DOE Office of Technology Development (OTD) has taken the position that mixed waste needs to be stabilized to the highest level reasonably possible to ensure that the resulting waste forms will meet both current and future regulatory specifications.
Vitrification produces durable waste forms at volume reductions up to 97% (3). Large reductions in volume minimize long-term storage costs making vitrification cost effective on a life cycle basis (4). The US DOE Savannah River Site (SRS), which is operated by Westinghouse Savannah River Company (WSRC), is currently investigating vitrification for disposal of various low-level and mixed wastes (3,5).
Vitrification has been demonstrated for in laboratory studies at SRS for 1) incinerator and 2) nickel plating line (RCRA F006) waste water sludge wastes. Stabilization of the heavy metals in the glass was achieved by use of reactive additives* such as diatomaceous earth, perlite (perflo), rice husk ash, and/or precipitated silica. The process/product models developed for high level radioactive waste glass were utilized to develop glass formulations which optimize glass processability, e.g viscosity, and product durability (6). This approach is currently being applied to the ORR Y12 West End Treatment Facility (WETF) RCRA listed waste water treatment sludges discussed in this study.
Reactive Additive Stabilization Process (RASP)
Reactive high surface area silica, as a waste form additive, was shown to greatly enhance the solubility and retention of hazardous, mixed and heavy metal species in glass (3). Highly reactive silica was found to increase the solubility and tolerance of Soda(Na_2O)Lime(CaO)-Silica(SiO_2) glass (SLS) and borosilicate (B_2O_3-SiO_2) glass formulations to atomistically bond waste species (8). Highly reactive silica lowers glassification temperatures, increases waste loadings which provides for large waste volume reductions, minimizes melt line corrosion, and produces EPA acceptable glasses. The Reactive Additive Stabilization Process (RASP) can be used to vitrify 1) spent filter aids from waste water treatment, 2) waste sludges, 3) combinations of spent filter aids from waste water treatment and waste sludges, 4) combinations

of supernate and waste sludges, 5) incinerator ash, 6) incinerator off-gas blowdown, 7) combinations of incinerator ash and off-gas blowdown, 8) cement formulations in need of remediation into glass, 9) ion exchange zeolites, 10) inorganic filter media, 11) asbestos or glass fiber filters, and 12) radioactive materials including TRU wastes.

West End Treatment Facility (WETF) Waste Water Treatment Sludges

The West End Treatment Facility at the Y-12 Plant on the Oak Ridge Reservation (ORR) treats nitrate-containing wastes by biodenitrification. Wastes are neutralized with lime and mixed with nutrients (acetate, triethylphosphate, etc.) and then transferred to a bioreactor for anoxic denitrification (7). The denitrified waste slurry is then subjected to bio-oxidation to complete the removal of residual organic compounds. The sludge is removed by gravitational sedimentation. The aqueous portion is decanted and sent to an effluent polishing unit which dissociates any residual uranium from its solubilizing complex with carbonate. The solution is then treated to coprecipitate any metals (including uranium) for removal. The sludge bottoms from the WETF clarifier are stored in four 500,000 gallon tanks awaiting further stabilization. Tanks 7, 8 and 9 are full and Tank 13 is partially full. The inventory as of 1992 was 250,000 ft3 or 1,900,000 gallons.

The WETF sludge is a RCRA listed waste (the EPA waste codes are F001, F002, F005 (from treatment of solvent residues), and F006 (from treatment of plating waste). The WETF sludge is primarily calcium carbonate, biomass, and iron oxyhydroxide (8). Depleted uranium (at an average of about 0.42% U-235 isotope, vs 0.71% in natural U) is the primary radioisotope of concern in this waste stream, with very low activity contributions from Tc-99 and transuranic isotopes (Np, etc) (8). Phenolic compounds represent the principal organic hazardous constituents in the sludge. Data from Tanks 7, 8, and 9 were compiled by Bostick (7) based on data supplied by SAIC and Y.F. Weaver of the ORR Y-12 plant (7). Bostick (7) derived a surrogate recipe for WETF Tank 7 wastes (Table I) during 1993.

VITRIFICATION TECHNOLOGY DEMONSTRATION

The vitrification demonstration of the ORR WETF wastes includes the following:

- Analyze wastes (FY93-94/ORR)
- Develop surrogate (FY93/ORR)
- Surrogate "proof-of-principle" laboratory scale studies (FY93-94/SRTC)
- Actual waste "proof-of-principle" laboratory scale studies (FY94-5/ORR+SRTC)
- Surrogate pilot-scale demonstration (FY94-95/SRTC and Clemson University)
- Actual waste pilot-scale demonstration (FY95/SRTC, ORR, and RUST Federal)
- Actual waste field-scale demonstration (FY96/SRTC+ORR-Ref. 9)

The initial testing of the surrogate and actual waste "proof-of-principle" testing being carried out jointly between SRTC and ORR under a Memorandum of Understanding (MOU) are discussed in this study. The pilot-scale demonstration on ORR WETF wastes is planned for mid FY95 at RUST Federal in Clemson, SC under a Cooperative Research and Development Agreement (CRADA) between RUST and SRTC. The field-scale demonstration will take place at ORR in a Transportable Vitrification System (TVS) being provided by SRTC (9) under a separate Memorandum of Understanding.

EXPERIMENTAL

The Tank 7 surrogate waste developed by Bostick (7) was used to optimize glass formulations at the Savannah River Technology Center (SRTC) for laboratory scale "proof-of-principle" testing. Reagent grade chemicals and varying sources of SiO2, e.g. silica sand, diatomaceous earth, Perlite, or precipitated silica. Cerium was substituted on a molar basis for uranium. Waste loadings were varied from 20 to 70 wt% waste on a dry oxide basis. All glasses were melted at temperatures between 1150 and 1350C in high purity A1203 crucibles for 4 hours. Small amounts of glass, ~100 gram batches, were made to optimize the best compositions for further testing. Each vitrified sample was submitted for x-ray diffraction (XRD) analysis so that the homogeneity of the resulting glass could be determined. For glasses which were not homogeneous, the crystalline phases were identified by XRD. If analysis by XRD was inconclusive, elemental scans by x-ray fluorescence (XRF) were substituted.

Real wastes were sampled at ORR from Tanks 8 and 13 and dried at 110C. Five samples of dried sludge from each tank were dissolved and analyzed. Glasses were made with the dried sludge and reagent grade chemicals and precipitated silica. All glasses were melted at temperatures between 1150 and 1350C in high purity A1203 crucibles for 4 hours. Small amounts of glass, ~150 gram batches, were made and submitted for waste form performance assessment via the EPA Toxic Characteristic Leaching

Procedure (TCLP). Each glass was doped with 20, 50 and 100 times the RCRA hazardous metals. These doped glasses will also be submitted for waste form performance assessment via the TCLP.

RESULTS AND DISCUSSION

WETF Waste Analyses and Accuracy Mass Balance

The compositions of the WETF Tank 8 and Tank 13 sludges as analyzed at ORR are given as wt% component species in Table I. Since no standards exist to assist in determining the accuracy of a sludge analysis, an accuracy mass balance was performed (10-11). The elemental cation weight percentages measured in the sludge are converted to oxides. An oxide mass balance is performed because the major anion remaining in a waste after vitrification is oxygen. In addition, waste analysis given on a dry calcine (oxide only) basis forms the basis for determining the "glass forming potential" of a waste.

Carbon dioxide will evolve from carbonate species in the waste, e.g. the $CaCO_3$, $NiCO_3$, and Na_2CO_3, and will be vaporized during vitrification. The CO_2 that will be volatilized from the glass melt during vitrification can be calculated from the molar concentrations of Ca, Ni, and Na in the waste (Table I). Likewise, the hydroxides present in the waste will vaporize as steam during the vitrification process. The OH that will be volatilized from the hydroxide species present in the sludge, e.g. $Al(OH)_3$ and $Fe(OH)_3$, during the vitrification process can be calculated from the molar concentrations of A1 and Fe (Table I). Although organics content was not measured in this study, the organic (oil and grease) and biomass reported in Ref. 8 for the WETF sludge was added to the analyses given in Table I. The organic and biomass will also be volatilized during vitrification. The mass balance of a sludge dried only at 110C, therefore, includes the volatiles (which will be lost at the 1150C vitrification temperature) and the glass oxide components (which will combine to form the glass during vitrification). A mass balance calculation of 100±5 wt% indicates (11) that the WETF analyses determined in this study were sufficiently accurate (Table I).

The WETF Tank 8 and Tank 13 analyses determined in this study are compared to earlier analyses reported in Refs. 7 and 12. These comparisons are shown in Table I. The earlier Tank 8 and Tank 13 analyses were comparable to those determined in this study but several minor constituents of the sludge had been omitted from the earlier analyses. Moreover, the analysis reported in Ref. 8 for Tank 8 was reported to be on a dry sludge basis. Application of the accuracy mass balance technique used in this study indicated that the composition given in Reference 8 for Tank 8 was on a wet sludge basis. The conversion from wet sludge basis to dry sludge basis has been accounted for in the data presented in Table I.

The WETF Tank 7 surrogate used in the simulated "proof-of-principle" studies and in the simulated "pilot scale" studies is also given in Table I for comparison. Since the simulant was developed from earlier composition analysis of Tank 7, 8, and 9, several of the minor constituents had been omitted from the surrogate. The accuracy mass balance methodology was applied to all of the analyses of real WETF sludge and the WETF Tank 7 surrogate. All of the analyses have a high degree of accuracy but the analyses presented in this study are within the mass balance accuracy criterion of 100±5 wt% while the previous analyses are not. All of the analyses indicate that there is very little chemical variation in the WETF sludges sampled from different tanks indicating that chemically the WETF sludge is very homogeneous.

WETF Glass Formulations

The high CaO content of the WETF wastes on a dry oxide basis provided the "lime" glass forming constituent for Soda-Lime-Silica (SLS) glass formulations. The SLS glass forming system is a well known system used to make window glass and it has been extensively studied by glass chemists since 1925 (13-16). Soda-lime-silica glass is known to readily incorporate heavy metals (17). SLS glass formulations have been used for In-Situ Vitrification (ISV) to solidify contaminated soils (18-19) and a barium analog (soda-baria-silica) glass has been used at Fernald to solidify residues from uranium ore processing that contain large amounts of uranium, radium, and lead (20). SLS glasses have also been successfully fabricated from reactive sodium metal contaminated during efforts to develop sodium-cooled fast breeder nuclear reactors (21). The SLS system has also been used in laboratory "proof-of-principle" testing to vitrify M-Area wastes and SRS incinerator ashes. The use of the SLS glass forming system and the use of the Reactive Additive Stabilization Process (RASP) was shown to extends the known glass forming region in

the SLS system (3) as shown in Fig. 2.
The WETF glass formulations are being optimized in the region of the SLS system where glasses are known to form stable homogeneous glasses. The process models developed for high level waste glasses were utilized to calculate the glass viscosity and durability as a function of temperature (6).
TABLE I
To date over 140 surrogate glass formulations were tested for the ORR WETF sludges using the Tank 7 surrogate developed by Bostick(7). The surrogate glass formulations examined the following effects:

- waste loading
- melt temperature
- varying alkali additives
- varying reactive silica additives (perlite, sand, and precipitated silica)
- melt line refractory corrosion
- general refractory corrosion
- predictability of process/product models

To date more than ten different WETF laboratory-scale "proof-of-principle" glass formulations have been made with real WETF Tank 8 waste. This adjusted Tank 8 composition from Ref. 7 was used to formulate the glasses for the crucible testing "proof-of-principle" with the real WETF Tank 8 sludge (the analysis shown for Tank 8 in Table I that was determined as part of this study was not available at the time at which the Tank 8 "proof-of-principle" studies were conducted). Approximately 150 grams of each formulation were melted and found to form homogeneous glass. Waste loadings varying from 20 to 70 wt% waste (on a calcine oxide basis, e.g. the compositions given in Table I normalized for the volatiles lost on ignition) were achieved at temperatures ranging from 1150C to 1350C (Fig. 1). One of the 35 wt% loaded waste glass compositions tested is of historical significance dating from the 1608 Jamestown, Virginia settlement.
All of the initial WETF Tank 8 glasses were subjected to the EPA Toxic Characteristic Leaching Procedure (TCLP) and met the EPA Universal Treatment Standards (UTS) promulgated September 19, 1994 in the Federal Register. Severe melt line corrosion was experienced with the higher waste loaded glass formulations and the compositions were further optimized using the Tank 7 surrogate. These optimized glass formulations which contain 35 to 50 wt% actual WETF Tank 8 waste, were doped with 20, 50, and 100 times the RCRA hazardous metals to test the flexibility of the glass formulations to retain hazardous species. These glasses are currently undergoing TCLP analysis.
The optimized glass formulations used for the actual WETF Tank 8 wastes were reformulated with actual WETF Tank 13 waste. The average Tank 13 waste analysis determined in this study was the analysis used to develop glass formulations for the crucible testing "proof-of-principle" with the real WETF Tank 13 sludge. The Tank 13 optimized glass formulations will also be doped with 20, 50, and 100 times the RCRA hazardous species. All of the Tank 13 glasses will be subjected to the EPA TCLP test. All of the actual Tank 8 and Tank 13 tests will also be subjected to the Product Consistency Test (ASTM C1285).
WASTE MINIMIZATION
The 35 to 70% waste loaded glasses correspond to volume reductions of 73 to 87% for the ORR WETF waste water sludges, assuming 40 wt% solids in the sludge and a density of glass of 2.7 kg/L. Therefore, based on the 1992 tank inventory of 1,900,000 gallons of sludge, this waste will produce between 513,000 to 247,000 gallons of glass. By comparison stabilization of the ORR WETF waste water sludges in cement will cause a 2X volume increase and the final waste form volume will be 3,800,000 gallons. Comparisons of the overall waste volume reduction compared to alternative stabilization strategies in cement (Table II) shows that vitrification of ORR WETF sludges reduces the stabilized volume by 87% (Option 2 at 35% waste loading) to 94% (Option 5 at 70% waste loading) relative to the base case cement stabilization.
ACKNOWLEDGMENT
This paper was prepared in connection with work done under Contract No. DE-AC09-89SR18035 with the U.S. Department of Energy. This work was funded by DOE Office of Technology Development Mixed Waste Integrated Program (MWIP).

ABSTRACT
Treatability studies have been conducted at the laboratory-scale to evaluate vitrification of waste water sludges at the Oak Rige Reservation (ORR). These studies are being conducted jointly by Westinghouse Savannah River Technology Center (SRTC) and Oak Ridge National Laboratory (ORNL). These studies include testing with surrogate waste formulations at both the laboratory-scale and pilot-scale, and testing with actual waste at the laboratory-scale, pilot-scale, and field-scale. ORR was chosen as the host site for the field-scale demonstration. The Y12 West End Treatment Facility (WETF) waste water treatment sludges, which are RCRA F-listed wastes, were chosen as the candidate waste stream for the first field-scale demonstration. The laboratory-scale "proof-of-principle" demonstrations reported in this study and the pilot-scale studies planned for FY95 on the WETF sludge will provide needed operating parameters for the planned field-scale demonstration. These laboratory-scale "proof-of-principle" and pilot-scale studies also provide needed data for the evaluation of the feasibility of vitrification as a stabilization option for a variety of wastes which do not currently meet RCRA/LDR (Resource Conservation and Recovery Act/Land Disposal Restrictions) requirements for storage/disposal and/or those for which treatment capacity does not presently exist.

INTRODUCTION

Technologies are being developed by the US Department of Energy's (DOE) Nuclear Facility sites to convert low-level and mixed wastes to a solid stabilized waste form for permanent disposal. One of the alternative waste forms is vitrification. The Environmental Protection Agency (EPA) has declared vitrification the Best Demonstrated Available Technology (BDAT) for high-level radioactive waste (1) and produced a Handbook of Vitrification Technologies for Treatment of Hazardous and Radioactive Waste.(2) The DOE Office of Technology Development (OTD) has taken the position that mixed waste needs to be stabilized to the highest level reasonably possible to ensure that the resulting waste forms will meet both current and future regulatory specifications. Vitrification produces durable waste forms at volume reductions up to 97%.(3) Large reductions in volume minimize long-term storage costs making vitrification cost effective on a life cycle basis.(4) The US DOE Savannah River Site (SRS), which is operated by Westinghouse Savannah River Company (WSRC), is currently investigating vitrification for disposal of various low-level and mixed wastes (3,5). Vitrification has been demonstrated for in laboratory studies at SRS for (1) incinerator and (2) nickel plating line (RCRA F006) waste water sludge wastes. Stabilization of the heavy metals in the glass was achieved by use of reactive additives* such as diatomaceous earth, perlite (perflo), rice husk ash, and/or precipitated silica. The process/product models developed for high level radioactive waste glass were utilized to develop glass formulations which optimize glass processability, e.g viscosity, and product durability (6). This approach is currently being applied to the ORR Y12 West End Treatment Facility (WETF) RCRA listed waste water treatment sludges discussed in this study.

Reactive high surface area silica, as a waste form additive, was shown to greatly enhance the solubility and retention of hazardous, mixed and heavy metal species in glass (7). Highly reactive silica was found to increase the solubility and tolerance of Soda(Na_2O)- Lime(CaO)-Silica(SiO_2) glass (SLS) and borosilicate (B_2O_3-SiO_2) glass formulations to atomistically bond waste species (9). Highly reactive silica lowers glassification temperatures, increases waste loadings which provides for large waste volume reductions, minimizes melt line corrosion, and produces EPA acceptable glasses. The Reactive Additive Stabilization Process (RASP) can be used to vitrify (1) spent filter aids from waste water treatment, (2) waste sludges, (3) combinations of spent filter aids from waste water treatment and waste sludges, (4)

combinations of supernate and waste sludges, (5) incinerator ash, (6) incinerator off-gas blowdown, (7) combinations of incinerator ash and off-gas blowdown, (8) cement formulations in need of remediation into glass, (9) ion exchange zeolites, (10) inorganic filter media, (11) asbestos or glass fiber filters, and (12) radioactive materials including TRU wastes.

West End Treatment Facility (WETF) Waste Water Treatment Sludges

The West End Treatment Facility at the Y-12 Plant on the Oak Ridge Reservation (ORR) treats nitrate-containing wastes by biodenitrification. Wastes are neutralized with lime and mixed with nutrients (acetate, triethylphosphate, etc.) and then transferred to a bioreactor for anoxic denitrification (8). The denitrified waste slurry is then subjected to bio-oxidation to complete the removal of residual organic compounds. The sludge is removed by gravitational sedimentation. The aqueous portion is decanted and sent to an effluent polishing unit which dissociates any residual uranium from its solubilizing complex with carbonate. The solution is then treated to coprecipitate any metals (including uranium) for removal. The sludge bottoms from the WETF clarifier are stored in four 500,000 gallon tanks awaiting further stabilization. Tanks 7, 8 and 9 are full and Tank 13 is partially full. The inventory as of 1992 was 250,000 ft3 or 1,900,000 gallons.

The WETF sludge is a RCRA listed waste (the EPA waste codes are F001, F002, F005 (from treatment of solvent residues), and F006 (from treatment of plating waste). The WETF sludge is primarily calcium carbonate, biomass, and iron oxyhydroxide (9). Depleted uranium (at an average of about 0.42% U235 isotope, vs 0.71% in natural U) is the primary radioisotope of concern in this waste stream, with very low activity contributions from Tc99 and transuranic isotopes (Np, etc) (9). Phenolic compounds represent the principal organic hazardous constituents in the sludge. Data from Tanks 7, 8, and 9 were compiled by Bostick (8) based on data supplied by SAIC and Y.F. Weaver of the ORR Y-12 plant (8). Bostick (8) derived a surrogate recipe for WETF Tank 7 wastes (Table I) during 1993.

TABLE I

VITRIFICATION TECHNOLOGY DEMONSTRATION

The vitrification demonstration of the ORR WETF wastes includes the following:

- Analyze wastes (FY93-94/ORR)
- Develop surrogate (FY93/ORR)
- Surrogate "proof-of-principle" laboratory scale studies (FY93-94/SRTC)
- Actual waste "proof-of-principle" laboratory scale studies (FY94-5/ORR+SRTC)
- Surrogate pilot-scale demonstration (FY94-95/SRTC and Clemson University)
- Actual waste pilot-scale demonstration (FY95/SRTC, ORR, and RUST Federal)
- Actual waste field-scale demonstration (FY96/SRTC+ORR-Reference 10)

The initial testing of the surrogate and actual waste "proof-of-principle" testing being carried out jointly between SRTC and ORR under a Memorandum of Understanding (MOU) are discussed in this study. The pilot-scale demonstration on ORR WETF wastes is planned for mid FY95 at RUST Federal in Clemson, SC under a Cooperative Research and Development Agreement (CRADA) between RUST and SRTC. The field-scale demonstration will take place at ORR in a Transportable Vitrification System (TVS) being provided by SRTC (12) under a separate Memorandum of Understanding.

EXPERIMENTAL

The Tank 7 surrogate waste developed by Bostick (8) was used to optimize glass formulations at the Savannah River Technology Center (SRTC) for laboratory scale "proof-of-principle" testing. Reagent grade chemicals and varying sources of SiO_2, e.g. silica sand, diatomaceous earth, Perlite, or precipitated silica. Cerium was substituted on a molar basis for uranium. Waste loadings were varied from 20 to 70 wt% waste on a dry oxide basis. All glasses were melted at temperatures between 1150o and 1350oC in high purity Al_2O_3 crucibles for 4 hours. Small amounts of glass, ~100 gram batches, were made to optimize the best compositions for further testing. Each vitrified sample was submitted for x-ray diffraction (XRD) analysis so that the homogeneity of the resulting glass could be determined. For glasses which were not homogeneous, the crystalline phases were identified by XRD. If analysis by XRD was inconclusive, elemental scans by x-ray fluorescence (XRF) were substituted.

Real wastes were sampled at ORR from Tanks 8 and 13 and dried at 110oC. Five samples of dried sludge from each tank were dissolved and analyzed. Glasses were made with the dried sludge and reagent grade chemicals and precipitated silica. All glasses were melted at temperatures between 1150o and 1350oC in high purity Al_2O_3 crucibles for 4 hours. Small amounts of glass, ~150 gram batches, were made and submitted for

waste form performance assessment via the EPA Toxic Characteristic Leaching Procedure (TCLP). Each glass was doped with 20, 50 and 100 times the RCRA hazardous metals. These doped glasses will also be submitted for waste form performance assessment via the TCLP.

RESULTS AND DISCUSSION

WETF Waste Analyses and Accuracy Mass Balance

The WETF Tank 8 and Tank 13 sludges dried at 110oC and analyzed at ORR are given as wt% component species in Table I. Since no standards exist to assist in determining the accuracy of a sludge analysis, an accuracy mass balance was performed (11,12). The elemental cation weight percentages measured in the sludge are converted to oxides. An oxide mass balance is performed because the major anion remaining in a waste after vitrification is oxygen. In addition, waste analysis given on a dry calcine (oxide only) basis forms the basis for determining the "glass forming potential" of a waste.

Carbon dioxide will evolve from carbonate species in the waste, e.g. the $CaCO_3$, $NiCO_3$, and Na_2CO_3, and will be vaporized during vitrification. The CO_2 that will be volatilized from the glass melt during vitrification can be calculated from the molar concentrations of Ca, Ni, and Na in the waste (Table I). Likewise, the hydroxides present in the waste will vaporize as steam during the vitrification process. The OH that will be volatilized from the hydroxide species present in the sludge, e.g. $Al(OH)_3$ and $Fe(OH)_3$, during the vitrification process can be calculated from the molar concentrations of Al and Fe (Table I).

Although organics content was not measured in this study, the organic (oil and grease) and biomass reported in Ref. 8 for the WETF sludge was added to the analyses given in Table I. The organic and biomass will also be volatilized during vitrification. The mass balance of a sludge dried only at 110oC, therefore, includes the volatiles (which will be lost at the 1150oC vitrification temperature) and the glass oxides components (which will combine to form the glass during vitrification). A mass balance calculation of 1005 wt% indicates (12) that the WETF analyses determined in this study were highly accurate (Table I).

The WETF Tank 8 and Tank 13 analyses determined in this study are compared to earlier analyses reported in Refs. 8 and 13. These comparisons are shown in Table I. The earlier Tank 8 and Tank 13 analyses were comparable to those determined in this study but several minor constituents of the sludge had been omitted from the earlier analyses. Moreover, the analysis reported in Ref. 8 for Tank 8 was reported to be on a dry sludge basis. Application of the accuracy mass balance technique used in this study indicated that the composition given in Ref. 8 for Tank 8 was on a wet sludge basis. The conversion from wet sludge basis to dry sludge basis has been accounted for in the data presented in Table I.

The WETF Tank 7 surrogate used in the simulated "proof-of-principle" studies and in the simulated "pilot scale" studies is also given in Table I for comparison. Since the simulant was developed from earlier composition analysis of Tank 7, 8, and 9, several of the minor constituents had been omitted from the surrogate. The accuracy mass balance methodology was applied to all of the analyses of real WETF sludge and the WETF Tank 7 surrogate. All of the analyses have a high degree of accuracy but the analyses presented in this study are within the mass balance accuracy criterion of 100 5 wt% while the previous analyses are not. All of the analyses indicate that there is very little chemical variation in the WETF sludges sampled from different tanks indicating that chemically the WETF sludge is very homogeneous.

WETF Glass Formulations

The high CaO content of the WETF wastes on a dry oxide basis provided the "lime" glass forming constituent for Soda-Lime-Silica (SLS) glass formulations. The SLS glass forming system is a well known system used to make window glass and it has been extensively studied by glass chemists since 1925 (14-17). Soda-silica glass is known to readily incorporate heavy metals (18). SLS glass formulations have been used for In-Situ Vitrification (ISV) to solidify contaminated soils (19-20) and a barium analog (soda-baria-silica) glass has been used at Fernald to solidify residues from uranium ore processing that contain large amounts of uranium, radium, and lead (21). SLS glasses have also been successfully fabricated from reactive sodium metal contaminated during efforts to develop sodium-cooled fast breeder nuclear reactors (22). The SLS system has also been used in laboratory "proof-of-priciple" testing to vitrify M-Area wastes and SRS incinerator ashes. The use of the SLS glass forming system and the use of the Reactive Additive

Stabilization Process (RASP) was shown to extend the known glass forming region in the SLS system (7) as shown in Fig. 1.
The WETF glass formulations are being optimized in the region of the SLS system where glasses are known to form stable homogeneous glasses. The process models developed for high level waste glasses were utilized to calculate the glass viscosity and durability as a function of temperature (6).
To date over 140 surrogate glass formulations were tested for the ORR WETF sludges using the Tank 7 surrogate developed by Bostick (8). The surrogate glass formulations examined the following effects:

- waste loading
- melt temperature
- varying alkali additives
- varying reactive silica additives (perlite, sand, and precipitated silica)
- melt line refractory corrosion
- general refractory corrosion
- predictability of process/product models

To date more than ten different WETF laboratory-scale "proof-of-principle" glass formulations have been made with real WETF Tank 8 waste. This adjusted Tank 8 composition from Ref. 8 was used to formulate the glass formulations for the crucible testing "proof-of-principle" with the real WETF Tank 8 sludge (the analysis shown for Tank 8 in Table I that were determined as part of this study were not available at the time at which the Tank 8 "proof-of-principle" studies were conducted.) Approximately 150 grams of each formulation were melted and found to form homogeneous glass. Waste loadings varying from 20 to 70 wt% waste (on a calcine oxide basis, e.g. the compositions given in Table I normalized for the volatiles lost on ignition) were achieved at temperatures ranging from 1150oC to 1350oC (Fig. 1). One of the 35 wt% loaded waste glass compositions tested is of historical significance dating from the 1608 Jamestown, Virginia settlement.
Table II
All of the initial WETF Tank 8 glasses were subjected to the EPA Toxic Characteristic Leaching Procedure (TCLP) and met the EPA Universal Treatment Standards (UTS) promulgated September 19, 1994 in the Federal Register. Severe melt line corrosion was experienced with the higher waste loaded glass formulations and the compositions were further optimized using the Tank 7 surrogate. These optimized glass formulations which contain 35 to 50 wt% actual WETF Tank 8 waste, were doped with 20, 50, and 100 times the RCRA hazardous metals to test the flexibility of the glass formulations to retain hazardous species. These glasses are currently undergoing TCLP analysis.
The optimized glass formulations used for the actual WETF Tank 8 wastes were reformulated with actual WETF Tank 13 waste. The average Tank 13 waste analysis determined in this study was the analysis used to develop glass formulations for the crucible testing "proof-of-principle" with the real WETF Tank 13 sludge. The Tank 13 optimized glass formulations will also be doped with 20, 50, and 100 times the RCRA hazardous species. All of the Tank 13 glasses will be subjected to the EPA TCLP test. All of the actual Tank 8 and Tank 13 tests will also be subjected to the Product Consistency Test (ASTM C1285).
WASTE MINIMIZATION
The 35 to 70% waste loaded glasses correspond to volume reductions of 73 to 87% for the ORR WETF waste water sludges, assuming 40 wt% solids in the sludge and a density of glass of 2.7 kg/L. Therefore, based on the 1992 tank inventory of 1,900,000 gallons of sludge, will make between 513,000 to 247,000 gallons of glass. By comparison stabilization of the ORR WETF waste water sludges in cement will cause a 2X volume increase and the final waste form volume will be 3,800,000 gallons. Comparisons of the overall waste volume reduction compared to alternative stabilization strategies in cement (Table II) shows that vitrification of ORR WETF sludges reduces the stabilized volume by 87% (Option 2 at 35% waste loading) to 94% (Option 5 at 70% waste loading) relative to the base case cement stabilization.

ABSTRACT

The Department of Energy (DOE), through the Mixed Waste Integrated Program, has identified a need to move mixed-waste vitrification technology from the laboratory to the field as rapidly as possible. A great deal of work over the last few years has shown the feasibility of immobilizing selected hazardous waste streams in a vitrified product. Lab-scale work has been extended to pilot-scale tests, usually with surrogates of the actual waste. DOE felt that the technology was mature enough to allow demonstration in the field on actual wastes, with units that would be prototypic of full-sized waste treatment equipment. To this end, DOE's Office of Technology Development sponsored the Westinghouse Savannah River Company (WSRC) to specify, procure, test, and operate a field scale demonstration using mobile equipment. Oak Ridge Reservation was chosen as the initial location for the field demonstration and Martin Marietta Energy Systems (MMES) was tasked with all permitting, site preparation, and field support activities.

During September 1993, WSRC used a "Vendor Forum" to solicit preliminary proposals for the Transportable Vitrification System (TVS). A number of quality proposals were received and evaluated. A vendor was selected and detailed negotiations were completed in August 1994, at which time a contract was signed for the TVS. In parallel, WSRC opened a dialogue with MMES to explore candidate waste streams at the Oak Ridge Reservation for the first TVS vitrification campaign. After some preliminary work, a group of waste water sludges were selected. The first of these to be demonstrated with the TVS will be the West End Treatment Facility sludge. This paper describes the development of specifications for the TVS, the design and construction activities to date, and ongoing efforts for permitting, site support, and the schedule for field application.

INTRODUCTION

The Transportable Vitrification System (TVS) is an outgrowth of a much larger US Department of Energy (DOE) program that deals with the large quantity and variability of mixed low-level and hazardous waste that exist in the DOE complex. The technology development aspect of this program is administered through the Mixed Waste Integrated Program (MWIP) of DOE's Office of Technology Development (DOE-OTD). The management of this program realized that the time had come to take selected mixed waste treatment processes from the laboratory to actual field application. The TVS and related programs are Westinghouse Savannah River Company's (WSRC) response to this challenge.

The concept of treating mixed waste using vitrification evolved from the high-level waste (HLW) vitrification program. Many of the personnel involved in the present program have extensive experience with the Defense Waste Processing Facility (DWPF), a high-level waste vitrification facility now undergoing non-radioactive shakedown testing at the Savannah River Site (SRS). Vitrification offers many of the same advantages for the treatment of low-level and hazardous waste as seen in HLW vitrification_namely, the ability to "lock up" dangerous chemical species in a durable glass form while achieving sizable volume reduction. The fact that low-level and mixed wastes (LLMW) does not require extensive shielding and remote operation as in the case of high-level waste allows the construction of LLMW vitrification equipment, of comparable throughput rates to DWPF, at a cost almost three orders of magnitude less.

As in the case of HLW, work in this program began with "crucible tests" to determine the feasibility of the process and the range of successful glass formulations in the selected glass systems (1,2). This work was initially carried out with surrogates of the candidate waste streams and is presently being extended to tests of actual waste, as described elsewhere (3,4).

Based on the success of early crucible studies in the summer of 1993, it was proposed to build a mobile vitrification facility capable of treating significant quantities (i.e., tons per day) of waste. This concept has evolved into the Transportable Vitrification System (TVS). In parallel with the development of the TVS concept, WSRC surveyed various waste streams as candidates for the first demonstration of the TVS. Negotiations during the fall of 1993 led to the selection of DOE's Oak Ridge Reservation as the first host site for the TVS. This was based in part upon the large number of suitable waste streams available and upon Martin Marietta Energy Systems (MMES) enthusiastic cooperation. Selection of the candidate waste stream will be discussed in this paper.

Early in the TVS program DOE and WSRC realized that the jump from crucible studies to field application is a considerable scale up of the technology. This point of view was strengthened by our experience with similar, smaller scale melters, at the DOE/Industry Center for Vitrification Research at Clemson University's Environmental Systems Engineering Department. Problems of feed handling, emissions control, melter operability, and a host of other issues can not be investigated adequately in crucible tests; therefore, a third element was added to the TVS program, testing of surrogate and actual material in "laboratory-scale" melters. Surrogate testing will take place at the vitrification facility at Clemson, while the testing with actual waste will take place at RUST Federal's facility next door to the Clemson vitrification laboratory. Both test programs will use smaller melters than the TVS, although similar in design. This work will be reported after its conclusion later this year.

As described above, DOE and WSRC have taken an integrated approach to the application of vitrification to mixed waste. This approach is carefully structured to provide testing at three different scales proceeding from crucible to laboratory melter to field application. The first two elements of the program are described elsewhere (3). The remainder of this paper will concentrate on the development of the TVS and preparations for field application.

TRANSPORTABLE VITRIFICATION SYSTEM

Procurement of the TVS

The original specification for the TVS was contained in the "Special Consolidated Solicitation, No. E10600-E1" which appeared in August 1993. The relevant section of this solicitation, entitled "Portable demonstration facilities with offgas treatment, melters, and analytical instrumentation for melter feed and product analyses", attracted nine proposals. A technical evaluation team (D. F. Bickford, A. L. Kielpinski, and J. C. Whitehouse) reviewed and ranked the proposals. After additional review by WSRC Procurement and DOE-SR, EnVitCo Inc., of Toledo, Ohio, was selected and asked to provide a detailed proposal. The detailed proposal was received in March 1994, and awarded to EnVitCo in August 1994.

The contract calls for EnVitCo to provide a complete, integrated, transposable vitrification system consisting of four modules: Waste and Additive Materials Preparation, Melter, Emissions Control, and Control and Services. The purpose of the system is to demonstrate treatment of small to medium quantities of low-level and mixed wastes to produce a durable glass product suitable for disposal in an approved repository.

Writing specifications for the TVS was difficult due to its broad mission to treat a wide variety of (mostly unidentified) low-level and mixed wastes. Therefore, the specifications were much less detailed than those for a fixed facility designed for one or two well characterized waste streams. Instead, the TVS must deal with waste streams which range from contaminated soils to waste water treatment sludges of widely varying chemical composition.

Some of the more important specifications include the following:

- Joule heated, cold top melter capable of producing 136 kilograms (300 pounds) of glass per hour with dry feed
- melter temperature range of 1100_1400-C
- slurried or dry waste feed
- provision for the simultaneous introduction of three additive materials with mixing tanks
- offgas system to maintain the melter under vacuum conditions
- 99.99% minimum particulate removal, at one micron
- ability to remove dilute acid gases from the offgas
- design to include features to make radiological decontamination easier

modules to be capable of shipment on standard trailers

TVS Design and Fabrication

EnVitCo began design activities as soon as the contract was finalized. It soon became apparent that the TVS would not be a mobile facility. The size of the melter was too large to fit completely on a single trailer; therefore, a modular approach was adopted. Where feasible, entire subsystems (i.e., the waste and additives equipment) are contained in a single sealed unit; similarly, the control and service equipment is contained in a single module. However, the melter unit is broken down into several separate modules for shipping. Once on site, it will be assembled by bolting the modules together. The emissions control equipment is broken down into three skids for shipment. EnVitCo expects that shipment of the TVS will require five tractor trailer loads. Figure 1 is a schematic layout of the TVS.

Fig. 1.

Referring to Fig. 1, waste to be processed is delivered to the Waste and Additives Module as either dry or slurried waste. While slurried waste is pumped directly to the Blend Tank, dry waste is dumped into the Waste Hopper where a screw feeder transports it to the Blend Tank. Glass-forming additives are supplied in bulk bag containers and transported to the Blend Tank by a metering screw feeder. Water is added as necessary. The Blend Tank is placed on load cells to aid the operator in achieving the proper mix of waste and additives. An agitator in the Blend Tank homogenizes the feed. Once the batch is ready, it is pumped to the Surge Tank, which is also provided with an agitator. A recirculation loop transports the slurried feed to the melter where a side stream is drawn off and metered for introduction into the melter.

The melter contains three main chambers. The largest is the central, refractory-lined processing chamber into which the feed is introduced. This chamber contains the primary electrodes. Slurried feed forms a "cold-cap" on the surface of the molten glass that helps to reduce emissions of volatile metals. Convective currents in the glass, set up by the electrodes, draw fresh material from the cold-cap into the glass pool where the vitrification process takes place. Glass is drawn through a refractory-lined "throat" into the glass drain chamber. A nuclear-level gauge controls the glass level in the melter by moving the spindle of a submerged drain valve. When this valve is open, glass drains by gravity into glass receptacles placed on a conveyor. After filling, the containers are allowed to cool and are removed by a forklift truck for storage or disposal. The third chamber, which has a separate drain mechanism, is designed to remove sulfates that may collect on the glass pool surface. The processing of some waste streams may result in the accumulation of metals in the main melter chamber; therefore, a third "metals drain" is provided for this eventuality.

Offgas from the melter is drawn off through a refractory-lined duct to the emission control module. This module will be supplied by Anderson 2000, of Peachtree City Georgia, under EnVitCo's contract. The unit consists of a quencher, packed bed cooler, variable throat venturi scrubber, mist eliminator, reheater, HEPA filters, and fans. Treated offgas is released through a 15 m (50 foot) stack, with provisions for Environmental Protection Agency (EPA) approved particulate and gas sampling.

The Control and Services Module contains the control room for the TVS, as well as the power supply and conditioning equipment for the melter. A standard programmable logic control system will be used to control most of the operations of the TVS from the control room.

Schedule and Status

As of early January 1995, 55% of the engineering work for the TVS has been completed. Long lead items, such as refractory and power conditioning equipment, have been ordered. EnVitCo expects to deliver the TVS within the one year contract duration (i.e., before August 16, 1995).

Prior to application of the TVS on actual waste, it will be fully tested on surrogate waste at Clemson University. This shakedown test is scheduled to last six to eight weeks, including assembly and disassembly. Both equipment and procedures will be tested with a non-radioactive surrogate of the actual waste to be run at Oak Ridge. Any problems encountered will be investigated and rectified before the TVS is released for field operation. Training of operators will also take place at this time. Processing of actual waste will begin at Oak Ridge in the fall of 1995.

PREPARATION FOR FIELD APPLICATION OF THE TVS

During the design and fabrication activities described above, Oak Ridge personnel

pursued activities in three areas to support TVS field operation: selection of waste stream(s) to be demonstrated; preparation of required permit applications; and site preparation activities.

Waste Stream Selection

Oak Ridge personnel reviewed candidate waste streams from the Y-12 and K-25 plants and selected a primary and backup waste. The primary waste stream will be the West End Treatment Facility (WETF) sludge, while the backup waste stream is the Central Neutralization Facility (CNF) sludge. Approximately 40,000 kg (88,000 pounds) of waste will be required for each waste stream demonstrated.

The West End Treatment Facility was constructed to treat nitrate-bearing aqueous waste generated at the Y-12 weapons plant located in Oak Ridge, Tennessee. The facility is a batch processing unit that neutralizes the nitrate-bearing wastes prior to biological denitrifying the waste. Hydrated lime is used to neutralize the acidic wastes. The nitrate waste is converted anaerobically to nitrogen and carbon dioxide. The hydrated lime reacts with the carbon dioxide to form calcium carbonate, which precipitates as the major part of the solids generated from the process. The remaining solids are generated from hydroxide precipitation of heavy metals.

The sludge is classified as low-level mixed waste, the average uranium content is approximately 1400 ppm. Average heavy metal concentrations are barium 540 ppm, lead 240 ppm, cadmium 45 ppm, chromium 410 ppm, and silver 25 ppm. The sludge has an average calcium content of 257,000 ug/g with a pH of 8.9.

The Central Neutralization Facility, located at the Oak Ridge K-25 Site, treats liquid effluent from the mixed waste incinerator, the K-25 Site steam plant, a metal cleaning facility, and various small quantity or infrequent streams. The process uses a hydrated lime slurry to neutralize the effluent and precipitate metals. The sludge, classified as a low-level mixed waste, averages a total radionuclide activity of 1600 pCi/g, with uranium, thorium and technetium-99 as the primary radionuclides. Average concentrations of the RCRA metals in the sludge are barium 90 ug/g, silver 4 ug/g, mercury 4 ug/g, cadmium 3 ug/g, chromium 95 ug/g, and lead 110 ug/g. The sludge has an average calcium content of 58,000 ug/g with a pH of 7.8.

Permitting Aspects

A Research, Development and Demonstration permit will be necessary for the demonstration because the volume of material to be treated exceeds the limits allowed by treatability study exemptions. In addition, the Tennessee Department of Environment and Conservation has a DOE Oversight office located in Oak Ridge that will allow for close coordination with the oversight office thereby expediting the review process for permit approval.

Because low-level radioactive waste will be treated, it is necessary to invoke the radioactive processing requirements of the National Emission Standards for Hazardous Air Pollutants (NESHAP) regulations. The preliminary Rad-NESHAP evaluation for the vitrification demonstration indicates that the process will not require Rad-NESHAP approval for construction. However, due to the large volume of material and temperatures greater than 100-C, an EPA approved continuous monitoring device will be required on the process exhaust (stack). The criteria for not needing an approval to construct from EPA is based on the source having an actual effective dose equivalent (EDE) of less than 0.1 mrem/yr at the site boundary. The criteria for needing to install an EPA approved continuous monitoring device is based on having a potential EDE of greater than 0.1 mrem/yr. The potential dose is calculated with no credit for air pollution control equipment. The TVS will employ continuous sampling of stack emissions. The samples gathered will be counted with radiation detection equipment to confirm that the TVS is operating below the required release levels.

Site Preparation

The major factors considered during site selection at the K-25 Site were:

- utility requirements
- site access
- site grading (size and slope of the area, amount of preparation work required for set up)
- proximity to other activities in the plant

Several utility requirements were identified for the demonstration. The single largest utility requirement was electricity with a requirement of 1600 amps of three-phase, 60 Hz current at 480 volts. The power requirement quickly narrowed the possible sites because significant power line upgrades would be required to place the demonstration in the majority of the areas available in the plant.

A significant amount of waste will be transported to and from the demonstration site; therefore, site access needs to be conducive to truck and tanker movement into and out of the site. Sites with small staging areas and located near busy roads in the plant were eliminated.
A 1/2 acre site was required to facilitate the set up of the vitrification equipment, staging pre- and post- treated wastes, and storage of secondly wastes. A level site with an impervious surface was desired to allow erection of the equipment and to contain any spills that could potentially occur during the demonstration. In addition, a site located away from other plant activities was preferred to minimize potential exposure of plant personnel to wastes being treated by the demonstration. The selected site for the demonstration is a former UF6 cylinder storage yard located near the main power distribution station for the K-25 plant. The yard is partially covered with a concrete pad, with the remainder of the yard having a compacted gravel base. Site preparation will be limited to paving the gravel portion of the yard. A road to the site, located at the west end of the plant (away from other activities in the plant), currently exists since the area was previously used for cylinder storage.

CONCLUSION

The TVS is an ambitious response to DOE's challenge to demonstrate mixed and low-level waste vitrification on a field scale. The TVS is designed to treat significant quantities of waste while maximizing the flexibility of the system to deal with a wide range of waste streams. Engineering is well advanced on this project, and we expect to perform the first demonstration with actual waste by the end of 1995.

ABSTRACT
Results from the application of a number of different diagnostic instrumentation systems to the processing of a surrogate mixed-waste stream are reported. Measurements have been conducted by personnel of the Diagnostic Instrumentation and Analysis Laboratory of Mississippi State University on a melter located at the DOE/Industry Center for Vitrification Research (administered by Westinghouse Savannah River Company) at Clemson University. Studies included measurement of the temperature of the molten glass within the melter and analysis of the thermal and compositional characteristics of the glass as it exited the melter. Velocities and off-gas compositions were also determined. The data obtained indicate that specific facility and waste product characteristics were successfully determined. The results will also allow for future comparison to different surrogate streams and remediation technologies and may be of interest for process scaling.
INTRODUCTION
The U.S. Department of Energy, through the Mixed Wasted Integrated Program, is sponsoring advanced vitrification research and development at the DOE/Industry Center for Vitrification Research (DOE/ICVR), located at Clemson University's Environmental Systems Engineering Department (CU/ESE). The focus of this work to date has been the vitrification of surrogates of mixed waste streams found at several DOE sites (1,2). Westinghouse Savannah River Company (WSRC) has administered this work for DOE.
During the fall of 1993, DOE identified an opportunity to employ advanced techniques, under development at the Diagnostic Instrumentation and Analysis Laboratory (DIAL) at Mississippi State University, to mixed-waste vitrification processes. Specific applications include measurements at high temperatures; evaluation of organics, particulates, and toxic heavy metals in the off-gas; and the implementation of suitable control schemes based on these systems. To this end a number of instruments are at various stages of completion. WSRC recognized the potential value of the information content from these methods and a collaboration was initiated.
Two field campaigns (July 25-29 and September 12-16, 1994) were conducted by DIAL at the DOE/ICVR during the summer of 1994. The primary objectives of the work were to gather data from operating, pilot-scale melters in order to a) characterize the melt and gas stream at selected measurement locations; b) obtain useful facility data; c) demonstrate the capability of the measurement techniques; and d) enable planning for future tests. Results were obtained on two ICVR melters: the Glass Tech Stir-Melter and the EnVitCo cold-top melter. The results given here correspond to surrogate waste stream (Savannah River Site M-Area) processing using the Stir-Melter.
The measurement strategy consisted of the determination of the temperatures of the molten pool within the melter and the associated glass pour (pyrometry methods); thermal profiles and shapes of the pour (multi-color imaging system); evaluation of the heavy metals in the glass stream (laser induced breakdown spectroscopy); determination of the flow characteristics exiting the melter (laser Doppler velocimetry); and analysis of the off-gas composition (Fourier transform infrared spectroscopy). To our knowledge such a concerted effort has not been reported previously. The results obtained describe some of the important characteristics of the glass and emissions produced from this particular waste stream surrogate and will allow for future comparisons with different surrogate streams and with different vitrification technologies.
The instrumentation systems were transported to the CU/ICVR facility using one of DIAL's Mobile Instrument Laboratories (MIL's). The MIL employed is a 18 wheel-type trailer which has been configured to allow instrument operation from a remote platform. In many cases, the instruments are entirely located within the MIL and fiber optics and signal cables are routed to the particular instrument/facility interface. Figure 1 shows the various instrumentation systems with respect to the Stir-Melter. Details of this melter have been reported previously (3).
Fig. 1.

In what follows, the results of the initial campaign on the Stir-Melter are presented. Each section begins with a brief description of the instrumentation employed followed by typical results. Full details of the field measurements at Clemson as well as those recently completed at the Western Energy Technology Office (WETO) at Mountain States Energy, Butte, Montana will be reported elsewhere.

PYROMETRY

Three types of pyrometer systems with different methods of data acquisition and data reduction were employed to measure temperatures of the molten glass within the melter (Fig. 1) and the glass pour. Measurement systems employed include a two-color pyrometer (TCP), a multi-wavelength pyrometer (MWP) and a ratio pyrometer (RP). Details of these instruments can be found elsewhere (4-6). Temperature ranges from the measurements at the two facility locations are collected in Table I.

TABLE I

The Two-Color Pyrometer was used to measure the molten glass temperatures inside the Stir-Melter through the facility camera port. Small temperature fluctuations were observed and are related to periodic current fluctuations in the Stir-Melter and to feed material floating through the instrument field-of-view; the current fluctuations occur because the Stir-Melter is operated in a constant power mode.

The Multi-Wavelength Pyrometer was used to measure molten glass temperature inside the Stir-Melter through the melter's camera port and the small diameter glass stream from the melter's pour exit. Two sets of data were recorded through the melter's camera port corresponding to different positions on the melt surface. At the first location the temperature was typically about 1250 K while at the second location temperatures were about 1185 K. Temperature fluctuations were significantly larger at the second location. The decreased temperature and fluctuations may indicate that the feed, which can stay on the melt surface before incorporation into the melt is affecting the temperatures. Temperatures obtained through the camera port are comparable to those measured by the TCP. Temperature fluctuations of the Stir-Melter glass pour observed by the RP and by the MCP are also evident in the MWP data.

The Ratio Pyrometer was used to monitor the molten glass stream temperature of the pour. As a result of the slow-moving slag stream (high viscosity glass, see below) and of the uneven temperature distribution across the slag stream surface, temperatures fluctuated between 1200 and 1380 K.

MULTICOLOR IMAGING

The DIAL/MSU multicolor imaging system (MCI) was used to take images of the glass stream emerging from the Stir-Melter. The imaging system consisted of a monochrome CCD camera with a 900nm interference filter (10 nm bandpass) that was used to provide an image of the thermal radiation from the melt stream. The television signals from the camera were digitized in real time and occasionally stored in a PC by the use of a frame grabbing board. The digital images allowed measurements to be taken of the size and shape changes of the stream and the corresponding intensities provided an indication of local temperature. Images of a temperature-controlled blackbody source were used to convert the intensities to temperatures. The spatial dimensions of the image have been calibrated by capturing the image of a millimeter scale placed at the same distance from the camera as the melt stream.

Figure 2 shows a series of images demonstrating the sub-millimeter spatial resolution obtained as well as the various shapes of the melt stream. The streams can be over four centimeters long, and range in width from 10 mm at the melter exit to less than 1 mm at distances approaching 4 cm from the melter. The viscosity of the molten glass has influence on the flow shapes, but extracting quantitative viscosity information will be difficult due to the temperature gradients that give rise to the variety of shapes seen. The range of intensities and hence temperature gradients of the glass streams can also be seen in these images. To highlight the temperature gradients, the actual intensities have been reduced to 12 false colors that represent temperatures from 760 to 1000C in 20 degree intervals as shown by the gray scale at the bottom of the figure. The two images on the left show the contrast between a high temperature gradient, high viscosity flow and the more desirable, steady, low-viscosity flow. Low viscosity flows can be routinely achieved by adjusting the glass forming chemistry. Pilot-scale experiments at the IVCR permits this optimization prior to processing the actual waste stream.

LASER INDUCED BREAKDOWN SPECTROSCOPY (LIBS)

LIBS is a laser-based diagnostic technique which is being used to measure the concentration of different elements in various environments. The experimental

arrangement of the LIBS system has been described elsewhere (7,8). In brief, a frequency-doubled Nd:YAG laser beam is focussed to produce a spark at the sample. The emission from the spark is coupled to an optical fiber, the other end of which is attached to a spectrograph with an intensified diode array detector. A controller is used for operation of the detector and to transfer the data to an acquisition/analysis notebook computer.

LIBS spectra of the molten glass pour of the Stir-Melter were recorded in the spectral range between 320 nm and 770 nm. By comparing the measured wavelengths and relative intensities with standard tabulations of atomic emission spectra, most of the observed emission lines have been identified (4). An attempt to calculate the concentration ratios of various species has also been made. The relative concentrations of the identified elements have been obtained by fitting the observed LIBS spectra with theoretical spectra and also by comparing the intensity of the spectral lines. Plasma temperature is an important parameter which affects the observed LIBS spectra. By assuming local thermodynamic eqilibrium and Boltzmann statistics shortly after the laser pulse, the plasma temperature was found to be about 7500 K. The concentration ratios have been computed by using the spectra recorded during the test run with the inferred plasma temperature. Twenty LIBS spectra in each observed wavelength region (about 40 nm) were analyzed to obtain the element concentration ratios. Relative mole fractions of various elements along with associated standard deviations are given in Table II. The inferred relative concentrations from the data on July 25 and 28 are very close except for the Fe/Mg ratios is not clear at this time since the feed is expected to be similar during both testing periods. The difference in the Fe/Mg ratio might be due to a slight change in the feed composition. The LIBS measurements on the Stir-Melter have illustrated that on-line concentrations of various elements in the molten glass can be determined.

TABLE II

LASER DOPPLER VELOCIMETRY

Laser Doppler Velocimetry (LDV) is a nonintrusive optical method for measuring velocity. Two laser beams are focused at a common crossing point in the flow, and light is scattered into the detector by particles that pass through the focal volume (or crossing point). The reenforcement and cancellation of the light from the two beams modulates the light intensity received by the detector, and the frequency of this ripple signal is directly related to the particle velocity.

The LDV system was installed in a vertical riser which carried the off-gas from the melter to the downstream treatment system. Optical access was obtained through a specially made test section of 2 inch pipe. There were two openings in the sides of this test section for optical access. The windows were kept clear of condensation and other fouling by introducing a small flow of nitrogen purge gas into the window cavity. Typically, we used a flow of 3 cfh for each window. This is small compared to the gas flow 100 cfh through the test section and should have a negligible effect on the flow outside the window cavity.

Since the flow is apparently unsteady, a number of data sets with the measurement volume fixed at the center line were collected to study the change in velocity with time. Figure 3 shows the variation in mean velocity over a period of one hour. An average velocity of about 3.8 m/s with a turbulence (axial direction) of 13% of this value. However, Figure 3 shows that the velocity fluctuates significantly. It is believed that the spikes in the mean velocity are due to an accumulation of the slurry which suddenly falls into the glass melt. The slurry then volatilizes creating an increase in the outflow velocity. The velocity profile across the pipe and further analysis of the data (4) will be reported elsewhere.

Fig. 3.

FOURIER TRANSFORM INFRARED (FTIR) SPECTROSCOPY

FTIR measurements were conducted by routing a portion of the gas from the melter to a multiple-pass (White) cell which was set to a path length of 75 m. The gas stream was initially conditioned by trapping particles on a glass wool filter pack and condensing the moisture from the nearly saturated effluent using an impinger cooled in an ice bath. The gas flowed continuously through the cell and typical pressures of 100-150 torr were used with the pressure controlled by valves on the vacuum line and the pumping system for the cell. All spectra were collected using an interferometer operating at a nominal spectral resolution of 0.5 cm-1. A dual-element HgCdTe/InSb detector and a CaF2 beamsplitter provided an effective

spectral range of 1000-5000 cm-1. Background spectra were taken after evacuating the cell to a pressure of between 2 and 8 torr.
Figure 4 contains two absorbance spectra with different arbitrary scaling factors. The top trace is for a sample of the melter effluent at 150 torr while the lower trace is a difference spectrum obtained by subtracting off transitions due to CO2 and H2O present in air (an air purge was employed for the video camera port on the melter). There is considerable H2O and CO2 in the original spectrum and subtraction of the water in producing the difference spectrum is not complete. Infrared signatures correspond to CO2, H2O, CO, NO, NO2, HCN, and a trace amount of methane. The feed for these experiments consisted primarily of inorganic nitrates, carbonates, acetates, hydroxides, and sodium phosphate along with phenol, dodecane, and yeast in a water slurry. The nitrogen molecules arise from the nitrates, and the CO and CH4 are thought to be incomplete pyrolysis products from the organics and/or acetates.
Fig. 4.
Some typical products that might be expected from the pyrolysis of phenol include benzene, toluene, and other small (< C 6) hydrocarbons. Examination of the CH stretching region around 3000 cm-1 (Fig. 4) does not reveal any broad absorption band features typical of these compounds. There are some unidentified transitions, particularly in the spectral region between about 1300 and 1700 cm-1 and some of these lines are thought to result from the incomplete subtraction of water. A further analysis of this region is in progress; however, it is safe to state that all of the remaining lines are consistent with small (diatomic or triatomic) molecules. The concentrations of the molecules in this spectral region can be estimated from an assumed absorption coefficient a of le-3 (10) using the Beer-Lambert law, a=(anRc), where a is the absorbance, l is the path length of the measurement and c is the concentration. Using an absorbance of 0.08 results in a concentration of 1 ppm. This value, when scaled by the pressures for the extractive experiment, would yield an effluent concentration of 5 ppm. These concentrations should only be considered as estimates. Further quantification of the results from this study will be reported elsewhere.
CONCLUSIONS
The results indicate that all of the initial test plan objectives were satisfied. Useful facility-dependent data such as velocities and melt temperatures were obtained. Specific characteristics of the glass and pyrolysis products from the surrogate feed were also determined. Some of the capabilities of the instrumentation have been demonstrated in the Stir-Melter measurements; however, there are a number of other potential applications to mixed-waste remediation processes that are currently under evaluatiion at DIAL. For example, the LIBS system is finding use in the on-line determination of entrained heavy metals in the gas stream, and high temperature infrared signatures are available from FTIR emission experiments. Valuable information on plasma characteristics is expected from multi-color imaging. The instrumentation described here and the other systems currently under development at DIAL are presently undergoing further evaluation/demonstration- Additional field measurements are in progress.

ABSTRACT

An X-ray fluorescence (XRF) technique is reported which shows promise for the elemental analysis of waste glasses. This technique can be used for both quantitative laboratory analysis and in process control. The glass-forming melt is cast into a graphite mold and the resulting disk is annealed and polished. The disk is then analyzed with a wavelength dispersive X-ray fluorescence spectrometer and the elemental intensities are converted into concentration with a fundamental parameters routine without the necessity of matrix-matched standards. The precision of the elemental determinations are all better than one percent relative standard deviation. The XRF analysis has been compared with a reference method utilizing conventional wet chemical dissolution techniques followed by atomic emission spectroscopy. There was no significant difference in the quantitative results between these two techniques.

INTRODUCTION

X-Ray Fluorescence (XRF) Spectrometry is a widely used technique for the routine quantitative elemental determination of ceramics (1) and ordinary glass (2), but it has received little application in the field of waste glass analysis. This is unfortunate since XRF is one of the most precise and potentially accurate analytical techniques available. There are several reasons why analysts in the vitrification arena have stayed away from XRF. High-level waste glasses produce large background count rates due to their inherent radioactivity. This, however, may not be such a problem with low-level, mixed waste glasses.

Another problem facing waste glass analysis by XRF has been the difficulty in quantifying the elemental composition from the spectral line intensities. The line intensities are not only a function of the analyte content but also depend on the presence of other species in the sample due to their matrix effects. These effects include absorption of the incoming and outgoing X-rays. Another matrix effect, enhancement, results when elements, with a higher atomic number than the analyte, are excited and their resulting secondary X-rays in turn cause additional fluorescence from the analyte. One approach, empirical calibration curves must be developed by first determining empirical coefficients relating one element's matrix effects on another. This is only accomplished with the use of many standards whose compositions closely match that of the samples. This becomes impractical with waste glass samples which have complex and widely variable compositions often containing more than 20 elements. Several studies on waste glass analysis have been reported using this tedious method of empirical coefficients with numerous standards. The XRF analysis of non-radioactive, surrogate high-level waste glass was reported in 1978

by Slates (3). This method was laborious and was limited to only a few of the many elements present. Sodium, iron, aluminum, and calcium could not be quantified and the procedure required the use of numerous matrix-matched standards. A recent XRF procedure for determining iron and cerium in waste slags has been reported by Carney (4) but the results were reported to be only semi-quantitative. This procedure also required the use of forty matrix-matched glass standards were prepared. In addition, glass samples were analyzed as powders thus reducing the accuracy and precision and increasing the sample preparation time. A truly useful analytical technique should provide the composition of all the major elements present because the major elements will affect the chemical durability of the final waste form.

An alternative approach for XRF quantification, called Fundamental Parameters (FP), uses mathematical equations with fundamental constants to convert the element intensities into composition (5). In this analysis, no standards are required but the accuracy depends upon knowledge of certain individual fundamental constants for each element such as absorption coefficients and fluorescence yields. The method was developed for XRF by Criss and Birks in 1968 (6) but it was of limited value due to the scarcity of accurate data on these fundamental constants. As measurements of these constants improved, so did the accuracy in the calculation of the elemental concentrations. This FP method is now in widespread usage for XRF analysis because of this improved accuracy and because it does not require standards.

Another reason that XRF has not been applied to high-level borosilicate waste glass analysis has been the difficulty in analyzing light elements such as lithium, boron, fluorine, and sodium. The fluorescent yields from these elements are diminished and their corresponding X-rays have greatly reduced penetrating power. As a result, the light element intensities are typically very low resulting in poor measurement precision. Developments in instrumentation and in the analyzing crystals have resulted in remarkable improvements in recent years in the analysis of sodium (7). Recent XRF measurements on borosilicate waste glasses showed that sodium line intensities could be determined with a high degree of precision but the boron intensity was still too low to be quantifiable (8). Boron, then, would have to be determined by difference. However, if the concentration of all the other species in the glass are accurately determined then boron could be determined by difference. This is the approach that will be employed in this study to determine boron.

In previous work in this laboratory, a rapid glass sampling technique was developed (8). It was reported that samples could be taken directly from the crucible or melter tank and prepared for analysis within 30 to 45 minutes. The intensities from replicate samples were measured and the precision was found to be better than one percent relative standard deviation. This paper reports the quantitative elemental analysis of waste glass samples using a wavelength dispersive XRF spectrometer and the FP method. These results are then compared to results from a reference analysis utilizing conventional wet chemical glass dissolution techniques and atomic spectroscopy.

EXPERIMENTAL

Glass Preparation

Seven waste glasses were prepared from platinum crucibles according to a procedure described elsewhere (9). Each melt was cast into graphite molds to produce three disks 40 mm in diameter by about 5 mm in height. The disks were then annealed at 450C for 30 minutes and then ground to prepare a flat surface using 1000 grit SiC paper on a Buehler polishing wheel. Next, the glass was carefully abraded manually using 600 grit paper, first in one direction, then orthogonal to the original direction. The disks all had a uniform 8-inch surface finish.

Glass Analysis

The reference analysis of these glasses was performed by wet chemical dissolution techniques followed by flame emission spectroscopy (FES) or inductively coupled plasma-emission spectroscopy (ICPES) by Corning Engineering Laboratory Services of Corning, New York. Three separate digestion techniques were employed to dissolve the glasses. Sodium was then determined by FES following digestion in hot hydrofluoric acid. Boron was determined by ICPES following digestion in cold hydrofluoric acid. The remainder of the elements were determined by ICPES following digestion with an alkali fusion technique. Instrument calibration was carried out with matrix-matched standards to compensate for matrix interference. Each determination was carried out in triplicate and averaged.

The XRF analysis of the disks was performed with a Rigaku Model 3271

wavelength-dispersive XRF spectrometer using 30 mm sample apertures and the instrument conditions listed in Table I. Samples were rotated at 30 revolutions per minute. An end window X-ray tube with a rhodium target was used to generate the X-rays. Among the analyzing crystals were three Ovonyx Multilayers for B, Na, and Si obtained from Osmic, Inc. of Troy, MI.

Conversion of the elemental intensities into concentration was carried out by an FP procedure developed by Rigaku. Element sensitivities were determined from Glass Sample #MMHO using the wet chemical analyses from Corning Laboratories.

RESULTS and DISCUSSION

The precision in the XRF analysis of these waste glasses was determined by comparing the measured elemental intensities from three replicate glass disks. The relative standard deviations (RSD) for each element from each of six glasses are shown in Table II. Boron intensity data were not included because it was too low to be quantifiable. The results show that the RSD is less than 1.0 percent for all measured elemental intensities. This level of precision for quantitative elemental determination is far better than is normally achievable with either ICPES or AA techniques (2). The precision reported here is representative of both the sample preparation technique and instrument data collection. Such a high degree of precision reduces the number of replicates necessary for an accurate quantitative analysis. In fact, this high degree of precision suggests that one sample might be sufficient for the elemental analysis of waste glass carried out in a process control environment, if the glass is sampled from a homogeneous melt.

The accuracy of the elemental analysis of these silicate waste glasses by XRF has been assessed by comparison with a reference method. The reference method employed here involved several wet chemical dissolution techniques, depending upon the analyte of interest, followed by one of several atomic spectroscopic techniques. The XRF analysis, on the other hand, involved the measurement of X-ray intensities from each element with a sequential wavelength dispersive spectrometer. The element intensities were converted into weight percent composition with a fundamental parameters routine utilizing a single glass standard (MMHO) to determine the element sensitivities. The composition of the standard was also determined by the wet chemical procedure.

The results of the elemental analyses from XRF are compared to the analyses from the reference method in Table III. Boron could not be analyzed directly due to the low intensities, therefore, its composition was calculated by difference. The results for B_2O_3, Al_2O_3, SiO_2, CaO, and Fe_2O_3 all agree within 0.65 percent of the reference values. Furthermore, Na_2O, NiO, BaO, and PbO all agree within 0.10 percent. It is clear that the elemental analyses of these wastes glasses by XRF are in excellent agreement with the results from the more conventional wet chemical method.

The time required to perform the XRF analysis was considerably shorter than that for the wet chemical reference analysis. The analysis of each sample required only 10 minutes while the reference wet chemical methods required many hours of lab work. Instrument calibration which involved the determination of elemental sensitivities using sample MMHO also took only 10 minutes, as well. The reference wet chemical method, on the other hand, required that each sample first be milled to a powder and then subjected to three separate digestion procedures. Each of the three resulting digestates was then analyzed by either ICPES or FES. Furthermore, separate calibration curves were developed for each digestate from each glass from a set of matrix-matched standard solutions. This wet chemical analysis was both labor and time intensive.

Potential limitations of this XRF technique are discussed briefly here. Actual waste glass samples will likely differ from these surrogate glasses in several ways. Waste glasses may likely contain more than the nine oxides in these test species, and concentrations of some species will be below one percent. The analysis of more complex matrices including trace elements should still be achievable with XRF but further work is required to demonstrate this capability. Furthermore, mixed waste glasses will contain one or more radioisotopes which may affect background count rates. An example of a low-level mixed waste scheduled for vitrification is the wastewater treatment sludge currently in storage in M-area at the Savannah River Plant in Aiken, SC (10). The resulting waste glass will include about 20 oxides ranging from boron through uranium.

This XRF technique should be capable of quantifying all elements from sodium through uranium. Elements lighter than sodium present special problems due to their

inherently low count rates. Further testing is required before the precision and accuracy of fluorine analysis can be established. Only certain specialized wastes, however, are likely to contain fluorine. Oxygen does not need to be calculated if one assumes all cations to be present as the oxide and the oxidation states are known. For determination of elements lighter than oxygen, direct analysis appears unlikely and quantification must be carried out indirectly by difference. This study has demonstrated that boron can be quantified by difference if it is the only light element present. If the glass contains lithium as well as boron, as is the case with certain high-level waste glasses, then this method would not be capable of distinguishing between the two.

Radioisotopes, present in low-level mixed wastes, could potentially cause spectral interference due the intrinsic radiation from the glass itself. Defense wastes can contain a variety of radioisotopes including 90Sr, 99Tc, 137Cs, 238U, and 242Pu. Further testing needs to be carried out in order to determine the maximum tolerable radioactive levels in glass without adversely affecting the analysis.

XRF could play an important role in vitrification quality control. It is known that chemical durability is largely a function of glass composition. Composition limits for the glass product would be predetermined and then compared to the actual product composition to ensure product durability. In all likelihood, trace oxides would not play a role in product acceptability because of the minimal effect that they would have on chemical durability.

The actual chemical composition of the glass product could be determined periodically by XRF and then compared to the predetermined limits with the aid of statistical process control charts (11). The key steps in the elemental determination will include the following:

1) rapid, representative glass sampling;
2) precise measurement of X-ray intensities; and
3) accurate determination of glass composition using "standardless" FP.

The glass product could be sampled directly as it flows from the melter by collection in a graphite mold. In this way the sample would be ready for analysis within 30 to 45 minutes. Even though the glass disks were polished in these experiments, previous studies on waste glass have shown that precision does not greatly suffer when disks are analyzed without prior polishing (8). The quantitative chemical analysis could then be available within one hour from the time the glass flows from the melter.

CONCLUSION

This study demonstrates that rapid, precise, and accurate XRF analysis can be obtained for waste glasses containing Al_2O_3, B_2O_3, SiO_2, Fe_2O_3, Na_2O, CaO, NiO, PbO, and BaO. Replicate sample precision is better than one percent relative standard deviation for all elements except boron which cannot be determined directly. The accuracy of this XRF procedure is comparable to the wet chemical methods traditionally employed. Boron, which must be determined by difference, has been shown to be within one percent, absolute, of the reference method.

This technique can potentially be used for both laboratory quantitative chemical analysis of waste glass or as a tool in vitrification process control by providing elemental analysis of the glass shortly after it is sampled from melter.

APPLICATIONS OF ATOMISTIC SIMULATION TO RADIOACTIVE AND HAZARDOUS WASTE GLASS FORMULATION DEVELOPMENT

Andrea L. Kielpinski
Westinghouse Savannah River Company

ABSTRACT

Glass formulation development depends on an understanding of the effects of glass composition on its processibility and product quality. Such compositional effects on properties in turn depend on the microscopic structure of the glass. Historically, compositional effects on macroscopic properties have been explored empirically, e.g., by measuring viscosity at various glass compositions. The relationship of composition to structure has been studied by microstructural experimental methods (nuclear magnetic resonance, x-ray spectroscopy, etc.). More recently, computer simulation has proved a fruitful complement to these more traditional methods of study. By simulating atomic interaction over a period of time using the molecular dynamics method, a direct picture of the glass structure and dynamics is obtained which can verify existing concepts as well as permit "measurement" of quantities inaccessible to experiment.

Atomistic simulation can be of particular benefit in the development of waste glasses. As vitrification is being considered for an increasing variety of waste streams, process and product models are needed to formulate compositions for an extremely wide variety of elemental species and compositional ranges. The demand for process and product models which can predict over such a diverse composition space requires mechanistic understanding of glass behavior; atomistic simulation is ideally suited for providing this understanding. Moreover, while simulation cannot completely eliminate the need for treatability studies, it can play a role in minimizing the experimentation on (and therefore contact handling of) such materials.

This paper briefly reviews the molecular dynamics method, which is the primary atomistic simulation tool for studying glass structure. We then summarize the current state of glass simulation, emphasizing areas of importance for waste glass process/product modeling.

At SRS, glass process and product models have been formulated in terms of glass structural concepts (1). These models are now being extended for application to both low-level mixed waste glass formulation (2) and to high-purity actinide stream immobilization (3). Atomistic simulation is providing input for the development of the process and product models for these new applications. Recent results are described in this paper.

INTRODUCTION

"Atomistic simulation" refers to a variety of computational techniques for determining structural and dynamic properties of materials. The most powerful of these, through its ability to provide dynamic as well as structural data, is the molecular dynamics method. Through this calculational process, the positions and

velocities of all particles are calculated for a succession of timesteps, thus defining the atomic structure and dynamics of the material. Through graphical representation of the calculational results, the glass network can be viewed "directly" as well as being analyzed statistically.

The visualization capabilities of the method alone provide valuable insight into the behavior of glass; the human eye is still the best computational tool for "discerning the presence of collective motions" (4). However, the wealth of properties which can be calculated from simulation can be correlated to macroscopic behavior as well, providing direct input to models suitable for process control.

MOLECULAR DYNAMICS SIMULATION METHODS

In the molecular dynamics simulation technique, Newton's equations of motion are solved for each of a collection of particles (atoms, ions, or molecules) as it interacts with all others. The numerical solution of Newton's equations is straightforward; thus, the key to solving this problem is the specification of the forces between the particles or, equivalently, the interatomic potential function between the particles. Time averages of various quantities and their variances can be related to macroscopic thermodynamic quantities such as pressure, heat capacity, enthalpy, etc., through well-known statistical mechanical developments (5).

Simulations are most commonly done holding fixed the volume of the simulation sample, the number of atoms, and the total energy (the "microcanonical ensemble" of statistical mechanics). Periodic boundary conditions are used to hold the number of atoms fixed and to eliminate surface effects in simulation of bulk materials. Computer technology limits the size of the simulated sample and the simulation time interval; most current published work is based on no more than about 1000 atoms, simulated over periods of the order of nanoseconds.

Many quantities of interest in glass processing, such as viscosity and chemical durability, have been modeled as functions of atomic phenomena such as bond length, bond strength, non-bridging oxygen content, etc. Atomic simulation provides a means of "observing" such phenomena directly, thus providing input to models couched in such terms. The positions of the particles at any given time can also be represented graphically (See Fig. 1), thus providing a powerful aid to conceptualizing the structure of a glass.

Fig. 1.

The veracity of the simulation must be checked by comparison to microstructural experimental data. Once this is done, simulation can be used to obtain additional quantities which can be obtained by experiment (sometimes with far more difficulty), as well as quantities for which no experimental technique has been developed. An example of the latter is the pair distribution functions, i.e., the radial distribution of atoms of type j around an atom of type i. These functions describe the environment of an atom in terms of each of the other types of atoms in the system. Experimentally, only the total radial distribution function can be obtained, i.e., the sum of all the individual pair distributions. The simulation results therefore show how to correctly deconvolute the experimental quantity to reveal the details of the local environments of each atom type.

Other quantities which can be calculated from the simulation results include:

Sizes, energies, and distribution of "holes" in the glass network. These quantities are related to macroscopic quantities such as electrical conductivity, gas solubility, and activation energies. Significant progress has been made on the well-known mixed-alkali problem in glass science using atomistic simulation (6).

Non-bridging oxygen (NBO) characterization. This includes the fraction of oxygens which are non-bridging, and the Qn distribution, where Qn denotes the fraction of silicon atoms (in a silicate glass) having n bridging oxygen atoms (i.e., Q4 denotes the fraction of completely-polymerized silicon tetrahedra, Q0 the fraction which are completely isolated from the network). These quantities have been related to macroscopic parameters such as viscosity (1).

Ring statistics. These characterize medium-range order in the glass (7). The presence of rings larger or smaller than the optimum for the network (e.g., six-membered rings for pure silica crystal) represents "defects" in the structure which have been used to characterize viscosity (8) and diffusion (9).

ATOMISTIC SIMULATION OF GLASS

At present, most of the simulation work which as been performed is on bulk glasses of one or a few components. The primary attention has been applied to silicate glasses, although studies of phosphate glasses (10) and borates (11) have also been

performed. Numerous studies have been made of vitreous silica (12-14), whose properties have been well-characterized experimentally and whose behavior, which is in several respects atypical of oxides, provides a rather stringent test of interatomic potential functions. Thus, the focus of many of these studies is on developing and verifying a proposed interatomic potential function. Potential functions which model silica gas structure well provide a good basis for extension to multicomponent silicate glass systems.

Oxide structure is uniquely determined by its mixed covalent-ionic character. Locally, the bonds are directional, a reflection of the covalent nature of the constituents. In this way the oxides are similar to very covalent materials like silicon. On the other hand, the bonding is also ionic, leading to long-range electrostatic interactions which are similar to the case of materials like NaCl. These aspects are interdependent. The available interatomic potentials which appear most suitable for glasses generally treat only the long-range, electrostatic interactions between pairs of atoms. A typical functional form for a two-body potential is the Born-Meyer-Huggins, i.e.,

Eq. (1)

where the first term represents the Coulomb potential and the second term represents the repulsion potential. The success of such ionic potentials in representing the major features of the silicate glass network is remarkable. Recently, improvement in results has been obtained by using interatomic functions which attempt to include the covalency via the introduction of explicit 3-body terms (10,13). One of a number of such potential forms is that due to Garofalini (13):

Eq. (2)

where the Coulomb potential term of equation (1) is modified to account for long-range Coulomb forces, and

Eq. (3)

if rij <ric and rik <ric, or equals zero otherwise. Here rij is the distance between atoms i and j; qjik is the angle between atoms i, j, and k whose vertex is at atom i; and qjikc denotes the unconstrained, minimum energy value of the angle. Other symbols denote constants.

Boron-containing glasses have proved challenging to model. The conversion between trigonal and tetrahedral boron-oxygen units, and the reproduction of the boroxyl unit, are stringent tests of interatomic potentials for borate and borosilicate glasses. At present, only one potential model has successfully reproduced the boroxyl grouping (11). This is important to waste glass modeling, since many waste glasses are of the borosilicate family.

Interatomic potentials for heavy elements have received little attention in the literature. There is currently a need to develop good potentials for both transition metals and actinides, in order to model waste glasses which typically contain such species.

Despite enormous advances in computing technology, simulations are of very small (in macroscopic terms) samples of material and over very short spans of time. Since numerical solution requires timesteps of the order of picoseconds, even a long simulation mimics only a small interval of "real" time. For glasses, the simulation is typically started from an arbitrary arrangement of atoms (often a crystal structure, if the composition being simulated has a crystalline form), is then randomized by simulation at high temperatures (e.g., 6000K) and is then "quenched" by a series of temperature decreases interspersed with equilibration periods. The short duration of the simulation thus imposes extremely high quench rates which are realized in practice only in a few physical processes, such as splat cooling of metals. These aphysical quench rates have some influence on the resulting structure, although the major features of the structure are accurately represented.

Spatial limitations of simulation impact the study of phase separation and of multicomponent systems. The characteristic wavelength for phase separation is of the order of 30-100 nanometers (15), while typical simulation sizes are considerably less than this. Phase separation has been studied, nonetheless, by exploiting the ability to calculate thermodynamic quantities from simulation results (15). Inhomogeneity in composition has been observed on the scale of the simulations themselves (16), which seems to imply that phase separation (or some precursor) could be directly observable via simulation.

The impact of size limitations on the study of multicomponent systems is one of statistics. This is, in simulating a system in which an element represents only a

trace quantity, a sufficient number of atoms of that element are required to be present, in order to obtain a statistically sound representation of the behavior of that element. For example, if 20 atoms of a given type are needed to achieve good statistics for a given property, all components must be present in quantities of at least two mole percent, for a 1000 atom simulation.

APPLICATION TO WASTE GLASS MODELING

Atomistic simulation has been used to simulate many phenomena of interest in waste glass modeling. Glass homogeneity is key in assessing the durability of waste glass (1); phase separation studies have already been noted above (15). Another key issue in waste glass durability is that of water attack on the glass surface. Water-silica interface simulations by Garofalini (17) represent an important step in this area.

Atomistic simulation is currently being used as part of the developmental extension of SRS product and process models, originally formulated for high-level waste glass. In-house simulation software, originally developed for studying gas-metal interactions (18), has been adapted for the study of glass. A unique feature of this software is that simulations can be conducted in a variety of statistical mechanical ensembles; alternate ensembles provide a means of calculating, or calculating more expediently, many thermodynamic quantities not easily computed in the standard microcanonical ensemble (i.e., where the simulation volume, number of atoms, and system energy are all conserved). Currently, two- and three-body interatomic potential functions are being used, although efforts have begun to develop alternate potential functions which should <allow a more accurate representation of multicomponent and heavy element-containing systems.

One of the SRS process models is for melt viscosity, which is characterized as a function of temperature and non-bridging oxygen content (1):

Eq. (4)

NBO, the number of non-bridging oxygens per silicon, is computed as

Eq. (5)

where M' is an alkaline element and M is an alkaline earth element. This reflects the conventional glass science view that each alkali cation produces one non-bridging oxygen, while the divalent alkaline earth cations each produce two such non-bridging oxygens. It was found (2) that the fit to experimental data was much improved by reducing the assumed relationship between alkaline earth cations and NBO, i.e.,

Eq. (6)

Aj = 1.2 for [MO]j] 0.45

Atomistic simulation (19) of a series of calcium silicates (xCaO(1-x)SiO2 with x = 0, 0.1, 0.2, 0.3, 0.4, and 0.5) was used to verify the NBO relationship for alkaline earth cations. The simulations confirmed a slight reduction of the NBO content below the theoretical value of two per Ca2+ cation, but the reduction was too small to be consistent with the Aj values of Eq. 6). These results were checked by simulating corresponding sodium silicate systems, where the expected NBO relationship obtained. From comparison of the simulation results of the xCaO(1-x)SiO2 series with those of the sodium silicate glass, we infer that the increase in viscosity effect of alkaline earth versus alkali (which is implied by the reduction in the NBO factor shown in equation (6) is due to the higher degree of order that the alkaline earth cation imposes on the relatively disordered glass network. This is shown in Fig. 2, where sodium silicate and calcium silicate compositions having equal proportions of cations have been compared. This figure shows the number of oxygen neighbors seen by the Na or Ca cation. For both cases, the sodium ions have a much broader distribution of oxygen neighbors. That is, although there may be a slight preference for one or two configurations (as indicated by the locations of the peaks), the sodium ions occupy a variety of local environments in the glass. In contrast, the calcium cations show a more sharply peaked distribution, implying that the calcium ion has a more definite "reference" for its environment. It therefore imposes more structure on the network, resists changes to that structure, and hence increases the viscosity.

Fig. 2.

These results suggest that an additional term is needed in equation (4) to represent both the non-bridging oxygen content and the strength of the cation's ability to order its environment. Future simulation work will focus on characterizing this phenomenon in terms of a simple parameter which can be incorporated into the viscosity model. Possible choices of this parameter are the width of the neighbor

distribution, or the energy required to alter the local cation environment. These are quantities which are directly obtainable from the simulation results.

CONCLUSIONS

The molecular dynamics method of simulating the behavior of atoms can provide insight into the structure of materials. A review of the recent literature shows that important waste glass modeling issues are currently being investigated by these means. Simulation is assisting glass process/product model development by SRS for novel applications such as mixed and low-level waste glass and actinide waste glass formulation. Simulation studies of sodium and calcium silicates show that the alkaline earth cation increases the local ordering of the glass network, thus increasing the structural rigidity of the glass. Future work will focus on characterizing this difference in terms of a simple parameter which can be incorporated into an improved process model for glass melt viscosity.

AN INNOVATIVE, REAL-TIME MONITOR FOR
AIRBORNE ALPHA EMISSIONS
Russ Gritzo
Jan Wouter

Malcolm Fowler
Los Alamos National Laboratory
Group CST-11
Los Alamos, NM 87545
ABSTRACT
The public is demanding real-time, high-sensitivity, continuous monitoring of any facility or operation that can potentially release radionuclides to the environment. In response to this demand, Los Alamos National Laboratory (LANL) is developing a new technology for on-line, real-time monitoring of off-gas stacks for low levels of airborne alpha activity. In this paper we briefly describe the requirements for such a system, our approach to meeting these requirements, and the present status of the development and fielding of this technology.
INTRODUCTION
Across the DOE complex, monitoring airborne emissions is one of the most pressing of the public's concerns. In particular monitoring for potential radioactive emissions is an issue that affects nearly every operation from handling radioactive material to site clean-up. As the public becomes more involved, limitations in current monitoring technologies are being identified and targeted for technology development. While the technology exists for long-term monitoring to ensure total emission compliance, most systems are poorly suited to monitoring at low levels on a real-time, fast response basis. Specifically, there currently exists no commercial system to monitor for alpha emitting radionuclides that works in real-time (i.e. seconds) on an entire off-gas stack or air effluent stream.
At Los Alamos we are developing a new detector technology that can monitor and measure the quantity of alpha emitting nuclides that may be present in a large volume of moving air. This detector is unique in that it can measure on-line, in real-time, a complete effluent stream without having to use sampling techniques or long measuring times. This technology provides a robust and fault-tolerant real-time safety monitor (i.e. a "smoke alarm") that can signal the need to shutdown a malfunctioning operation before the public is exposed to significant amounts of radioactive material.
Background
Our development of this monitoring system is an out growth of our long history of innovation in radiation detector technology. Several years ago, members of the Rocky Flats Fluidized Bed Incinerator Project approached our group about solving their need for advanced monitoring technologies. More specifically they were concerned about the lack of a real-time alarm for low-levels of radionuclides potentially present in the off-gas stream.
An extensive survey of available commercial products revealed that, with some minor variations, nearly all commercial alpha monitoring techniques are based on a common approach. This approach consists of extracting a sample of the gas being monitored and passing it through a filter placed close to a detector sensitive to alpha decay radiation. Particulates bearing alpha emitting radionuclides are entrained on the filter and subsequent alpha decays are measured by the detection system. This approach, while useful in many applications has severe limitations in real-time applications. Primarily, this limitation arises because these detectors extract a small sample which is measured for a relatively long period of time. Additionally, the small volume of gas measured is assumed to be "representative" of the remainder of the stack. Sampling a relatively small fraction of the total flow in the stack limits the useful sensitivity of the instrument.
With these limitations in mind, we took a "clean sheet of paper" approach to determine what else could be done. Based on concepts being developed for a different application, we proposed the development of a new monitoring technology with a large measurement volume, and thus high sensitivity, that can be inserted directly into the effluent stream
APPROACH
This new technology was originally called the Large Volume Flow Through Detector System (LVFTDS). Now called the Flow-Through Alpha Monitor (FTAM), this approach is designed to quantitatively detect, in real-time, low concentrations (in the range of picoCuries/liter) of alpha-emitting radioactive materials potentially present in an off gas stream. The key obstacle to overcome in making this type of measurement is the short range of the alpha particles. For typical decay energies alpha particles travel only a few centimeters in air, making their detection difficult. Our detector

overcomes this difficulty by using multiple, alpha-sensitive, scintillating panels spaced closely together, but covering a large volume. Figure 1 illustrates this approach. With this arrangement approximately 75% of the alpha particles from radioactive decay in the detector active volume can reach a panel and generate a detectable light pulse. The light pulse is transmitted to a set of photomultiplier tubes by optical light guides.

A key feature of the FTAM detector is that the radioactive materials measured are not filtered, sampled, or otherwise removed from the primary gas stream for detection. The radioactive materials are detected directly when they emit an alpha particle. For most flow conditions, the entire gas stream, or a substantial fraction of the stream, can be monitored directly with the FTAM. The large active volume of the detector permits direct detection with high sensitivity without using concentration techniques (such as filtering) that require substantial collection times and thus limit the real-time capability of the system. For short response times of a few seconds our detector has a sensitivity more than an order of magnitude higher than commercially available systems. Filtering techniques also lead to a reduction in sensitivity over time because of the accumulation of radioactive materials on the filter. With its unique, real-time capability the FTAM system can respond essentially instantly in the event of airborne contamination, at levels that remain constant over time.

Fig. 1. The flow-through alpha monitor approach.

FTAM ADVANTAGES

The FTAM technology offers a number of advantages. First, as discussed earlier, the entire volume of gas flows through the detector, eliminating the need for sampling trains. Second, the detector's large active volume may permit as much as an order of magnitude improvement in sensitivity over current technology at the short (less than one minute) integration times needed for real-time monitoring and control. Third, without a filter, the maintenance requirements are greatly reduced. The detector sensitive elements are easily cleaned, and with a modular design can be replaced easily should they be damaged. Additionally, the inherent redundancy of the multi-plate design offers built-in fail safe operation. Since the detector is intended to provide an alarm in the event of an emergency, the FTAM is designed to respond over a very wide dynamic range.

Although designed for monitoring alpha radiation, experiments are being conducted to extend the detector into beta and gamma monitoring applications. While the ability of the detector to distinguish between alpha and some beta emitters may be poor, the detector should be able to provide the alarming feature on both alpha and beta radiation simultaneously. This "total radiation monitoring" feature is an attractive possibility, providing system operators comprehensive radiation alarming in a single device.

DEVELOPMENT PROGRAM

Two versions of the detector have been built and tested to date, and a third is being designed at the time of this writing. The first version was a laboratory scale prototype unit designed to allow us to test the detector concept, using a radioactive gas, on a scale large enough to be indicative of the design issues, but small enough to be easily fabricated, assembled, and modified. This version used a stack of five scintillation plates, with a 2 cm inter-plate spacing, giving a total detector volume of 10,230 cm3 (~0.4 ft3). A number of closed loop tests were conducted in which radon (Rn^{220}) from a thorium source was introduced into the detector box for a short time and then stopped. The radon concentration during these tests was typically less than 4 nCi/liter. We continued to circulate the air in the box while the contained radon decayed, allowing us to confirm the radon half-life and the detector's long-term stability. During these tests we typically set the data acquisition system to integrate the detector count rate over 5 second intervals.

From this series of tests we reached three important conclusions. First, we demonstrated that the overall detector concept was sound and workable. Second, we were able to measure the detector efficiency to be around 73%, very close to our expectations. Finally, we found that the background in the detector was higher than we had hoped for based on the early work we had done.

The second version of the detector took the development to an intermediate step, beyond the lab-scale prototype, but not as large as the unit to be field tested. The development and testing of this detector allowed us to concentrate on improving the detection sensitivity by both increasing the size of the detector and decreasing the

background. Engineering issues such as the airflow were also addressed. Table I shows a comparison between the prototype, second generation, and field test systems. The most significant change between the prototype and second generation systems is the reduction in the detector background of around a factor of 37. This achievement is the result of a combination of passive and active shielding. The passive shielding consists of a layer of steel and a layer of lead, which together reduce the background by around a factor of 3. The balance of the reduction comes from the active shielding. This technique uses the detector elements themselves to provide veto signals whenever cosmic rays or other highly penetrating external radiation passes through the detector. A data processing algorithm processes signals from each detector plate, looking for plate-to-plate coincidences. Knowing that an alpha particle can only excite a single plate allows us to veto background events exciting more than one plate simultaneously. This process is aided by the use of guard plates on the top and bottom of the plate stack. These thicker plates are optimized to ensure nearly 100% detection efficiency for the cosmic rays that can contribute to the alpha detection plate background.

The increase in sensitivity brought on by the background reduction and the increase in size has allowed us to test the second generation detector in several interesting ways. Rather than testing the detector solely on radon recirculated in a closed loop around the detector we configured the system to monitor ambient levels of naturally occurring radon in room air pulled through the detector in a single pass. In a second set of tests we were able to detect short bursts of radon (Rn220) injected into the single pass airstream just ahead of the detector. Again in these tests we integrated the detector signals for short (i.e. 5 second) intervals and demonstrated real-time response to airborne alpha activity in the 10s of picoCuries per liter range.

FIELD DEMONSTRATION PLANS

We have selected the Incineration Research Facility in Arkansas as the most suitable site for the initial field tests. Testing is planned for June 1995, and will consist of three phases. The functional test phase, the first of the three, will verify the detector background and alpha detection performance under nominal incineration off-gas conditions. The second phase will consist of a series of challenges such as temperature and humidity excursions. During this phase we will most likely include one or more plates designed to fail at certain temperatures to test the fail-safe operability. The final phase will consist of long-term exposure of the detector to the off-gas environment for life-cycle testing. At the close of FY 95 we plan to have successfully field tested and documented the system performance in anticipation of installation at a mixed waste treatment facility.

BEYOND INCINERATORS

While monitoring incinerator off-gasses is certainly a pressing need, the base technology of FTAM has a wide range of exciting applications. Examples of applications within the DOE complex include monitoring of gas/ventilation systems such as those on high-level radioactive waste storage tanks or other storage areas, and the monitoring of ventilation systems in buildings with combined labs and offices. Monitoring during site remediation activities is an application of particular interest. Only the FTAM technology offers the ability to monitor in real time the very large (hundreds to thousands of cubic feet per minute) volumes of air needed to do credible monitoring during large scale site remediation or decommissioning.

Commercial applications include some segments of the radon monitoring market, including large facilities or a trailer mounted mobile monitoring service. Another market which falls under this general category is the monitoring of mines and mine shafts. Given the dynamic nature of mining operations a single sampling type monitoring system is insufficient. The FTAM would be used in the mine ventilation system, thus monitoring much more effectively the worker's exposure. As a real time monitor, this detector could be very effective in shutting down dangerous operations (ones that result in a high airborne radon exposure) quickly.

Although poised for field testing within the year, a series of improvements and enhancements have been identified. These include a dramatic cost and complexity reduction, extension into higher temperature and harsher environments, and simultaneous alpha, beta, and gamma monitoring.

SUMMARY

The development of this new technology is being driven by the need for improved

on-line monitoring technology for alarming in real-time at low levels. This technology directly addresses the public concern over limitations in present monitoring capabilities. It must be emphasized that this new technology is intended to compliment, rather than entirely replace, current monitoring techniques. The sampling and long integration times of conventional detectors are necessary for the ultimate sensitivities required for regulatory compliance. The fast response, large active volume, and complete stack gas measurement of the FTAM technology is necessary to adequately provide fast real-time alarming.
With the promise of providing the incinerator site a comprehensive, fast responding, on-line alarm , the FTAM technology will soon establish the state of the art of incinerator monitoring for radioactive materials.
We wish to acknowledge and thank Paul Hart and Nina French of the DOE Mixed Waste Integrated Program, and Paul Williams of the Rocky Flats Fluidized Bed Incinerator project for their support of the development of this technology.

ABSTRACT
Large volumes of mercury-contaminated aqueous and solid mixed wastes are stored on Department of Energy (DOE) sites. These mixed wastes contain sufficient radioactivity and mercury that they need to be handled both under the Atomic Energy Act and the Resource Conservation and Recovery Act. Removal of volatile mercury from the aqueous waste is desired before potential water evaporation and thermal treatments are implemented. Vitrification and plasma hearth technologies are being tested at DOE facilities as thermal treatment methods for solid mixed waste. Due to mercury's volatility, treatment methods such as mercury leaching must be developed as pretreatment methods for mercury-contaminated solid mixed wastes.
Laboratory work has been conducted to investigate the feasibility of using inexpensive sulfur-impregnated activated carbon beads for mercury removal from aqueous waste. Laboratory studies have shown that mercury can be removed to levels below the current Environmental Protection Agency toxic characteristic level (0.2 mg/L). When comparing the use of inexpensive carbon beads with a more expensive ion exchanger, carbon beads had favorable process economics.
Clean, synthetic soil material was artificially contaminated with 20,000 mg/kg total mercury (Hg) prior to treatment in laboratory bench-scale experiments. The resulting surrogate waste was treated with KI/I2 solutions at concentrations in the range of 0.33 M KI/0.033 M I2 to 2.5 M KI /0.25 M I2 at temperatures of 25, 40, and 55C. It was observed that KI/I2 leaching solutions could effectively reduce the mercury concentration in soil by as much as 99.8%. It was also demonstrated that the mercury removal efficiency achieved with KI/I2 leaching was independent of mercury speciation or initial mercury concentration for the conditions studied.
A group of laboratory experiments was conducted with crushed fluorescent bulbs doped with small amounts of elemental mercury to simulate contaminated waste glass. The following leaching solutions were used to treat the prepared glass: NaOCl, KI/I2, HCl, HNO3, NaBr, NaBr + acid to pH 2, NaCl, and NaCl + acid to pH 2. The three most effective agents for leaching mercury from the crushed fluorescent bulbs were KI/I2, NaOCl, and NaBr + acid, which removed 98.8, 98.1, and 57.5% of the dosed mercury respectively.

INTRODUCTION
Large volumes of mercury-contaminated aqueous and solid mixed wastes are stored on Department of Energy (DOE) sites. These mixed wastes contain sufficient radioactivity and mercury that they need to be handled both under the Atomic Energy

Act and the Resource Conservation and Recovery Act. Removal of volatile mercury from the aqueous waste is desired before potential water evaporation and thermal treatments are implemented. Vitrification and plasma hearth technologies are being tested at DOE facilities as thermal treatment methods for solid mixed waste. Due to mercury's volatility, treatment methods such as mercury leaching must be developed as pretreatment methods for mercury-contaminated solid mixed wastes.

This goal of this project was to develop treatment processes for the removal of mercury from mixed waste. Processes that are applicable to aqueous waste include sulfur-impregnated activated carbon, ion exchange resins, and ion exchange membranes. To focus development activities on realistic process variables, target wastes were selected from the U.S. Department of Energy (DOE) mixed waste inventory. Inventoried wastes were evaluated based on seven criteria ranging from waste characteristics to regulatory drivers. The aqueous target waste selected was the Idaho Chemical Processing Plant (ICPP) sodium-bearing acid waste. The solid target wastes selected consisted of soils/sediments stored at the Oak Ridge Y-12 Site and crushed fluorescent tubes/lamps found at all DOE sites.

MERCURY REMOVAL FROM LIQUID MIXED WASTE

The specific objective of the laboratory studies was to investigate the ability of sulfur-impregnated activated carbon to remove mercury from acid solutions. Effects of pH, sorbent-to-liquid ratio, mass transfer versus kinetic control, competing ions, and mercury bead loading on the adsorption were examined. In addition, the sorbent capacity was determined in batch tests. After completion of batch experiments, column studies were performed to investigate design parameters.

Methods

Two types of surrogate wastes were used in this study. The first was an aqueous solution of mercuric nitrate [Hg(NO3)2] prepared from either 1,000 or 10,000 mg/L National Institute of Standards and Technology standards diluted with deionized water. In some cases, crystalline Hg(NO3)2 was directly dissolved in deionized water. The acidity of the surrogate waste was adjusted with nitric acid (HNO3) or sodium hydroxide (NaOH) to achieve the desired pH. The second surrogate waste, which simulated the sodium-bearing liquid waste, was prepared based on a formulation obtained for the ICPP waste. The average acidity (from HNO3) of the ICPP waste was 1.4 mol/L (M), and mercury levels were in the range of 100 to 860 mg/L (as Hg2+) with an average value of 476 mg/L. Other metal contaminants were present in the following average concentrations (in mg/L): aluminum, 15,000; cadmium, 184; iron, 1,475; lead, 213; manganese, 744; and nickel, 140.

Sulfur-impregnated granular activated carbon was obtained from Nucon International, Inc. (Columbus, Ohio). The Mersorb pellets had a diameter of 3 mm and a length of 3 to 8 mm. The data sheet obtained from the pellet manufacturer listed the sulfur content to be 13% and the mercury capacity to be 85% of the theoretical value. This translates to a "real" capacity of 0.71 g mercury/g beads.

Jar mill studies were conducted using a US Stoneware (Mahwah, New Jersey) variable-speed jar mill using 1-L Pyrex glass bottles as jars. Column studies were performed in Kontes (Vineland, New Jersey) liquid chromatography columns with a diameter of 48 mm, and the length could be varied by adjustable plunger-type end caps. The feed was supplied to the bottom of the column with a variable speed/flow Masterflex pump (Cole Parmer Instrument Co., Niles, Illinois). Except for pump tubing, all surfaces in contact with the liquid were glass or Teflon.

Mercury concentration in the aqueous solutions was measured using an 1100B atomic absorption spectrometer (Perkin-Elmer, Norwalk, Connecticut) equipped with a cold vapor injection system (Model FIAS 400, Perkin-Elmer) and automatic sampler (Model AS 90, Perkin-Elmer). Argon was used as the gas carrier and 0.36 M hydrochloric acid (HCl) was used as liquid carrier. The reducing agent was 0.30 M stannous chloride (SnCl2) in 0.36 M HCl. Typically, 4 mL of the aqueous sample was filtered, and 1 mL of the filtrate was diluted with 4 mL preservative solution [3.4 mM potassium dichromate (K2Cr2O7) in 0.80 M HNO3]. Serial dilutions of the preserved sample were made with preservative solution to a final mercury concentration in the range of 1 to 20 g/L. Standards were prepared by serial dilution with preservative solution from a 1000-mg/L primary standard to final concentrations of 1, 10, and 20 g/L.

Results and Discussion

Initial batch experiments were carried out in a jar mill in which Mersorb pellets were contacted with an acidic solution containing mercuric nitrate. Tests were made to investigate the effects of jar mill speed on the uptake rate of mercury from a

100-mL solution at a pH of 2. Jar mill speeds tested were 11, 22, and 38 revolutions per minute (rpm) with an excess of pellets (5 g). The Mersorb pellets were capable of reducing mercury concentrations to <0.2 mg/L. The initial mercury uptake rate followed first-order kinetic behavior (which was expected) and is described by the equation

$$\log[Hg2+] = -0.4343kt + \text{constant} \qquad \text{Eq. (1)}$$

where k is the apparent reaction rate constant and t is time. Based on the result of the initial experiments, it was determined that a jar mill speed of approximately 22 rpm would be used for the remainder of the study to avoid external (to the pellets) mass transfer limiting conditions.

The effect of pH on mercury uptake was investigated for three initial pH levels (pH 2, 3, and 4) using 100 mL of a 10 mg/L mercuric nitrate solution and 5 g Mersorb pellets. Mercury levels decreased to less than 0.5 mg/L in a 30-min contact time, and the overall mercury uptake was approximately the same for each of the pH conditions studied.

Mersorb saturation loading (or capacity) at a low and neutral pH was evaluated at various mercury and sorbent concentrations. The measured saturation loading at pH 2 was on average 0.04 g mercury/g dry pellets. At a pH of 8, the loading increased to 0.12 g/g. These correspond to 5.6% and 16.9% of the theoretical capacity respectively.

Surrogate waste (to simulate ICPP waste) was prepared from a waste description obtained from Idaho National Engineering Laboratory. Mercury uptake from a 100-mL solution was monitored for the ICPP surrogate waste and for a well-defined mercuric nitrate solution using two liquid/Mersorb ratios (100:0.9 and 100:0.5 mL/g). Compared with the mercuric nitrate solution, mercury loading on the beads was reduced by 50% when the ICPP surrogate waste was used (see Fig. 1). This was not unexpected because the ICPP surrogate waste contained competing ions such as iron, lead, cadmium, and nickel.

Fig. 1. Mercury loading of 0.5g of pellets from two simulated wastes.

Large-scale separation of mercury from solutions would most likely be accomplished by passing the contaminated stream through columns packed with Mersorb pellets. A small laboratory column was designed and constructed to obtain mass transfer data and mercury capacity for columns. The column length (and thus the amount of sorbent) could be adjusted, and the solution was pumped through the bed by a variable-speed pump.

An absorption column in operation has three distinctive zones: 1) the saturated zone which is close to the feed inlet; 2) the mass transfer zone (or absorption zone), in which active absorption of the solute occurs; and 3) the unsaturated zone, which is essentially free from the solute and the sorbent retains its original absorption capacity. The mass transfer zone is mobile during the course of the operation and is positioned at the inlet of the column at start-up and moves toward the outlet with time. The length of the mass transfer zone is dependent upon fluid flow and absorption kinetics. The mass transfer zone length is calculated from breakthrough curves (obtained by monitoring effluent concentration during continuous column operation). Typically, absorption columns are designed to operate until 5% breakthrough is noticed in the effluent. In general, the shorter the mass transfer zone length, the more efficiently the absorption column is used.

An initial column experiment was conducted with a bed depth of about 2.5 cm. The feed solution concentration was made from $Hg(NO3)2$ to contain approximately 1000 mg/L mercury and had a pH of 2. The feed flow rate of 7 mL/min was a factor of ten lower than typical process flow rates but was chosen as a conservative first attempt. The first fraction of effluent, consisting of 6.5 bed volumes, had a mercury concentration of 222 mg/L, indicating immediate breakthrough. This also indicated that the length of the mass transfer zone was longer than the total length of the column.

To improve mercury removal and to find the mass transfer zone length, a second column experiment was performed with bed depth of 7.6 cm under the conditions mentioned above. Based on the results from this experiment, it was concluded that the mass transfer zone length was approximately 6.2 cm at a liquid superficial velocity [(volumetric feed rate/(cross-sectional column area)] of 0.0068 mm/s. A mass balance revealed that at exhaustion the column had reached 5.8% of the theoretical mercury capacity, which is consistent with results from jar mill tests at this pH. As previously reported, capacity increases with solution pH. This result

may be used to design large-scale columns operating at similar liquid superficial velocities. The initial effluent that exited the column contained 20 mg/L Hg, which is 100 times higher than the Environmental Protection Agency's (EPA's) limit (0.2 mg/L). The column length was subsequently increased (to 12.7 cm) in the next experiment, which resulted in a tenfold decrease in the initial effluent concentration from the column. The results of the three experiments are shown in Fig. 2.

Fig. 2. Effect of column length on mercury removal from a feed stream containing approximately 1000 mg/L mercury.

EPA's toxic characteristic level (0.2 mg/L) was reached in a column test with a bed length of 56.5 cm. This column experiment worked so well that it was shut down after 127 bed volumes of feed (350 mg/L, pH 3) had passed through the column. The effluent at shutdown contained 0.025 mg/L mercury. A variety of liquid superficial velocities were tested throughout the experiment with essentially no change in the effluent concentration. A mass balance over the column indicated that 45 g mercury was absorbed in the column.

Process economics will be much more favorable for Mersorb when applied for solutions at the higher pH. Even at the lower pH, Mersorb may be competitive with ion-exchange resins. This may be illustrated by comparing sorbent costs with a typical ion exchanger (Duolite GT-73) used for mercury removal. Mersorb costs on the order of $3/lb, and even when loaded to only 3% of theoretical capacity, the cost for Mersorb is about $0.28 per g of mercury absorbed. Duolite GT-73 costs about $17/L with a capacity of about 30 g Hg/L resin(1). This gives a cost for Duolite GT-73 of about $0.56 per g of mercury absorbed. It is assumed that neither sorbent is regenerated. A complete economic analysis would consider many other process costs, but the sorbent costs cited here indicate that Mersorb may find some applications for DOE mixed wastes.

MERCURY REMOVAL FROM SOLID MIXED WASTES

The second focus of this research was to evaluate chemical leaching as a technique to treat soils and glass contaminated with either elemental mercury (Hg0) or a combination of several mercury species, including elemental mercury (Hg0), mercuric oxide (HgO), mercuric sulfide (HgS), and mercuric chloride (HgCl2). Potassium iodide/iodine (KI/I2) solution was investigated as chemical leaching agents for contaminated soils, and in addition to KI/I2 solution, several halide solutions and dilute acids were evaluated as leaching agents for glass wastes.

For a leaching solution to be effective, it must be capable of both solubilizing solid mercury compounds and of forming mercury complexes that will remain in solution, making separation from the treated solids possible. Halides, including bromide (Br-), chloride (Cl-), and iodide (I-), have been shown to form soluble complexes with mercury (II) species. According to chemical data2, halogen ions such as I-, Br-, and Cl- have large formation constants (Kf) with mercury and low oxidation potentials, thus allowing the formation of stable mercury-halide complexes.

Researchers at the General Electric Company (GE) have developed a mercury removal process in which I2 is used to oxidize mercury to the 2+ state and KI is used as a source of I-. When KI/I2 leaching solutions are applied to a mercury-contaminated solid, the various solid mercury species are transformed to the soluble complex HgI42- according to the following reactions:(3)

$$HgO + I2 = HgI2 \quad (2)$$

$$HgI2 + 2\ I- = HgI42- \quad (3)$$

$$HgO + H2O + 4\ I- = HgI42- + 2\ OH- \quad (4)$$

$$HgS + I2 + 2\ I- = HgI42- + S \quad (5)$$

A review of the literature suggested that halide solutions and some acids should be effective leaching agents for mercury-contaminated glass. Radian Corporation (Oak Ridge, Tennessee) conducted a soil treatability study in 1992 with several leaching agents, such as ammonium hydroxide, sodium hypochlorite (NaOCl), bromic acid (HBr), KI/I2, thiourea, acetic acid, ethylenediaminetetraacetic acid (EDTA), synthetic acid rain, and deionized water. It was reported that KI/I2, HBr, and NaOCl were the most effective in leaching mercury-contaminated soils. Because KI/I2 and NaOCl were found to be effective in leaching mercury from soil, it was to decided to evaluate their effectiveness on glass waste. Sodium bromide (NaBr) was evaluated as a leaching agent instead of HBr to avoid safety hazards associated with HBr. Wang and co-workers used sodium chloride (NaCl) to remove mercury from freshwater

sediments(4). Sodium chloride was evaluated in this study because if it were found to be applicable, its use on a larger scale would be very cost-effective. Because both Br- and Cl- form complexes primarily with Hg2+, adjustment of pH to a value of 2 was investigated as a means to improve the leaching efficiency of the NaBr and NaCl solutions. Also, dilute HNO3 and hydrochloric acid (HCl) solutions were investigated because it is well known that most forms of mercury are soluble in these acids.

Methods

For the soil leaching experiments, EPA synthetic soil material5 was contaminated by adding measured amounts of HgO, HgS, or HgO to aliquots of 10 g soil in 125-mL Erlenmeyer flasks. In all experiments, the target pretreatment total mercury concentration was 20,000 mg/kg. Surrogate radionuclides CeO2 and CsCl (approximately 0.025 g of each) were also added to the soil in some of the experiments. The flasks were capped after mercury addition and agitated for 24 h at 40C on a rotational shaker to allow the soil and the mercury to equilibrate.

Deionized water and reagent-grade KI and I2 were used to prepare KI/I2 solutions at least 12 h prior to soil treatment. Thirty milliliters of leaching solution was added to each flask containing soil to be treated. Deionized water that had been pH adjusted was added to control flasks instead of KI/I2 leaching solution. A blank consisting of surrogate soil without added mercury was also treated with the KI/I2 leaching solution. The flasks containing soil and leaching solution were either capped or covered with parafilm (depending on treatment temperature) and placed in preheated environmental shaking chambers (Lab-line Instruments, Inc., Melrose Park, Illinois).

After the 4-h reaction time had elapsed, the contents of the flasks were vacuum filtered through 0.45-m membrane filters. The residuals remaining in the flask and the filter cake were washed with an additional 30 mL of deionized water. The volume of the supernatant and wash water was measured, and the liquids were combined in 80-mL glass sample jars. The filter and filter cake were returned to the Erlenmeyer flask for digestion. All samples were stored at room temperature in glass containers prior to analysis.

For glass leaching experiments, 30.5-cm-long by 2-cm-diameter (8-W) GE fluorescent bulbs were used. The following leaching solutions were used to treat the prepared glass: NaOCl, KI/I2, HCl, HNO3, NaBr, NaBr + acid to pH 2, NaCl, and NaCl + acid to pH 2. The fluorescent bulbs were prepared for leaching by first removing the aluminum end cap with pliers and then breaking the glass into small pieces (less than 1.3 cm) inside a sealed plastic bag. The broken glass and phosphor material were then weighed and transferred to an Erlenmeyer flask for treatment. The average mass of crushed glass in each flask was 24 0.9 g. A small amount of HgO was added to the glass in each flask to achieve mercury contamination levels similar to those found in larger bulbs, such as those used at DOE facilities. The target mercury contamination level was 250 mg/kg HgO. After glass contamination, approximately 75 mL of prepared leaching solution was added to each flask. Blank and control samples were also prepared. The flasks were then covered and placed on the rotational shakers. All of the glass treatment experiments were conducted at room temperature (25C).

The mercury concentration in the post-treatment samples was measured as described above. The presence of iodine in concentrations greater than 5 mg/L significantly interfered with the analysis of Hg because of the competition for the reducing agent. Therefore, it was necessary to dilute samples in the range of 50,000- to 200,000-fold. Using this method, Hg recoveries in excess of 93% were observed. A flame atomic absorption spectrometer (Perkin-Elmer, Model 5000) was used to measure the cesium concentrations, and cerium concentrations were measured by an outside analytical laboratory using inductively coupled plasma (EPA method 200.7).

Results and Discussion

Results of the mercury leaching studies from contaminated soil and glass are summarized in Figs. 3 and 4. The mercury removal percentages presented may reflect more than one mercury removal mechanism, including the aqueous solubilization of the mercury compounds and the chemical leaching of mercury with KI/I2 or other leaching solutions. Because the overall removal of mercury from solid mixed waste was of most interest in this study, the reporting of these combined removal efficiencies was deemed appropriate. Control studies in which mercury-contaminated soils were leached with deionized water instead of KI/I2 leaching solution revealed that less than 1%

of the mercury was removed as a result of the aqueous solubilization of the mercury.
Fig. 3. KI/I2 leaching of mercury-contaminated EPA synthetic soil.
Fig. 4. Mercury removal from crushed glass contaminated with Hg0. (Data for treatment with NaCl, NaCl + acid, NaBr, dilute HCl, and dilute HNO3 are not shown; no mercury removal was observed for these solutions.
The KI/I2 leaching solutions were able to reduce the mercury concentration in the contaminated soil by as much as 99%. It was observed that KI/I2 leaching is applicable to multiple forms of mercury, including Hg0, HgO, HgS, and HgCl2, and that treatment efficiency is independent of temperature for the KI/I2 leach solution concentrations evaluated. The experiments conducted with the surrogate radionuclides revealed that CeO2, which was a surrogate for uranium, did not solubilize and remained with the solids following treatment. Cesium, in contrast, was found in both the solid and liquid phases following treatment.
Of the eight different leaching solutions evaluated for the crushed fluorescent bulbs, only three, 1.0/0.1 M KI/I2, 0.8 M NaOCl, and 0.5 M NaBr + acetic acid, were able to remove any mercury from the glass. The percentages of removal reported were calculated using the mass of mercury added to the glass and the measured mercury concentration in the glass after treatment. Of the three treatments that worked for the crushed glass, KI/I2 removed the greatest amount of mercury and resulted in the lowest Hg0 residual concentration. NaOCl was almost as effective as the KI/I2, but the NaBr + acid removed less Hg0 than the either KI/I2 or NaOCl. The post-treatment mercury concentration in the glass treated with either KI/I2 or NaOCl was less than 10 mg/kg. The lower Hg0 residuals were probably obtained with glass compared with soils because of the much lower initial mercury concentration and the simplicity of the glass matrix.

CONCLUSIONS

Based on the bench-scale laboratory experiments, the following conclusions have been reached:
1. Sulfur-impregnated, activated carbon pellets (Mersorb) can be used to remove mercury (Hg2+) from aqueous solutions to below EPA's toxic characteristic level (0.2 mg/L).
2. Mersorb works under acidic conditions (pH of 2), but its capacity is reduced by approximately 50% compared with neutral conditions.
3. Competing ions present in the target waste stream reduced the Mersorb capacity by 50%.
4. Mersorb appears to be economical compared with leading ion-exchange resin.
5. KI/I2 leaching solution can be used to remove up to 99% of the mercury in contaminated soil and glass.
6. KI/I2 leaching solution worked well with several mercury species, including Hg0, HgO, HgS, and HgCl2.
7. KI/I2 leaching solution worked well with a wide variety of initial mercury concentrations.
8. Radionuclide surrogate studies suggested that uranium will not partition into KI/I2 leaching solutions. Cesium may partition into the KI/I2 leaching solution because of the high solubility of cesium salts.

ACKNOWLEDGMENTS

This research was funded by DOE's Mixed Waste Integrated Program and conducted at Oak Ridge National Laboratory. Oak Ridge National Laboratory is managed by Martin Marietta Energy Systems, Inc., under contract DE-AC05-84OR21400 with DOE.

ABSTRACT

In this paper we describe our ongoing project to develop and apply a family of on-line process monitors based on tunable diode lasers (TDLs). We focus on a continuous emission monitor for volatile organic compounds (VOCs) likely to be present in trace amounts in the off-gas of thermal waste treatment processes. Partnering with PSI Environmental Instruments Corp. of Andover, MA, we have demonstrated TDL-based technology for the real-time monitoring of ammonia at ppm levels in the harsh environments of power plants and municipal incinerators. We are extending this technique to the detection of VOCs through a combination of laboratory spectroscopic measurements and field trials.

INTRODUCTION TO TUNABLE DIODE LASER-BASED CONTINUOUS EMISSION MONITORS

There are a number of industrially-produced, gas-phase species for which reliable real-time monitors are currently not available. The Department of Energy's Mixed Waste Integrated Program has identified the need for such instrumentation in order to provide for rapid and cost-effective regulatory compliance. In addition, there is demand in numerous industries for real-time information about important process variables that can be incorporated into process-control algorithms. We are investigating the use of tunable diode lasers (TDLs) for the purpose of both continuous emissions monitoring and process control.

Essential characteristics of a useful continuous emission monitor (CEM) are as follows: 1.) The CEM must be robust and sensitive; it must detect the species for which it is designed, but not suffer from interferences due to other species in the effluent. 2.) The CEM must be reliable and rugged; it should function continuously with very little down-time and maintenance required. The CEM should be sufficiently sturdy to survive in the hostile environments that must be probed to provide the desired information. 3.) The CEM response should be rapid, providing information sufficiently quickly that the information can be used (if desired) for process control. 4.) The CEM should be affordable, providing clear benefit for the money invested in its purchase, preferably recovering its own cost in a reasonable time period.

There are additional features that are attractive in CEMs. In many cases in situ measurements are desirable. User interaction, such as calibration, should be minimal and preferably automatic. In addition, versatility is an advantage: a single piece of hardware that can do the job of several monitors is preferable. Unfortunately, all or most of these requirements are rarely met in a single instrument.

The technical basis of TDL-based monitors is the detection of molecular gas-phase species through optical absorption of laser radiation by molecular vibrational transitions in the mid-infrared (mid-IR) or near-infrared (near-IR) wavelength region. TDLs emit extremely narrow, single-mode radiation that can be tuned across molecular absorption lines by varying injection current or device temperature. In general, the operating temperature of the diode is held constant while the current supplied to the diode is modulated rapidly to vary the wavelength.

Single-mode tuning of diode lasers can be accomplished over a small spectral range for a given temperature at rates faster than 1 KHz. The wavelength range over which a TDL will lase is determined by the composition of the semiconductor laser; appropriate choices of diode material and temperature/current combinations lead to detection of different molecular gas-phase species. While the small spectral tuning range of these lasers is a liability for the simultaneous detection of many gas-phase species, the extremely narrow laser line width permits the resolution and unambiguous identification of specific molecules in contrast with other optical

methods such as Fourier transform infrared (FTIR) spectroscopy (see below).
TDLs are extremely compact, robust solid-state devices. These lasers have been extensively developed for other industries (such as the communication and entertainment industries) and have been demonstrated to be low-cost, reliable, physically compact, and easily adaptable to spectroscopic applications. Since they are semiconductors, they can be manufactured by mass production methods, thus greatly reducing the cost of an individual laser component.
The implementation of TDL-based monitors is simple. Laser radiation traverses the volume of interest while the laser wavelength is repeatedly scanned. The degree to which the radiation at each wavelength is absorbed is related to the presence of specific absorbers in the sample. Quantification of the absorption can be straightforward and provides a measure of the concentration of the absorbing species. The sensitivity of this technique to molecular species is greatly enhanced by high-frequency modulation of the laser beam and phase-sensitive detection. This can be a great advantage when monitoring species in a high-temperature, particle-laden environment where blackbody radiation interferes with measurements. Since background signals are invariant over the small wavelength region scanned by high-frequency modulation, application of lock-in amplification suppresses the contribution of background radiation to the absorption signal thereby improving the signal-to-noise ratio. Contributions to the signal from other nearby, molecular-absorption features can also be minimized by the use of frequency modulation, which improves the selectivity and sensitivity of the absorption sensor. Detection limits lower than 1 ppm-meter of absorbing pathlength have been demonstrated for small molecular species by this method (1).
Other analytical techniques, such as gas chromatography coupled with mass spectrometry (GC-MS), have also been applied to monitoring off-gas streams from industrial processes. In general these methods are able to provide molecular identification, but are necessarily extractive in nature. Extensive sample pretreatment may be required prior to analysis, and real-time information is unavailable due to time lags associated with extraction, particulate removal and separation on the chromatographic column. In addition, the process gas-temperature information is also lost.
Alternate methods employing optical techniques for gas-phase molecular detection are being actively pursued by others. A leading candidate is long-path optical absorption in the mid-IR region by FTIR spectroscopy (2). While FTIR has been used extensively in the analytical laboratory, developing this technology into a field monitor is difficult for many applications due to the limitations imposed by the characteristic low spectral resolution of hardened, field instruments.
The great strength of FTIR spectroscopy is its inherent wide spectral bandwidth, which allows for the simultaneous detection of many molecular species in the mid-infrared spectrum. Spectral resolution for real-time monitoring purposes, however, is on the order of 1 cm-1 or worse, which is more than ten times the line width of typical gas-phase absorption transitions. This makes the speciation and quantitative measurement of many VOCs very difficult due to distorted and strongly overlapping absorption features.
Laser-induced fluorescence (LIF) is another diagnostic technique for the detection of trace amounts of specific small molecules and atomic species. Although this approach is well suited for the measurement of extremely low concentrations of absorbing species, serious problems impede its utilization as an CEM monitor for complex effluent streams. While LIF is a suitable laboratory for a few small molecules, the necessary laser systems tend to be bulky, sophisticated, expensive, and not well suited to rapid wavelength switching which would be necessary for the rapid detection of more than one molecular species. With suitable calibration, broad-band excitation and fluorescence spectroscopy may be useful for quantifying certain classes of VOCs (aromatics, halogenated hydrocarbons, etc.).
In summary, many of these analytical techniques offer complementary capabilities to TDL spectroscopy for continuous monitoring. Requirements for a CEM are highly application-dependent and, as a result, an instrument that combines one or more of these methods may offer the most comprehensive approach to real-time monitoring of molecular emissions and process variables in off-gas streams.
TDL-BASED CEMS: TRACE GAS DETECTION FOR COMPLIANCE MONITORING
Direct laser absorption coupled with high-frequency modulation and lock-in detection can be very sensitive. Successful detection of trace species present in

concentrations less than ppm with TDL-technology has been demonstrated in the field (3). This can be of great value in industries where it is desirable to monitor chemical emissions on a real time-basis for the purpose of regulatory compliance. An important example of a need for a CEM is ammonia monitoring. Ammonia is used as a reactant or released as a by-product in the Selective Catalytic Reduction (SCR) or Selective Non-Catalytic Reduction (SNCR) methods for controlling NOx emissions from large combustion facilities. Ammonia that is not consumed by NOx is released into the atmosphere ("ammonia slip"). Excess ammonia slip not only wastes costly chemicals, but leads to plugging and fouling of heat exchange surfaces, especially when sulfur is present.

There are numerous obstacles to monitoring ammonia in boiler environments. For example, electrical and mechanical noise abounds, the operating temperature is high, and particulates are pervasive. Because current EPA regulations demand extractive sampling, and since fast response times are desired, there must be a high rate of gas exchange within the sampling cell. Both the sampling cell and tubing between the sampling point and the cell must be heated to prevent formation of ammonium sulfate powders. All surfaces that contact ammonia must be constructed using stainless steel in order to withstand temperatures as high as 260C (500F) and a corrosive gaseous environment.

Other techniques for measuring ammonia have drawbacks in their use as CEMs. FTIR spectroscopy cannot rapidly provide 1 ppm sensitivity. Wet chemistry techniques require about 30 minutes and human participation. Ion-mobility spectroscopy requires about 10 minutes in order to achieve 10 ppm sensitivity. Ultraviolet spectroscopy suffers from interferences due to the presence of SO2 in the gas stream. Gas correlation spectroscopy suffers H2O and CO2 interferences.

PSI Environmental Instruments Corp. has developed a TDL-based ammonia monitor (the trade name is SpectraScanTM) that overcomes each of these barriers (4). Figure 1 provides a schematic of this monitor. The modular design of this instrument is well-suited to field measurements. The heated, multi-pass gas cell is located near the process gas stream and is connected to the duct via a heated pipe with appropriate filters to remove particulate matter. The laser and associated electronics are mounted in a standard 19" equipment rack which can be remotely located, for example in a control room. An important feature of this monitor is the use of a near-IR TDL that can be operated near room temperature. This obviates the need for cryogenic cooling as is required for mid-IR TDLs. In addition, there are inexpensive and robust fiber optics available to transmit the near-IR laser beam long distances, improving the ease of remote operation.

Fig. 1.

PSI Environmental performed several series of field trials of the ammonia monitor in commercial power plants in Massachusetts and New Jersey. For these tests, continuous monitoring of ammonia was performed in conjunction with the operation of NOx suppression hardware. Results demonstrated ammonia detection in the ppm range when compared with independent wet chemical analysis. One set of results from these tests is shown in Fig. 2. The large variation in the ammonia content of the gas stream at the sampling point is clearly evident.

Fig. 2.

EXTENSION OF TDL-BASED MONITOR TO VOC DETECTION

We are partnering with PSI Environmental to extend this TDL-based technology to monitor other molecules. Of particular interest are volatile organic compounds (VOCs) in the off-gas streams from thermal waste processes. DOE's Mixed Waste Integrated Program has identified the need for such instrumentation in order to provide for rapid and cost-effective regulatory compliance and assurance of process control of a number of developing thermal waste treatment technologies. We are identifying wavelength regions where molecules of interest absorb radiation. The required diode laser is specified, and high-resolution absorption and calibration measurements are made to appropriately configure the monitor. After laboratory testing is complete, the prototype monitor will be tested at thermal waste treatment sites and its performance will be compared to other CEM methods and standard analytical results. Our TDL-based monitor is well suited to easy modification. Due to its designed modularity, laser wavelengths can be changed simply by substitution of TDL modules in the instrument. Future plans call for the incorporation of multiple TDL modules into a single instrument, allowing real-time monitoring of multiple species.

Unfortunately, the near-IR absorption signature of many VOCs and light inorganic species have not been well determined at sufficiently high resolution for our purposes. In order to identify optimal wavelength regions for analysis by TDL spectroscopy, we have surveyed the near-infrared absorption spectrum for a variety of species using FTIR spectroscopy at moderate spectral resolution. Certified mixtures of individual species at low concentrations in nitrogen or in permeation tubes were obtained for calibration purposes. Results for several chlorinated VOCs for the wavelength 1.58-1.74 mm region are displayed in Fig. 3.
Fig. 3.
The improved sensitivity attainable with the TDL-based absorption technique is demonstrated in Fig. 4 by comparing a portion of the near-infrared absorption spectrum of ammonia recorded with our FTIR spectrometer at moderate resolution (0.1 cm-1), and the TDL absorption signal for a "single" feature in that spectrum. The TDL signal clearly indicates that multiple absorption lines are actually present in the unresolved FTIR peak. Frequency modulation has been shown to improve the sensitivity of absorption measurements by several orders of magnitude, and is an important feature of the TDL monitors under development.
Fig. 4.
We are currently in the process of characterizing a tunable diode laser that emits in the 1.65-mm wavelength region. Figure 3 shows that a number of VOCs absorb in this region, and a CEM based on this laser will be tested in the laboratory shortly.
SUMMARY
Sandia and PSI Environmental have completed developmental work on a TDL-based ammonia monitor that serves as the basis for a CEM for VOC detection. Spectroscopic survey work using a laboratory FTIR spectrometer revealed absorption signatures for several VOCs in the 1.58-1.74 micrometer wavelength range, and a prototype TDL-based monitor was fabricated and is currently being tested. The FTIR measurements are used to specify the TDL wavelength range required for a given VOC. Future work includes: detailed spectroscopic analysis with the TDLs to determine optimum wavelengths for detection of target VOCs; laboratory calibration of the monitor for each VOC; development of a protocol for field trials including on-line calibration; and tests of the VOC monitor under field conditions.

ABSTRACT
This report describes the first set of experiments performed on transuranic (TRU) precipitation sludge produced in Building 774, to determine the operating parameters

for the microwave vitrification process. Toxicity Characteristic Leach Procedure (TCLP) results of the raw sludge showed concentrations of lead, silver and cadmium which were in excess of land disposal restrictions (LDR). Crushed, borosilicate, glass was used as a frit source to produce a highly desirable, vitrified, product that required less energy to produce. TCLP testing, of microwaved samples, showed favorable results for 40 and 50 percent waste loading. The results of this study are encouraging and support the development of microwave vitrification technology for the treatment of various mixed waste streams at Rocky Flats Environmental Technology Site. However, additional experiments are required to fully define the operating parameters for a production-scale system.

INTRODUCTION

The Department of Energy's (DOE) Rocky Flats Environmental Technology Site was a production facility for the nuclear weapons complex for more than forty years. As a by-product of production at Rocky Flats, a variety of hazardous and radioactive wastes were generated, stored, and treated. Most of the stored wastes do not meet the current Department of Transportation (DOT) shipping requirements or the waste acceptance criteria (WAC) for land disposal. The WAC requires that the waste form passes the TCLP testing as required by the Resource Conservation and Recovery Act (RCRA) for land disposal.

The microwave vitrification process has been in development at RFP since 1986 to set forth the critical operating parameters for the vitrification of wastes suitable for land disposal (Petersen, R. D., 1990). The objective of the microwave vitrification bench scale testing is to determine if microwave energy is capable of melting actual TRU precipitation sludge generated in Building 774 to reduce its volume, and produce a waste form acceptable to the Waste Isolation Pilot Plant. The hydroxide precipitation sludge from Liquid Waste Treatment operations in Building 774 was one of the waste streams treated during the experiment. This sludge is produced during a coprecipitation process in the liquid waste treatment facility (Building 774) and is dewatered using a vacuum drum filter precoated with a filter aid media. The TRU precipitation sludges are currently treated in a cementation process. The negative aspects of this process are:

1) Increase in waste volume
2) Process did not produce a consistent repeatable product
3) Product did not meet the requirements of DOT or LDR.

The experimental test plan and design matrix, used for the hydroxide precipitation sludges, was developed from previous testing surrogate wastes using a bench scale microwave in Building 701 (Eschen, Fenner, Splett, and Sprenger, 1994). The testing of the surrogate waste produced a window of operation which was validated by the microwave vitrification testing of the actual hydroxide precipitation sludges in Building 774. This report discusses the results of the tests.

EXPERIMENTS

The following subsections describe the procedure for performing the experiments and the results of the experiments.

Procedure

Hydroxide sludge was not available for the experiment due to curtailment of the coprecipitation process in the liquid waste treatment facility (Building 774). Residue Treatment Technology (RTT) personnel developed a procedure to sample one of the feed tanks (tank 40) to extract enough liquid and particulate material to filter for conducting the microwave vitrification experiment. Twenty four 4-liter bottles of liquid were sampled from the feed tank 40. The liquid was then vacuum-filtered through a Buchner funnel, which was precoated with the same filter aid media used on the vacuum drum filter of the coprecipitation process. The sludge was scraped from the filter and collected for microwave vitrification testing. Approximately 2 kilograms of material was collected. This filtering process yielded material with a composition of sludge to filter aid media that was similar to the current production vacuum drum filter process. A sample of the filtered sludge was sent to the Plutonium Operations Support Laboratory in Building 771 for TCLP analyses to determine if any element that would restrict land disposal were present. Table I, TCLP Analyses of Raw Sludge from the Coprecipitation Process of Liquid Waste Treatment Facility (Building 774), provides the results of these analyses. Shaded boxes exceed land disposal restrictions.

TABLE I

Procedure RTT986277-50-2, Operating Procedure, Microwave Solidification - Building

774, is the operating procedure used for microwave vitrification testing. The microwave vitrification developmental equipment used in Building 774 is in room 210, and consists of a 6 kW, 2450 MHz Cober microwave generator, waveguides, tuner, resonant cavity, glovebox, turntable, screwfeeder and stand alone chiller. The generator has a variable output of 0 to 6 kW of microwave energy. The waveguide is separated from the glovebox with a 1/4-inch-thick teflon window.
The following operating parameters were controlled during the experimental test runs:
  Waste loading (S/F) -- Weight percent ratio of waste sludge (S) to the frit (F).
  Temperature (oC) -- Measured with an infrared thermometer or a thermocouple.
A range of waste load ratios was selected based on previous testing of surrogate waste (Eschen, Fenner, Splett, and Sprenger, 1994). Table II, Test Matrix for Microwave Solidification of Hydroxide Coprecipitation Sludge (Building 774), provides the matrix of waste loading and temperature per test run.
TABLE II
For this series of tests, crushed, borosilicate glass was used as a frit source to produce the desired vitrified product. In each test run, 150 grams of the feed material (sludge / frit) was vitrified in a ceramic crucible, insulated on all sides, and held within a commercially available 3 liter, stainless steel, container. The time required for each test run was very consistent, approximately 60 minutes, but did vary slightly due to the composition of the feed material and the amount of reflected power produced.
The final waste forms produced from the tests were prepared for TCLP analyses in accordance with Environmental Protection Agency (EPA) protocol. Material from the vitrified samples was removed from the ceramic crucibles and fractured with a hammer to collect a representative sample. No further size reduction was required for the TCLP analyses. Table III, TCLP Results of Microwaved Vitrification Samples, provides the volume of each vitrified sample collected and sent to the Plutonium Operations Support Laboratory in Building 771 for TCLP analyses.
TABLE III
TCLP analyses was performed in accordance with SW 846 Method 1311, Toxicity Characteristic Leaching Procedure. The samples were radiologically "hot" (>70 pCi/gm activity), so TCLP extracts were prepared within A-box containment. TCLP Extraction Fluid No. 1 was determined to be the proper extraction fluid by performing pH tests on the samples. The solid extracts were prepared and agitated in a standard rotating TCLP extractor at 30 2 rpm for 18 2 hours, following EPA SW-846 Method 1311. The solids extracts were immediately filtered through 0.7 micron borosilicate glass fiber filters to obtain the final TCLP extracts. Particle size reduction was not performed on the samples since they were visually determined to be smaller then the 9.5 mm mesh size reduction criterion stipulated in Method 1311.
The samples then underwent total metals digestion following EPA SW-846 Method 3010A, Acid Digestion of Aqueous Samples and Extracts for Total Metals by Flame Absorption or ICP Spectroscopy. The final nitric/hydrochloric acid sample digest solutions were analyzed for the requested RCRA metals using a Varian Model SpectrAA 30/40 atomic absorption spectrometer.
Results
The results of the TCLP analyses for the raw sludge obtained from the coprecipitation process of the liquid waste treatment facility (Building 774) are provided in Table I. The concentrations of cadmium, lead and silver exceeded the WAC for land disposal.
The results of the TCLP analyses for the microwave vitrified sludge samples are provided in Table III. These results showed the concentrations of silver, cadmium and lead, in four of the samples (774-RAW, 774-TPS-1, 774-TPS-6, and TPS-16), exceeded the WAC for land disposal. The shaded boxes in Table III identify where LDRs are exceeded.
However, the test samples with the sludge to frit ratios of 40/60 and 50/50 produced acceptable results. Since only one sample per test were prepared, the confidence level of the TCLP analyses results is low. The 774-RAW sample was a raw sludge sample submitted to verify the TCLP results in Table I. However, the TCLP analyses results are encouraging because samples with sludge/frit ratios of 40/60 and 50/50 did pass the TCLP tests.
CONCLUSIONS
The Microwave vitrification experiment was performed to determine if microwave

energy is capable of melting the TRU precipitation sludge, immobilizing the hazardous constituents, reduce its volume, and produce a waste form acceptable to the Waste Isolation Pilot Plant.
The following conclusions have been determined:
The TCLP analyses results concluded that the 40/60 and 50/50 sludge to frit ratio samples are acceptable to DOT and WAC requirements.
Although acceptable, TCLP analysis on the limited samples produced a scatter of the data. Therefore, specific operating parameters for the microwave vitrification system cannot be defined, necessitating further testing.
The results of the TCLP analyses are encouraging and support the continued development of microwave vitrification technology at the Rocky Flats Environmental Technology Site.

POLLUTION PREVENTION AND SAFE VENTILATION OF NUCLEAR, HAZARDOUS AND MIXED WASTE CONTAINERS USING ACTIVATED CARBON-CARBON CARTRIDGES AS POROUS ADSORBENTS: A MATHEMATICAL AND EG&G ROCKY FLATS PLANT FIELD REVIEW
Terry J. Wickland
Nuclear Filter Technology, Inc.
Darrel Snyder
EG&G Environmental Technology Site
ABSTRACT
Nuclear, hazardous and mixed waste containers are exposed to extreme environmental atmospheric conditions resulting in head space vapor expansion. The waste generator or TSD facility is then faced with a dilemma: Either risk violation of RCRA Legislation (40 CFR Section 264, 265) by allowing the expansion gases to freely vent to atmosphere or, if sealed, risk drum rupture and the uncontrolled release of VOC pollutants and liquids. Nuclear Filter Technology, Inc., has developed an organic vapor adsorption system, the NucFilTX200, for use on nuclear / hazardous, or mixed waste containers. The NucFilTX200 utilizes a regenerable, activated carbon cartridge housed in stainless steel, that offers an economical solution to this dilemma. EG&G Rocky Flats Environmental Technologies Site, recently retro-fitted three existing containers of VOC waste with the NucFilTX200. Upon installation, a significant decrease in fugitive emissions within the drum storage area was measured and it was noted that drums no longer become pressurized. Prior to use at the Rocky Flats Environmental Technologies Site, an estimate of the activated carbon-carbon cartridge life was needed. A mathematical equation that predicts the volatile organic mass to challenge the cartridge was derived and, given several known variables, a computer application designed to model cartridge life.
INTRODUCTION
Drums that contain volatile organic compounds (VOCs) may become over-pressurized if sealed. If the drum is not sealed, gasses will vent to atmosphere causing increased fugitive emissions. A low cost solution to this dilemma is to vent the drum head space gasses through an adsorbent activated carbon media. Allowing the ventilation of head space gases to atmosphere through an activated carbon media assures ambient pressure within drum head space, and eliminates fugitive emissions. One device manufactured by Nuclear Filter Technology, Inc., is the NucFilTX200 Hazardous Waste Adsorption System, utilizing an activated-carbon-bonded-carbon cartridge, shown in Fig. 1.
Fig. 1.
The NucFilTX200 housing is designed to fit inside the container to allow for drum stacking, and to protect the filter housing from physical damage. The housing may be manufactured from a variety of materials to suit almost any adverse storage condition. Although this paper address a very specific application of the NucFilTX200, it should be noted that the filter can be adapted for general use on hazardous waste containers.

Computer Model

Use of the NucFilTX200 at the Rocky Flats Environmental Technology Site required an accurate estimate of cartridge life since the activated carbon-bonded-carbon cartridge has a limited life. An estimate of cartridge life was first established using an equation derived from Ideal Gas and corresponding state arguments, and then by applying a computer to model cartridge organic vapor loading.

Adsorption of VOCs onto granular carbon is well understood, and that adsorptive capacity is finite. The active sites available for adsorption of gases eventually become fully loaded with VOCs, depending on several known variables. Useful adsorptive life of the activated carbon-bonded-carbon cartridge is a function of diffusion rates and time, changing atmospheric conditions, head space available within drum, and the nature of the organic constituent. The two primary atmospheric variables include temperature and atmospheric pressure variation, of which temperature, is the largest driving mechanism for vapor expansion within the drum head space. For example, it is often observed in the field that drums exposed to bright sunshine will pressurize and in some cases show signs of drum deformation.

The amount of organic vapor to challenge the activated carbon-bonded-carbon cartridge should follow the general form:

Eq. (1)

where the total adsorptive challenge to the activated carbon cartridge, AT, is the sum of the adsorptive challenge from gas expansion at constant pressure, AEP, and at constant temperature, AET, and the adsorptive challenge from gas diffusion, AD.

Solving the equation yields*:

Eq. (2)

where VHS (liters) is the volume of the head space within the drum, Wi, and gi, are constants relating to vapor pressure as a function of temperature of some VOC species i. The initial or low temperature of a diurnal cycle is given by TL (Kelvin), and the high or maximum temperature of the diurnal cycle is TH (Kelvin). The term Pi is a constant relating to barometric pressure for some VOC species i. The initial or low barometric pressure in a 24 hour cycle is given by PL (Torr), and the high or maximum barometric pressure of the cycle is PH (Torr).

A vent tube of length LT (cm), and cross sectional area aT (cm2), provides a path for gasses to diffuse from the drum head space to the activated carbon cartridge. Time, in hours, is t. The constant, gi, relates diffusion characteristics of some VOC species i in air.

The term AET, the adsorptive component at constant temperature resulting from a decrease in atmospheric barometric pressure, is assumed to be negligible if the geographic site of drum storage does not change. Indeed, in any region, even given a substantial barometric pressure decrease, e.g. from 31" Hg to 28" Hg over a 24 hour period, the pressure component challenge is an order of magnitude less than the diffusional component over the same period of time.

The constants gi, Wi, Pi and gi, for five commonly used VOCs is presented in Table I

TABLE I

Using Eq. 2 and a computer model, one can calculate the total amount of organic vapors to challenge the activated carbon cartridge AT. Table II below demonstrates model predicted values of total organic vapor to challenge adsorbent, AT, for 1,1,1 trichloroethane (TCA), acetone, isopropanol, and methyl ethyl ketone (MEK). Various head space volumes are given, as are two 24 hour, diurnal temperature swings: One from 60F (288 K) to 65F (291 K), typical storage room conditions, and one from 65F to 85F (302 K), extreme storage room conditions. It should be noted that a 55 gallon drum filled, leaving a six inch head space, provides a head space volume, VHS, of 40 liters.

Table II

Estimate of Cartridge Change-Out Cycle

The NucFilTX200 utilizes a 200 gram activated carbon-bonded-carbon cartridge. Bruaner, Emmet and Teller (BET) surface area analysis conducted internally at Nuclear Filter Technology, Inc., verifies adsorptive surface area of about 700 m2/g. Desiccator studies of activated-carbon-carbon composites soaked in a continuous vapor phase of acetone, carbontetrachloride, or 1,1,1 trichloroethane indicates the cartridges' adsorptive capacity is 20% of its mass, or about 40 grams.

In order to estimate the number of days until the cartridge needs to be replaced or regenerated, assume a 'typical' storage area where temperature cycling occurs between 60F and 65F, and an 'extreme' storage area where temperature cycling occurs

between 65F and 85F. Assume that each consecutive day's temperature cycle is precisely the same. Assume two different drums are stored in the same geographic area, each of standard 55 gallon capacity but with different degrees of used capacity; one is filled with liquid organic solvent to within six inches of the top providing about a 40 liter head space, and a second drum that is partially filled to within 30" of the lid top (VHS =200 l) but maintains a saturated vapor condition. Then, given the two different drum's, one can quickly see that not only the temperature range, but also the available head space, or void volume, is important to estimating the cartridge change-out period. Table III below demonstrates the usefulness of the computer model given a full drum and a partially full drum given a series of typical and extreme storage conditions for five common volatile organic solvents.

Table III

BENCH SCALE LABORATORY TESTING OF COMPUTER MODEL

Bench scale laboratory testing was conducted to determine reliability of computer model predictions. In this test, over 1300 hours of activated cartridge exposure to isopropyl alcohol demonstrated that organic vapor loading may be predicted with about 75% accuracy given known environmental conditions.

Test Procedure

In order to test reliability of Eq. 2, and the computer model, a test was designed where a test vessel of known volume, containing 200 milliliters of isopropyl alcohol, was cycled though controlled simulated changes in temperature.

An activated carbon cartridge was off-gassed for 3 hours at 150C, weighed at 34.215 grams, then fitted to aluminum end caps, one end of which was specially fashioned so that it could be easily threaded on and off a special flange that attaches to a vent tube. The flange is equipped with a needle valve. The vent tube extends about 7 centimeters into the test vessel and has an overall length of 13 centimeters. A thermocouple is fitted to the test vessel so that temperature measurements can be made of the head space.

Fig. 2.

The steel test vessel with VHS equal to 19.40 liters, contained 200 milliliters of isopropyl alcohol (IPA) at the start of the test. The ventilation tube is 13 cm long and has a cross sectional area of 0.114 cm2. The carbon sample is then securely attached to the flange of the test vessel. The test vessel was placed in a refrigerator where the temperature was kept at a constant -1C. After a period of time, the needle valve was closed and the sample detached from the vessel, weighed, and the mass, and elapsed time recorded.

Similarly, the test vessel was placed in a warm environment and kept at a constant 24C. The time of each phase was varied from 25 to 378 hours. Since barometric pressure variation is impossible to control in the laboratory setting, for simplicity, it is assumed to be negligible. With the known time and temperature for each cycle, the computer model predicted the adsorptive challenge, AT, which was compared to actual measured values of adsorbed isopropanol.

RESULTS

Test results are summarized in Table IV and compared with predicted values for total adsorptive challenge, AT. Predicted and measured results are shown graphically in Fig. 3.

Table IV

Results indicate that model predictions explain about 75% of adsorbed isopropyl alcohol on the activated carbon-bonded-carbon cartridge. The very large error noted in the first two cycles may in part be because the sample had been completely off-gassed prior to use. Upon exposure to air, the highly active surface may have adsorbed additional contaminates from the air in the laboratory. Nevertheless, given normal temperature ranges and shorter periods of time between sample measurements, results may further improve. Likely causes of error include: Measuring error; effects of barometric pressure variances; mathematical error in the computer model; the fact that some desorption of the cartridge occurs; and, although slight, the fact that the cartridge is about 99% efficient as an adsorber.

Fig. 3.

FIELD USE OF NUCFILTX200 AT ROCKY FLATS ENVIRONMENTAL TECHNOLOGIES SITE

The Rocky Flats Environmental Technologies Site recently had a problem with pressurization of three liquid waste drums. The waste was generated as a result of laboratory processes and primarily consists of mixtures of organic solvents

including, carbontetrachloride, isopropyl alcohol and acetone. The drums were vented under controlled conditions whenever signs of pressurization were present. This practice raised concerns about employee safety and compliance with the RCRA legislation.
The NucFilTX200 met all requirements; it offers a low cost treatment alternative, the housing is constructed of stainless steel and fastens at the 2" bung of the drum, it is designed to reduce the possibility of liquid infiltration to the adsorbent, and it utilizes the highly activated carbon-bonded-carbon cartridge that provides longevity and chemical resistance from the harsh solvent atmosphere. Most importantly, the cartridge eliminates pressurization, and has sufficient adsorbent capacity to cost-effectively reduce volatile organic emissions significantly below important levels including the Lower Explosive Limit (LEL) and the Immediate Danger to Life and Health (IDHL). The LEL and IDHL regularly exceeded levels of 1000 ppm. Although statistically significant data is not available at this time, preliminary measurements suggest a 95% reduction in VOCs emitted to atmosphere. Emissions which would normally read above the LEL and IDLH (greater than 1000 parts per million) at the 2" bung, have been reduced to quantities well below the limits. The following data provides evidence of the filter's adsorptive efficiency.
Table V
Since installation of three NucFilTX200 at the Rocky Flats Environmental Technologies Site, there is no longer drum pressurization. Measurements of VOC concentrations within the storage room are now well below LEL and IDLH levels. Safety and environmental issues have been resolved since personnel are not venting pressurized gasses from the drum to atmosphere. After over five months of use, cartridge breakthrough has not been detected. According to the computer model, capacity (breakthrough) should occur after about 200 days. With organic reductions at greater than 95%, the NucFilTX200 could qualify as a closed vent system and control device per 40 CFR 265.1087, although slight engineering modifications may be required to facilitate cartridge change-out. Although additional data is required, it may be noted that measurements reproduced in Table V are well below established RCRA detection limits for detectable organic emissions which is equal to or greater than 500 ppm.
CONCLUSION
As pollution prevention measures become tightened, fugitive VOC emissions from existing containers of waste will become targeted for control. Tightly sealing drums of VOCs increases the risk of drum rupture allowing the uncontrolled release of VOC emissions and liquids. The NucFilTX200 assures pollution prevention and safe ventilation of drums that contain nuclear, hazardous or mixed waste constituents. It has also been shown that cartridge life may be predicted with reasonable accuracy to efficiently gauge cartridge change-out cycles.

UPFRONT DELISTING OF F006 MIXED WASTE (U)
Dan G. Poulos
John B. Pickett
Carol M. Jantzen
Westinghouse Savannah River Company
Savannah River Site
Building 730-M
Aiken SC 29802
ABSTRACT
The U.S Department of Energy at the Savannah River Site (DOE-SRS) will petition the Environmental Protection Agency (EPA) to "upfront" delist treatment residues generated from the vitrification of approximately 650,000 gallons of a Resource Conservation and Recovery Act regulated mixed (hazardous and radioactive) waste. The upfront petition, based on bench-scale treatability studies and pilot-scale system data, will exclude the vitrified wasteform from hazardous waste management regulations. The EPA encourages the use of the upfront delisting method as it allows applicants prior knowledge of waste specific treatment standards, which when met will render the waste non-hazardous, before generating the final wasteform.
To meet the EPA performance based treatment standards, the waste must be stabilized to control the leaching of hazardous and radioactive constituents from the final wasteform. SRS has contracted a vendor to stabilize the mixed waste in a temporary

Vitrification Treatment Facility (VTF). The EPA has declared vitrification as the Best Demonstrated Available Technology for high level radioactive wastes (1) and the DOE Office of Technology Development has taken the position that mixed waste needs to be stabilized to the highest degree possible to ensure that the resulting wasteform meets both current and future regulatory specifications. Treatability studies conducted on a VTF pilot-scale system unit indicates that the mixed waste can be converted into a highly durable glass form, which exceeds the projected EPA performance based criteria. Upfront petitions can be processed by the EPA concurrently during facility construction or permitting activities; therefore, the SRS VTF will be capable of producing wastes which are considered non-hazardous sooner than otherwise expected. At the same time, EPA imposed conditional testing requirements to verify that the delisting levels are achieved by the fully operational VTF, ensures that only non-hazardous wastes are removed from hazardous waste management regulations.

Vitrification of the above waste will result in a volume reduction of approximately 75%. Volume reduction combined with excluding the waste from hazardous waste management regulations through delisting will significantly reduce overall management and disposal costs, resulting in an approximate $2.5 million cost savings.

INTRODUCTION

Fuel and target assemblies for the Savannah River Site (SRS) nuclear reactors were fabricated in metal finishing and aluminum forming facilities within the 300 M-Area. 300 M-Area manufacturing operations ended in 1992 as a result of the cessation of the cold war. Liquid effluents generated from past 300 M-Area manufacturing operations consisted primarily of metal finishing and aluminum forming process effluents, including nickel electroplating process effluents. These process waste effluents contained rinsewaters, stack acid scrubber effluents, and spent process solutions. Area support facilities (e.g., degreasing activities, laboratory effluents) contributed halogenated organics to the above wastestream to a lesser degree.

Since July 1985, area process wastewaters have been discharged to the M-Area Liquid Effluent Treatment Facility (LETF). The LETF utilizes the Best Available Technology Economically Achievable for the aluminum forming and metal finishing industries. The LETF is composed of three closed-coupled treatment facilities: the Dilute Effluent Treatment Facility (DETF), an Industrial Wastewater Treatment Plant; the Chemical Transfer Facility (CTF); and the Process Waste Interim Treatment/Storage Facility (PWIT/SF). Wastewater treatment sludges generated from both CTF and DETF operations are characterized as a Resource Conservation & Recovery Act (RCRA) listed F006 mixed waste (contains both hazardous and radioactive constituents). Approximately 1.5 million gallons of F006 mixed wastes were generated, with 650,000 gallons remaining in the PWIT/SF awaiting stabilization. The remainder of the waste, a supernate which separated from the residual precipitate, was treated in the DETF and released via a National Pollutant Discharge Elimination System permitted outfall.

The above M-Area Plating Line Wastes (MPLW) are subject to the Land Disposal Restrictions (LDR) in 40 CFR 268. The LDRs prohibits any storage of a land disposal prohibited waste except for the purpose of the accumulation of such quantities of hazardous waste as are necessary to facilitate proper recovery, treatment, or disposal. F006 wastes were restricted from land disposal on May 8, 1990. However, due to a national capacity extension for mixed wastes granted by the EPA, disposal and or storage was not prohibited until May 8, 1992. Subsequently, the PWIT/SF waste was added to the Land Disposal Restriction - Federal Facility Compliance Agreement (LDR-FFCA) between EPA and DOE, on March 13, 1991 to allow continued storage until a stabilization/solidification facility became operational.

Stabilization of this waste is not only required for compliance with hazardous waste regulations, but for the M-Area sludges, the LDR-FFCA specifies that the sludges will be treated in a vendor-supplied temporary Vitrification Treatment Facility (VTF). The LDR-FFCA sets strict milestones for completing the vendor stabilization program. SRS has contracted a vendor to stabilize the MPLW in a temporary VTF located in the 300 M-Area immediately adjacent to the PWIT/SF. The resultant treatment residues will be stored in a RCRA permitted container storage facility while awaiting confirmation that analyses are below the EPA imposed regulatory thresholds.

UPFRONT DELISTING OVERVIEW

The EPA recognizes that listed wastes may not be hazardous due to differences in feed stocks or industrial processes. Therefore, 40 CFR 260.20 & 260.22 contains a procedure whereby anyone can petition the EPA to "delist" or exclude such a listed waste from hazardous waste regulations. Originally, the intent was to ease the regulatory burden of the hazardous waste management of listed wastes improperly captured by the broad listing definitions. Since then, delisting has evolved to include those wastes sufficiently treated such that they no longer pose a threat to human health or the environment.
The DOE-SR will request the EPA for an upfront exclusion for certain wastes yet to be generated, as described in the "derived from" rule [40 CFR 261.3(c)(2)(i)] based on: bench-scale treatability studies; pilot-scale system data; the untreated waste characteristics, and detailed facility process descriptions. To be successful, the analyses of the treatment residues from the bench-scale waste treatment process must show that the waste no longer meets the criteria for which it was originally listed; must not exhibit a hazardous waste characteristic; and must not exhibit any other factors including additional 40 CFR 261 Appendix VIII constituents above regulatory threshold levels.
Regulatory threshold levels are calculated by the use of appropriate fate and transport models, for example the EPA's Composite Model for Landfills (2). The EPA believes that the primary pathway for a contaminant to adversely affect human health is through the ingestion of contaminated groundwater from the leaching of chemicals from land filled waste. Therefore, delisting petitions are evaluated by comparing leachate concentrations for specific contaminants contained within the petitioned waste against health-based levels, usually the Maximum Contaminant Levels for safe drinking water. The maximum allowable leachate concentration for specific contaminants are a function of waste volume, the smaller the volume of petitioned waste the larger the allowable dilution factor. Site-specific disposal conditions are not considered by the EPA in the evaluation of an upfront delisting petition since the generator is not required to dispose of the excluded wastes in a specific facility once the exclusion is granted.
To determine leachate concentrations for upfront delisting petitions, the EPA requires that treatment residues be analyzed by the Toxicity Characteristic Leaching Procedure (TCLP) and the Multiple Extraction Procedure (MEP)(2). The MEP is a test developed by the EPA to assist in predicting the long-term leachability of stabilized wastes. This procedure consists of the TCLP extraction, followed by nine sequential extractions on the same sample using synthetic acid rain to simulate multiple washings of percolating rainfall in an improperly designed sanitary landfill. It is estimated that these extractions simulate approximately 1,000 years of rainfall. In addition, total concentration analyses of all the 40 CFR 261 Appendix VIII constituents will be conducted to verify their absence.
Once the EPA grants an exclusion based upon the above information, the treatment residues would receive an upfront delisting with imposed verification testing requirements, which must be met through an EPA approved statistical sampling plan when the VTF becomes operational. The full-scale verification testing requirements may involve more then one round of waste characterizations to address any concerns regarding the potential for waste variability.
M-AREA PLATING LINE WASTES
The M-Area Plating Line Wastes (MPLW) are primarily wastewater treatment sludges generated from electroplating operations, since the wastewaters originated from electroplating
processes involving nickel plating of aluminum-clad, depleted-uranium slugs. The majority of the wastestream is considered a listed F006 mixed waste as it is specifically listed as hazardous per RCRA, Title 40 of the Code of Federal Regulations (CFR) 261.3(a)(2)(ii), and also contains a radioactive component consisting of source material (i.e., depleted uranium) as defined by the Atomic Energy Act Title 10 CFR 20.3(a)(15)(i). The primary hazardous constituent of concern is nickel, while the primary radioactive constituent of concern is depleted uranium (i.e., 238U). The sludges also contain significant levels of nitrate.
To a lesser degree, additional wastes generated from the electroplating process (i.e., Watts Type Nickel Bath Plating Line Solution, Spent Plating Bath Sludge, Mark 15 filtercake) as well as treatment residues generated from bench-scale treatability studies will be incorporated with the PWIT/SF F006 sludge prior to vitrification.
The MPLW partially occupies three 500,000 gallon tanks, six 35,000 gallon tanks, and

approximately one hundred and eight 55 gallon drums (i.e. Mark 15 filtercake, and Nickel Plating Line Solution). The quantity of MPLW (i.e., 650,000 gallons) combined with tank capacity limitations (i.e., largest tank capacity equivalent to 500,000 gallons) requires homogenization of the MPLW into two macro batches. The homogenization is designed to ensure that each macro batch will approach each other compositionally to the greatest extent possible. Table I provides a detailed chemical composition of the homogenized MPLW(3).

BENCH-SCALE DATA

Vitrification involves the exposure of hazardous materials to molten glass and related process conditions to effect the destruction, removal, and/or permanent immobilization of hazardous constituents. Vitrification is defined as the conversion of such solids into a glass residual form through the application of heat to the point of fusion. This process forms a molten, vitreous mass, and produces a glass-like residual product upon cooling. The residual solid is a solid (super-cooled liquid) containing an amorphous mixture of oxides (primarily silica and alumina) with little or no crystallization present (4).

Vitrification was chosen as the desired stabilization technique for the MPLW due to: destruction of hazardous organic constituents by pyrolytic decomposition and/or oxidation; removal of inorganic constituents in the residual glass product through chemical incorporation and/or encapsulation; and the chemical composition of the MPLW is amenable for vitrification as it already contains high levels of glass forming compounds (i.e., Si, Al, Na, Ca). The resulting glass residue exhibits excellent structural, weathering, and biotoxicity characteristics making it suitable for long term environmental exposure and is therefore capable of surpassing the EPA TCLP threshold levels. Vitrification will also result in an approximate 75% volume reduction resulting in reduced waste management costs.

Representative samples of the MPLW were submitted for bench-scale studies. Proportional amounts were homogenized thoroughly prior to vitrification. The resultant treatment residues were analyzed by the TCLP for inorganics only (i.e., Ba, Cr, Pb, Ni, U), as organics compounds are completely destroyed at the high temperatures at which vitrification occurs. All of the treatment residues passed the projected upfront delisting petition regulatory threshold levels by a wide margin (5) (Table II).

CONCLUSION

Bench-scale waste treatment studies using the process of vitrification have been successfully performed. The success of vitrification is attributable to a number of factors including:

the powerful solvating properties of glass melts and their ability to incorporate a wide range and large amounts of hazardous inorganics and radioactive components;

the complete destruction of organic compounds at the high temperatures at which vitrification occurs;

a stable, relatively homogeneous waste form that is highly resistant to aqueous corrosion; and

relatively high density waste form resulting in an accompanying large volume reduction.

The upfront delisting petition will show that the resultant treatment residue generated from process vitrification will not: meet any criteria for which it was listed; exhibit any hazardous waste characteristics as identified in 40 CFR 261 Subpart C; and will not exhibit any other factors or additional constituents which would render it to be considered hazardous.

AN INTEGRATED CHEMICAL/THERMAL TREATMENT SYSTEM FOR MIXED WASTE
R. C. Eschenbach

Lockheed Environmental Systems & Technologies
ABSTRACT
Lockheed has developed an integrated technology train that incorporates existing technologies used in the petroleum, mining, and hazardous waste treatment industries for use in treating mixed radioactive and hazardous wastes, using a Retech-developed plasma vitrification process to 1) completely destroy the organic constituents, 2) result in a final waste that meets RCRA land disposal restricted criteria, and 3) permit permanent storage or disposal of the encapsulated radionuclides. The treatment system is very robust, in that wastes having a variety of chemical radiological, or physical characteristics can be successfully processed. No comprehensive pre-processing characterization is required; therefore costs and the potential for personnel exposure and contamination release (either chemical or radiological) are dramatically reduced. The only pre-processing measurement is the assay for the radionuclide concentration, needed for treatment decisions and criticality safety.
Volatile organic compounds (VOCs) in waste and soil are removed using low temperature solvent extraction with triethylamine. Radionuclides and other heavy metals in soil are removed using a nitric acid leach. The radionuclides combine with the nitric acid into primarily a nitrate form. This solute is removed using a counter-current ion exchange system, which also removes heavy metals. The clean soil is transferred from the leach circuit after dewatering to a rotary kiln to remove residual nitrates. The soil fines plus the concentrated residues from the triethylamine extraction and nitric acid leach are transferred to a plasma melter for stabilization as a glassy slag.
The non-soil wastes and residual concentrate from the soil treatment system are sent to the plasma melter which destroys any remaining organics and produces a virtually non-leachable cast slag that immobilizes both heavy metals and radionuclides. Significant volume reductions of the final waste to be disposed can be realized. Tests using various combination of soil and waste with variable organic and heavy metal constituents have shown that a volume reduction of greater than 90 percent will be achieved in its initial application for remediating Pit 9 at the Idaho National Engineering Laboratory.
INTRODUCTION
An integrated technology train to treat mixed and radioactive and hazardous wastes has been developed by Lockheed Environmental & Advanced Technology (LESAT) and its subcontractors (Retech, Inc., Merrick & Co., Sonsub, MSE, Inc., S. M. Stoller and Jason Associates) for remediating Pit 9 at the Idaho National Engineering Laboratory (INEL). The wastes are retrieved in containment inside a movable retrieval building. Ionization counting of boxes or drums of waste determines whether treatment is needed. Lumpy wastes are shredded and fed to a plasma melter, while rocks and soil are washed with triethylamine to remove organics and leached with nitric acid to remove actinides. Organics and actinides also go to the melter, where all organics are destroyed, and inorganics are melted into a non-leaching slag. Off-gases are cleaned before discharge. Process liquids are concentrated and recycled, while oxide particulate caught in the off-gas cleanup is recycled to the melter. Figure 1 is a process functional diagram.
Fig. 1.
The stabilized waste form made by the plasma melter is a synthetic basalt which easily passes the TCLP and meets INEL TRU waste acceptance criteria. This waste is containerized in fifty-five gallon drums for compatibility with long-term storage materials handling. The other solid output is soil and metal containing less than 10 nCi/g, meeting LDR disposal criteria, which will be placed back into Pit 9.
The treatment train avoids any liquid effluent, and the exhaust gases will comply with federal and Idaho air emission standards.
PIT SOLIDS RETRIEVAL

Retrieval will be performed within a double-walled building that spans the pit crosswise and that will be moved lengthwise on rails along the pit. A mobile gantry within the retrieval building supports all retrieval tools, which are remotely operated to prevent worker exposure to pit waste hazards. A negative pressure, oxygen deficient atmosphere is maintained in the retrieval building to prevent escape of contamination to the environment and to suppress combustion of any pyrophoric material uncovered.

To meet program completion objectives, it is planned to excavate 600 pounds per hour (30 cubic feet) of waste and 8000 pounds per hour (70 cubic feet) of soil. Since an average of 1000 pounds per hour of water mist will be sprayed at the dig face to suppress dust, 9000 pounds per hour of wetted soil will be excavated.

Soil less than one inch in size and waste with soil greater than one inch in size are separately excavated. The two separate material streams will be transported in steel boxes to/from the retrieval building. Since it is estimated that half the waste and half the soil will have less than 10 nCi/g TRU activity and therefore will not be processed, the retrieval subsystem will handle the return and emptying of boxed non-treated material to Pit 9 at the rate of 300 pounds per hour of waste and 4500 pounds per hour of damp soil. Clean rocks/metal at 90 pounds per hour and clean soil at 3900 pounds per hour will also be returned to the pit in this manner.

The retrieval building is a movable steel structure with three isolated layers of steel skin over a disposable internal liner. It fully contains all excavation work in a relatively small containment volume that is easy to control and decontaminate. The structure is moved along the pit as the dig face advances. Remotely adjustable segmented steel skirts, with sealing between segments, extend down to the bottom of the pit. The skirts control and protect the pit liners which are deployed to cover the cut surface as the retrieval building advances.

The block diagram in Fig. 2 shows retrieval and size reduction operations.

Fig. 2.

The proposed bridge crane retrieval system offers a unique advantage in that the operator can observe the nature of the waste as it is retrieved and call for more frequent use of the dig face monitor when suspect materials are encountered.

Retrieval of interstitial soil begins after survey with the dig face monitor. The two lowest bridges are fitted for this task after overburden removal is complete. Soil retrieval tools include modified street sweeper brushes which can clean down to the irregular basalt surface if necessary to retrieve waste that an excavator bucket would leave behind. Bristles with stiffness chosen to suit soil conditions scratch away the surface of the soil and sweep it through 1-inch slots. Loose items larger than an inch are swept past the slots and deposited behind the brush.

The tool cleans a path five feet wide but is built in eight-inch wide segments to allow it to conform to irregular surfaces. A shroud around the tool contains the dust. An air intake inside the shroud creates a negative internal pressure to scavenge fugitive dust. A fine mist is sprayed under the skirt to dampen the soil and help reduce the dust load in the air.

Soil, after being swept through the grating, is dampened for dust control and periodically transferred to a box for removal from the retrieval building. Waste items are retrieved by tools which have been used and refined on a DOE mixed waste retrieval project. Soil and waste are retrieved in alternating passes over the excavation face.

Items too large to be boxed are size-reduced by a portable shear. Sonsub used this approach extensively at Kerr Hollow Quarry. Pipes and other large items were sized in this manner during retrieval at the INEL cold test pit. The throat of the shear is 24 inches deep and opens 22 inches wide. The blade of the shear develops 110 tons of cutting force. The shear is suspended from its center of gravity. Controls on the remote console can be used to shift the shear from vertical to horizontal and rotate it about a vertical axis. The shear can therefore approach an oversized item from the most effective angle.

Loads of up to 15 tons can be lifted by a retrieval bridge. Items such as reactor vessel segments may be too heavy to lift and too thick to be size reduced by the portable shear. Any such items will be surveyed by an instrument on the maintenance and intervention system and left in place in the pit. If necessary, special tools and procedures can be developed and the gantry can return to process these items at a later date.

COUNTING, SHREDDING AND SEPARATION

This subsystem selects for processing boxes of soil and boxes of waste from Retrieval with greater than 10 nCi/g TRU activity, and returns boxes with less than 10 nCi/g TRU activity to Retrieval. This subsystem also shreds TRU waste to a manageable size and separates magnetic metal (mostly carbon steel) from other TRU waste to control the iron content of the final TRU waste slag product.
The TRU activity of boxed material is measured with a high-performance box counter. Boxes of soil and waste from Retrieval with less then 10 nCi/g TRU activity will be returned to Retrieval. Waste with greater than 10 nCi/g TRU activity will be shredded into pieces no larger than 4 inches size. This shredded waste stream goes to a high-intensity magnetic drum separator that removes more than 95 percent of the magnetic ferrous metal. Both the magnetic and non-magnetic shredded waste streams will be boxed and sent to Box Storage and Feeding, along with the boxes of soil with greater than 10 nCi/g TRU activity.
The boxes of treated rock/metal (from Pre-Leach Treatment) and processed soil (from Concentration and Conversion) are also measured for TRU activity to verify that these cleaned materials have less than 10 nCi/g TRU activity. Validated boxes of these materials will be returned to Retrieval, while boxes that fail the TRU activity test will be reprocessed.
Drums of treated material from the plasma melter are also returned to the counter for measurement prior to disposition.
Inside the transfer room, empty boxes are lowered into waiting carriers. Box lids are remotely unlatched and stay with the lid operators to maintain the boundary between the gantry interior and the transfer room as the boxes, inside box carriers, are lowered and then moved horizontally onto trolley cars. The box carrier keeps the outside of the box clean while it is in the retrieval area. This helps minimize the decontamination time and effort when filled boxes are transferred back to the truck. The box carriers stay in place to maintain the boundary between the gantry and the transfer room while a box is moved between the retrieval area and the transfer room.
Soil (material less than one inch in size) is retrieved and handled separately from the waste. Retrieved soil is dampened to prevent generation of dust and transferred to a conveyor which runs the length of the retrieval building. The conveyor moves the soil to a metering hopper at the west end of the retrieval building.
Each time it is cycled, the metering hopper dispenses a quantity of soil which fills a standard box not more than half full. As shown in Fig. 3, this transfer of soil from the hopper is done through a double lid transfer system which keeps the outside of the box clean.
Fig. 3.
CHEMICAL SEPARATIONS
These operations separate actinides from the soil so that essentially all the radioactivity in the material processed can be bound by the melter into a leach-resistant slag.
Pre-Leach Treatment
This subsystem treats a mixture of minus 1-inch soil and magnetic metal waste. It removes water and liquid organic waste from this mixture, cleans radioactive and heavy metal contamination from rocks and metal, and separates the clean rocks/metal, then separates floatable solid organics and +400 mesh soil, and generates a slurry of -400 mesh soil in acidic leach solution to the Leaching and Stripping subsystem. The system can process an average of 4500 pounds per hour. Soil and shredded magnetic waste is fed to a triethylamine (TEA) solvent wash. This EPA-approved BDAT process dissolves water and all liquid organics into TEA, separates the TEA/water/organics single-phase liquid from the soil/metals, and separates this liquid into TEA, water, and liquid organic streams. The TEA is reused, the water is reused as cooling or process water, and the oily liquid organics stream is sent to the plasma melter.
The dry solids stream is then mixed with nitric acid leach solution in a pre-leach tank. Agitation of the resulting slurry in the pre-leach tank scrubs radioactive and heavy metal particulates from the rocks and metal. The rocks and metal sink to the bottom of the pre-leach tank, and this underflow is washed clean of soil and leach liquor and fed into boxes as clean product material. Floatable solid organics rise to the top of the pre-leach tank and are removed there. Metal carbonates (primarily calcite) in the soil react with the nitric acid to form metal nitrates in solution.
The slurry of soil and acidic leach liquor passes through a sizing separator that creates a small quantity +400 mesh soil solids stream and a larger quantity -400

mesh soil slurry. This slurry is sent to the Leaching and Stripping subsystem, while the +400 mesh solids are combined with the float from the top of the pre-leach tank and put in boxes for feed to the plasma melter.
Chemical leaching and stripping is sufficient for removal of TRU metals from soil to below 10 nCi/g TRU activity.
Leaching and Stripping
This portion of the mixed waste remediation process is used to dissolve radioactive/heavy metal particulates into the liquid portion of the soil slurry from Pre-Leach Treatment, and to extract these dissolved metals from the soil slurry. About three hours of slurry residence time is provided at 80-90C temperature, sufficient for complete rad/heavy metal dissolution. The leached soil slurry is thickened, then diluted with metal nitrate solution to adjust the slurry chemistry for anion exchange. The slurry will then be thickened and diluted with clean water for cation exchange. The soil slurry, now free of rad/heavy metal contamination, and the contaminated ion exchange strip solutions will then go to Concentration and Conversion for further processing.
Concentration and Conversion
In this subsystem, contaminated ion exchange strip solutions are transferred from Leaching and Stripping into a concentrated radioactive/heavy metal sludge for plasma melter feed and a metal nitrate reagent for recycle to Leaching and Stripping. The treated soil slurry from Leaching and Stripping is transformed into a clean soil product, strong acid reagent for recycle to Pre-Leach, and fresh ion exchange strip solutions for recycle to Leaching and Stripping.
Spent strip solutions are concentrated by water removal and treated to make a rad/heavy metal precipitate, which is then separated from the resulting metal nitrate recycle solution. This rad/heavy metal sludge is closely monitored to ensure criticality safety. Clean soil slurry is thickened, calcined at about 400 C temperature to decompose metal nitrates to solid oxides and nitrogen dioxide off-gas, and the remaining solid is cooled with water to make a clean soil product which is boxed for return to Pit 9. Spent leach liquor, separated from the soil slurry, goes to Off-Gas Treatment and returns enriched in nitric acid. It is then concentrated by water removal to a strong (azeotropic) acid and metal nitrate solution. Strong acid is separated by distillation, leaving a metal nitrate sludge. The strong acid is recycled, and a little is mixed with clean water to make fresh anion strip solution. Some of the metal nitrate sludge is dissolved in water to make fresh cation strip solution. The remaining nitrate sludge, representing the metal carbonates originally dissolved from the soil, is returned to the soil.
PLASMA MELTER TREATMENT
Retech's unique plasma melter (1,2) transforms all material fed to it into glassy basaltic slag and off-gas. The primary chamber of the melter contains a centrifuge rotating at 10 to 50 revolutions per minute. The floor of the centrifuge has an axial throat used for periodic tapping of the molten slag into molds. Water and organics are volatilized in the refractory-lined primary chamber, and organic material is oxidized to carbon dioxide, water vapor and acid gases (mostly nitrogen oxides with some sulfur dioxide and hydrochloric acid vapor).
Wastes to be treated are fed to the melter at up to 1000 pounds per hour. The feed material will contain all organics extracted from the soil, all actinides extracted from the soil, all shredded waste and a small amount of INEL soil to ensure good leach properties in the slag formed. Any oxide particulate waste separated from the off-gas downstream of the melter will also be recycled into the melter.
A 1200 kW plasma torch with the arc current flowing between the torch and the rotating slag bath transfers energy to the bath to melt the input material and vaporize the water and organics. Oxygen is added to ensure complete oxidation of organics and desired slag properties. The processing chamber is a double-walled, water-cooled vessel containing the rotating crucible (centrifuge). The chamber has ports for feeders, off-gas viewing systems, pouring and the torch. The chamber is hermetically sealed and operates at 25 to 50 millibars below atmospheric pressure. A surge tank and appropriate valves ensure that the chamber pressure can never exceed the design pressure of 15 psig.
The water-cooled plasma torch mounts on the process chamber lid in a vacuum tight ball joint allowing the torch to tilt up to 15 about the vertical centerline, and permits lowering and raising the torch nozzle to and from the slag bed. Horizontal and vertical torch motion is by servo controlled hydraulic actuators. Torch motion

over the slag bed, its position for starting, material feeding and slag pouring will be pre-programmed. Remote manual positioning of the torch by the operator is permitted for the control of unusual events. A pylon provides repeatable positioning for automated removal and replacement of the torch from the chamber lid to a glove box for routine maintenance. All water, gas and hydraulic lines pass through the axis of the pylon such that torch removal repair and replacement is accomplished in a timely manner and under containment. This remote maintenance capability was demonstrated in the Lockheed Pit 9 Interim Action Proof of Principle Test for Maintenance-In-Containment (3).

The slag collection chamber receives and transfers the slag safety mold and the slag receiving drums. The safety mold is kept in place under the processing chamber throat during a melt, and is shuttled aside when a slag receiving drum is positioned for a pour. The slag collection chamber operates at a negative pressure and has air-lock valves for moving slag receiving drums in and out. This chamber is also ported to allow the safety mold to be moved out for emptying or as required. The safety mold is sized to accept an entire centrifuge load of slag (3 to 4 drums full) should there be a power failure or some other event that slows or stops the rotation of the centrifuge.

When the level of the molten slag in the centrifuge reaches the appropriate level, as determined by the operator, the slag safety mold is translated to the side and another mold with a slag receiving drum positioned in its center is positioned under the pour throat of the centrifuge, and raised hydraulically to effect a seal with the separation chamber.

At this point the rotation of the centrifuge is slowed in a pre-programmed manner so as to allow the molten slag to pour through the throat into the slag receiving drum. Sensors determine the fill level/rate and signal the hydraulic rotation mechanism to spin the centrifuge back up to operating velocity thus stopping the slag flow.

When the slag receiving drum is filled, it and the mold in which it rests are translated to the side and the empty safety mold is repositioned under the throat. The filled slag drum is moved through an isolation air lock valve into the slag storage system by conveyor. After cooling, the slag receiving drum and containment bag are sealed into a 55 gallon drum and transported by a manually operated, battery driven fork lift through the isolation air lock out of the melter bay. New, clean slag receiving drums are brought into the melter by conveyor through an isolation air lock.

Figure 4 is a cross-sectional view of the processing, separation and slag collection chambers.

Fig. 4.

Downstream of the melter chamber is a secondary combustion chamber (SCC) which ensures that off-gas temperature remains above 2000F for at least two seconds. At startup, the SCC is preheated with a propane/air flame for several hours prior to feeding any waste into the primary chamber. When starting a campaign, the plasma torch is also operated for a few hours to melt any slag remaining in the primary chamber prior to feeding waste.

OFF-GAS AND PROCESS LIQUID TREATMENT

Low oxygen off-gas streams, containing dust but no acid gases, are produced from the oxygen-deficient atmosphere in the shredder/separator enclosure and the TEA solvent wash process. The TEA wash process off-gas also contains noncondensable organic vapors separated from the feed soil. These gas streams are merged and dust is removed by a fabric bag filter.

Contaminants to be removed from the melter off-gas are mainly nitrogen oxides, plus some sulfur oxides, halogen acids and ozone. The two streams are merged, then dust, humidity, and heat are removed by a venturi wet scrubber and a condensing water separator. The dust slurry is thickened in a rotary microscreen filter, then mixed with dust from the bag filter to form a dust sludge for melter feed. Filtrate water supplies the venturi scrubber, with excess water (from humidity removal) supplying the plasma melter off-gas quench.

The gas stream is now treated by an acid gas removal sequence. A packed-bed caustic wet scrubber removes sulfur oxides and halogen acids, with the caustic soda blowdown going to Leach and Strip for acid neutralization. A noble metal catalyst bed then decomposes ozone and oxidizes nitric oxide to the nitrogen dioxide required by the acid scrubber. Oxygen is added to the gas stream to maintain the five-to-one oxygen-to-nitrogen-dioxide molar ratio required by the acid scrubber. This packed-bed

catalytic wet scrubber absorbs nitrogen dioxide and oxygen into spent leach liquor to recover nitric acid solution for concentration and conversion feed. Finally, the cleansed gas goes to Air and Exhaust Management for backup (safety) charcoal/HEPA filtration before return to the ambient atmosphere.
The concentration and conversion subsystems transform dilute contaminated strip solutions and weak strip solutions into fresh reagents for recycle and radioactive/heavy metal sludge for stabilization. This results in minimal chemical consumables cost and no liquid effluent.
SUMMARY
This integrated system will transform the contaminated buried waste and surrounding soil in Pit 9 into clean material and highly stable TRU waste. The treated waste form is very leach-resistant with excellent long-term durability. The estimated volume reduction of contaminated feed material is over 97 percent.

ABSTRACT
Rust's patented SOIL*EXTM process is designed to process and treat difficult mixed waste forms including soils, sludges, and contaminated debris that contain hazardous and radioactive contaminants. The treatment of these waste forms is a national environmental priority since there are numerous sites contaminated with mixed waste that require safe, cost-effective remediation technologies.
SOIL*EXTM has been designed to remove radioactive and other heavy metal contamination while also removing and destroying any volatile organic compounds in the solid waste forms. The process consists of two subsystems labeled ACT*DE*CONSM and PO*WW*ERTM. ACT*DE*CONSM is designed to extract the contaminants from the solid waste forms using constituent-specific, aqueous-based chemistry. PO*WW*ERTM receives the extractant from ACT*DE*CONSM and concentrates the inorganic materials in the waste stream while destroying the volatile organic compounds (VOCs) in the vapor phase using catalytic oxidation.
The SOIL*EXTM process has been demonstrated on a pilot plant scale. This paper discusses the pilot plant test criteria and results along with the salient design features for the SOIL*EXTM system.
INTRODUCTION
The remediation of difficult-to-treat waste forms containing radioactive and hazardous constituents is one of the most challenging tasks confronting the American technology sector. Large volumes of soil and debris that are contaminated with radioactive and hazardous constituents exist at government and industrial locations. To answer this challenge, Rust International Inc. has developed and patented a unique, innovative mixed waste treatment scheme called the SOIL*EXTM process. The process removes the radioactive and hazardous metals from the solid waste while destroying the volatile organic compounds VOCs often associated with soil and debris.
The SOIL*EXTM treatment process incorporates constituent-specific, aqueous-based chemical extraction with solids separation, evaporation, and catalytic oxidation of the VOCs in the vapor phase. The configuration discussed utilizes the extraction

ACT*DE*CONSM chemistry in conjunction with Rust's demonstrated PO*WW*ERTM technology. In addition to destroying the VOCs, PO*WW*ERTM is used to concentrate the inorganic contaminants and subsequently reduce the extractant volume from ACT*DE*CONSM.

PROCESS OVERVIEW

Figures 1 and 2 are schematics for the ACT*DE*CONSM and PO*WW*ERTM subsystems which constitute the SOIL*EXTM treatment process.

Fig. 1. ACT*DE*CONSM Process Flow Diagram.

Fig. 2. PO*WW*ER Process Flow Diagram.

ACT*DE*CONSM basically consists of a multi-stage, counter-current flow extraction system equipped with continuous stirred tank reactors (CSTR) and conventional settlers for solid/liquid separation. Located at the "liquid" end is a membrane filter that removes the suspended solids from the extractant, which contains the dissolved actinide and heavy metal contaminants. The membrane filter is used to prevent the treated solids from flowing with the solubilized contaminants to PO*WW*ERTM. This process step minimizes the secondary waste volume produced in the evaporator for the PO*WW*ERTM treatment system. A conventional filter, located at the "solids" end of the ACT*DE*CONSM process, removes the treated solids from the system. The type of filter used depends upon the physical nature of the solids treated.

The ACT*DE*CONSM chemistry consists of a chelating agent, Ethyl-Diamine-Tetra-Acetic acid (EDTA), carbonate, and other solution conditioning agents. Since the chelant forms a stable ring structure with strong co-ordinate bonds to the metal contaminant, its presence assures that once the metals are dissolved they remain solubilized in the liquid phase and do not re-precipitate onto the solids. In cases when there are significant organic contaminants in the waste, a surfactant can be added to assist in extracting them from the solids.

The ACT*DE*CONSM process is a versatile mixed waste treatment system. The treatment process operates most efficiently on a continuous solids feed basis. However, it can be operated in a batch mode to clean debris such as metals and plastics. The mixed waste solids are fed to a hydropulper where a slurry containing 5 to 15 weight percent solids is produced. The hydropulper is a high shear mixing device that mechanically provides intimate contact between the contaminants in the solid phase and the aqueous chemistry. The slurry flows from the hydropulper into the membrane filter feed tank designed as a settler. The concentrated slurry is pumped from the bottom of the tank into the first CSTR. The extract containing the contaminants is fed from the tank to a membrane filter designed to remove virtually all of the suspended solids before it is sent to PO*WW*ERTM for volume reduction. The solids in the slurry flowing from the membrane filter feed tank are processed through a series of CSTRs and settlers. Each paired CSTR and settler is an equilibrium-stage operation. The solids from the previous unit or stage is mixed with the liquid from the succeeding unit, and the resulting mixture is sent to the settler where the solids are thickened to produce a 20 to 30 weight percent slurry. The underflow from the settler is then transferred to the next succeeding CSTR while the liquid in the settler overflow flows to the previous CSTR. As the liquid flows from unit to unit, it becomes enriched with the solubilized radionuclides and heavy metals, and as the solids flow in the opposite direction, they are depleted of the contaminants. The proficiency of the extraction depends upon the amount of chemicals and the number of equilibrium stages used. Since fewer equilibrium stages require more chemicals, a comparison study between operating expenses and capital costs should be made for each application. Given the required decontamination factors and operating conditions, the number of stages is determined using a McCabe-Thiele diagram. Any number of stages can be used, but the typical number is in the range of 3 to 6. Following the final extraction stage, the treated solids, i.e. the filter cake, are filtered and washed with water recovered from the PO*WW*ERTM process. Thorough filter cake washing is necessary to remove trace amounts of the solubilized contaminants from the solids.

The extractant, rich in contaminants, exits ACT*DE*CONSM 's membrane filter and is fed to the PO*WW*ERTM process. The dissolved metals and organics are pumped to a forced circulation, single- effect evaporator designed to vaporize the water and VOCs. The evaporator produces a concentrated waste product containing the radionuclides, inorganic salts, and heavy metals extracted by ACT*DE*CONSM. The evaporator overhead stream, containing the vaporized components, flows to the

catalytic oxidizer where the VOCs are destroyed to produce carbon dioxide and acid gas. The acid gas is removed from the vapor stream by a conventional scrubber located down-stream of the oxidizer. The salts formed from the neutralization of the acid gas are fed back to the evaporator and combine with the concentrated waste product. Following the scrubber, a condenser is used to recover the water vapor from the scrubber overhead stream. This water is reused as filter cake wash and for chemical makeup in the ACT*DE*CONSM treatment system.

PILOT-SCALE TESTING

Background

A pilot-scale SOIL*EXTM system was designed, fabricated, and tested at the Rust Clemson Technical Center (CTC). The pilot plant was fully instrumented with computer control. Computers were also used for real-time data acquisition and management. To preclude the need and associated expense for building a pilot plant capable of processing mixed waste containing transuranic components, the treatment process was tested using surrogate metals in the solids feed. The test program involved treating soils and oily sludges spiked with Neodymium (Nd), Thorium (Th), Manganese (Mg), and Bismuth (Bi). These metals mimicked the responses to the ACT*DE*CONSM chemistry for Americium (Am), Plutonium (Pu), and the hazardous metals Chromium (Cr), and Lead (Pb), respectively. The surrogate decontamination factors obtained in the pilot plant study were then compared to those established in a bench-scale surrogate validation test program. The pilot plant test program also included treating sludges spiked with VOCs, Trichloroethylene (TCE) and Carbon Tetrachloride (CCl4). These tests were performed independently from the surrogate metal tests to preclude the possibility of mixed waste production.

Test Criteria

The performance of the SOIL*EXTM pilot plant was measured using the following criteria: a) the treated solids, i.e. the filter cake from ACT*DE*CONSM, must represent at least 90 percent of the solids fed to the system; b) with an average waste feed activity of 100 nanocurries per gram (nCi/g) TRU equivalent, the treated material's activity must comply with applicable low-level waste acceptance criteria, i.e. the treated material's activity shall be less than 10 (nCi/g) TRU equivalent; c) the TRU waste product from PO*WW*ERTM, i.e. the concentrate from the evaporator, must satisfy applicable TRU waste acceptance criteria; and d) the on-stream or operability factor must be at least 60 percent.

Test Procedures

The pilot plant was operated and evaluated as a continuous, steady-state process. A computer simulation program, developed by Rust Engineering, was used to establish the time required to reach steady-state solids concentrations throughout the ACT*DE*CONSM process for each test operating condition. The effectiveness of the SOIL*EXTM treatment process was tested by tracking the fate of each hazardous and radioactive surrogate in the soil/sludge feed streams. Chemical equilibrium and performance were determined from scheduled sampling of the major process streams which were analyzed for the spiked contaminants and process chemistry.

Test Results

The pilot plant test program was successfully accomplished from July 1994 to November 1994. During this time, nearly 20 tons of soil and sludges were processed to demonstrate SOIL*EXTM 's ability to treat soils and sludges contaminated with mixed waste. Approximately 600 samples, 5000 analyses, and 17,000 pages of analytical data were produced in accordance to EPA Category II Quality Assurance Criteria.

A series of tests were performed to show that the treatment process is capable of meeting or exceeding the test criteria.

During Test 1, the waste feed to ACT*DE*CONSM included soil mixed with sludges containing only the VOCs. The test results demonstrated that all the VOCs volatilize in the ACT*DE*CONSM system since none were detected in the filter cake or the extract at a Minimum Detection Limit (MDL) of 0.005 parts per million (ppm). An addendum test was performed to demonstrate PO*WW*ERTM's effectiveness for destroying the VOCs. During this test, the extract feed to PO*WW*ERTM was spiked with TCE and CCl4 to concentrations corresponding to the most conservative values. The TCE and CCl4 feed spike concentrations of 500 and 1000 ppm, respectively, were chosen by assuming that all the VOCs are extracted into ACT*DE*CONSM's chemistry rather than volatilized. TCE was detected in some product concentrate samples ranging in concentration from non-detectable to 0.12 ppm. The maximum concentration is an order

of magnitude below the LDR standard of 5.6 ppm. CCl4 was not detected in any concentrate sample. Neither VOC was found in the PO*WW*ERTM off-gas system (MDL=0.139 mg/L) demonstrating the system's ability to destroy the compounds. The data clearly demonstrate SOIL*EXTM's ability to process and destroy volatile organics while producing a residual material (filter cake) meeting applicable Low-Level Radioactive Waste Acceptance Criteria and a concentrate meeting applicable TRU Waste Acceptance Criteria lacking RCRA hazardous characteristics for VOCs.
Tests 2 and 3 were designed to establish SOIL*EXTM ' s response to a waste feed containing the actinide and RCRA metal surrogates without the VOCs present. The treated material, recovered as filter cake, represented 96.5 percent of the test feed material. This result substantially exceeded the 90 percent threshold.
Table I lists the surrogate background concentrations naturally occurring in the soil along with the spiking and final concentrations in the treated material (i.e., filter cake) for each test. All values are reported on a dry weight basis. The results show that the ACT*DE*CONSM process successfully removed the surrogate constituents from the soil/sludge mixtures. The mean final Th and Nd concentrations for both tests demonstrate that the process was able to dissolve and remove the entire spike amount as well as a portion of the naturally occurring background constituent. In Test 2, the entire U spike was extracted from the solids matrix while Test 3 results indicated that 99.7 percent of the spike was removed.
Combining these test results with the decontamination factors authenticated during the surrogate validation tests, yields the TRU equivalent specific activities for the treated solids as listed in Table II. These activities, reported on a dry weight basis, range from 2.2 to 9.0 nCi/g with an average value of 4.7 nCi/g. This is less than 50 percent of the requisite 10 nCi/g assigned as the maximum activity for a low level TRU waste.
The TRU waste product generated in PO*WW*ERTM 's evaporator met the applicable TRU waste acceptance criteria. The volume reduction ratio, defined as the volume of extractant feed to PO*WW*ERTM divided by the volume of the waste product generated, averaged 30 to 1.
To demonstrate the pilot plant's mechanical dependability, a 100 Hour Operability Test was conducted. The test was designed to last for a maximum of 167 hours to achieve the 100 hours of operation. The system proved to be very reliable, and the test was completed in less than 108 hours of clock time, providing an availability factor of 93 percent. Six hours of the downtime were caused by filtration system failure. With the exception of the filter press, the SOIL*EXTM treatment system proved to be simple to operate and maintain throughout the test program. A significant advantage for using the SOIL*EXTM process is that the processing equipment used is commercially available from established vendors. This results in short downtimes for required maintenance and repair.

APPLICABILITY

As demonstrated in the pilot plant studies, the SOIL*EXTM process uniquely combines a highly selective dissolution for radionuclide and heavy metal removal from a solids media with a concentration/volume reduction technology for treatment of residues. This combination provides a state-of-the-art approach for treatment of hazardous and radioactive mixed waste. The waste can be in the form of sludges, soil, or debris. In addition, SOIL*EXTM is a simple, cost effective, low temperature process that can be modularized and installed at the contaminated site with minimal effort.
The treatment system can be readily modified to further diminish the secondary waste product volume. This is accomplished by either regenerating the chelant or removing it entirely from the extractant prior to PO*WW*ERTM treatment.
The SOIL*EXTM technology is ideally suited to treat wastes containing any combination of the contaminants listed in Table III.

ABSTRACT

Estimations of waste materials throughput and the potential radiological and chemical releases resulting from the proposed treatment of U.S. Department of Energy (DOE) low-level mixed wastes (LLMWs) were used to support analyses of risks and costs associated with various waste management alternatives outlined in the Office of Environmental Management Programmatic Environmental Impact Statement (EM PEIS). The modeling of material flow and contaminant releases through a consolidated waste management flowchart was performed by the WASTE_MGMT computational model developed by Argonne National Laboratory. This paper 1) briefly describes the process used to model estimated material and contaminant flow through the proposed treatment scenarios for the EM PEIS, 2) discusses the key site- and/or waste-stream-dependent factors involved in the determination of radiological and chemical emissions, and 3) explains the assumptions used to integrate the available LLMW database with the computational model.

INTRODUCTION

The November 1994 internal draft of the U.S. Department of Energy (DOE) Office of Environmental Management Programmatic Environmental Impact Statement (EM PEIS) addresses the environmental and health risks and the costs associated with managing DOE radioactive and hazardous wastes. An important part of this effort is the identification and quantification of the risks and costs resulting from the treatment, storage, and disposal (TSD) of DOE low-level radioactive mixed wastes (LLMWs). LLMW is considered both hazardous under the guidelines of the Resource Conservation and Recovery Act (RCRA) (Title 40, Part 261 of the Code of Federal Regulations [CFR]) and meets the definition of low-level waste (LLW) under the 1954 Atomic Energy Act (codified under 10 CFR, Part 61).

To support the EM PEIS effort to determine the risks and costs of LLMW management, Argonne National Laboratory (ANL) estimated source terms for chemical and radiological contaminant emissions and for the waste material flow during the proposed processing of LLMW. The source terms were estimated by applying waste input data derived from various DOE LLMW databases to a computational model that tracks the flow of materials and contaminants through the proposed waste-processing facilities. The model does not track contaminant emissions from waste disposal facilities.

The source term results from the model have been utilized in the overall EM PEIS program to 1) calculate chemical and radiological risks to site workers and the general public, 2) estimate waste-processing facility costs and resource requirements, 3) project the risks associated with transportation of LLMW and disposal products, and 4) provide comparative estimates of LLMW management activities across sites under various alternatives.

This paper briefly 1) describes the model used to estimate material and contaminant flow under the various proposed treatment scenarios for the EM PEIS, 2) discusses the key site- and/or waste-stream-dependent factors involved in the determination of radiological and chemical emissions, and 3) explains the assumptions used to integrate the available LLMW database with the computational model.

METHODOLOGY

The modeling of proposed LLMW treatment is based on a consolidated waste management flowchart (CWMF) developed by the Mixed Waste Treatment Project (MWTP) (1). The flowchart consists of a series of waste-processing modules common to all sites; the modules are designed to process the major LLMW streams identified in the 1994 Mixed Waste Inventory Report (MWIR-2) (2). Each module delineates one step in waste processing and may include one or more distinct process technologies. The complete treatment sequence for each waste type is called the waste "treatment train." The tracking of material and contaminant flow through the waste-processing modules identified in the CWMF is accomplished by the WASTE_MGMT computational model, an analytical tool that quantifies the throughput of LLMW and estimates the emissions of radionuclides and hazardous chemicals during the operation of proposed

waste-processing facilities (3).
The overall modeling process requires 1) the development of data on LLMW amounts, composition, and shipping routings that are used as inputs to the computational model; 2) determination of the waste-processing module operational parameters used as multiplication factors within the computational model; and 3) operation of the model.
The ANL WASTE_MGMT computational model is run on an IBM-compatible personal computer using the Microsoft FOXPRO relational database system (4). The model is run using information from three types of data files: a waste volume and contaminant characterization file, a waste-processing module characterization file, and a waste-shipping configuration file.
The computational model tracks the flow of contaminants through each treatment module through the entire treatment train for each waste treatment category. The model utilizes the volume partitioning for each treatment module and the densities of both primary and secondary waste-processing streams to establish a consistent mass balance flow through the entire treatment train for a given waste. The model conserves the waste input mass; added solidification materials (i.e., grout cement) are counted in the final disposal product, but added treatment materials (e.g., process water and incinerator fuel) are not tracked by mass.
In addition to partitioning by volume, the computational model also tracks the partitioning of radionuclide and chemical contaminants through treatment at each waste-processing module. At each step in the treatment train, a contaminant may partition into the air, liquid, or solid portions of the process. Summing over all the waste streams, the model calculates the mass (and/or concentration) of each contaminant in air, water, and solid (including final disposal product) discharges.
Five major types of LLMW are followed in detail in the model; aqueous liquids, organic liquids, solid process residues, soils, and debris waste. These wastes constitute over 90% of the inventory and projected generation volume of LLMW that will require waste processing as described in the EM PEIS. The current CWMF does not include the processing of the remaining 10% of special category LLMW (e.g., contaminated lead, beryllium, and certain reactive wastes). To facilitate the comparative analyses of waste management costs and risks at each site, the consolidated flowchart was assumed to be site-independent. A particular waste treatment train may contain as few as four or as many as 10 distinct processing modules; moreover, each module may be a part of the treatment sequence for several waste types. The integrated flowchart contains approximately 25 individual treatment modules. The CWMF applies to both Waste Management (WM) inventory and operations LLMW and to LLMW derived from Environmental Restoration (ER) activities. However, material and emissions source terms are modeled separately for the processing of WM- and ER-derived LLMW.
As wastes are transferred between modules in a treatment train, treatment processes may alter the volume and/or mass throughput and the chemical/radiological composition of the waste. The flow of contaminants through the model is driven by how the contaminant chemistry interacts with the specific operational conditions in each processing module. The movement of bulk waste mass is a function of the physical changes in material volume and density through each module. Thus, the flow of contaminants is independent of the bulk mass throughput in the flowchart. Changes in bulk mass between modules are computed by multiplying the processing-induced changes in waste volume by the expected changes in waste density. Changes in the contaminant mass between modules are calculated by multiplying contaminant-specific partitioning coefficients by the input mass of each contaminant. The partitioning of contaminants is dependent on the solubility and volatility of the specific chemical/radiological species, the waste stream matrix, and the operating conditions (e.g., temperature) of each module (technology).
LLMW INPUT DATA
Input data to the computational model consist of 1) site waste stream volumetric data, 2) radioactive waste handling characteristics, 3) waste-treatment-category-specific chemical profiles, 4) site-specific radionuclide profiles, and 5) the waste-shipping configuration that is dependent on the management alternative considered. This section briefly discusses the derivation and limitations of the model input data.
Approximately 128,000 m3 WM LLMW is in storage (1994 inventory) at 44 DOE sites; another 146,000 m3 of additional LLMW is expected to be generated through 2014. (An

additional 140,000 m3 of waste from the Hanford and Oak Ridge sites is considered as LLMW but was not modeled for the EM PEIS). Under the semi-restricted treatment case, ER-derived LLMW is expected to total approximately 7.3 million m3 through 2030 (5). Contaminant emissions are modeled separately for WM and ER LLMW. For WM LLMW, processing of the total waste volume (inventory plus generated waste) is annualized into an expected 10-year processing period. For ER wastes, the model calculates waste treatment conducted over 30 years.

LLMWs are organized into one of four radiological handling categories depending on the nature and activity of the radioactivity in the waste: contact-handled (CH) non-alpha, CH alpha, remote-handled (RH) alpha, and RH non-alpha. By far the largest volume of waste (>99%) is CH. In the computational model, CH wastes are tracked separately from RH LLMW. The type of radiation emitted also determines LLMW classification and affects emissions modeling. The majority of the modeled LLMW (approximately 75%) is non-alpha waste (less than 10 nCi/g transuranic radionuclide alpha activity). The remaining 25% of LLMW is alpha LLMW (between 10-100 nCi/g transuranic alpha activity) (over 99% of ER LLMW is projected to be CH non-alpha). Because of regulatory concerns about commingling of waste types, contaminant flow and emissions modeling are performed separately for alpha and non-alpha wastes.

For the purpose of the model, the majority of the 2,000 individual MWIR-2 waste streams were grouped into 23 general waste treatment categories (each category is a subset of one of the five major waste types described in the previous section) (6). The 23 waste treatment categories were grouped according to similar chemical/physical treatment characteristics, which allows for common waste processing. Some of the more significant LLMW treatment categories include aqueous waste waters (acidic, basic, neutral, or cyanide), halogenated organic liquids, non-halogenated organic liquids, inorganic particulates and sludges, salt wastes, halogenated organic particulates/sludge, non-halogenated organic sludge, contaminated soils with debris, soils without debris, inorganic non-metal debris, metal debris, combustible debris, heterogeneous debris, and various lab pack wastes. Each waste treatment category follows a distinct treatment train.

Estimation of emission source terms for LLMW requires quantification of the composition and concentration of hazardous chemicals, radionuclides, and certain physical parameters (e.g., ash content) in each waste stream at a site. However, because the current empirical information is insufficient to develop complete chemical/radiological profiles for each waste stream/site combination, the model uses data that assume 1) site-independent chemical profiles based on the generic waste treatment category and 2) site-based radiological profiles that are independent of the particular waste treatment category. The development of LLMW chemical/radiological profiles is detailed in other documents (6, 7, 8).

Chemical profiles for the 23 treatment categories of WM-derived CH non-alpha LLMW were developed from compilation of the chemical concentration data presented in MWIR-2 and an engineering assessment of the industrial processes that generated the respective LLMW streams. Hazardous chemical profiles for ER LLMW were primarily derived from compilation of chemical data from the secondary waste streams expected to be sent to WM for treatment as outlined in the Automated Remedial Assessment Methodology (ARAM) database provided by Pacific Northwest Laboratory (PNL) (5, 9). Information about historical DOE site operations, industrial processes, and waste generation, suggests that the waste streams of a given treatment category classification at sites across the DOE complex are similar. Thus, the model input data assume that chemical profiles for both WM and ER-derived LLMW are waste-treatment-category-specific and are independent of the site that generated the waste. To provide a consistent assessment of chemicals that is comparable across waste treatment categories, the over 100 individual chemical species identified in DOE LLMW were condensed into 16 distinct chemicals and/or grouped into classes of chemicals that are common to most waste streams. These include six toxic metals (silver, barium, cadmium, chromium, lead, and mercury); three inorganic chemicals (arsenic, selenium, and cyanide); and seven classes of organic chemicals that are grouped according to important treatment parameters such as density, solubility, volatility, and degree of chlorination. These classes are 1) acetone, butanone, and methanol; 2) toluene, xylene, and benzene; 3) trichlorethanes; 4) tetrachloroethanes; 5) dichloroethanes; 6) methylene chloride; and 7) chlorofluoro-hydrocarbons.

The input ash content of a waste stream is related to the amount of particulate

emissions from the incineration treatment module. The input ash content is an important component of the LLMW compositional profile because most air releases of hazardous heavy metals and non-soluble radionuclides tend to follow the flow of particulate emissions through the model.
Radiological profiles for LLMW were estimated from the information about the concentrations and activities (Ci) of various radionuclides in LLW compiled in the Integrated Data Base (IDB) (10). The data on LLW radiological profiles were applied to LLMW because it was assumed that the particular radionuclide profiles of LLW and LLMW at a site are dependent on the site operation(s) that generated the radionuclides. The IDB outlines five radiological source profiles that represent the groupings of radionuclides according to the source and time of generation: 1) fission products, 2) induced activity, 3) uranium/thorium, 4) transuranics, and 5) tritium. Each of the DOE sites has a distinct proportion of these five radiological source profiles that is dependent on the site's operational history. A single mission site would be expected to have a radionuclide profile derived primarily from one radiological source category (e.g., uranium-235 concentration facilities like Portsmouth or Paduch have radiological profiles derived almost 100% from the uranium/thorium source profile). Multipurpose sites like Oak Ridge with uranium-235 concentration facilities, reactor operations, and specific isotope production would have an estimated profile that is a proportional combination of the five source profiles (e.g., for Oak Ridge, 30% fission products, 1% uranium/thorium, 1% tritium, and 68% induced activity).
The relative intensities (activity per unit volume in Ci/m3) of LLMW radionuclides were adjusted from the baseline LLW profiles by "aging" the radionuclides to account for the greater age of LLMW at the assumed time of treatment relative to LLW data in the IDB. The age of LLMW radionuclides is site-specific and depends on the site operational history and whether the LLMW is in current inventory or has yet to be generated. The model uses LLMW radiological profiles aged to the median proposed treatment year of 2008.
The ER LLMW radionuclide profiles correspond to those used for WM LLMW with two adjustments: 1) the mean time for generation of radionuclides in all ER wastes was assumed to be 1965, which would produce a different adjustment to aging for the ER wastes compared with most WM LLMW at each site, and 2) the intensity of ER LLMW was assumed to be 10% of the intensity for the equivalent WM LLMW at the site. Both the increased time for radioactive decay and dilution of ER wastes by nonradioactive external materials, such as soil and old packaging materials, account for the lower intensity.
Input volumes of LLMW were also adjusted according to one of seven waste-shipping configurations described in the EM PEIS. Each shipping scenario represents a treatment alternative that delineates the sites for LLMW processing. The alternatives range from each site treating its own waste to requiring shipment of all LLMW to the Hanford site for processing. The input information on LLMW volumes, chemical/radiological profiles, and radiation treatment category was adjusted according to the shipping configuration prior to input to the computational model.
FLOWCHART MODEL
The CWMF covers five basic processes: front-end waste handling, pretreatment, primary treatment, secondary treatment, and tertiary (final disposal form) processing (Fig. 1).
Fig. 1.
The waste input is represented by the five waste types (and their 23 subset waste treatment categories). Each of the processing steps consists of one or more modules. Each module may contain one or more specific process technologies. A particular series of modules represents the treatment train for a specific waste treatment category. The arrows in Fig. 1 represent the contaminant/waste mass flowpaths through the CWMF. These generic flowpaths apply across sites and for each of the 23 waste treatment categories. The bulk mass partitioning factors along the flowpaths were determined separately for each waste treatment category. The contaminant partitioning coefficients along the flowpaths were determined by how module conditions affect each contaminant and are not dependent on the waste treatment category.
As currently proposed, waste-processing options rely on flame treatment (incineration) for most combustible wastes and grouting as the preferred final waste disposal form. Except for a few existing facilities (e.g., the Liquid Effluent

Treatment and Disposal Facility at the Idaho National Engineering Laboratory [INEL]), the processing facilities outlined in the flowchart have yet to be designed. Specific facility operational parameters will be designed on a site-by-site basis. For the computational model, common module operational parameters are used for each generic module, irrespective of site. The flowchart and model are flexible enough to allow for modification of individual waste-processing modules as new waste data, technology information, or DOE waste management guidance are introduced.

The assumed operational conditions of each waste-processing module used in the CWMF are based on empirical data and engineering assessments of similar existing technologies. Proportional waste volume fractions (volume splits) for each module were provided by the MWTP. Waste densities were estimated from data in MWIR-2, along with engineering judgement based on comparison of LLMWs with wastes generated in similar industrial processes. The chemical/physical partitioning factors are specific for each of the 16 chemical species and depend on the technology used in the module, the waste stream matrix, species solubility/volatility, destruction efficiency, and the residual media (i.e., air emissions, water releases, or incorporation into solid product). For example, the air residual of a particular species (e.g., tri-chlorinated organics) is different in the incinerator module (9.90 E-08 of input is released) than in the wet oxidation module (1.0 E-06 of input). In this case, the factors differ as a result of the effect of the higher incinerator operational temperatures on species volatility and destruction (i.e., the incinerator destroys 99.99% of the tri-chlorinated organics compared to a 99.9% destruction for wet oxidation). A list of the module operational parameters is given in Wilkins et al. (6).

The initial waste mass inputs were determined by multiplying the LLMW volume data with the empirical waste stream gross densities derived from wastes at INEL. The INEL data were used because they represent the most complete information currently available on LLMW densities.

ASSUMPTIONS/UNCERTAINTIES

As described in this paper, two primary factors contribute to uncertainty in the LLMW processing model: 1) the existing DOE data on LLMW are incomplete, and 2) the operational requirements for the CWMF remain more conceptual than specific. To estimate emissions and waste flow source terms, several assumptions were applied to the modeling process. The primary purpose of the assumptions is to provide consistent baseline data that, when run through the computational model, furnish comparative source term results across the DOE sites. The more important assumptions and some of the uncertainty introduced by each are reviewed in this section.

The input data assume different origins for the chemical and radiological contaminant profiles for the LLMW waste streams; chemical profiles are waste-treatment-category-specific, while radionuclide profiles are site-specific. In reality, each of the 2,000 LLMW streams may vary in chemical composition by site and in radiological composition by waste treatment category compared to the generic profiles; however, the current incomplete data do not allow for quantification of these potential differences. In the future, more refined LLMW input data may alter modeled emission output at each site.

The condensing of over 100 chemical contaminants into 16 distinct chemical species and/or chemical groups may oversimplify the differences inherent in how each chemical partitions in a given waste-processing module. For a waste that may contain an unusual species of a given chemical, the model may not provide accurate output data. For example, barium, one of the six toxic metals, is assumed to be water insoluble throughout the model; however, if a particular waste actually contains a soluble form of the chemical (e.g., barium chloride), the partitioning between air and water fractions could be different than that modeled. The generalizing of related compounds into chemical groups can also introduce uncertainty. The model uses volatility and solubility coefficients that represent averaged values for a group of related compounds (e.g., four-chlorine halogenated organics). If a waste contains a preponderance of one particular species in the group, and if the volatility/solubility values of that species differ from the assumed group averages, the model may give an inaccurate emissions output. With more complete data on LLMW, the model could be refined to account for such differences.

The assumption that waste input density adjustments for all sites are based on data from INEL may introduce uncertainty if the waste composition and, thus, densities of

the equivalent LLMW from other sites vary from the INEL data. Because this density adjustment is applied at the front end of the computational model to determine waste input mass, inaccurate density values would affect the mass flow throughout the model. At present, not enough data are available from other sites to make a consistent refinement of the input density adjustment.

The model only tracks the mass balance of input contaminants; emissions from the addition of treatment chemicals are only minimally quantified. For example, the amount of fuel (e.g., fuel oil) needed in the incinerator module is dependent on the heat content of the input waste. The amount of added fuel will affect the emission source terms of such gases as sulfur dioxide (SO2), nitrogen oxide (NOx), and carbon monoxide (CO).

Tracking the flow of contaminants independent of the bulk waste mass flow works best when the contaminant mass is a small percentage of the waste mass. For the majority of non-special category LLMW, the contaminant mass constitutes less than 1% of the bulk mass (for inorganic contaminants the value is usually less than 0.01%; certain organic waste streams have organic contaminants concentrations that exceed 1%). A high (greater than 10%) contaminant concentration (especially of an inorganic contaminant that is not destroyed in the treatment process) in a waste stream would result in an inaccurate mass balance through those modules where the chemical partitioning factors differ from the bulk mass partitioning. This would not significantly affect the modeling of the contaminant emission source terms; however, the sum of the contaminant emission mass and the bulk mass output would appear to be greater than the waste input mass. Currently, wastes with known high concentrations of inorganic contaminants (e.g., lead bricks and beryllium wastes) are not run through the model. High concentrations of organic contaminants are less likely to upset the model mass balance because these contaminants are largely destroyed in the treatment process.

The LLMW radiological profiles were assumed to be similar to the profiles for corresponding LLW at each site (adjusted for the age of the waste), as adapted from the IDB (10). This assumption is probably reasonable for the radionuclide profile of LLMW. However, the assumption that the initial intensities (in Ci) of the two waste types are the same may be less accurate. If the initial radiological intensities differed between LLW and LLMW, the level of activity for each radionuclide projected for the model's air emissions, water releases, and residual solids would differ from the current result.

CONCLUSION

The modeling of contaminant and waste material flow and the estimation of emission source terms are important in the effort to understand the risks and costs associated with the proposed alternatives to manage DOE LLMW. The modeling of waste and contaminant throughput by use of the WASTE_MGMT computational model is one possible method of estimating emission source terms. Clearly, current model results are uncertain because of the assumptions applied to fill in gaps in the existing LLMW data and the conceptual (as opposed to designed) nature of the proposed waste-processing flowchart. Since the proposed waste-processing operations will not be fully realized for several years, changes in management alternatives and regulatory requirements can also affect the validity of the currently modeled data. The modeling process as outlined here is dynamic and can be adapted to future changes in LLMW data, waste-processing module operational criteria, and management alternatives.

ABSTRACT

Thermal desorption is an innovative technology that has seen significant growth in applications to organically contaminated soils and sludges for the remediation of hazardous, radioactive and mixed waste sites. This paper will present the results of a bench- and pilot-scale demonstration of this technology for the removal of mercury from the Lower East Fork Poplar Creek floodplain soil. Results demonstrate that the mercury in this soil can be successfully removed to the target treatment levels of 10 milligrams per kilogram (mg/kg) and that all process residuals could be rendered RCRA-nonhazardous as defined by the Resource Conservation and Recovery Act. Sampling and analyses of the desorber off-gas before and after the air pollution control system demonstrated effective collection of mercury and organic constituents. Pilot-scale testing was also conducted to verify requirements for material handling of soil into and out of the process.

This paper will also present a conceptual design and preliminary costs of a full-scale system, including feed preparation, thermal treatment, and residuals handling for the soil.

INTRODUCTION

Thermal desorption is being considered by the U.S. Department of Energy (DOE) as a potential treatment process for floodplain soils from the Lower East Fork Poplar Creek (LEFPC), a tributary which drains the Y-12 site in Oak Ridge, Tennessee. The LEFPC soils are being addressed under the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA); the technology demonstration was in support of the feasibility study to select an appropriate remedy. Successful treatment would provide the opportunity for considering replacement at the site.

Thermal desorption is a low to moderate temperature separation process that removes contaminants from soil and other solids. It has been proven on a wide variety of organic chemicals, including polynuclear aromatic hydrocarbons (PAH), polychlorinated biphenyls (PCB), chlorinated pesticides, and others having low volatility (1). The technology can also be applied to solids containing mercury, due

to mercury's relatively high vapor pressure, although experience in this application has been very limited. Thermal desorption consists of an indirectly heated desorber unit and an off-gas treatment system, which collects the volatilized contaminants and water from the soil using condensation, scrubbing, adsorption and other conventional control devices. For treatment of mixed waste, thermal desorption offers the ability to separate the hazardous chemicals (RCRA) or toxic constituents (Toxic Substances Control Act [TSCA]) from the radioactive constituents, which remain in the bulk solids (2).

Based on the positive results of bench-scale treatability testing (3), Martin Marietta Energy Systems subcontracted with IT Corporation (IT) to conduct pilot-scale thermal desorption demonstration tests. The scope of work was to evaluate the various major process components of a complete treatment facility through a test program that confirmed that cleanup goals could be achieved, determined that desorbed contaminants could be effectively collected/controlled, and provided key scale-up data for preparing a conceptual full-scale design and cost estimate.

SOIL CHARACTERISTICS

LEFPC soil was excavated by hand from an area that had been identified during extensive site assessment to have the highest concentration of mercury (3). Ten drums of soil were shipped to IT's Environmental Technology Development Center in Oak Ridge, Tennessee. The soil was prepared for testing and analysis by sieving to remove oversize material, partial air drying, and thorough manual blending. This preparation is routinely done for treatability tests to ensure a uniform feed material for all testing, and to achieve material handling characteristics suitable for the pilot desorber system.

Chemical analysis included selected metals, volatile and semivolatile organics, and PCBs. Mercury concentration of the composite sample was 283 mg/kg. Eight grab samples were analyzed for mercury to show that the soil was well homogenized; the relative standard deviation was 11 percent. Trace levels of various PAHs were identified; these were the only semivolatile organic compounds (SVOC) detected. Arochlor-1260 was the only PCB detected. No volatile organic compounds (VOC) were detected. Total activity was 1.5E-4 microcuries/gram and total uranium of 48 picocuries/gram. The total organic carbon (TOC) value for the soil was 4.7 percent. Physical properties were also measured since these affect materials handling as well as thermal processing. The prepared soil particle size distribution showed approximately 60 percent silt, 20 percent clay (less than 2 micron), and 20 percent fine sand. The moisture content of the soil as received was 24.4 percent; the Atterberg limits were 32 for the liquid limit and 50 for the plastic limit. Air drying of the soil in the trays for several days resulted in the moisture dropping to about 15 percent for use in the pilot tests.

BENCH-SCALE THERMAL DESORPTION TESTING PROGRAM

Bench-scale testing was performed to confirm the effect of primary treatment variables on reduction of mercury. The tests also enabled an assessment of the characteristics of the residuals collected from the off-gas, which was an important step in preparing for the pilot tests. The treatment goals for the bench-scale tests were to reduce mercury to 10 mg/kg; other constituents were not investigated.

The test program involved two types of thermal desorption systems: the static tray test and the rotary thermal apparatus (RTA). Testing began with the RTA because previous laboratory thermal desorption testing directed by Martin Marietta Energy Systems (3) provided a basis for selecting soil temperature and residence time values. The first series of RTA tests were to determine the effectiveness of 350C for removing the mercury from the soil. The second series of tests were for investigating, at one residence time, the effect of air, steam, and nitrogen as different purge gases. The third series consisting of four tests was to determine the effect of particle size of the RTA feed on mercury removal. The feed soil was screened through wire cloth to produce a very coarse (0.5- to 1-inch) material. This material was treated in the RTA at the same conditions as the fine soil. The final series of RTA tests were conducted at selected conditions to fill in specific additional data needs.

The original test plan was modified because residual mercury concentrations were above the 10 mg/kg goal. Supplemental static tray screening tests were performed at a range of temperatures from 350oC to 650oC. Ten tests were conducted; all used nitrogen as a purge gas, and nine used a time-at-temperature of 10 minutes.

Bench-Scale Equipment Description

Tray Desorption Test Apparatus - IT's "tray test" apparatus is identical to that described in EPA's 1992 guidance document (4). Typically, a 30- to 100-gram (g) sample of soil is spread in a thin (2-3 millimeter [mm]) layer in an open metal tray, which is placed in a standard muffle furnace. The temperature is rapidly adjusted to the desired desorption condition, while a purge gas is passed through the furnace interior. Temperatures of the soil layer and furnace interior adjacent to the tray are measured.

Rotary Thermal Apparatus - IT's RTA consists of a batch-loaded, indirectly heated rotating tube and associated off-gas collection/treatment train. The rotating tube portion of the system is 12.7 centimeter (cm) in diameter by 30.5 cm long; it rotates at five revolutions per minute (rpm) and is externally heated with a custom-made electrical oven. Temperatures of the soil bed, the gas in the rotating cylinder, the oven, and off-gas system temperatures are recorded. The off-gases (purge gas, water vapor, and desorbed contaminants) from the cylinder exit through a heated quartz tube into a collection/treatment system that is configured according to the chemicals being desorbed and the data objectives of the testing. Typically, the off-gas first enters a heavy glass-walled spray tower scrubber where a caustic solution is recirculated through the spray tower. Uncondensed gases passing the spray tower are pulled through a carbon bed by an air-aspirated venturi pump before being discharged into a high-efficiency particulate air (HEPA)-filtered laboratory fume hood.

Bench-Scale Thermal Desorption Results

The results for the RTA tests are summarized in Table I. Only one test achieved a residual mercury concentration below 10 mg/kg; this test had the longest residence time at temperature (1 hour). There was no significant difference between all the RTA results considering the typical variability to be expected in sampling and analytical accuracy for multiple tests from the same prepared soil batch. Residence time (between 10 and 20 minutes) and purge gas type did not have a definite influence on mercury removal. The oxygen concentration in the RTA vent gas from the first four experiments was higher than expected due to leakage through the seals, which were replaced; this variance is noted in the table (*). The use of nitrogen and steam purge reduced the oxygen level to approximately 2 to 5 percent for Tests 5 and 7. These results are typical of what could be achieved in a full-scale desorber with an inert gas purge.

The tray test results were comparable to the RTA results. Residual mercury values ranged from 16.1 to 6.3 mg/kg over the range from 350 to 650oC. All the results were below 10 mg/kg at temperatures above 400oC. Increased temperature appeared to have a minor influence on residual mercury values, although a definite correlation could not be established due to the limited number of tests and the small range of mercury values. Increased residence time did not have a definite effect on treatment.

PILOT-SCALE THERMAL DESORPTION TESTING PROGRAM

The pilot program consisted of several tasks that were conducted separately. Initial objectives were as follows:

- Reduce mercury in the soil to below 10 mg/kg.
- Demonstrate accountability for mercury throughout the process.
- Generate treated soil that is RCRA nonhazardous.
- Demonstrate the effectiveness of off-gas treatment.
- Minimize residuals and treat any RCRA residuals.
- Evaluate soil material handling/preparation characteristics.
- Obtain sufficient engineering data to enable full-scale conceptual design and budgetary costing for use in feasibility study.

After the bench-scale desorption test results had been evaluated, the first objective was modified to demonstrate less than 20 mg/kg residual mercury. It was decided by the project team that it was preferable not to increase the desorption temperature substantially in order to achieve a residual mercury concentration of 10 mg/kg because this increase was expected to have a deleterious effect on the treated soil properties relative to replacement/reuse at the site.

Desorption Pilot Test Plan

A series of three pilot-scale tests were performed on LEFPC soil. The first test was to establish operating conditions for the desorber in order to obtain the throughput and treatment goals desired; soil residence time and temperature were selected based on the RTA results.

Test 2 was the official verification test, performed at 350oC. The operating conditions developed during Test 1 were used to treat 330 kg of soil. Samples of soil feed, treated soil, desorber off-gas, scrubber liquids and solids, activated carbon, demister pad, and final vent gas were sampled and analyzed for various chemical parameters including mercury, selected other metals (e.g., cadmium, arsenic), VOCs, SVOCs, and PCBs. Treated soil was also analyzed for chlorodibenzodioxins/chlorodibenzofurans (CDD/CDF). Scrubber water was analyzed for total organic carbon and pH. Off-gas and vent gas were also sampled and analyzed for particulate, acid gases, ammonia, oxygen and carbon dioxide.

Test 2 was also used to generate sufficient soil for two other types of subsequent testing. Forty-five kg of treated soil was used by the project team to evaluate its characteristics relative to being replaced in the floodplain (e.g., ability to support plant growth). Another portion of treated soil (197 kg) was used for back-end material handling tests.

Test 3 was performed at a higher desorption temperature of 600oC; all other operating conditions were the same. This test was to demonstrate that the improved treatment to below 10 mg/kg mercury that was measured in the tray tests could be accomplished at the larger scale. The sampling and analysis program was similar to Test 2 with the exception of the gas sampling, which was limited to Orsat measurements of oxygen and carbon dioxide.

Table II lists the key process parameters for both the 350oC verification test and the 600oC test.

Materials Handling Tests

The materials handling test program consisted of physical property measurements, feed chute drop tests, reagglomeration tests, and wet drag flight conveyor tests. The physical property tests were performed to assess handling characteristics such as adhesion, cohesion, and properties important to the design of soil preparation and feed systems. The "as received" soil was tested for initial moisture content and Atterberg limits.

Lime addition, calcium hydroxide, was also evaluated in an effort to produce a material that had less tendency to agglomerate and stick to surfaces. An addition of 1 and 2 percent lime by weight to two soil samples caused no significant change in Atterberg limits. Therefore, lime addition was not pursued as a method of preparing the soil feed for the thermal desorber.

The feed chute drop tests were designed to evaluate the tendency of the feed soil to stick to surfaces upon impact. The simplest method of introducing solids to a rotary desorber is by dropping the material onto an inclined chute, which directs it onto the soil bed. A pilot chute system was set up to test the effect of moisture content and chute angle on the degree of soil deposition on the chute surface. Moisture content was varied from 17 to 39 percent by adding water to the prepared soil batch; chute angle was varied from 45 to 71 degrees. A drop height of 13 feet was used for all tests; this was considered representative of a full-scale system.

The reagglomeration test was designed to observe any tendency of the soil to reagglomerate from tumbling and mixing in the rotating desorber. Soil was placed in a rotating drum and observed to see if a ball or "sausage" was formed. Soil moisture content was varied from 9 to 40 percent to determine at what point agglomeration began and at what point soil stuck to the rotating surface. Both phenomenon were considered detrimental to proper desorber performance.

To simulate a wet quench system with drag-flight conveyor, a slurry of treated soil from the 350oC verification test was prepared in a shallow tank. An inclined metal plate was placed in the tank at a 35 degree angle as a "dewatering beach"; the bottom section was submerged but the majority of its length was above the water level. A modified garden hoe was used to pull wet soil up the dewatering beach at a rate of 3.0 meters (m) per minute. The angle of the beach and the drag rate and corresponding drainage time were selected to be representative of a full-scale system. The dewatered soil was stockpiled and weighed. The amount of soil retained by the "drag flight" and its moisture content were measured. The test was repeated until sufficient drained material was collected to form a pile for determination of the angle of repose before and after vibration. This characteristic is important in determining the practicality of stockpiling the wet soil prior to transport. The test was repeated using a longer drainage time (1 versus 0.3 minute). Two sets of additional tests were performed using higher water-to-soil ratios.

Residuals Treatment Tests

All liquid and solid residuals generated from the pilot testing were evaluated for RCRA hazardous characteristics (toxicity characteristic [TC]), both to determine if this was an issue for applying the technology and to enable return of these materials to Martin Marietta Energy Systems. If a residual had a constituent exceeding TC limits, it was treated in an appropriate manner based on initial bench-scale testing. For the liquid residuals, a treatment system was assembled consisting of a modified open-top drum, stir paddle, diaphragm pump, and specially made laboratory glass filtration vessel. Treatment chemicals were weighed, added to the tank, and blended manually. The pH was monitored continuously using a meter. The final settled solids "flock" was dewatered using a two section glass vacuum filtration vessel with filter media pad. Solid residuals from the desorption tests that contain mercury above toxicity characteristics leaching procedures (TCLP) limits were treated in the RTA or by acid rinsing in a small vessel.

Pilot-Scale Thermal Desorption System

The pilot testing of LEFPC soil was performed at IT's Environmental Technology Development Center in Oak Ridge, Tennessee. The pilot thermal desorption system has been used for dozens of thermal desorption tests beginning in 1985 (5,6,7). In addition to thermal desorption tests, pilot-scale materials handling and residuals treatment testing was performed. This section describes the pilot facilities, with emphasis on the thermal desorption system.

IT's pilot thermal desorber process is essentially a scaled-down version of a full-scale system. The pilot system has in past studies given comparable results to bench-scale tests. The thermal desorber is a standard-design pilot calciner that consists of a continuously rotating tube partially enclosed with a gas-fired furnace shell. A flow diagram of the pilot system is shown in Fig. 1.

Fig. 1.

The tube, constructed of Castalloy H-H, has a 16.5-cm internal diameter and is 4.3 m long; the heated section is 2.3 m long. Small flights are placed at intervals within this tube to provide soil agitation. A stationary thermowell extends from the discharge end into the tube, with six thermocouples to monitor the soil temperature and three to monitor the gas temperature along the tube length. The soil residence time is a function of the soil bed volume and the soil feed rate. Soil bed volume is controlled by the rotational speed and inclination of the desorber tube. The soil feed rate is controlled by the rotational speed of a feed-screw conveyor. The furnace is a refractory-lined chamber with 14 equally spaced burners (propane) controlled by a standard burner control system with appropriate safety features. Burner firing rate is manually controlled to give the desired soil temperature profile.

The discharge end section of the desorber tube is enclosed by an air-cooled casing. Soil exits the desorber tube through a gas plenum/transition section and a rotary air-lock valve into a metal receiver can. Purge gas is introduced at a low flow rate at the soil discharge end to help flush desorbed contaminant vapors and to maintain the proper atmosphere for the treatment process. The off-gas flows from a plenum at the soil feed end of the desorber containing the purge gas, volatilized contaminants and water, and some particulates. The off-gas is transferred through a short electrically-heated, insulated duct to the off-gas treatment system.

The off-gas treatment system was comprised of a hot cyclone, a spray scrubber with demister pad, a wet electrostatic precipitator (WESP), a chilled, noncontact condenser, a mist eliminator, a HEPA filter, a two-stage carbon adsorber, and an induced-draft fan.

Pilot-Scale Test Results - LEFPC Soil

Thermal Desorption Results, Soil and Residuals - A summary of the analytical results for mercury for both the 350oC and 600oC verification tests is given in Table III. Mercury was reduced to approximately 14 and 8 mg/kg for the 350oC and 600oC desorption temperatures, respectively. A series of temporally related feed and treated soil mercury results showed a relative standard deviation of 20 percent or less.

Table III shows the accountability/distribution for mercury throughout the system. Mercury was recovered primarily in the scrubber system; it concentrated in the scrubber solids and as elemental (liquid) mercury. During inspection of the off-gas treatment system after each test, elemental mercury was found throughout the scrubber system. The greatest amount was in the demister pad located on top of the scrubber. Elemental mercury was recovered from the demister pad and scrubber system

at 12 and 13 g for the two tests, respectively. A small amount of floating semisolid material collected from the scrubber system tank for the 600oC test had a very high concentration of mercury. The elemental mercury values in the table represent the total combined liquid mercury isolated from all sources, including as a result of residuals treatment to achieve nonhazardous criteria. The carbon adsorber also collected some mercury. The data for 600oC test show less mercury collected in the scrubber and more collected in the carbon. In fact mercury broke through the primary adsorber, as indicated by the separate analysis of the primary and secondary carbon. Approximately 45 percent of the total mercury (95 and 70 g) calculated to be contained in the feed soil for Tests 2 and 3, respectively, was accounted for in all the process output streams. Despite very thorough removal of all liquid and solid materials from the scrubber system, the accountability was low, presumably due to the size (surface area) and complexity of the pilot system and the tendency of the condensed mercury to spread and adhere to surfaces.

Organics found in the feed soil (PAHs and PCBs) were reduced in the treated soils to below the analytical method detection limit. Several other SVOCs, mostly tentatively identified compounds (TIC), were found in the treated soil from the 350oC test at concentrations below 1 mg/kg. For the 600oC test, the only organic compound detected in the treated soil was naphthalene at 39 micrograms per kilogram (mg/kg) (parts per billion). Various CDD/CDF were detected at levels under 1 mg/kg for the treated soil from the 350oC test; only octachlorodibenzodioxin was detected at less than 1 mg/kg, for the 600oC treated soil. Treated soil from both tests passed TCLP for metals and organics.

The organic analytical data for the residuals showed PAHs and PCBs, as well as VOCs and SVOCs, that were not detected in the untreated soil. The type of compounds found in the residuals were comparable to those measured in the off-gas sampling, which is discussed in the next section, except for a few notable exceptions. Highly volatile compounds, such as chloromethane, were not detected in the residuals; pyridine, which was found at relatively high levels in the scrubber liquid and sludge, was not found in the off-gas analysis. The type of organics present in the residuals from the 600C test were very similar to those found in the 350C test, but the concentrations were higher. For the 350C test, PCBs concentrated in the scrubber sludge to slightly greater than 50 mg/kg, the TSCA limit; the PCB content was lower in the sludge from the 600oC test.

Less soluble compounds tended to concentrate in the scrubber sludge, whereas the phenols and pyridine distributed between the scrubber liquid and sludge. The activated carbon from both tests had VOCs, particularly the more volatile ones; naphthalene and several other lower molecular weight SVOCs were also found in the carbon from the 600oC test.

Total uranium and gross alpha/beta values measured for the untreated soil and various residuals indicate that there is no significant partitioning of radionuclides to any residual. The residuals are generally lower in uranium than the untreated soil. However, final determination of the potential for concentration of radioactive constituents in certain residuals could not be made from the limited results of this testing.

Off-Gas Treatment Results - The off-gas (downstream of the cyclone) and final vent gas were sampled and analyzed to demonstrate the removal efficiency of the off-gas treatment system. Parameters that were evaluated include particulate; metals (mercury, arsenic, cadmium, and uranium); volatile and semivolatile organics; acid gases and ammonia; and for the vent gas only, oxygen, carbon monoxide, and carbon dioxide.

The total particulate loading from the desorber, determined from combining the mass of solids collected in the hot cyclone and scrubber liquid, represented approximately 1.5 percent of the soil feed; the majority of these solids collected in the scrubber.

VOC results for the off-gas indicate aromatic hydrocarbons, several aliphatic hydrocarbons (paraffins and olefins), several oxygenated paraffins (e.g., ketones), and furans. In addition, chlorinated hydrocarbons and carbon disulfide were detected. The most significant VOCs included benzene, toluene, acetone, 2-butanone, furan, 2-methyl furan, chloromethane, and carbon disulfide.

A large number of SVOCs were found in the off-gas, including phenolics, PAHs, and other cyclic hydrocarbons and some oxygenated paraffins (e.g., aldehydes). The total SVOC content was similar to the total VOC content. Phenol and methyl phenols

contributed most of the confirmed SVOCs; the major TIC contributed approximately 40 percent of the total SVOCs. This data corresponds with the residuals data, except no pyridine was detected in the off-gas.
The off-gas contained only trace levels of most acid gases based on analysis of anions. However, ammonia was found in the off-gas at a relatively high level (790 g/m3). The source of the ammonia was not determined. It could have originated from decomposition of nitrogenous soil organic matter.
The off-gas treatment system proved very effective in controlling all parameters, which was expected because of the variety and number of control devices. Table IV shows the off-gas and vent gas concentrations, as well as overall removal efficiency for each parameter.
Materials Handling Test Results - The data indicates that as the moisture content of soil approaches the plastic limit (32 percent) of the untreated soil, the soil tends to fail both the drop test and agglomeration test. To avoid difficulties, the moisture content should be maintained at less than 25 percent; excavated soil having higher moisture could be partially air dried or blended with dryer material in the storage area.
The back-end materials handling data demonstrated that the treated soil can be processed effectively using a drag-flight conveyor and can be stockpiled.
Residuals Treatment Results - The purpose of the residuals treatment was to ensure that none of the residuals were classified as a RCRA hazardous waste. The aqueous scrubber solution from the verification pilot tests exceeded TC limits for mercury and pyridine. The liquid was treated using chelation/chemical precipitation followed by carbon adsorption. Mercury in the scrubber liquid was reduced from several milligrams per liter (mg/L) to 0.008 mg/L, well below the TC limit of 0.2 mg/L. Pyridine was reduced from 120 mg/L to less than 1 mg/L. Other aqueous residuals which were above the mercury TC limit were also successfully treated by chelation/chemical precipitation.
The sludge collected in the filter bags from all three pilot tests was air dried and placed in the RTA for thermal desorption treatment. Mercury was not detected in the TCLP extract of the treated solids; the total mercury had been reduced to 20 mg/kg. The precipitated and dewatered solids generated from treatment of the scrubber liquids and decon water were composited and successfully treated in the RTA in the same manner.
The liquid elemental mercury (approximately 30 g) collected from all sources was combined and treated with powdered zinc and powdered sulfur to produce an amalgam. This mixture was then stabilized using cement and water. The resulting TCLP mercury concentration was 0.008 mg/L.
The synthetic fabric filter bags, demister media, and HEPA filter media were treated by washing with dilute nitric acid which reduced the mercury (and other metals in the case of the HEPA) to below TC limits.
ENGINEERING AND COST ASSESSMENT
The information from the pilot tests was used to assess the application of a full-scale thermal desorption system to treat LEFPC soil. A preliminary process design was developed, which included an overall material and energy balance, list and sizing of major equipment, and operating requirements. The basis was 32 metric tons per hour (90 percent on-stream factor) of soil containing 300 mg/kg mercury and 25 percent moisture. The facility scope included all process components, from desorber feed system to treated soil material handling system; residual treatment prior to off-site disposal and effluent treatment and recycle was included.
The budgetary capital cost estimate was $12.3 million (plus or minus 25 percent), with the desorber and off-gas system representing 58 percent of this total. Estimated major operating and maintenance costs including labor, utilities, consumables, maintenance materials, and off-site disposal represent a total processing cost of $45 per metric ton. Other remediation costs, including excavation, transport, replacement, and other site activities, would be additional to this processing cost.
CONCLUSIONS
The LEFPC pilot testing demonstrated that thermal desorption is applicable to remediate the LEFPC floodplain soils. The process removed mercury from 300 mg/kg to below 15 mg/kg at treatment conditions of 350oC for 10 minutes at temperature, and to below 10 mg/kg at 600oC for 10 minutes at temperature. The desorber off-gas can be cleaned using a series of conventional air pollution control devices to

approximately 99 percent or greater removal of all measured contaminants. Mercury emissions were controlled by greater than 99.99 percent. More than 85 percent of the mercury recovered was collected in the wet scrubber, with approximately 60 percent of this isolated as elemental liquid mercury. Several process residuals were generated that could be RCRA hazardous. These residuals can be treated using conventional processes to render them nonhazardous. The capital cost of a high capacity desorption facility is estimated to be $12.3 million with operating costs of $45 per metric ton.

ABSTRACT

DETOXSM is a cocatalyzed wet oxidation process in which the catalysts are a relatively great concentration of iron ions (typically as iron(III) chloride) in the presence of small amounts of platinum and ruthenium ions (1,2). Organic compounds are oxidized completely to carbon dioxide, water, and (if chlorinated) hydrogen chloride. The process has shown promise as a non-thermal alternative to incineration for treatment and/or volume reduction of hazardous, radioactive, and mixed wastes (3-5).

Design and fabrication of a demonstration unit capable of destroying 25. Kg/hr of organic material is now in progress. This paper describes the Title II design of the demonstration unit, and the planned demonstration effort at Savannah River Site (SRS) and Weldon Spring Site Remedial Action Project (WSSRAP).

BACKGROUND

Oxidation of materials in the DETOXSM process is at present conducted in a stirred tank containing an acidic (3. - 4.% HCl) aqueous solution of the cocatalysts at temperatures of 400. - 473. K. System operating pressure ranges from atmospheric at 400. K to approximately 700. kPa at 473. K. Organic compounds are oxidized in the catalyst solution by iron(III) ions. In the oxidation process, iron(III) is reduced to iron(II). Oxygen introduced into the solution oxidizes iron(II) back to iron(III). Figure 1 illustrates the process.

Fig. 1.

Laboratory tests have determined the apparent rate constants and activation energies for oxidation of a wide variety of organic materials, including cellulosic materials, hydrocarbon oils, chlorinated and non-chlorinated aromatic and aliphatic solvents, energetic compounds, plastics, and chlorinated aromatic compounds such as polychlorinated biphenyls (PCBs). Measured rates indicate that at a temperature of 423. K approximately 0.5 to 10. moles/L-hr of organic material can be destroyed at organic material/catalyst solution contact areas of 300. to 6000. cm2/L.

There are many low level and mixed wastes which are organic in nature and could be treated using DETOXSM as an alternative to incineration. Mobile treatment units could be used to destroy the organic components of wastes on site, thus eliminating the costs and concerns of transportation and other forms of disposal. Heavy and radioactive metals remain in the DETOXSM process solution. The process solution can be converted to an iron oxide residue by boiling off HCl, and the residue stabilized for ultimate disposal.

TITLE II DESIGN

Design Basis

A site selection evaluation was conducted in parallel with the start of Phase II design. Ten (10) DOE sites were considered as possible demonstration sites due to the types of wastes available for the demonstration effort. The list was reduced to seven sites based on expressions of interest, and these seven sites were ranked according to evaluation criteria provided by the DOE. The two most highly ranked sites, Savannah River Site (SRS) and Weldon Spring Site Remedial Action Project (WSSRAP), were recommended for the proposed demonstration. The wastes at these sites helped define the requirements for the demonstration unit.

Waste types available for the demonstration include high and low boiling organic liquids (including chlorinated solvents), some paint sludges and similar solids, tributyl phosphate, and polychlorinated biphenyl (PCB)-contaminated liquids. For the purposes of mass and energy balance calculations, three organic compounds were chosen which would represent compositions typical of the range of waste types in the demonstration. These were a completely saturated aliphatic hydrocarbon (i.e., -CH2-), tributyl phosphate, and a PCB having 60.% by weight chlorine content.

Further requirements for the demonstration unit were provided in discussion with DOE EM-50 representatives. The requirements were for the most versatile unit possible consistent with a reasonable cost. It was decided in these discussions that the unit would have a method of feeding both liquid and solid organic materials to the reaction vessel and that the unit would have a system for semi-continuous removal of inert particulates or particulates generated during waste processing. These features at least doubled the unit size and cost over a liquid-only unit without solids removal, but it was felt important to demonstrate as wide a range of waste treatment ability as reasonably possible. Transportability of the demonstration unit was also an important consideration in design.

After consideration of the types and amounts of wastes at the demonstration sites, and particularly at WSSRAP, in combination with what was considered a reasonable throughput consistent with unit size and cost, a nominal capacity of 25. kg/hr was chosen for the demonstration unit. Once the reaction vessel is at temperature, the unit will operate 24. hrs per day.

Critical issues in the design effort were: operator and environmental safety and health; process effluents of minimum environmental concern; and ability to achieve the planned capacity.

Special considerations in the design effort were: modularity and transportability of the demonstration unit; ability to treat both liquid and solid waste materials; ability to remove solids from the process solution during waste treatment; design conformance with demonstration site requirements; compatible materials of construction for components contacting the process solution or its vapors; and secondary or tertiary containment in critical areas.

The design effort also took into account the requirements of 40 CFR Parts 264 and 265, the OSHA Standards for General Industry, 29 CFR Part 1910, and all applicable sections of DOT regulations, 49 CFR.

Title II Design Format

Jacobs Applied Technology (JAT), a subsidiary of Jacobs Engineering Group (JEG), was chosen for the Title II design effort due to JAT's extensive experience in modular chemical process design and construction, the resources and experience in chemical process design and environmental applications which were available through JEG, and the estimated cost and schedule for designing and constructing the unit.

The Title II design effort was conducted in a logical progression of preliminary PFD and P&ID preparation and review, revised PFD and P&ID preparation and review, HAZOP review, final review, and construction cost estimate.

Title II Design

PFD. Figure 2 is the final PFD for the demonstration unit. Flows 1 and 2 are liquid and solid organic feeds to the reaction vessel. Flow 3 is oxygen feed to the

reaction vessel. Flow 4 is product gas and water vapor exiting the reaction vessel, and flow 5 is water return to the reaction vessel from the reflux condenser. The reflux condenser serves to reduce the amount of water vapor in the product gases to the overhead condenser, provide some cooling for the reaction vessel (the reaction vessel is also cooled with an oil-filled jacket), and knock down any heavy organics in the product gases. Flow 6 is product gas to the overhead condenser, and flow 7 is condensed water to a receiver tank. Flows 20 and 21 are product gas, which contains a small amount of excess oxygen, through a carbon bed and to vent. Analyzers for oxygen, carbon dioxide, volatile organic compounds, HCl, and radiation are on the product gas lines.

Fig. 2. Demonstration Unit PFD.

In order to remove inert solids or inorganic solids formed during treatment of organics, a flow of process solution is taken from the reaction vessel, cooled, filtered, and returned to the vessel. Flows 8 and 9 are process solution through a solution cooler and to the filter. Flows 10 and 11 are filtered process solution to a surge tank and returned to the reaction vessel. Flow 12 is solids removed from the process solution, which have been rinsed thoroughly and are fed into a drum for stabilization and disposal. The solids are rinsed with a dilute citric acid solution (Flow 22) and water (Flow 23) before the are removed from the filter. Flow 29 is the solids rinses fed to an evaporator, where excess water is removed in Flows 14 and 15 to a receiver tank. Flow 26 is water from the evaporator receiver tank used to make up new citric acid solution or for rinsing collected solids. Flow 16 is the bottoms from the evaporator returned to the reaction vessel.

Water is produced in the destruction of most organic compounds. The water collected in the overhead receiver is this product water. Although most of the HCl in the product vapors will have been removed by the reflux condenser, it is expected that some HCl will be in the collected product water. Flow 24 is caustic solution to a neutralization tank to neutralize the acid content of the distillate. The neutralized distillate can then be fed to the evaporator (Flow 13) to return non-product water to the reaction vessel, or it can be taken directly to the evaporator overhead receiver (Flow 27) and from there to water treatment by Flows 17 and 19.

Materials of Construction

The 1000. L reaction vessel is specified to be tantalum-lined titanium. This construction provides excellent corrosion resistance (6) plus a strong and corrosion resistant pressure shell. The tantalum liner is expected to last the estimated 10. year lifetime of the unit, but even should it be breached the titanium shell will provide effective double containment until the process solution can be cooled and removed so that the liner can be replaced or repaired. A potentiometer connected between an electrically isolated counterelectrode in the process solution and the pressure shell will be able to detect any breach in the tantalum liner.

Other areas where the process solution will contact materials are in the solution cooler, filter, evaporator, evaporator bottoms pump, and evaporator bottoms return line. The solution cooler will be tantalum on the process side. Once the process solution has been cooled, it is compatible with Grade 7 titanium, which will be the material of construction for the solution filter, surge tank, evaporator, and associated plumbing.

Due to the HCl content of the hot gases exiting the reaction vessel, the reflux condenser and the overhead condenser will have process sides of tantalum. Once the gases have been cooled, Teflon-lined carbon steel will be used for the vent gas and condensate.

Design Issues

Reliably feeding solid materials to the pressurized reaction vessel is a challenge. Solids will be shredded and slurried with water, then fed to the reaction vessel through redundant pinch valves using a progressive cavity slurry pump. Shredding will also increase reaction rate by increasing the surface area of the solids.

Effective agitation is vital to achieving good organic destruction rates, since the oxidation rate for most organic compounds is dependent on the surface area of contact between the organic compound and the process solution. Achieving effective agitation in the demonstration units reaction vessel is complicated by the range of waste forms. More volatile materials will be in vapor form, which will require good gas/liquid contact. Less volatile materials will be in liquid or solid form. Effective oxidation of liquids and solids will require good liquid/liquid and

solid/liquid contact. In consultation with agitator companies, one of the more versatile arrangements was determined to be the combination of a standard 45. pitched blade turbine mounted somewhat below solution level to pull vapor from the headspace of the reaction vessel into the process solution, and a disk/paddle turbine near the bottom of the reaction vessel to provide high shear. Baffles in the vessel will help provide good turbulence.

The combination of organic compounds and oxygen presents the potential for formation of explosive mixtures in the reaction vessel headspace. Computer simulations, conducted at Sandia National Laboratories (SNL), have indicated that below approximately 10.% by volume oxygen content in the reaction vessel headspace gases there is no flammability possible regardless of organic concentration. This is illustrated in Fig. 3, which is presented here as a generic figure only and is not meant to represent actual data. Design parameters for the process specify operation at 5.% by volume oxygen in the vent gases, which translates to less than 1.% by volume oxygen in the reaction vessel headspace gases at operating conditions in the reaction vessel. These operational parameters give a large safe operating range (approximately 10x) for the process. Redundant, calibrated oxygen sensors on the vent gas line will ensure correct measurement of oxygen levels. Additional tests are planned at SNL to identify the flammability limits for some representative volatile organic compounds at the operating conditions of the process.

Fig. 3.

An important issue in the unit's ability to destroy TBP was the ability of the filter system to remove ferric phosphate precipitate from the process solution at a rate sufficient to allow operation at the unit's design capacity of 25. kg/hr. Results of laboratory particle size measurements and filtration/rinsing experiments using ferric phosphate precipitated under the conditions of the process were used to size the filter. A sealed, Nutsche type or helical filter with a scraper/agitator will be used, so that filter cake rinsing and discharge will not normally require handling of the solids by the unit operators.

A preliminary layout of the equipment is shown in Fig. 4. The demonstration unit is to be assembled as two transportable process modules plus a module for the oil cooling/heating system (not shown). A vertical module approximately 9.75 m tall x 3.66 m x 2.44 m will include the solids feed, reaction vessel, reflux condenser, solution cooler, particulate filter, surge tank, process solution return pump, evaporator and evaporator overhead condenser, evaporator bottoms return pump, and reaction vessel quench tank. A horizontal module approximately 7.32 m long x 2.44 m x 3.66 m high will include the remainder of the pumps, the overhead condenser, overhead receiver, evaporator overhead receiver, distillate neutralization tank, vent knock out tank, and vent gas carbon bed. A third module 7.32 m long x 2.44 m x 3.66 m high will contain the oil cooling/heating system. The oil module can be placed away from the process modules and must in any case be placed in an exterior location so that excess process heat may be rejected.

Fig. 4.

Fabrication and assembly of the demonstration unit is scheduled for fiscal year 1995.

DEMONSTRATION PLAN

The demonstration plan is a progression from tests with minimally hazardous or non-hazardous organic materials through treatment of hazardous organic wastes, and finally to demonstration of the process on a variety of mixed wastes. Non-hazardous and hazardous waste treatment is planned at SRS. Mixed waste treatment is planned at WSSRAP. The demonstration effort is planned to take place in Fiscal Years 1996 and 1997. A successful demonstration will establish the DETOXSM process as a versatile, mobile on site mixed waste treatment method.

Non-Hazardous Materials Testing

After installation of the unit at SRS, functionality tests will be conducted to determine the ability of the unit to operate as designed, to identify any obvious flaws in control algorithms, equipment, materials, or construction, and to run through safety and emergency response procedures. Functionality tests will follow a progression from operation with cold water to operation with hot water and finally to operation with the process solution.

Following functionality testing the filter system will be tested for its ability to remove inert solids from the process solution, the solids feed will be tested separately for its ability to reliably deliver solids slurry to a pressurized

environment, and the unit will be used to destroy a selection of minimally- or non-hazardous organic materials.
The liquid organic materials to be oxidized will be white petroleum oil and tributyl phosphate. The solids to be used in the solids feed will be a mixture of polyethylene, paper, latex rubber, and poly(vinyl chloride). The process vent gas, condensate, and solution will be monitored and analyzed to determine the levels of any volatile organics and to establish destruction efficiencies. After these tests, the unit will be inspected thoroughly to determine equipment compatibility and performance.

Hazardous Waste Treatment

Hazardous wastes to be treated include contaminated oils, non-halogenated solvents, halogenated solvents, and, if time and funding permit, combustible solids. The test regimen will most likely include benzene, trichloroethylene, tetraphenyl borate in water solution, and mineral oils contaminated with lead and/or mercury.
Vented product gas will be monitored for levels of volatile organic compounds, and the condensate product and process solution will be sampled and analyzed for organic residues to determine destruction efficiencies. When wastes containing toxic metals are destroyed, the process solution will be analyzed for the metals as well.
At the conclusion of hazardous waste treatment, the process solution will be boiled to evaporate HCl until approximately 95.% of the iron is in the form of the hydrated iron oxide. The iron oxide, which may contain toxic metals, will be filtered from the solution as it forms, and may be stabilized if SRS desires. The HCl will be condensed with the boiled water, neutralized with caustic, and disposed.
Following the hazardous waste campaign, the demonstration unit will be cleaned, thoroughly inspected, maintained, and any desired changes in design made before it is shipped to WSSRAP.

Mixed Waste Treatment

Mixed wastes to be treated include ethylene glycol, oils, non-halogenated solvents, halogenated solvents, paints and sludges, PCBs and PCB-contaminated liquids, and tributyl phosphate. The demonstration may be extended to other materials including combustible solids.
The unit will be installed, checked out, and an Operational Readiness Review conducted before mixed waste treatment is begun. The order of waste treatment will be as given above.
Calculations indicate that at least two process solutions will have to be used over the course of waste treatment to ensure that radioactivity is kept at low levels in the process solution residue. Vented product gas will be monitored for volatile organic compounds and radioactivity. Product water will be analyzed for volatile organic content and radioactivity, then sent to the on-site water treatment plant. The process solution will be analyzed periodically for organic compounds, radionuclide content, and toxic metals. The process solution residue and the ferric phosphate residue from treatment of tributyl phosphate will be stabilized and disposed at WSSRAP.

Demonstration Requirements

Requirements for the demonstration tests include: operating, safety, and maintenance manuals for the demonstration unit; formal test plans and procedures; hazardous materials handling and emergency response training for operators; lock out/tag out procedures; site-specific safety and operations training; NEPA documentation; a RCRA Part B R&D permit for tests with hazardous wastes at SRS; review of estimated water and air emissions by the cognizant regulatory agencies; and preparation of Radcon procedures, Safe Work Plans, and Task-Specific Safety Assessments for operations at WSSRAP.

ACKNOWLEDGMENTS

ABSTRACT

A test bed capable of evaluating several different hydrothermal oxidation (HTO) reactor concepts and other HTO components, has been designed and is planned to be constructed at the Idaho National Engineering Laboratory (INEL). A vessel reactor will be designed, fabricated, installed, and tested with a series of simulated wastes selected to represent the types of mixed radioactive wastes currently stored and/or generated by the U.S. Department of Energy (DOE). The major HTO component in the process is a chemical reactor into which simulated mixed waste, water, and gaseous oxygen are injected. The process pressures and temperatures are above the critical point of water. In this environment, organics become highly soluble and are transformed into benign chemicals or elements. The test bed is to be built and initially perform 2 years of vessel reactor testing. After the initial testing, other reactor types such as a transpiring wall, may be installed and evaluated.

INTRODUCTION AND BACKGROUND

To support the development of a full-scale Hydrothermal Oxidation (HTO) mixed waste plant for treating U.S. Department of Energy (DOE) mixed wastes, a 189 liters per hour (lph) (50 gallons per hour [gph]) HTO test bed has been designed and is planned to be constructed at the Idaho National Engineering Laboratory (INEL). The test bed has been designed so several different HTO reactors and associated components may be tested. The first reactor planned for testing is a vessel reactor. The test bed will be located in an existing building, the Water Reactor Research Test Facility (WRRTF), located at the north end of the 890 square mile INEL. During FY-95 procurement of long lead materials will begin, and construction will start in early FY-96 with start up planned for mid to late FY-96. The DOE is currently storing a large volume of organic wastes mixed with radioactive constituents (mixed waste). Various methods are being explored to reduce the volume of wastes being stored to protect the environment, and to reduce costs. HTO may be a technology that can be employed to effectively and economically destroy organic compounds in certain mixed waste streams that include hydrocarbons, Polychlorinated Biphenyls (PCB's), fuels, lubricating oils, solvents, and paints.

HTO involves heating and pressurizing water above the critical temperature of 374C (705F) and critical pressure of 2.21 x 107 Pascals (Pa) (3,208 pounds per square inch [psi]). This condition is referred to as supercritical. Water above the critical point does not boil or condense when heat is added or removed, rather it undergoes a continuous change in density. When water is above the critical point, the solvating characteristics change significantly. The bonding force between

hydrogen and oxygen atoms is also reduced resulting in increased mobility of the hydrogen atom and, therefore, reduced molecular polarity. Because of this change, many organic compounds that are only somewhat soluble in water at subcritical conditions become highly soluble in supercritical water. When water loses its normal polar behavior, many ionic salts are less soluble than under standard conditions. As a result, many salts in aqueous solution precipitate out of solution as the critical temperature of water is neared. This property is useful because a large portion of metals present in a waste stream can be removed as oxides or precipitated salt. Another important feature of the technology is that gases can be added to supercritical water in all proportions, and specifically, oxygen can be added to a supercritical water and organic waste mixture in sufficient quantities to ensure complete oxidation of the organics. When oxidation is complete, complex organic wastes are transformed into carbon dioxide, water, nitrogen, or other innocuous compounds.

There are several key advantages for using HTO as a means to destroy organic wastes. First, the HTO process destroys organic wastes by converting them into harmless substances such as water, nitrogen, or other nonhazardous chemical compounds. Second, emissions from the HTO process are completely controlled and can be sampled and tested before discharge and, if required, can be further treated to ensure safe emission to the environment. Most of the gaseous emissions from a HTO process are carbon dioxide, excess oxygen, nitrogen, and small amounts of oxides. Third, and the most pronounced advantage of the process is the reduction of volume of liquid wastes. Especially in the case of mixed wastes, the HTO process will destroy the organic constituents and separate the water leaving only a small fraction of the original volume of the waste radioactively contaminated. This concentration of dilute waste streams will help with the final disposal of the residue by means of vitrification, encapsulation, or other methods. A final advantage of the process is the potential for thermal energy, electrical energy, and clean water as process byproducts.

Technical challenges in using HTO technology include the generation of severely corrosive acids during the oxidation process. Developing materials for use in HTO process systems which resist the effects of corrosion over the long term, has been difficult. To combat the effects of corrosion, a neutralizing agent is often added to the process. The addition of the neutralizer forms salts that precipitate near the critical point of water and tend to deposit on the interior of process equipment. The deposition is often well adhered to equipment surfaces, difficult to remove, and requires frequent cleaning. If not removed from the process equipment, deposition will impede system performance. Finally, control of HTO systems is complicated by wide and varying operating ranges.

The HTO process is illustrated in Fig. 1. A mixture of waste and water is pressurized, heated, and injected into the reactor. Water, also pressurized and heated to supercritcal temperature and pressure, is injected into the reactor. Oxygen at ambient temperature and pressure is injected and mixed with the water and waste. The oxidation process occurs inside the reactor. The reacted fluid exits the reactor where it is cooled, and the pressure and temperature are reduced. The gas is then separated and released to the atmosphere (after appropriate filtering and monitoring). The effluent is further cooled, depressurized, and the solids separated. The water from the effluent can be either recycled or discharged to an evaporation pond.

Fig. 1.

OBJECTIVES

The primary objective of the HTO test bed is to provide the capability for testing and evaluating reactors and HTO system components and to determine the applicability of the test bed in treating mixed wastes. Primary evaluation criteria include demonstrating that effective Destruction/Removal Efficiency (DRE) rates of at least 99.99% can be achieved for the organic portion of mixed wastes, eliminating or mitigating corrosion and deposition, and operating a facility that demonstrates reasonable longevity and safe operation. To accomplish these objectives it was proposed that the test bed be built so several different reactor types can be installed, tested, and evaluated to determine which configuration best meets the stated goals. Reactors that could be tested include a transpiring wall, tubular, and vessel. Initially, a vessel reactor will be designed and installed in the test bed, with plans to design, build, install, and test other reactor types in later years.

The vessel reactor appears at this time to have the most promise to obtain the DRE rates while limiting deposition and corrosion for DOE mixed wastes.
Long-range objectives of the proposed testing program are to prove that HTO technology is both a technically and economically feasible approach for eliminating DOE hazardous and mixed wastes.
DESCRIPTION OF TEST BED AND REACTOR DESIGN*
The following is a description of the HTO process design. Definitions of key terms follow:
Waste Constituents-Undiluted materials such as salts, hydrocarbons, heavy metals, and chlorides.
Waste-Simulated waste constituents such as salts, hydrocarbons, heavy metals, chlorides, and deionized water.
Deionized Water (or "Water")-Water with ions of dissolved salts removed.
Reactor Mixing Water-Heated deionized water mixed with the waste.
Cooling Water-Deionized water that is added to cool the reacted fluid after oxidation.
Vessel Makeup Water--Deionized water heated and added to the vessel brine pool.
Gaseous Oxygen-(GOX)GOX added to the process to provide adequate oxidation of organic material in the waste.
Supplemental Fuel-Hydrocarbon-based fuel added to wastes to provide adequate BTUcontent for oxidation, or used to heat up the reactor during startup.
Neutralizing Agent-Chemical that neutralizes acids in the reactor effluent.
Reacted Fluid-Liquid and gas that remains after oxidation, is not entrained in the brine pool, and has not been cooled.
Reactor Effluent--Liquid and gas that remain after oxidation, is not entrained in the brine pool, and has been cooled.
Brine-A mixture of injected vessel makeup water and salts (generated after the neutralizing agent reacts) that collects in the bottom of the vessel reactor. Brine may also contain small amounts of metals, corrosion products, or other solids.
The test bed is designed to handle 189 lph (50 gph) of waste and reactor mixing water, will run continuously for up to 100 hours (most testing will be from 10 to 20 hours), and has a design life of 5 years. Figure 2 illustrates the HTO process.
Fig. 2.
Demineralized Water Supply
The demineralized water supply consists of a 11,355 liter (3,000 gallon) storage tank, a mixed bed resin designed to strip free ions of salt and mineral contaminants from a raw water supply source, and acid and caustic are used to regenerate the resin. The conductivity (resistivity) of the effluent is monitored to control water quality. The demineralized water is of a purity satisfactory for use in the HTO process. The system is capable of supplying 45.4 liters per minute (lpm) (12 gallons per minute [gpm]) of water (although greater maximum flows are available because of the storage capacity). The feed line from the demineralized storage tank supplies two booster pumps. One pump supplies water to the waste mixing tanks at a rate of 189 lpm (50 gpm), 1.03 x 106 Pa (150 psi), and ambient temperature. The other booster feeds a variable speed high-pressure pump that delivers reactor mixing water at 189 lpm (50 gpm), and 2.41 x 107 Pa (3,500 psi). After passing through a direct current electric heater, the temperatures of the water from the booster pump is 593C (1,100F), and the water is injected into the reactor. A branch line from the booster feeds a cooling water pump that operates at 2.41 x 107 Pa (3,500 psi) and supplies 22 lpm (6 gpm) of water at ambient temperature. After the water exits the cooling water pump, the line branches again. One branch passes through a heater at 200C (418F) to supply makeup water to the reactor brine pool. The other branch is used for cooling water to reduce the temperature of the reacted fluid after it leaves the reactor.
Waste Mixing and Delivery
Waste mixing is achieved by flowing demineralized water into two 22,171 liter (600 gallon) waste mixing tanks. Waste constituents are measured and poured manually into the tanks or fed by small metering pumps. The concentration of waste constituents in the water will vary depending on the specific test to be conducted; however, the maximum concentration of waste constituents with respect to the waste and reactor mixing water is 5 to 10% by weight. A paddle type mixer is supplied with each mixing tank to homogenize the waste. Two mixing tanks are provided because as waste is being mixed in one tank, the other tank can be used to feed the reactor. Waste is

fed from the tanks to a high-pressure variable speed pump, which operates at 2.41 x 107 Pa (3,500 psi). Just before the waste enters the pump, supplemental fuel, such as methanol, may be added to the waste. The supplemental fuel is added in varying quantities depending on the waste to ensure the BTU content of the waste is sufficient to initiate and sustain oxidation inside the reactor. After the waste is pressurized, it passes through a direct current electric heater that elevates the temperature of the waste to a maximum of 300C (598F) (the amount of heat added to the waste stream varies depending on the BTU content of the waste). A neutralizing agent is also added to the waste in varying quantities depending on the simulated waste. The waste stream is then injected into the reactor.

Oxygen Supply

Because of the volume of GOX required to support the test bed, and for reasons of economy and convenience, a storage tank is used to store liquid oxygen (LOX) and a vaporizer converts it to GOX. The LOX storage tank is 22,710 liter (6,000 gal) capacity. The LOX is drawn out of the storage tank by a high-pressure pump 3.1 x 107 Pa (4,500 psi) and is then vaporized. The temperature of GOX is ambient as it enters the reactor. Flow rates into the reactor vary from .142 to 1.98 cubic meters per minute (5 to 70 standard cubic feet per minute [scfm]) depending on the specific type of waste being tested. A maximum stoichiometric ratio of 3:1 can be achieved to ensure complete combustion of organics (the normal stoichiometric ratio is expected to be 1.5:1 or less).

Vessel Reactor and Cooling

Figure 3 shows the process that occurs inside the reactor during HTO. The waste, water, and GOX are connected to a header at the top of the reactor. Each line is routed separately through the header, and mixing of the water, waste, and GOX occurs in the reactor nozzle as shown in Fig. 3. As the oxidation process proceeds, the neutralizing agent combines with chlorides and salt is formed. The temperature at the reaction is approximately 600 to 800C (1,138 to 1,498F). At this temperature and pressure, the salt solidifies and complete combustion of organics with minimal residence time is likely. The salts, metals, and other solid particles drop into the brine pool. The brine pool is fed with makeup water at a temperature of 200C (418F). At this temperature, the salts redissolve in the brine pool and the volume of flow in the pool is maintained so that salt deposition on the walls of the reactor is minimal. The brine is fed to the reactor effluent discharge line, just upstream of the first stage letdown vessel. After oxidation, the reacted fluid leaves the reactor and is fed into a mixing tee or other device to reduce the temperature of the fluid to approximately 200C (418F). Cooling water is introduced into the cooling device to reduce the temperature of the reacted fluid. As the effluent leaves the cooling device, it passes through a series of orifice plates that reduce the pressure from 2.41 x 107 to 1.37 x 104 Pa (3,500 to 2,000 psi). The effluent then passes through a control valve that further reduces the pressure to 6.89 x 106 Pa (1,000 psi). The control valve receives input from a pressure indicator located on the upstream side of the cooling device. The effluent is then ready to enter the first stage let down vessel.

Pressure Let Down

Once past the control valve located on the downstream side of the reacted fluid cooling device, the reactor effluent enters a first stage let down vessel. As fluid enters, there is some flashing and gas separation. During this first stage letdown approximately 90% of the oxygen and 50% of the CO2 and liquid separate (these are the two primary gases entrained in the fluid; there are trace amounts of other gases). The gas exits the vessel and is routed through the filtering and emission control system. The volume of liquid in the vessel is maintained at about half the vessel volume. The liquid is discharged from the vessel and passes through a series of orifice plates to reduce the pressure from 6. 89 x 106 to 4.82 x 106 Pa (1,000 to 700 psi). A control valve linked with a level controller on the vessel helps maintain a constant level within the vessel and further reduces the pressure from 4.82 x 106 to 4.83 x 105 Pa (700 to 70 psi). The liquid then enters the second stage let down vessel. A manifold located inside of the vessel sprays the liquid onto the vessel walls and helps liberate the remaining gas from the liquid. After separation, the remaining gas is routed to the emission control and filtering system. A control valve on the discharge line and a pressure controller on the vessel help to maintain a constant pressure and volume of gas inside the vessel. The liquid occupies about half the vessel volume and is discharged from the vessel to a heat exchanger. The

heat exchanger reduces the temperature of the liquid from 149C to about 38C (300 to 100F). A control valve on the discharge side of the heat exchanger is linked with a level controller on the vessel to regulate the level of fluid inside the vessel. Fig. 3.

Gas Filtering and Emission

As the gas is discharged from the first stage let down vessel, it is reduced in pressure through a series of orifice plates and then travels through a control valve. The control valve is linked with a pressure indicator located on the upstream side of the orifice plates. The control valve controls the pressure (and therefore the flow) of gas through the line. The flow of gas from the second stage let down vessel tees into the line from the first stage letdown vessel. The gas is then routed through a series of charcoal filters designed to remove trace amounts of wastes that may be present in the gas stream. The gas is then discharged to atmosphere. The quantity of gas emitted to the atmosphere is estimated at about 145 kilograms per hour (320 lb per hour). An additional 272 kilograms per hour (600 lb per hour) of steam is released. The gas is mostly oxygen, CO_2, and trace amounts of other elements. All emissions are within regulatory guidelines.

Fluid Filtering and Evaporation

As the fluid (reactor effluent) leaves the heat exchanger, it passes through a bag filtering system. Two bag type filters are provided, but only one is used at a time, so one may be bypassed and changed out while the process continues to operate. The filters are designed to filter particles as small as 1 micron and are primarily used to remove metals and salts that may have solidified during pressure letdown. The fluid is then routed to two 11,355 liter (3,000 gal) storage tanks. The fluid is stored in these tanks, sampled, tested, and a determination is made if it can be discharged to the evaporation ponds. If certain constituents are below permit levels, then the fluid will be routed to the ponds. If the constituents are higher than permit levels, the fluid will be routed to an evaporator where it will be concentrated. The residue left in the evaporator will be collected and disposed of as hazardous waste. It is anticipated that a small volume (less than several gallons) of residue would be left after evaporation. The residue would be comprised of salts and heavy metals.

Control, Data Acquisition, and Sampling Systems

The control system will be comprised of off-the-shelf hardware and software, configured as a process data acquisition, display, control, and archival system. An operators console will be located remotely from the test bed (no personnel will be allowed near the test bed when the system is pressurized or at temperature). The control system will use the National Instruments LabVIEW application. This software is a graphically oriented user interface that allows simple user configuration of the hardware to perform acquisition and control applications. The application communicates to process interface hardware via general purpose interface bus to two remotely located cabinets. The cabinets contain low and high analog inputs, voltage and current outputs, digital I/O and serial communication interfaces fed from instrumentation located in the test bed.

The sample system includes a series of drains (on low pressure, low temperature lines) from which samples of fluid can be obtained manually. A series of sample bombs will be used to collect gas just after the effluent leaves the reactor and at other locations along the gas filtering and discharge system. A Residual Gas Analyzer (RGA) will be used to obtain on line samples from certain process streams (e.g. reactor effluent). The RGA is capable of giving nearly instantaneous feedback on the composition of samples. This information shall be used to make adjustments in the control and operation of the test bed.

PLANNED TEST PROGRAM

Initially a series of eight waste types are planned for testing in the INEL HTO test bed and vessel reactor. The test series have been selected to be representative of a wide variety of hazardous elements found in DOE mixed wastes (the test series will contain surrogates of radioactive materials but no actual radionuclides). The waste series are

Series 1. Aromatics with Mercury
Series 2. Nonchlorinated Solvents with Metals
Series 3. Paper, Cloth, and Plastic
Series 4. TRIMSOL
Series 5. Mixed Oils

Series 6. Activated Carbon
Series 7. Scintillation Fluid
Series 8. Tributyl Phosphate.
A total of 40 tests using the eight waste series are planned over a period of 2 years. Most tests will average about 10 to 20 hours in length with at least one 100-hour test planned. In addition to monitoring for DRE and deposition, other data will be collected during the testing to include information on power consumption, efficiency of various process components, erosion and corrosion of process components, material characteristic studies, temperature and pressure of certain process hardware, flowrates, consumption of neutralizing agents and supplemental fuel, and other aspects of testing that will help gain understanding of the overall process. This information will be the basis for deciding the configuration of a full scale HTO plant to be used for the destruction of hazardous and mixed wastes. A detailed testing and operations plan is currently being prepared as the basis for conducting the field testing, addressing how requirements will be met, and defining information and data to be gathered and analyzed during the testing that will be used for future design work.

RESULTS OF DETAILED CHARACTERIZATION ON CH-TRU MIXED WASTE AT ARGONNE NATIONAL LABORATORY-WEST
Carla C. Dwight
Bruce A. Jensen
David S. Duncan
Argonne National Laboratory-West
ABSTRACT
Argonne National Laboratory-West and Lockheed Idaho Technologies Company have jointly participated in the Department of Energy's (DOE) Waste Isolation Pilot Plant Experimental Test Program since 1990. A new facility at Argonne was developed to improve the effectiveness and efficiency of contact-handled transuranic mixed waste characterization and to decrease the potential for facility contamination and personnel exposures. This new facility, the Waste Characterization Area, was approved for radioactive operations in March 1994. Between April and September 1994, forty-two waste drums containing mixed debris waste were characterized to support a study being performed to evaluate volatile organic compound concentrations in the void volume headspaces of waste drums. This paper presents the results of characterization performed at Argonne, emphasizing parameters important from a facility standpoint. Specifically, information is presented on drum surface dose rate, fissile content, number and type of gas samples, volatile organic compound concentration, and facility contamination levels. Actual values are compared to enveloping conditions assumed in the safety assessment for the characterization facility. Argonne-West is one of the first DOE sites to perform detailed waste characterization under the DOE's Transuranic Waste Characterization Program. The information presented herein could aid other storage and generator sites in developing characterization procedures and facilities.
BACKGROUND
Argonne National Laboratory-West (ANL-W) and Lockheed Idaho Technologies Company (formerly EG&G Idaho) have jointly participated in the Department of Energy's (DOE) Waste Isolation Pilot Plant (WIPP) Experimental Program (1) since 1990. Detailed characterization of contact-handled transuranic (CH-TRU) mixed waste was performed on thirty-two drums of waste which were loaded into seven test bins between March 1991 and July 1993. The detailed characterization included non-destructive and destructive examinations. Non-destructive examinations were performed at the Idaho National Engineering Laboratory Stored Waste Examination Pilot Plant (SWEPP); they included real-time radiography, passive/active neutron fissile assay, and ultrasonic container integrity measurements. The destructive examinations were performed in Argonne's Hot Fuel Examination Facility (HFEF); they included collection and analysis of gas samples in most of the layers of confinement within the drum, as well as removal, categorization, measurement or estimation of various physical parameters, and repackaging of the waste contents. The description of these operations and results of characterization were presented in previous Waste Management conferences (2,3).
Since the last of the 32 drums was characterized in July 1993, a new facility within

HFEF at ANL-W has been developed to improve the effectiveness and efficiency of CH-TRU mixed waste characterization and to decrease the potential for facility contamination and personnel exposures. This new facility, the Waste Characterization Area (WCA), was approved for radioactive operations in March 1994 (4). Between April and September 1994, forty-two additional waste drums containing mixed debris waste were characterized at Argonne to support a study being performed to evaluate volatile organic compound (VOC) concentrations in the void volume headspaces of waste drums. This VOC study was conducted by EG&G Idaho to demonstrate compliance to Environmental Protection Agency requirements for drums destined for WIPP (5,6,7).

SUMMARY OF CHARACTERIZATION PROCEDURES

Following nondestructive examination of drums at the SWEPP, which includes fissile assay by passive and active neutron methods and gamma scanning, they are transported 32 kilometers to Argonne in a TRUPACT-II cask. Drums are unloaded in the HFEF truck lock and transported to the preparation room within the WCA. One drum at a time is then transferred by cart into the transfer room beneath the waste characterization chamber. The drum is raised to one of two drum ports and physically attached. After the drum is mechanically locked in place and a plastic bagging sleeve is in place, the drum port cover inside the waste characterization chamber is opened to initiate characterization operations. Prior to characterization, a number of quality control samples are collected for the gas sampling system, including field blanks, manifold blanks, and reference standards. The first gas sample collected from the drum is a drum headspace sample. The sampling needle is inserted through the filter on the drum lid before the lid is removed. Then the lid is removed and the plastic rigid liner lid is removed. A gas sample is then collected from the large drum bag. The drum bag is then opened and any inner bags which are not breached and which contain at least 100 ml of void volume are sampled. Following gas sampling, the drum contents are individually removed and various physical parameters are either measured or estimated. The waste package shapes and contents are described and then the waste is placed in a new drum which is interfaced to the other drum port. All of the characterization operations are videotaped, and a data report is written. Drums, waste packages, and chamber surfaces are smeared often during the characterization process to monitor contamination levels. Decontamination is performed often to keep the chamber as clean as practical.

RECENT CHARACTERIZATION DATA

This section summarizes characterization data obtained from 42 drums of CH-TRU debris waste. Waste code descriptions and the number of drums within each waste code are presented in Table I. Parameters presented in Table II include minimum, maximum, and average values for surface dose rate, plutonium and americium content, waste weight, number of gas samples collected by type, and contamination levels encountered. Where applicable, the corresponding maximum allowable or assumed value used in the WCA safety assessment is included for comparison. Finally, Table III lists the highest VOC concentrations measured.

CONCLUSION

Including the first 32 drums designated for the WIPP Bin Tests, Argonne has completed detailed characterization and repackaging of 74 CH-TRU, mixed, debris drums. The characterization and repackaging was performed in accordance with DOE and EPA quality assurance programs. The 42-drum campaign was completed in 22 weeks from the initial hot startup of the WCA. The drum throughput increased over this period from approximately 1 drum per week to 3 drums per week. This improvement was partly due to a change in shift length; from 8 hours per day 5 days per week, to 12 hours per day on 3 days and 8 hours on one day per week. Another factor in the improved efficiency was operator experience and proficiency, which improved as the campaign progressed. Activities in the WCA were completed without any contamination incidents. This can be attributed to the design and operational philosophy implemented at Argonne; confinement is paramount to success.

At least six major DOE sites in the United States store and/or generate CH-TRU waste. Before waste from these sites can eventually be disposed at WIPP, waste characterization must be performed. Argonne-West is one of the first DOE sites to perform detailed waste characterization under the DOE's TRU Waste Characterization Program (8). The information presented herein could aid other storage/generator sites in developing characterization procedures and facilities.

HEAT SOURCES IN HANFORD'S TANK C-106
U. von Wimmersperg
Brookhaven National Laboratory
Upton, NY 11973
ABSTRACT
A calculation of the heat generation in nuclear wastes due to the decay of cesium-137 and strontium-90, using a simple parametrization to determine the energy partition between betas and neutrinos, is applied to evaluate the missing heat in Hanford's tank C-106. The possibility is examined of accumulating stored energy in the form of lattice dislocations in solid waste layers via highly non-relativistic daughter recoils from heavy alpha emitters. This work was prompted by the observation that calculations converting beta decay activities into heat deposition within nuclear waste have in the past been based on a variety of widely varying conversion factors. In order to eliminate such unnecessary uncertainties, these factors are here calculated ab initio from fundamental principles. Use is made of a closed-form Fermi function which is capable of reproducing the shapes of beta spectra to better than one percent. Application of these results to tank C-106 confirm that 2/3 of the heat source is not accounted for by the activity measured in sludge samples. The possibility is examined that the missing heat source, comprising fission fragments as well as transuranics, may be located in hard deposits formed on the tank bottom early on in the operation history and estimates are made of the density of stored energy that might have accumulated in such solids as a result of displaced atoms.
AB INITIO CALCULATION OF HEAT GENERATION FROM 90Sr AND 137Cs DECAY
The calculation of heat generation due to weak radioactive decays requires a knowledge of energy escape via neutrino leakage. In large volumes of radioactive material the energy carried by gamma photons is absorbed, except at the surface. In the case of large waste storage tanks, the energy of gamma rays escaping from the waste surfaces is almost completely absorbed and converted to heat in the tank walls. Although heat generation from beta emitters like 90Sr and 137Cs can be determined calorimetrically, such measurements have low sensitivity. In this paper the energy loss via neutrino leakage is calculated ab initio using weak interaction theory and experimentally determined nuclear energy levels, which are known to high accuracy and are readily available from the published literature (1).
Five separate decays are taken into account in this analysis (we have neglected the 0.01% g branch in 90Y.
Eq.

The energy sharing between the b- and the neutrino can be expressed in a simple parametrization (2), which is more than adequate for a 1% calculation. In terms of the ratio K of the kinetic to rest energy, the b- distribution can be written:
Eq.
where * corresponds to zero neutrino energy and z Zh c/e2
with Z being the daughter nuclear charge. The parameter ki represents shape-factor sealing and takes the following values:
Eq.
Eq.
The value of k2 for the 5.4% branch in the decay of 137Cs has been determined experimentally (3). Numerical integration yields the neutrino energy leakage fractions for the various transitions:
Expressing ground-state and excited-state transitions by subscripts 0 and 1 respectively, we get the following:
Eq.
where b denotes the branching ratio.
The energy deposited as heat for each decay is (in units of the electron rest mass):
Eq.
Taking the electron rest mass as 0.511 MeV we get:
Eq.
The above particle decay heats are equivalent to:
Eq.
We estimate these heat conversion factors to be accurate to better than one percent, based on the knowledge of energy levels and the parametrization of the beta spectra involved. Comparison with the factors (4) applied, for example, to Hanford's tank SY-101, shows the following discrepancy:
Eq.
APPLICATION EXAMPLE:
We now consider some possible implications of discrepancies between measured heat generation and the concentration of radionuclides in Hanford's tank C-106.
In tank 106-C only one third of the thermodynamically calculated heat source term is accounted for by the radioactivity present in sludge samples (see WHC-SD-WM-PSE-010, Rev. 0):
Eq.
We test here the assumption that the missing heat source term Q3 = Q1 - Q2 = 20.6 kW may be due to the a-decay of plutonium in heavy metal waste residues left on the tank floor (see WHC-SD-W320-ANAL-001, Vol II, Rev. 0). Taking the average a-particle energy from plutonium decay to be 5.156 MeV we get a daughter nucleus recoil energy per atomic mass unit: 373 Ev/amu.
These recoils are thus highly non-relativistic since b = 2.8 x 10-4, so that energy dissipation via lattice dislocations is strongly favored. We assume, as a bounding extreme, that the entire daughter recoil energy is stored as atomic displacement energy. The contribution from a-particle stopping is neglected. Now we have stored power: Eq.
and stored energy since 1947 ES = QSt = 0.52 TJ.
Taking the latent heat of vaporization of water to be LV = 4.07 x 104 J/mol, the release of stored energy ES would be able to generate a volume of steam:
Eq.
If we take the heel thickness to be 30 cm then the volume of the solid layer is calculated to be 50,000 l (WHC-SD-W320-ANAL-001, Rev. 0, p. AAtt 19-3).
This implies a stored energy density of order 10 MJ/l. If it is assumed that the specific heat of this material is similar to Cp for bismuth, the release of ES as a result of the dissolution of the solid would raise the temperature by:
Eq.
This result should, of course, be seen in perspective. First, it should be noted that a heat generation discrepancy by a factor of order 3 would be apparent using older conversion factors. Nevertheless, we consider it desirable to base such calculations on the most accurate parameters available. Secondly, the stored lattice energy result is no more than an illustration of the upper limit in the magnitude of such an effect. The assumption that the missing heat is entirely due to plutonium is not credible; rather it is expected that fission products would be responsible for the bulk of any heat generation found in the heel layer. It is, however, prudent to consider potential hazards associated with the dissolution of solids that have the

capability to accumulate radiation induced lattice energy.

ACHIEVEMENT OF PROCESS CONTROL, SAFETY, AND REGULATORY COMPLIANCE IN A MIXED WASTE EVAPORATOR SYSTEM AT THE HANFORD SITE
USING DATA QUALITY OBJECTIVES
Brian H. Von Bargen
Westinghouse Hanford Company
Kenneth S. Redus
Jennifer A. Sheriff
MAC Technical Services
ABSTRACT
The Data Quality Objectives (DQO) Process was applied to the operation of the 242-A Evaporator at the Hanford Site. A team consisting of representatives from process engineering, environmental engineering, regulatory compliance, analytical laboratories, and DOE utilized the step by step DQO process to define the issues, variables, and inputs necessary to develop the decision rules which govern plant operations. The sampling and analyses required to make these decisions was then optimized concerning factors such as sample number, total analyses, cost, radiation exposure, quality assurance, and deliverables.
PROCESS DESCRIPTION
The 242-A Evaporator process (see Fig. 1) employs a conventional forced circulation, vacuum evaporation system designed to concentrate mixed waste solutions. Candidate waste feed tanks are characterized, then pumped to the Evaporator feed tank. This feed stream is then separated into three process streams: concentrated slurry, process condensate, and a gaseous process exhaust stream. Two non-hazardous effluent streams, steam condensate and cooling water, are also produced and discharged to an evaporative pond.
The concentrated bottoms, or slurry, contains the majority of the radionuclides and inorganic constituents. This stream is recycled back through the plant until it is concentrated to target levels, then is pumped to double shell tanks to be stored for further treatment. The condensed boiloff, or process condensate, contains primarily water as well as trace organic material and a greatly reduced concentration of radionuclides. This stream is stored at the Liquid Effluent Retention Facility awaiting treatment capacity in the Effluent Treatment Facility. The process exhaust, or vessel vent stream, consisting primarily of non-condensible gasses drawn from the condenser system, is filtered and discharged through an exhaust stack. The Evaporator process is continuous with typical feed flow rates of 303 L/min (80 gal/min) to 454 L/min (120 gal/min) resulting in process condensate flow rates from 114 L/min (30 gal/min) to 227 L/min (60 gal/min).
Fig. 1.
PROBLEM STATEMENT
The primary goal of the Evaporator program is to operate the facility for the purpose of reducing the volume of mixed waste received and stored in the underground tank system. In today's environment, the requirements to achieve that primary goal have become considerable and complex. The Data Quality Objective Process, as applied to the Evaporator program, was used in the planning and design of data collection activities in order to support the decisions related to the successful operation of the Evaporator facility. Successful operation is defined as meeting the campaign objectives while operating within established requirements.
DECISION VARIABLES
Each subsystem of the facility was evaluated with respect to three issues, process control, safety, and environmental compliance, to identify data requirements for each of the process streams. Process control issues are those that are directly related to maintaining the Evaporator system within acceptable process parameters; safety issues are related to operation of the plant within acceptable safety parameters; and environmental compliance to those parameters defined by federal,

state, and local regulations.
The primary issues were further subdivided into secondary issues in order to adequately address specific requirements for each of the process streams (see Table I).
TABLE Ia
TABLE I, cont'd
DECISION LOGIC
A decision rule integrates a particular parameter of interest to its action level into a single statement that describes a logical basis for choosing among alternative actions. For the Evaporator process, the decision components were divided into the various streams to address each of the parameters of interest. The decision process for all of the process streams was portrayed graphically in a set of decision logics (see Fig. 2 for an example of a decision logic diagram). This compilation of rules into a single controlling document, the Evaporator DQO Document (2), is a major advantage to engineering personnel in planning the processing campaigns. Prior to the DQO Process, the requirements for plant operations were contained in many different documents, often without basis and in many cases incompatible with one another. These problems have been corrected through utilization of the DQO Process.
Fig. 2.
DQO IMPLEMENTATION DOCUMENTATION
Many organizations support the Evaporator program and have varying areas of concern. The Evaporator DQO document forms the basis for all of the implementation documents. These lower level documents contain the details of the analyses, sampling requirements, and specific decisions that are necessary to support the operation of the 242-A Evaporator. The documents used by supporting organizations are as follows:
Tank Characterization Plan - Provides sampling and analysis requirements for candidate Evaporator feed solutions. The data is used to evaluate process control, safety, and compliance decisions prior to plant operations.
Waste Analysis Plan - Provides sampling and analysis requirements for Evaporator streams subject to Resource Conservation and Recovery Act (RCRA) requirements.
Quality Assurance Project Plan - Provides the Quality Assurance and Quality Control necessary for sampling and analysis of Evaporator streams listed in the Waste Analysis Plan.
Process Control Plan - Provides a systematic evaluation of each decision rule in the DQO (prior to starting plant operations) resulting in a control strategy for a discrete Evaporator campaign.
Facility Sample Schedule - Provides sampling and analysis requirements for process control and safety decisions while the Evaporator is operating.
CONCLUSIONS
The application of the DQO process at the 242-A Evaporator has proven to be a very successful venture. The implementation of the DQO has resulted in focused decision-making, better management control as well as savings in sampling and analysis. Table II illustrates in detail the major benefits of implementing the DQO Process.

REMOVAL OF REGULATED ORGANIC COMPOUNDS FROM A TARLIKE MIXED-WASTE MATRIX
S. Amrit, P.E.
B. Kapoor
R. Foster
E. Newberry
M. Jocelyn
Bechtel National, Inc.
Oak Ridge, TN
ABSTRACT

Closure of a Department of Energy low-level radioactive waste facility under the Resource Conservation and Recovery Act resulted in the generation of mixed-waste sludge. This material had the consistency of tar and contained extractable organic halides (EOX) and volatile organic compounds (VOCs) in concentrations above regulatory criteria. Typical examples of EOX compounds are carbon tetrachloride; chloroform; 1,4-dichlorobenzene; and vinyl chloride. These organic compounds in the feed material were treated using a combination of technologies. The objective of this treatment was to meet the toxicity characteristic leaching procedure regulatory levels, land disposal restrictions criteria, and the waste acceptance criteria for a commercial land disposal facility.

The initial EOX concentration in the waste feed was 6,880 ppm. The initial VOC concentration, primarily tetrachloroethene (PCE), was in the order of magnitude of 1,000 ppm. A total quantity of approximately 110 kg of mixed-waste sludge was oxidized using concentrated nitric acid. Two small batches (1 kg each) were processed concurrently because of the tarlike consistency of the feed material, the exothermicity of the oxidation reaction, and the limited amount of waste.

In the oxidized product, the EOX concentration was reduced to 756 ppm, and the VOC concentration, primarily PCE, was reduced to 150 ppm. The efficiency of the oxidation process in removing the EOX and VOCs, primarily PCE, was approximately 53 percent and 36 percent, respectively; EOX and VOC (primarily PCE) concentrations in the oxidized product were adjusted for product mass increase. The pH of the oxidized product was less than 2.0 because of unreacted acid in the product matrix.

The acid remaining in the oxidized product was neutralized with concentrated sodium hydroxide solution. The purpose of the neutralization process was to raise the pH. It was noted from visual observation, analytical data, and thermodynamic data that the exothermicity of the neutralization process helped "steam-strip" the remaining EOX and VOCs. In this oxidized, steam-stripped product, the concentration of EOX was further reduced to 366 ppm, and the VOC concentration, specifically PCE, was reduced to 8.4 ppm (estimated value). The efficiency of the steam-stripping process in removing PCE was approximately 92 percent (adjusted for product mass increase). The final treated product had a matrix of low viscosity and was amenable to solidification with portland cement. The solidified product met all the above-mentioned standards for land disposal.

BACKGROUND

During the closure of the Colonie Interim Storage Site (CISS), a Department of Energy (DOE) facility in Colonie, New York, radioactively contaminated sludge waste was treated for disposal. This waste was regulated under the Resource Conservation and Recovery Act (RCRA).

The sludge had a component of tarlike consistency that contained extractable organic halides (EOX) and volatile organic compounds (VOCs) at concentrations above regulatory levels (1,2). EOX is essentially the same as halogenated organic compounds, which are analyzed following an extraction method. A thermal treatment process was used in an effort to desorb the VOCs and EOX from the sludge matrix. However, heating the sludge to a temperature of 393-423K caused the tarlike component in the sludge to become wet, sticky, and oily, consequently hindering the desorption process. As a result, the thermal treatment approach was unsuccessful in meeting treatment standards. The tarlike component was separated from the sludge; the subsequent removal of organic compounds from this component of the sludge using a two-phased treatment approach is the subject of this paper.

The mixed-waste sludge was listed under RCRA as F001, F007, F008, and F009 waste. The regulatory guidelines governing the treatment goals are the toxicity characteristic leaching procedure (TCLP) regulatory levels, land disposal restrictions (LDRs), and the waste acceptance criteria (WAC) for a commercial land disposal facility. The treatment standards are reported in later sections of this paper.

The site is a facility primarily contaminated with low-level radioactive waste (LLRW) and is being prepared for decommissioning. Because of radiological controls, waste treatment had to be performed within the facility. Considering the limited quantity of the waste to be treated, it was not cost-effective to procure a ready-made system. Therefore, equipment was fabricated onsite, and a system was set up to treat the waste.

TREATMENT METHODOLOGY

A two-phased treatment methodology was designed to treat the EOX and VOCs in the

waste matrix:
Phase 1: Nitric acid (67 percent by weight) was used as the oxidizing agent to remove EOX and VOCs, primarily tetrachloroethene (PCE), from the waste feed. This process was effective in breaking up the tarlike consistency of the material, in removing approximately 53 percent of the initial EOX content, and in meeting the treatment standards for EOX. Approximately 36 percent of the initial VOC content (primarily PCE) was removed from the waste matrix. The primary VOC, PCE, may have been broken down into its oxidation by-products, but it was probably not desorbed because the temperature attained by the reactants was 377K, which is lower than 394K, the boiling point of PCE.
Phase 2: The unreacted acid in Phase 1 was neutralized using sodium hydroxide solution (50 percent by weight). The exothermic neutralization process and consequent steam generation caused the removal of 92 percent of the Phase 1 residual VOC content, primarily PCE. It also further reduced the EOX concentration.
It is postulated that the removal of organic compounds (EOX and VOCs) resulted from the decomposition or steam-stripping of the compounds. Steam-stripping is considered to be the primary mechanism in the removal of organic compounds, primarily PCE, because of the copious amounts of steam generated as a product of the neutralization process.
PHASE 1: OXIDATION
Nitric acid was used as the oxidant to break down the EOX and VOCs. Typical examples of EOX compounds are carbon tetrachloride; chloroform; 1,4-dichlorobenzene; and vinyl chloride. A specific oxidation reaction mechanism could not be established because of the variety of halogenated organic compounds in the waste matrix. The effluent gas composition indicated that nitric acid helped fragment the organic compounds into smaller molecules.
Process Setup, Operation, and Maintenance
The initial EOX and PCE concentrations of the waste feed were 6,880 ppm and in the order of 1,000 ppm, respectively. Approximately 110 kg of mixed-waste sludge was treated. Because of the tarlike consistency of the feed material, the exothermicity of the oxidation reaction, and the limited quantity of waste, the amount of waste to be treated was limited to 1 kg for each batch.
Two 1-gal (3.8 10-3 m3) reactor vessels were placed in the work area under the fume hood. Each reactor was sealed with a lid that had an effluent gas emission port, pressure vent, dial thermometer port, and nitric acid dispensing port. Each mixer was connected to a "knockout" drum, an alkaline scrubber, and an activated carbon drum, all connected in series. The outlet from the activated carbon drum was connected to a vacuum pump and finally to the high-efficiency particulate air (HEPA) system. Fig. 1 shows the system setup for the oxidation process.
Fig. 1.
The knockout drum was a 55-gal (0.2-m3), 17C drum. A cooling jacket constructed around the drum consisted of an overpack filled with blue ice. The knockout drum was cooled to condense the steam generated by the process and minimize the flow of steam to the subsequent units. Entry of steam into the scrubber could dilute the scrubber liquid.
A 55-gal (0.2-m3) drum containing 40 gal (0.15 m3) of 35 percent sodium hydroxide solution served as the alkaline scrubber unit. A diffuser was fabricated and installed at the bottom of the unit to sparge effluent gas into the scrubber liquid at a rate that was sufficient to scrub the gas. The diffuser frame was fabricated from 1.3 10-2-m diam, 0.3-m-long polyvinyl chloride pipes joined in a square configuration. The gas inlet was fabricated on the side using a "T" connector. Twenty-four diffuser holes (0.0625-in. or 1.6 10-3-m diam) were drilled on each of the other three sides. The holes faced the bottom of the drum so that the effluent gas bubbles would have a longer contact time with the scrubber liquid. A metal rod (anchor) tied diagonally to the diffuser frame weighed it down and kept it from floating. These design details of the scrubber unit were determined after a series of trial runs. Additionally, stoichiometric calculations were performed to determine the specifications of effluent gas lines. Fig. 1 includes a sketch of the diffuser.
The 55-gal (0.2-m3) activated carbon drum was a vendor-supplied unit. When monitoring instruments indicated imminent breakthrough of the activated carbon, the drum was replaced.
Based on bench-scale study results, approximately 2.1 10-3 m3 of 67 percent nitric acid was required to treat 1 kg of feed material; however, 20 percent additional

nitric acid was used to ensure completion of the oxidation treatment. Therefore, approximately 2.5 10-3 m3 of nitric acid was used for 1 kg of feed material. Two batches of feed material were processed concurrently in two 1-gal (3.8 10-3 m3) mixer-reactors.
Nitric acid was dispensed slowly into each mixer-reactor through a separatory funnel while the mixer was operating. The effluent acidic gases (nitrogen dioxide, carbon dioxide, chlorine, and hydrochloric acid) were neutralized in the alkaline scrubber. The temperature was monitored closely. The completion of reaction could be determined by the stabilization of the temperature and a visual inspection of the treated product. The temperature ranged between 339 and 377K for different batches, and treatment duration for each batch was approximately 35 minutes (2,100 s). The oxidized product was transferred into a lined 55-gal (0.2-m3), 17C drum. Engineering controls were used to ensure that the entire process was conducted safely.
Engineering Controls
The work area was lined and bermed to contain any potential spills of waste or chemicals. Workers used chemical-resistant suits and gloves to handle nitric acid. The reactor drum was placed under a fume hood connected to a 9.44 m3/s HEPA vacuum system. This system vented any fugitive emissions from the immediate work area. Any gases escaping from the alkaline scrubber were also captured onto the activated carbon canister connected to a HEPA vacuum system. Class A, B, C, and D extinguishers were kept nearby.
The effluent gases that were expected to be generated during the oxidation were primarily nitrogen dioxide, chlorine, hydrochloric acid, and carbon dioxide. Generation of carbon monoxide by the reaction of hot nitrogen dioxide gas with activated carbon in the carbon adsorption unit was also possible. These gases were drawn into the units by a vacuum pump operating at a flow rate of 7.1 10-3 m3/s. Continuous monitoring of effluent gases was performed to ensure that levels in the breathing zone did not exceed health and safety limits prescribed by the National Institute for Occupational Safety and Health and the Occupational Safety and Health Administration. Additionally, organic vapor analyzer (OVA) monitoring was performed during the process operation; VOCs were not detected.
Results
The analytical results for the target organic compounds in the oxidized product are summarized in Table I. The oxidation process was successful in meeting regulatory criteria for EOX, and the efficiency in removing the EOX was approximately 53 percent (adjusted for product mass increase). The efficiency in removing the PCE during the oxidation process was approximately 36 percent (adjusted for product mass increase); the treatment standard for PCE was not met.
PHASE 2: STEAM-STRIPPING
Unreacted nitric acid (67 percent by weight) caused the pH in the oxidized product to be less than 2. To make this product amenable to final disposition, the acid had to be neutralized with a suitable alkali. Also, the heat generated during the neutralization process would help desorb the VOCs (primarily PCE). The physical, chemical, and thermodynamic properties of PCE are presented in Table II.
Reaction Chemistry
Sodium hydroxide solution (50 percent by weight) was selected for the neutralization process for the following reasons:

- Equimolar amounts of nitric acid and sodium hydroxide solution are required to effect the neutralization.
- Nitric acid and sodium hydroxide solutions are both strong electrolytes and hence generate substantial heat during neutralization. This heat, if properly distributed within the waste matrix, would help desorb the VOCs.
- Neutralization of nitric acid with sodium hydroxide can be accomplished with minimal generation of nitrogen dioxide gas.

Neutralization of nitric acid with sodium hydroxide produces an environmentally benign, water-soluble salt (sodium nitrate) and water (Reaction #1, Table III). This reaction is exothermic and generates 89.6 kJ of enthalpy for every g-mole of nitric acid neutralized. Thermodynamically, approximately 50 percent of this enthalpy is absorbed by the water in Reaction #1 (Table III) to be vaporized to steam in Reaction #2 (Table III). This steam helps in stripping the VOCs (primarily PCE) from the waste matrix.
The thermodynamic values calculated for the nitric acid-sodium hydroxide neutralization reaction are summarized in Table III.

Process Setup and Operation

The product of Phase 1 was the feed of Phase 2. The feed mass (471 kg) was made up of acid-digested sludge (133 kg) and unreacted acid (338 kg). The EOX concentration in the feed was 756 ppm, and the PCE concentration in the feed was 150 ppm.

The feed was divided into nine approximately equal volume batches. Because of the corrosivity of the feed material (pH less than 2), each batch of feed material was put into a 90-mil, high-density polyethylene (HDPE) liner, contained within a 55-gal (0.2-m3), 17C steel drum. The neutralization process was carried out in these lined drums. The batches of feed material weighed an average of 52 kg, and each batch occupied approximately one-sixth of the reaction drum. Feed batches were kept small because of the exothermicity of the reaction and consequent steam generation and to allow room for expansion of the contents during the reaction.

Sodium hydroxide solution was added at an average rate of 1.7 10-6 m3/s. The reactants were manually mixed continually with a four-blade paddle agitator. The gradual addition of alkali and the continual mixing of the reactants ensured a uniform reaction characterized by gradual generation and distribution of heat and steam. The temperature readings were taken outside the wall of the drum; the temperature was approximately 422K. Fig. 2 shows the process setup.

Fig. 2.

The reaction drum was connected to the activated carbon drum. The effluent gases from the reaction process (primarily steam and gaseous PCE) were drawn out by a vacuum pump operating at a flow rate of 7.1 10-3 m3/s. Additionally, OVA monitoring was performed during the process operation; VOCs were not detected. From qualitative industrial hygiene data, it is postulated that steam-stripping is the mechanism of VOC (PCE) desorption from the matrix. Phase 2 process parameters and a summary of the stoichiometric and thermodynamic calculations are presented in Table IV.

Result

PCE(l) + 10-3)Hrxn,T' PCE(g) + PCE (l)

(1.00 wt. fract.) (0.92 wt. fract.) (0.08 wt. fract.)

It was concluded that a substantial amount of enthalpy is generated during the acid-base neutralization process. After 50 percent loss of this heat is accounted for by conduction and radiation and with a heat transfer efficiency of 10 percent, only one one-thousandth of this heat was required to desorb about 92 percent of the PCE from this waste matrix.

Although the regulatory treatment standard for EOX was met during Phase 1, the EOX concentration was further reduced by 29 percent during Phase 2. The Phase 2 steam-stripping analytical results are summarized in Table V.

The Phase 2 treatment result for PCE (8.4 j ppm) is not the final result; the concentration of this compound was further reduced during the solidification process (see "Final Disposition").

HEALTH AND SAFETY

Before the treatment work began, a hazardous work permit was issued, and workers participated in a prejob briefing. The action level protective gear was equivalent to EPA level C (7). The respiratory protection included National Institute for Safety and Health-approved full-face respirators with GMC-H cartridges. The protective clothing included a chemical-resistant suit, hard hat, chemical-resistant gloves, and chemical-resistant boots. Additional protection included a buddy system and two-way radio communications systems. Industrial hygiene monitoring of the workers and breathing zone in the work area was conducted during the work.

Both the treatment phases were exothermic, resulting in dissipation of heat to the surroundings. Workers donning the protective clothing and working in the hot surroundings were vulnerable to heat stress. Therefore, workers were monitored for heat stress, and work assignments were rotated to alleviate this potential health effect.

FINAL DISPOSITION

The oxidized, steam-stripped product was a matrix of low viscosity that was amenable to solidification. A bench-scale test was performed using portland cement. The pH of the waste was adjusted close to 11. Approximately 25 ml (2.5 10-5 m3) of a plasticizer and 1.4 kg of portland cement were used to solidify 1 kg of the waste. The material was allowed to set at least 24 hours.

The solidified material was analyzed for isotopic uranium, thorium-232, radium-226,

total volatiles, EOX, ignitability, total cyanides, percent solids, pH, paint filter test, reactivity for cyanide and sulfide, and TCLP-total.
Based on successful completion of a bench-scale test, full-scale solidification was performed, and the solidified material was devoid of free liquid in the waste matrix. The solidification results are presented in Table VI and Table VII a, b. The solidification test results met the LDR standards, TCLP regulatory levels, and all WAC for the commercial disposal facility contracted for final disposition of the waste.

DISCUSSION

Figure 3 presents the percentages of residual organic compounds in the waste stream following Phases 1 and 2 and the final disposition.

Fig. 3.

It is reported in published literature and corroborated by the present work that destructive oxidation of organic compounds with nitric acid is energetically favorable. The oxidation of organic compounds is usually initiated by the production of organic radicals generated by dissolved nitrogen dioxide and nitric oxide in solution. The oxidation rate for nonaliphatic organic compounds is surface-area dependent and relatively fast compared to the aliphatic organic compounds (10). The removal of EOX from the subject waste matrix was achieved primarily by the nitric acid oxidation method.

Nitric acid could be regenerated in a standard air-driven acid recovery system by reoxidizing the released nitric acid, nitric oxide, and nitrogen dioxide. A small amount of waste was treated; therefore, this recovery system was not implemented in the Phase 1 treatment because this oxidant regeneration process would not have been cost-effective for this project.

Steam-stripping can be used to desorb VOCs (like PCE), which have vapor pressures in the range of 1.3 10-2 Pa to 2.4 104 Pa at 298K (11). In the past, acid-base neutralization has been used successfully to treat the corrosivity characteristic of hazardous waste. In the present case, it is postulated that the exothermicity of the neutralization process helped in making the waste matrix flowable, and the consequent generation of steam aided in stripping the VOCs (primarily PCE) from the matrix.

ACKNOWLEDGMENT

This work was successfully completed under DOE Contract DE-AC05-91OR21949.

PROCESSING OF STEAM GENERATOR CHEMICAL CLEANING SOLVENT AT THE PALO VERDE NUCLEAR STATION

Arizona Public Service Company
ABSTRACT
Arizona Public Service Company (APS) and B&W Nuclear Technologies (BWNT) recently completed chemically cleaning the steam generators at Units 2 and 3 of the Palo Verde Nuclear Generating Station. Over 1,433,000 liters of low-level radioactive solvents that were generated during these cleanings are currently being processed on-site. Chemical cleaning solutions containing high concentrations of organic chelating wastes are difficult to reduce in volume using standard technologies. Normal methods for evaporating low-level radioactive waste solutions often use high maintenance evaporators that can be costly to maintain and have heat transfer surfaces that are easily fouled. To address the volume reduction of spent, low-level radioactive, chelating-based chemical cleaning solutions, BWNT developed the ECOSAFER Liquid Volume Reduction System (LVRS).
The process being used at Palo Verde involves three distinct processing methods*:
The evaporation step uses BWNT's submerged combustion evaporator (SCE) that has been successfully used at Arkansas Nuclear One-Unit 1, Three Mile Island-Unit 1, and Oconee on similar waste.
The Synthetica DetoxifierR reduces the concentrate from the SCE to its elemental form (i.e., metals and metal oxides only) for the best possible volume reduction.
The polishing step of the distillate uses filtration and reverse osmosis (RO) technology that has been used extensively by Ontario Hydro to assist in their processing of chemical cleaning solvent.
INTRODUCTION
Due to corrosion mechanisms associated with the secondary side deposits of the Palo Verde steam generators (SGs), APS implemented a program to chemically clean Units 1, 2 and 3 steam generators. Units 2 and 3 were cleaned in early 1994 with excellent results. Early indications show that the cleaning has had a positive effect on reducing the effects of the corrosion mechanisms, and should therefore, result in a longer life for these steam generators. The Unit 1 cleaning is scheduled for April 1995.
Unfortunately, in early 1994 some of the waste solvent remaining at the completion of each cleaning was determined to be "mixed" waste, i.e., it was "low-level radioactive" waste and contained chromium (a hazardous metal) at levels just above the regulatory limit of 5 ppm. On-site interim processing successfully treated the Unit 2 waste to reduce the chromium concentration to less than 5 ppm and thus remove the solvent from the "mixed" waste classification. All remaining wastes were successfully blended to a uniform concentration of organics and metals with a chromium concentration of less than 5 ppm, in preparation for future volume reduction. The volume reduction process reduces the remaining solvents to a dry residue suitable for long-term storage as low-level radioactive waste. Planning and equipment to process the waste to be generated in April 1995 from the Unit 1 cleaning are being formalized at this time.
BACKGROUND
Unit 2
Based on previous steam generator chemical cleanings conducted in the U.S. prior to 1994, APS anticipated that the waste solvent remaining after the cleaning of Unit 2's steam generators would be low-level radioactive waste with less than 5 ppm chromium. When a portion of the actual waste solvent was analyzed to have a chromium content of approximately 10 ppm, the initial waste processing plans of volume reducing the solvent by evaporation, and then incinerating the concentrated waste needed to be modified. Current incinerator facilities can only accept low-level radioactive waste (not licensed for the treatment of hazardous or mixed waste streams).
The chromium source has since been determined to be cumulative corrosion (during the iron solvent step application) of the SGs stainless steel components. Even though the corrosion levels were minute, the surface area of stainless steel components is sufficiently large to significantly contribute to, and increase, the chromium level above the 5 ppm hazardous material classification limit.

APS evaluated options and decided to use a chromium precipitation approach implemented by an experienced vendor. This method involved blending the "mixed" waste iron solvent with the waste rinse solvent to lower the iron concentration, raising the pH with sodium hydroxide, adding large volumes of lime, adding a flocculent, filtering the solution through a filter press to remove the precipitated metals (including chromium), and then lowering the pH of the remaining solution. The lime cake containing the chromium and a portion of the iron was packaged and sent off-site for volume reduction after acceptable chromium leachability was verified using the Toxicity Characteristics Leaching Procedure (TCLP). Though the remaining solvent was verified to have chromium levels below 1 ppm, it still remained a low-level radioactive waste. Processing all the hazardous waste was completed within 60 days from the time of generation.

Unit 3

The Unit 3 steam generators were cleaned soon after Unit 2. Due to the large volume of the radioactive lime cake that was generated during the Unit 2 processing, APS immediately starting investigating more environmentally sound, economical and technically superior processes that could be used. Many potential technologies indicated that a uniform waste stream composition would be required to ensure proper and efficient operations. Based on this knowledge, APS blended the waste solvent from the Unit 3 cleaning with the waste rinse solvent from the Unit 3 cleaning. All of the resultant uniform waste from Unit 3 was verified to be less than 5 ppm chromium.

Due to the unique nature of the waste involved; requirements to minimize the final waste volume for long-term, on-site storage; and the zero-release criteria at the Palo Verde site, all potential technologies involved "first-of-a-kind" equipment or processes. APS decided to implement the process with the lowest environmental risk and the highest probability for success. The chosen technology would allow for all processing to be conducted on-site, under APS control, with no waste being shipped off-site. This technology and process would destroy the chemical organics, allow the release of the purified water to the on-site evaporation pond and result in the lowest overall dry radioactive waste volume to be stored on-site.

PROCESSING EXISTING UNIT 2 AND 3 WASTE

BWNT uses field-proven technology for the reduction of chemical cleaning waste volumes, including treating and releasing of gaseous and liquid effluents. This system volume reduces cleaning waste solvent and rinse solutions by more than 99%. The solvent waste and rinse water waste are evaporated with a Submerged Combustion Evaporator (SCE) to achieve an initial volume reduction of 70% to 90%. The distillate from the SCE undergoes filtration and then reverse osmosis to meet the required secondary side discharge limits at Palo Verde. The concentrates from the SCE are fed to a high temperature detoxifier that destroys all organics and further reduces the waste volume leaving a dry end product.

This unique approach provides a straightforward, flexible and efficient evaporation, purification and detoxification system for processing these low-level radioactive waste solutions.

The presence of chromium in the solvent adds a complexity to the processing. A test program was completed to show that the residue from the detoxifier process will result in a waste that will pass the TCLP test. No significant amount of chromium is seen in the distillate since less than 1% of the chemical constituents in the SCE carry over to the distillate.

The flow diagram for the waste processing task at Palo Verde is shown in Fig. 1. Each process is fully explained in the following sections.

Fig. 1.

Evaporation Step

All of the Palo Verde waste is first fed to the SCE. Air from a blower and propane are mixed and enter the burner tube of the SCE, which is below the level of the waste liquid. Combustion of the propane/air mixture takes place in the burner tube after ignition by an electric element. The 1 MW of heat generated leaves the burner as sensible heat in the combustion gases. The hot gases are released, under the liquid level, as a tremendous number of bubbles, creating the maximum surface area for heat transfer. Since these gases are bubbling through the waste solvent and are therefore, directly in contact with the solution, the heat is transferred immediately to the liquid. The combustion gases in transferring their heat energy, are cooled, and escape the solution at the same temperature as the liquid. The

temperature of the solution is raised to its boiling temperature and the water vapor leaves the solution, intimately mixed with the off-gases of propane combustion. Since the SCE does not have heat transfer surfaces that could become fouled during operation, it requires only minimal maintenance.

Bubbling combustion gases through a liquid lowers its boiling point. Therefore, under submerged combustion conditions, the solvent boils at a temperature appreciably below its atmospheric boiling point. For example, when burning propane with 5% excess air, the boiling point of water is approximately 89C. As the amount of excess air is increased, the boiling point decreases accordingly (1).

The waste-liquid feed to the SCE passes through a magnetic flow meter with a flow totalizer that is used to meter and control the feed to the evaporator. An operator sets the evaporator feed control valve at an equilibrium flow rate of approximately 15 liters per minute. When the evaporator concentrate reaches the desired concentration (determined by specific gravity measurement), a process valve is opened to allow pumping of the bottoms to the detoxifier system. The operator controls the evaporator level by adjusting the feed to, and/or discharge from, the evaporator. When the system reaches equilibrium, the rate of evaporator concentrate removal plus the rate of distillate production is equal to the rate of feed.

The exhaust gases from the SCE are drawn into the vent trailer. The gas stream is scrubbed with a unique narrow-gap venturi scrubber to remove particulates. These gases are cooled to remove any excess moisture and then reheated in the stack to vaporize any residual moisture and minimize fouling the HEPA filters.

Detoxification Process

The concentrated bottoms from the SCE are fed to the Synthetica Detoxifier process. The Synthetica DetoxifierR involves several steps. In the first step, the liquid organics are vaporized in a heated screw evaporator (HSE) by continuously feeding the liquid. The dry residue at the outlet of the HSE collects in a 55-gallon drum that is periodically changed. Within the HSE, the organic vapors (ie. ethylenediaminetetraacetic acid, ethylenediamine, hydrazine) are first exposed to superheated steam. In the HSE, steam reforming chemistry starts to occur at temperatures from 315 to 593oC. The steam reforming gases enter the second step (approximately 1370oC), which takes place in the Detoxification Reactor. Here, all the organics that were vaporized continue to undergo steam reformation and are converted to non-toxic synthetic vent gas (syngas) (2). The dry residue from the HSE contains the elemental metals or associated metal oxides removed from the Palo Verde steam generators and is stored in stainless steel 55-gallon drums. Testing indicates that any chromium in this state passes the TCLP test and that the final residue will fall within the Class A radioactive waste category.

Reverse Osmosis

The final major processing step is the purification of the distillate from the SCE to ensure it can be discharged to the secondary side evaporation ponds. The treatment train consists of filtration followed by single- or double-pass reverse osmosis (DPRO).

Table I shows the characteristics of the components of concern in the distillate stream that is fed to the membrane filtration system. Table II lists the effluent criteria for the final permeate stream released from the RO system to the Palo Verde evaporation pond. A volume reduction factor of 90% has been achieved using this treatment train. The remaining 10% concentrate is either fed back to the SCE or to the Detoxifier.

TABLE I

TABLE II

SUMMARY

APS is utilizing the Evaporator/Detoxifier/Reverse Osmosis system to process all waste generated from chemically cleaning all Palo Verde SGs. This process is believed to be the option that produces the least amount of long-term storage solids, is the most economical, and provides for the most environmentally sound method for dealing with the large amount of existing or future spent cleaning solvents.

CONVERSION OF ELEMENTAL AND AQUEOUS MERCURY-BEARING MIXED WASTES TO NON-HAZARDOUS FINAL WASTE FORMS

J. D. Davis
Advanced Recovery Systems, Inc.
1219 Banner Hill Road
Erwin, TN 37650

ABSTRACT

A variety of radioactively-contaminated, mercury-bearing wastes have been generated at DOE facilities. These wastes are classified as D009 characteristic and, therefore, are considered as mixed wastes. Disposal of these special wastes in a licensed radioactive landfill requires that the final waste form be non-hazardous. Advanced Recovery Systems, Inc. (ARS) has developed technology to convert a variety of mercury-bearing mixed wastes to final non-hazardous waste forms. This paper presents the results of two successful treatability studies to render mercury-bearing mixed waste as non-hazardous per requirements in 40 CFR.

The first treatability study was conducted on elemental mercury contaminated with low levels of tritium. The study successfully demonstrated the effectiveness of the amalgamation treatment process to immobilize elemental mercury to meet the RCRA treatment standard for D009 wastes. The amalgam produced in proving tests using two kilograms of elemental mercury had TCLP leach mercury concentrations averaging 0.06 mg/l, below the regulatory limit of 0.2 mg/L. Several significant findings were derived from this study. The first is that the waste mercury only comes in contact with the ultimate disposal container and does not contact processing equipment. The second is that expensive blending/mixing equipment is not required to convert the waste to a final non-hazardous waste form.

The second treatability study was performed on samples of aqueous and organic-bearing mercury solutions contaminated with trace levels of tritium. The mercury treatment process selected for this study was demonstrated as an effective treatment for the mercury-bearing solutions. Both the organic and aqueous phases of the treatability samples were treated to produce test filtrates containing 0.02 mg/L mercury and solid residues having TCLP leachate mercury concentrations averaging 0.003 mg/L. This result is nearly three orders of magnitude less than the RCRA treatment standard of 0.02 mg/L mercury in TCLP leachate. An additional finding of this work was that the final waste form was a solid, free-standing monolith with good handling and storage characteristics.

In summary, the above studies have successfully converted several different forms of mercury mixed wastes to non-hazardous waste forms that fully achieve land disposal requirements. A treatment system has been designed and is to be permitted for treating mercury bearing debris generated at a fuel production facility. This technology is applicable to other DOE mercury wastes and may have merit for mercury mixed wastes containing other hazardous metals such as cadmium, silver, and lead.

INTRODUCTION

A variety of mercury-bearing, radioactively-contaminated wastes have been generated at DOE facilities. These wastes have been classified as D009 mixed wastes. Disposal of these special wastes in a licensed radioactive landfill requires that the final waste form be nonhazardous. Advanced Recovery Systems Inc. (ARS) has developed technology for removing the hazardous characteristic of mercury from a variety of radioactive waste materials. This paper presents the results of two successful treatability studies to render D009 mixed wastes as nonhazardous per 40 CFR treatment standards.

The first study was conducted on elemental mercury contaminated with low levels of tritium. The objective of this study was to demonstrate the effectiveness of an amalgamation process for immobilizing bulk liquid mercury to meet the RCRA treatment standard for D009 wastes.

The second study was performed on mixtures of organic and aqueous solutions containing dissolved mercury and trace quantities of tritium. The objective of this study was to demonstrate the effectiveness of a chemical stabilization process for removing mercury from the waste solutions while producing a solid waste matrix meeting RCRA D009 treatment standards. This process utilizes a proprietary reagent (patent pending) which has been shown to destroy mercury complexes and stabilize the mercury in a non-leachable solid matrix.

DISCUSSION AND RESULTS

Mercury Amalgamation

Scoping Tests. Scoping Tests were performed in order to estimate the required processing parameters for treating the elemental mercury. The primary requirement of the process was to produce amalgam having TCLP leachate mercury concentrations below the 40 CFR 268.41 treatment standard of 0.2 ppm for D009 waste. In the Scoping Tests an arbitrary limit of 0.1 ppm mercury was chosen as a target to insure results were safely below the 0.2 ppm standard. Testing was performed per the requirements of 40 CFR 261, Appendix II, Method 1311 and SW-846 analytical and characterization guidelines. The parameters of the Scoping Tests were selected such that the data could be evaluated in a 23 Factorial Experimental Design Matrix. Table I details the layout of the test matrix. The three variables studied were:

TABLE I

1. Metal quantity;
2. Acid strength;
3. Acid quantity.

Table II contains the data from the Scoping Tests. Evaluation of this data in the experimental design matrix indicated the following:

1. Metal quantity was the most significant variable studied. Increasing the metal to mercury molar ratio from 3 to 10 decreased the average TCLP leachate concentration from 0.47 to 0.07 ppm.
2. Acid strength was a marginally significant variable. Increasing acid strength from 1N to 5N decreased the average TCLP leachate mercury concentration from 0.30 to 0.24 ppm.
3. Acid quantity was not a significant variable over the range studied.
4. There were no significant interactions between the variables.

Figure 1 is a visual representation of the effectiveness of amalgamation for stabilizing elemental mercury. The bars on this chart represent the average TCLP leachate mercury concentrations from the Scoping Tests and the solubility of elemental mercury in water. The solubility of elemental mercury in water was selected as an approximation of a TCLP performed on an untreated sample of liquid mercury (0:1 reagent to Hg molar ratio).

TABLE II

Fig. 1.

Proving Tests

Three Proving Tests were performed to evaluate the processing parameters established as a result of the Scoping Tests on larger samples of elemental mercury. Each test was performed using about 2000 grams of elemental mercury. In addition to TCLP evaluations, the amalgam produced in these tests was subjected to a centrifuge test to ensure that no free liquid mercury existed in the final stabilized form. The centrifuge tests consisted of centrifuging 200 gram samples of the amalgam for 30 minutes at 2000 RPM.

Table III contains the data from these tests. The first two tests, Tests 17 and 18, were simply scale-ups of the successful Scoping Tests. The final test, Test 19, was a demonstration of a proposed actual treatment process.

The data from Tests 17 and 18 demonstrated that the amalgamation process described in this report is an effective treatment for elemental mercury contaminated with radioactivity. The upper limit of the 80% confidence intervals of the TCLP leachate mercury concentrations for Tests 17 and 18 were 0.10 and 0.05 ppm respectively. These are both safely below the RCRA regulatory limit of 0.2 ppm mercury. The centrifuge tests for these amalgams produced no detectable liquid mercury. The treated material from these tests had an average pH of 6.37 (per Method 1311 TCLP protocol) and therefore do not exhibit the hazardous characteristic of corrosivity.

TABLE III

Test 19 was performed as a demonstration of a proposed treatment process. The purpose of this test was to demonstrate the production of homogeneous amalgam without the use of intrusive mixing. The basis for the test was the observation that a globule of liquid mercury would disperse as small droplets throughout the amalgamating metal with minimal mixing intensity. Addition of the acid caused an immediate reaction of the mercury and metal to produce a uniform matrix.

The reagent quantities and mixing times for Test 19 were basically the same as those used for Tests 17 and 18. The primary difference between Test 19 and the other Tests was the method of mixing. Tests 17 and 18 were mixed intrusively using an electric

mixer. Test 19 was mixed by rotating the reagents and mercury sample end-over-end in a closed 2-liter polyethylene bottle. As the bottle was rotated, the liquid mercury flowed through the bed of metal and after about 5 minutes was uniformly dispersed. Addition of the acid resulted in the production of uniform amalgam. The upper limit of the TCLP leachate mercury concentration for this material was 0.04 ppm. The centrifuge test did not produce any detectable liquid mercury.

The significance of this demonstration was the fact that amalgam can be produced without the use of intricate and expensive processing equipment. A secondary benefit from this technique is that the mercury does not contact any equipment or containers except for the container it will be ultimately disposed in. The final 2-liter package weighed about 9 kilograms. Packages of this size and weight could be easily packaged in larger containers, such as 55-gallon drums, for disposal.

Treatment of Mercury Bearing Solutions

Sample Characterization. The treatability sample consisted of five bottles of various types of mercury waste solutions. Table IV is a description of these solutions prior to characterization. The treatability sample was prepared by compositing the five bottles of waste and mixing. This produced a milky-white emulsion which was stable for about one minute. Twenty milliliters of a non-ionic surfactant were added to the sample and the solution mixed. The resulting emulsion was stable for about two hours. While in one phase, the sample was characterized for mercury content by cold-vapor atomic absorption analysis. The sample was found to contain 3965 ppm mercury.

Table IV

Scoping Tests

Scoping tests were performed to estimate the required processing parameters for treating the mercury waste using the ARS treatment process. The objectives for this study were to produce solid residues having TCLP leachate mercury concentrations below the RCRA treatment standard of 0.2 ppm for D009 wastes while producing process filtrates containing less than 0.05 ppm mercury. This was achieved by performing tests to determine the correct balance of proprietary reagent, ferrous sulfate, and basic oxide.

Table V is a summary of the tests performed for this study. The following were the significant findings resulting from the Scoping Tests:

1. Due to interference from the organic compounds contained in the waste, greater than anticipated quantities of treatment reagents were required to produce precipitates meeting TCLP requirements.
2. The waste could not be treated as one stream. Addition of the treatment reagents coalesced the waste emulsion into two phases. This could present a significant concern at full-scale processing.
3. An appropriate absorbing medium, when slurried with the separated aqueous phase, decolorized the solution and removed nearly all organic odor.
4. The separated organic phase could be treated by absorbing the liquid into an appropriate substrate and treating the resulting paste with the ARS process.
5. Sufficient pH adjustment is required in order for the pH's of the process filtrate and TCLP leachate to be greater than 9.
6. The large quantities of pH adjustment chemicals and iron sulfate required to treat this waste created a solid waste product. The quantity of sulfate compounds contained in the test precipitates would cause the residues from the test to set up as a solid mass. This created a final waste form with characteristics similar to what would be obtained by solidifying the stabilized mercury in a plaster-of-paris type compound.

Table V

Proving Tests

Two proving tests were performed to evaluate the parameters established as a result of the Scoping Tests using larger aliquots of the waste samples. Test 5 was performed using 2000 mL of the aqueous sample. Test 6 was performed using 250 mL of the organic phase. Figure 2 is a visual representation of the effectiveness of the ARS mercury stabilization treatment for treating this difficult waste stream.

The filtrate from Test 5 contained 0.02 ppm mercury and the average TCLP leachate mercury concentration was 0.02 ppm. These results were far below the RCRA regulatory limit of 0.2 ppm mercury. The final volume of solids generated from Test 5 was slightly less than 4 liters. This is only about twice the initial waste volume of 2 liters. As in Test 4, the precipitants from Test 5 set up into a solid mass.

Fig. 2.
The filtrate from Test 6 contained 0.02 ppm mercury. The mercury concentration of the TCLP leachate was 0.003 ppm. As in Test 5, these results were safely below the RCRA limit and the test precipitants solidified overnight.

CONCLUSIONS

Mercury Amalgamation

Amalgamation was demonstrated as an effective treatment for the tritium contaminated elemental mercury. Two-kilogram samples were treated to produce amalgam having TCLP leachate mercury concentrations averaging 0.06 ppm. These results were all safely below the RCRA treatment standard of 0.2 ppm for D009 wastes.

The amalgam from these tests set into solid masses with total weights of about 9 kg and volumes of about 2 liters for each 2 kg of mercury treated. The amalgam from these tests was subjected to a centrifuge test to ensure that free liquid mercury did not exist in the stabilized matrix. All samples tested passed this evaluation. The process tested did not generate any excess solutions. Such solutions, if produced, would create handling and possibly secondary treatment concerns.

Retesting of the amalgam after storage for two weeks indicated improvement in the sample matrices. The average TCLP leachate mercury concentrations for the samples retested decreased from 0.08 to 0.04 ppm.

The final two-kilogram test was a demonstration of a process for producing amalgam without the use of intrusive mixing or blending. The upper limit of the 80% confidence interval of the TCLP leachate mercury concentration for the amalgam from this test was 0.04 ppm. This is significant from the following standpoints:

1. Can work with small quantities of mercury at a time. This reduces occupational exposure concerns and reduces the potential for a large mercury spill.
2. Would not contaminate processing equipment. The mercury only comes in contact with its ultimate disposal container. Will not have to decontaminate processing equipment after completing mercury treatments.
3. Expensive blending/mixing equipment not required.

Stabilization of Mercury-Bearing Solutions

The mercury treatment process selected for this study was demonstrated as an effective treatment for the tritium contaminated mercury bearing-solutions. Both the aqueous and organic phases of the treatability samples were treated to produce test filtrates containing 0.02 ppm mercury and solid residues having TCLP leachate mercury concentrations averaging 0.003 ppm.

The treatment process was modified to include a pretreatment of test solutions with absorbing media. This was required to bind the organic constituents which were apparently re-extracting mercury out of the stabilized matrix. The absorbing media was slurried with the test solutions and ultimately became part of the final waste matrix. The use of absorbing media in this manner did not adversely affect the performance of the solids when evaluated by TCLP protocol.

Greater quantities of reagents were needed than anticipated based on the mercury content of the samples. This may have been due to interference by the organic constituents of the waste. The use of such amounts of reagents produced a larger volume of treated solids than anticipated. The volume of waste was increased from 4 liters to about 12 liters. The quantity of reagents used caused the final waste to solidify. This produced improved waste forms with favorable handling and storage characteristics.

Jorge Vernazza
Lawrence Livermore National Laboratory

ABSTRACT

This paper describes a secondary combustion chamber (SCC) for hazardous waste treatment systems that uses a plasma arc torch as the heat source. Developed under a

cooperative research and development agreement (CRADA) between Retech, Inc. and Lawrence Livermore National Laboratory (LLNL), the unit is intended primarily to handle the off-gas from a Plasma Arc Centrifugal Treatment (PACT) system. It is designed to heat the effluent gas which may contain volatile organic compounds, and maintain the gas temperature above 1000C for two seconds or more. The benefits of using a plasma arc gas heater are described in comparison to a conventional fossil fuel heated SCC. Thermal design considerations are discussed. Analysis and experimental results are presented to show the effectiveness in destroying hazardous compounds and reducing the total volume of gaseous emissions.

INTRODUCTION

The Plasma Arc Centrifugal Treatment (PACT) system uses heat from a plasma torch to treat a wide variety of hazardous waste materials. Figure 1 is a diagram of a typical PACT system. To process waste, material is fed into a sealed centrifuge where it is exposed to intense heat from a transferred-arc plasma torch. Organic materials are thermally decomposed soon after entering the primary chamber and become an effluent gas. When treating hazardous substances, this off-gas must pass through a secondary combustion chamber (SCC) to assure complete oxidation of hydrocarbons and destruction of toxic compounds. Nonvolatile inorganic materials are melted in the primary PACT chamber and reduced to a molten slag. The centrifugal motion of the refractory lined tub and the pressure of the plasma arc serve to uniformly heat and mix the material.

Fig. 1.

An oxygen lance is used to provide supplementary oxygen that gets consumed by oxidizing metals and organics. By slowing the centrifuge, molten slag is discharged through the throat region into a collection mold in the collection chamber below. The final product is a glass-like solid that easily passes toxicity characteristic leachability procedures (TCLP) and may therefore be disposed of safely.

RATIONALE FOR A PLASMA HEATED SCC

The purpose of the SCC is to ensure that all of the volatile organic and inorganic material leaving the PACT unit has been completely oxidized and effectively destroyed. To achieve destruction and removal efficiency (DRE) of 99.999% or greater for organic material, the standard design for a secondary chamber keeps the gas at 1000 C in an oxygen rich environment for at least two seconds. The conventional method to achieve this temperature is to use a combustion burner fueled by oil or natural gas. This adds a substantial amount to the gas stream. A plasma torch heated SCC is more efficient in heating gas and can provide more heat for a given volume of added gas than a fossil-fuel burner. For example, a 200-kW plasma torch operates with a typical gas flow rate of 8.5 Nm3/h. Assuming a nominal loss of 40 kW in the torch head, the plasma torch system can provide 18.8 kWh/Nm3 of process energy at temperatures above the needed 1000C. In comparison, a standard natural gas burner consuming a stoichiometric amount of oxygen derived from air, at best provides only 5.3 kWh/Nm3 for the same volume flow rate. Typically, for an equivalent heat input, a plasma torch will introduce only one eighth the gas flow added by a natural gas burner. This increased efficiency reduces the volume of the SCC as well as any downstream gas scrubbing equipment and auxiliary systems.

PACT-1.5 OFF-GAS MEASUREMENTS

To gain a better understanding of the process conditions that the SCC must contend with, we measured and analyzed the gaseous output from a representative PACT unit. Measurements were made for selected feed materials under various operating conditions. LLNL developed a diagnostic module that could be inserted into Retech's existing PACT-1.5 experimental testbed. The PACT-1.5 is a small (1.5-foot diameter) unit suitable for batch processing. The gas sampling section included thermocouples to measure gas and wall temperatures, pitot tubes to measure flow rates, and sampling lines to extract hot gases for on-line or subsequent off-line chemical and particulate analysis.

The basic feed material for all of these experiments was soil from Mendocino County, California. The composition of the soil is approximately 64% SiO_2, 15% Al_2O_3, 8% Fe_2O_3, 4% MgO, and 3% CaO, along with minor amounts of other trace elements. The total organic content in the soil was determined to be approximately one percent. The water content is estimated to be between five and ten percent. Diesel fuel was used as a representative organic contaminant material. Polyethylene (PE) and polyvinyl chloride (PVC) were added in modest quantities to the feed soil for some tests. Nitrogen was used as the primary torch gas, but helium and air were also

tested.
Figure 2 represents typical data from one series of runs. It shows the gas temperature (Tg2) rising rapidly after starting the plasma torch and increasing as the system begins to warm up. The gas temperature drops dramatically when the torch is turned off to make adjustments to control settings. The inner wall temperature (Ts4) of the gas sampling section is lower than the gas temperature and indicates the amount of heat loss through the thermal insulation as well as the inefficient convective heat transfer from the gas to the wall.
Fig. 2. Plot of data from PACT-1.5 off-gas measurements.
Figure 2 also shows the amount of gas (in scfm) introduced by the plasma torch, oxygen lance, and the pinhole camera viewport for these runs, as well as the times when gas samples were drawn into cylinders (C-x) or bags (B-x). The comb-like trace indicates when and how material was fed in using an Archimedes-screw feeder. Each spike represents one turn of the screw feeder which introduces approximately 350 g of soil containing 10% diesel fuel. For this series of runs the feed was added incrementally at a rate of one turn every minute. A sharp temperature excursion can be seen each time material is fed in, while there are slower changes in average temperature as equilibrium conditions are reached for different processing conditions.
With these experiments we were able to quantify the amount and chemical composition of gaseous effluent the SCC has to handle for typical PACT operating conditions. Table I has summary information for some of the experiments. Each column represents a different set of run conditions. It is worth noting that in four of these runs there was insufficient oxygen introduced for full combustion of all the hydrocarbons. The last column contains data from the run where enough oxygen was added for complete combustion. With an SCC there will be flexibility in adding supplemental oxygen either in the primary or the secondary chamber and adjusting the process heat source accordingly.
TABLE I
Chemical analysis of the gas samples showed good agreement with the expected gas makeup for the process conditions and gas inputs. While time-averaged gas sampling and chemical analysis can provide sufficient information to determine destruction and removal efficiency (DRE) of targeted compounds, time-resolved chemistry measurements are important in understanding the chemical kinetics and ways to optimize the SCC performance.
Calculations of kinetic chemical reactions were performed by LLNL for several gas mixtures resembling the chemical composition of the effluent gas from a PACT system treating contaminated soils. The chemical kinetics code follows a Lagrangian element (bubble of gas) in its path through a chemical reactor. This time-dependent, zero-dimensional code can calculate the chemical reactions and chemical composition for any number of chemical species. The objective of these calculations is to find the optimum conditions of temperature and residence time for the destruction and oxidation of any remaining hydrocarbons and carbon monoxide in the PACT effluent gas.
Calculations show that for a temperature of 1000 C, and an abundance of oxygen 30 % greater than the stoichiometric amount, all the hydrocarbons exiting the PACT-1.5 are oxidized below the levels currently measurable. Carbon monoxide (CO) is the most difficult compound to oxidize, especially to levels below 10 ppm. Figure 3 shows a series of curves indicating the CO abundance verses time for different gas temperatures. These calculations were run for 20 seconds. In this particular calculation the temperature was kept constant as a function of time. While higher temperatures (1200C) reduce the CO abundance quite rapidly, the final asymptotic value is relatively high. With lower temperatures (700C) the reaction takes longer to complete, but reaches a much lower final level. These results imply that a preferred temperature profile would heat the effluent gases very rapidly to 1200C and then allow the gases to cool down to 800C in two seconds while passing through the SCC. This scenario is certainly possible with a plasma arc gas heater in the secondary combustion chamber. Experiments are needed to to confirm these predictions.
Fig. 3. Calculations of kinetic chemical reactions in SCC.
SCC DESIGN CONSIDERATIONS
A prototype secondary combustion chamber was designed and constructed, and has been operational since July of 1994. Whereas the PACT unit typically employs a

transferred-arc plasma torch, the SCC uses a non-transferred-arc plasma torch. Schematic diagrams of both types of plasma torches are shown in Fig. 4. These swirl-flow, hollow-electrode plasma torches can operate with a wide variety of gases at moderate flow rates.

Fig. 4. Plasma torch types.

The basic chamber design for a plasma heated secondary chamber is a refractory lined cylinder incorporating an inner baffle to divert the gas flow. A schematic of the chamber is shown in Fig. 5. The chamber is water cooled utilizing the double jacketed steel construction. This insures all seal surfaces are maintained at or near room temperature. This type of design minimizes the possibility of leaking unprocessed off-gas from the secondary chamber, and minimizes the possibility of air leakage into the chamber. The plasma torch is also water cooled and is further protected by a surrounding layer of refractory material.

Fig. 5. Plasma-arc heated secondary combustion chamber.

Maintaining the exhaust gas stream at 1000C for two seconds requires a well insulated vessel. High temperature refractories, having melt temperatures ranging from 1500C to 2200C, are used for insulation. The insulation material and thickness was chosen to limit the heat losses but keep the inside wall temperatures below the melt rating. A temperature gradient exists along the axial direction of the inner walls because the torch preferentially heats the region nearest it.

The insulation in the SCC stores a significant amount thermal energy. A typical warm-up time was estimated to be approximately five hours based on an instantaneous temperature rise at the inside refractory wall to 1500C . Once steady state operation is reached in the SCC, the plasma torch only needs to provide enough power to heat the effluent gases from the PACT along with any supplemental oxygen, and to compensate for any heat losses. The primary heat loss is by conduction heat transfer through the insulated walls of the chamber and the jacket surrounding the water cooled torch. The exhaust gas exiting the SCC also represents a heat loss to the system. Estimates of these heat losses are given in Table II, along with the required torch power, assuming an 80% torch efficiency.

TABLE II

PRELIMINARY RESULTS WITH PROTOTYPE SCC

A series of test runs were conducted during July of 1994 in which 2500 grams of polyvinyl chloride (PVC) was fed into the PACT-1.5. Under ideal conditions, PVC (C_2H_2HCl polymer) will convert completely to carbon dioxide, water vapor, and hydrogen chloride. The expected concentrations of O_2, CO_2, H_2O and HCl were calculated based on the PVC feed rate and rates of gas flow into the PACT and SCC, assuming complete burning. Continuous emissions monitoring during these experiments recorded the quantities of these same compounds in the effluent stream before the gas scrubber.

Table III compares the calculated estimates and the measured quantities of gas concentrations when PVC is being fed into the PACT unit. The measurements during run times are in agreement with the predicted values to within a few percent. This shows that a simple analysis can be used to estimate the amount of oxygen to feed into the PACT unit for a particular waste stream. To handle waste streams with widely varying amounts of organic material, the SCC should have on-line monitoring of oxygen levels and proportional control of oxygen feed to insure conditions for complete combustion.

TABLE IIIa

TABLE IIIb

TABLE IIIc

During this same series of test runs, calorimetry measurements were taken on all the SCC cooling circuits. The readings from the SCC chamber circuit show that chamber heat losses had not reached steady state levels by the end of the run. This is as expected since the operating time for the SCC during any one of the tests was less than 80 minutes. The greatest heat loss from the SCC chamber circuit was 8 kW.

The average torch power into the SCC during this series of tests runs was 130 kW. An average of 90 kW was removed from the SCC by the torch cooling system. During these tests, the torch was fully extended into the hot center of the chamber and was not fully covered with insulating refractory material, therefore becoming a sizable heat sink. Approximately 40 kW was available to heat the off gas and chamber walls. Previous analysis had predicted that 16 to 18 kW of torch power would be needed for steady state operation. Measurements made with thermocouples placed at selected

points within the SCC showed that temperatures never exceeded 1500 C; however, it was apparent that substantially more power was being applied than was needed for steady state operation. Further testing must be done to gain operational experience and provide a thorough evaluation of the SCC performance.

SUMMARY

A plasma-arc heated secondary combustion chamber is being developed under a CRADA between Retech, Inc. and LLNL. The unit is being designed to handle the effluent gas from Retech's PACT system. Experiments have been conducted to characterize the off-gas flows from a PACT system processing contaminated soils. Design analysis shows the unit will meet the requirements of heating the effluent gas and maintaining its temperature above 1000C for two seconds. Calculations of kinetic chemical reactions are being performed to investigate optimal processing conditions. A prototype unit has been in operation since July 1994, and work is proceeding to demonstrate and validate its performance in actual processing runs as part of a PACT-2 system.

ACKNOWLEDGMENTS

The authors would like to acknowledge the contributions of Roger Richardson, John Sze, and Richard Gilliam at LLNL for their efforts in preparing and executing the first series of PACT-1.5 off-gas measurements, Russ Berger at LLNL for code development and computational analysis, and Dick Eschenbach at Retech, Inc. for expert advise and many helpful discussions.

THERMOSET MACROENCAPSULATION OF SURROGATE BERYLLIUM FINES WASTES

Andrea M. Faucette

Michael J. Serra
EG&G Rocky Flats
Linda J. Wood
Lanier County High School

ABSTRACT

Several drums of debris wastes contaminated with beryllium fines are included in the Rocky Flats mixed waste inventory. These drums contain a variety of debris wastes, including HEPA filters, a vacuum cleaner, and soft wastes such as Kimwipes and coveralls. Recovery of the beryllium fines is not feasible because the waste is co-contaminated with uranium. Moreover, the debris wastes contain very small amounts of beryllium fines and any attempt to recover these fines is likely to generate additional debris wastes contaminated with fines. As an alternative to recovery, Rocky Flats is investigating solidification of entire drums of this debris waste using an epoxy resin system.

The encapsulation system tested is a mixture of epoxy resin, curing agent, and flyash filler that has been successfully demonstrated on lead wastes at Rocky Flats. This system was selected because of its low viscosity, low peak exotherm, and relative safety (the resin does not contain RCRA hazardous components and does not have the regulatory characteristic of flammability). Other factors influencing this selection decision included toughness, durability, impact resistance, and relative ease of chemical processing.

The epoxy resin encapsulation is a viable treatment option for the beryllium contaminated debris wastes and other debris wastes in storage at Rocky Flats and elsewhere in the DOE complex. This option has several advantages over recovery of the beryllium fines, including reduced cost, reduced worker exposure, reduced complexity, and compressed treatment schedules relative to other options.

INTRODUCTION

Fifteen drums of debris wastes contaminated with beryllium fines are included in the Rocky Flats stored waste inventory. The waste was generated from production machining operations and from a research application that used a high temperature, high pressure process to form beryllium powder into a beryllium casting (1). The spilled or unused beryllium powder from this forming process is a discarded commercial chemical product and thus an EPA listed P-series hazardous waste. The beryllium fines waste stream is classified as a low level mixed waste because of uranium contamination in addition to the beryllium fines.

An examination of real-time radiography (RTR) tapes showed that the drums contain a

variety of debris wastes, including HEPA filters, a vacuum cleaner, and soft wastes such as kimwipes and coveralls. The waste is packaged in 55-gallon carbon steel drums with two polyethylene bag liners.

The EPA hazardous waste number is P015, beryllium, for these wastes. In the June 1990 Rule on Third Third scheduled wastes, the EPA promulgated "Recovery" as the "Method of Treatment" for all forms of P015 wastes (2). In the Rule, the EPA stated that "recovery is a viable and preferred treatment method in light of the high economic value of the recovered beryllium." The EPA also noted that Congress expressed a strong preference in the land disposal ban legislative history for recovery as opposed to treatment followed by disposal. The Rocky Flats beryllium waste, however, also contains uranium contamination, which greatly reduces the economic viability of recovering the beryllium. Moreover, the debris wastes contain very small amounts of beryllium fines and any attempt to recover these fines is likely to generate additional debris wastes contaminated with fines.

The beryllium fines waste meets the definition of hazardous debris as specified in the August 18, 1992 Debris Rule (3). One of the immobilization technologies that can be used as an alternative treatment standard for hazardous debris is macroencapsulation. This requires application of surface coating materials such as polymeric organics (e.g., resins and plastics) or use of a jacket of inert inorganic materials to substantially reduce surface exposure to potential leaching media. The EPA recently provided clarification by stating that using a sealed, preformed container into which the waste has been placed does not meet the definition of macroencapsulation because it would contain void spaces between the debris and container (4).

As an alternative to recovery, Rocky Flats is investigating macroencapsulation of beryllium fines debris waste using an epoxy resin system. This would remove the beryllium fines characteristic and would render the waste LDR compliant.

EXPERIMENTAL RESULTS

The encapsulation system selected for these tests was an epoxy resin/amidoamine curing agent/fly ash filler that has been successfully demonstrated on lead wastes (5). This system was selected because of its low viscosity, low peak exotherm, and relative safety (the resin does not contain RCRA hazardous components and does not have the regulatory characteristic of flammability). Other factors influencing this selection included toughness, durability, impact resistance, and relative ease of chemical processing.

Three surrogate wastes were evaluated using the epoxy thermoset system. Small scale (5-gallon) testing was performed on two surrogate wastes, a small tube-shaped vacuum cleaner with a hose and two 8" X 8" HEPA filters. After the initial success of the two small scale tests, a large scale (55 gallon) test was performed on nine 8" x 8" HEPA filters.

Small Scale Test Results

The vacuum cleaner and HEPA filters were separately bagged in polyethylene bags and taped closed. The bagged vacuum cleaner and HEPA filters were placed in separate 5-gallon metal drums with 0.100 inch thick high density polyethylene (HDPE) liners. Two type K thermocouples were placed in fluoroethylenepropylene (FEP) type sleeves with a sealed end and one thermocouple was placed inside each drum next to the surrogate waste. This allowed for temperature monitoring and thermocouple retrieval after the final cure. The thermocouple output was monitored using a strip chart recorder to identify the initial onset of the gel state as well as the peak exotherm temperature.

The epoxy resin and curing agent were mixed in a ratio of 70:30 (by weight) using a powered hand mixer. After the resin/curing agent were adequately mixed (approximately two minutes), 40% by weight fly ash filler was added to the mixture and power mixed. The epoxy charge was then poured into the drum containing the vacuum cleaner. Due to trapped air in the polyethylene bag, the vacuum cleaner and hose floated to the top of the drum. The bags were pierced, the air was vented, and the items were manually pressed to the bottom of the drum. The process was repeated for the HEPA filters; however, a metal screen was placed over the top of the filters to prevent them from floating to the top.

The curing of the castings was monitored with the thermocouples and by visual and tactile observation. The gel state commenced approximately 90 minutes after the initial mixing based on tactile and visual observations. A peak exotherm of 137C was recorded after 2.5 hours in the drum containing the vacuum cleaner. The drum

containing the HEPA filters recorded a peak exotherm of 104C approximately 2.5 hours after the initial mixing. The higher peak exotherm in the drum containing the vacuum cleaner is probably caused by the higher void volume in the drum.
After curing overnight, the encapsulated wastes were removed from their metal drums and visually examined. The waste form containing the vacuum cleaner was a hard, dark grey monolith with some cured foam on the top surface, probably resulting from the venting of excess air in the polyethylene bag. On one side of the waste form, a large crack formed where the vacuum cleaner had contacted the drum liner.
The top of the waste form containing the HEPA filters was relatively smooth, probably due to the fact the bagged HEPA filters were held in place by a screen, thus eliminating the need to vent the bag. On one side of the monolith, a very small portion of the wooden frame of one of the HEPA filters showed through the epoxy. Otherwise, no cracks or apparent weaknesses in the monolith were noted.
Several possible explanations for the crack in the waste form containing the vacuum cleaner were considered. One hypothesis was that the crack was caused by excess heat build-up due to the metal vacuum cleaner touching the drum liner. The epoxy surrounding the contact point may have cooled quicker than the epoxy at the contact point. This may have created a stress point, resulting in the crack.
An alternate explanation was that the trapped air inside the polyethylene bags expanded as the epoxy cured and contracted as the epoxy cooled. This appears less likely because the waste form containing the bagged HEPA filters did not crack. Also, the air was released from the bags soon after the epoxy charge was placed in the drum in order to keep the waste from floating.
The most probable explanation is that the crack was caused by interferences during the curing process. As the vacuum cleaner began to float to the top during the gel stage, it was manually pushed back into the container. This probably disrupted the waste matrix, resulting in the observed crack.
In order to identify the source of the crack and, therefore, eliminate it, the experiment with the vacuum cleaner was repeated with a few modifications. The vacuum cleaner was simulated using a metal cylindrical filter cartridge housing. The simulated vacuum cleaner was bagged and placed in a 5-gallon drum as before. A metal screen was placed inside the drum to keep the vacuum cleaner from floating above the epoxy. The epoxy, curing agent, and fly ash filler were mixed and poured as in the previous experiments. A peak exotherm of 149C was observed approximately three hours after the epoxy was poured.
After curing overnight, the waste form was removed from the drum and visually examined. It was light grey, very smooth on top, with no cracks or other imperfections detected on the outside.
These results support the hypothesis that the crack was caused by manual interference during the gel stage in an attempt to keep the bagged waste from floating to the top of the epoxy. This problem was effectively eliminated by the placement of the metal screen on top of the bagged waste. The theory of the crack being caused by excess heat build-up was eliminated because the second waste form containing the vacuum cleaner had a similar packing configuration, a slightly higher peak exotherm, and no crack.
Large Scale Test Results
The large scale 55-gallon drum test was conducted on nine 8" x 8" HEPA filters which were placed in three columns of three filters each, double bagged, and put into a 55-gallon standard drum containing a standard rigid drum liner (nominally 0.1 inch thick, carbon black-filled HDPE). Type K thermocouples were located in various areas of the waste, between the rigid drum liner and the inside drum wall, and on the outside surface of the drum. A 1-inch metal standoff allowed resin to flow between the bottom of the bagged HEPA filters and the inside bottom surface of the rigid liner. A metal cross was placed on top of the surrogate waste, about two inches below the top of the rigid drum liner to keep the bagged HEPA filters from floating. Approximately 25 gallons of the epoxy encapsulant was used to fill the void volume in the drum. A peak exotherm of 152C occurred approximately 5.5 hours after mixing. During the mixing of the epoxy resin, curing agent and flyash filler, a more rigorous, high shear mixer was used which provided improved mixing but also resulted in more entrained air in the mixture. As the mixture approached gelation, the additional entrained air, coupled with the relatively high surface tension of the epoxy system, resulted in excessive foam formation on the top surface of the drum. After complete cure the encapsulated monolith was removed from the drum and several

inches of closed-cell foam structure material were removed from the top surface. A "cap" charge of the epoxy system was then added to the monolith to fill in void space left by removal of the foam material.
After curing, the rigid liner was cut away and the exterior surface of the monolith was examined for excessive cracks and areas where low compressive strength foam might exist. Only one small surface crack was observed. Even though the closed-cell structure of the cured material appeared to exist several inches below the level of the epoxy "cap", the apparent compressive strength of this closed-cell material relative to the remaining areas of epoxy was adequate. In future large scale tests, a different mixing system will be evaluated to avoid excessive foam formation.
After examining the exterior surface, a small section of the monolith was cut away and removed. The section revealed a portion of one HEPA filter. The degree of encapsulation of the HEPA filter was qualitatively judged to be more than adequate to meet regulatory guidelines.
Future large scale surrogate tests will evaluate the following:

a new curing agent which has over three times the pot life of the present curing agent resulting in lower peak exotherms,

lower shear mixing system to minimize foam formation, and

an improved mechanical system to position and hold down the buoyant HEPA filters.

These evaluations will precede tests performed on low level radioactive waste drums containing debris wastes contaminated with beryllium fines.

NON-DESTRUCTIVE TESTING OF WASTE FORMS

In previous investigations, epoxy/fly ash castings of lead wastes were destructively examined by sectioning in order to determine the penetration of the epoxy into the waste material and to look for internal cracking and large voids. Although enumerated standards have not been established for macroencapsulated waste forms, researchers at Rocky Flats are pursuing methods for nondestructive testing in order to facilitate certification of the final waste forms. Of particular interest would be any crack pathways penetrating into the casting that could lead to possible escape routes for the beryllium particles. The current nondestructive method for inspection of packaged waste uses real time radiography (RTR) equipment. Drums, crates, and other containers are examined by X-ray exposure in real time. A monitor allows for direct viewing and a videotape is used to store the inspection record for future retrieval.
The small scale HEPA filter casting and the original vacuum cleaner casting with the surface crack were selected for RTR evaluation. Two very different results were obtained on these castings. The HEPA filter casting was viewed first and, under X-ray exposure, the HEPA filters were visible inside the casting. The individual metal screws used in the outer wood frame of the HEPA filter were also visible, as were the aluminum separators and filter media. No large cracks or voids were detected in the casting.
Under RTR examination, no internal features could be visually resolved in the cracked vacuum cleaner casting. The reason for this lack of X-ray resolution was the additional amount of epoxy/fly ash encapsulant present in this casting relative to the HEPA filter casting. The vacuum cleaner casting had a larger void volume than the HEPA filter casting since the vacuum cleaner occupied less volume than the HEPA filters. Therefore, there was more fly ash for the X-rays to penetrate in the vacuum cleaner casting compared to the HEPA filter casting. The fly ash composition includes some higher atomic number (Z-number) elements that act as attenuators to the transmission of X-rays through the casting. This results in poor resolution and a lack of discernible features in the X-ray image.
In spite of the mixed results with the RTR examinations, this technique is still a viable option for nondestructive testing of the thermoset castings. In the near future, RTR examination of the large scale HEPA filter casting will be performed. Depending on the outcome of these tests, other nondestructive testing techniques, such as digital radiography and computed tomography, may be evaluated.

CONCLUSIONS/RECOMMENDATIONS

The epoxy resin/curing agent/fly ash filler encapsulation system is a viable option for treating the fifteen drums of beryllium contaminated debris wastes in storage at Rocky Flats. This option has several advantages over recovery of the beryllium fines, including reduced cost, reduced worker exposure, reduced complexity, and compressed treatment schedules when compared to other options. Moreover, recovery of the beryllium fines is not feasible due to the paucity of fines in the drums and the

likelihood of generating additional beryllium contaminated debris during the recovery process.

ABSTRACT

A technology has been developed that employs new photocatalysts that have the capacity of both sequestering and converting heavy metal ions from aqueous solution to their less toxic, readily recoverable metallic forms. The technology exploits a strategy to enhance the reactivity of semiconductor photocatalysts for selected toxic compounds by derivatization of the photocatalyst surface with metal-binding ligands. Titanium dioxide (TiO2) colloids prepared from titanium chloride (TiCl4) were used as photocatalysts in the experiments. Cysteine was selected as the model derivative for the surface modification of the TiO2 nanoparticles. Testing of TiO2 photocatalysts conducted in the absence of organic compounds demonstrated that adsorption of lead ions (Pb2+) occurred in the system with either untreated (virgin) or treated (modified using cysteine) TiO2 photocatalysts. Adsorption rates of the metal ions in the systems that used treated TiO2 photocatalysts were about three times faster than those where untreated TiO2 photocatalysts were used. Lead ion concentrations in the irradiated solutions decreased as the UV irradiation time increased; greater metal removals were achieved at longer irradiation times. The rate of decreasing lead ion concentrations in the system that used treated TiO2 photocatalysts was about two to three times faster than that in the system using untreated TiO2 photocatalysts.
Experiments were also performed in which organic compounds (naphthalene or phenol) and heavy metals (Pb2+) were simultaneously treated with TiO2 photocatalysts. The presence of lead ions did not interfere with the photo-degradation of the selected organic compounds from solution. The presence of phenol compound appeared not to affect the photoreduction of lead ions, while addition of naphthalene compound resulted in a "lag-time" effect on the photoreduction of lead ions from solution. All of the experimental results showed that the cysteine-modified TiO2 resulted in faster and more effective removal than that for the untreated TiO2 system. This technique has resulted in the simultaneous photocatalytic removal/recovery of organic and inorganic compounds in the system.

INTRODUCTION

Toxic organic and inorganic contaminants in waste streams generated by chemical, metallurgical, and other industries must be destroyed or removed before the waste streams are released to the environment. Waste streams containing toxic organics and heavy metals have also been generated by DOE activities. It has been estimated (1-3)

that more than 200,000 m3 of aqueous mixed waste, contaminated with both toxic organics and metals, will have to be treated at DOE sites over the next 20 years. In the last ten years, extensive studies of photocatalytic methods for the removal of organic and inorganic contaminants from aqueous waste streams have been undertaken (4-13). Such semiconductor particles as TiO2 can act as microelectrodes that consist of cathodic and anodic parts. These materials are excellent light-harvesting materials and mediators for photochemical degradation of various environmental contaminants. The principle behind semiconductor-assisted photocatalysis involves the photoexcitation of the semiconductor with light energy greater than the semiconductor band gap, followed by generation of electron-hole pairs. The electrons and holes diffuse to the semiconductor particle surface and can be exploited for the various REDOX processes analogous to those of an electrochemical cell.

Application of semiconductor-assisted photocatalysis is primarily focused on TiO2, because it is cost-effective, non-toxic, insoluble under most conditions, and photostable. It is effective for oxidative destruction of the most resistant organic compounds, such as polychlorinated aromatics (14) or polyaromatic hydrocarbons (such as those prevalent in oil spills) (15), and for reduction of several heavy metals (Hg2+, Pt4+, Au4+ , Rh4+). The principal advantage of these systems is the potential for accumulation of charges on the particle surface, resulting in simultaneous injection of multiple charges if a suitable scavenger of the opposite charge is present on the surface. However, the reduction of toxic heavy metal ions such as Pb2+ or Cd2+ with negative REDOX potentials of the first one-electron transfer process was not reported in aqueous suspensions of TiO2.

Because the charge carriers created on an illuminated semiconductor are trapped on the surface, and the REDOX reactions occur at the solid/solution interface, the surface of the particles plays an important role in electron/hole transfer reactions and can be engineered to improve both light-harvesting and/or REDOX characteristics of a semiconductor.

It has been recently shown (16) that the modification of the particle surface of colloidal TiO2 enhances the reduction properties of conduction band electrons and enables effective removal of lead and mercury ions from aqueous solutions. These surface-modified TiO2 colloids form the basis of an engineering study whose objective is to develop an industrial process for selective heavy metal recovery and for simultaneous removal of organic and metal contaminants from aqueous waste streams.

This paper briefly describes the mechanism of lead reduction initiated by colloidal TiO2 photocatalyst, in which the particle surface has been modified by cysteine and presents the results of bench-scale engineering studies in which surface-modified TiO2 colloids have been used as photocatalysts for the combined removal of organic compounds and lead from aqueous solutions.

UNDERLYING CHEMISTRY

Unmodified and Modified TiO2 Catalysts

Electron-hole pairs generated during the illumination of TiO2 particles (Eq. (1)) can be exploited for various REDOX processes. Conduction-band electrons that have the potential of -0.3 V (vs. NHE) at pH 317 are trapped on the particle surface in about 30 picoseconds, and valence-band holes with potential of +2.9 V at pH 3 are trapped in the hundred-nanosecond range (18). As the energy levels of the surface traps lie within the band gap, the actual reduction and oxidation properties of photogenerated charges are reduced and are dependent on the REDOX potential of surface trapping sites. EPR investigations of surface trapping sites in colloidal TiO2 suggests that electrons are trapped at metal centers (Ti3+), while the holes are trapped on the surface OH groups as a (TiO2)nTi(IV)O radical intermediate (19,20).

Eq. (1)

Eq. (2)

where (TiO2)n represents bulk material.

We have found that in the presence of the tridentate ligand cysteine, the characteristic oxygen radical signal in the EPR spectrum disappears, and an axially symmetrical, lattice-defect-type EPR signal with g=2.004 is observed (21). These results suggest that cysteine is strongly bound to a colloid surface and passivates the surface states, which act as hole traps. Infrared spectroscopy results indicate that cysteine is bound to a surface Ti atom through the carboxyl group, with

formation of the corresponding salt. As oxygen is covalently linked to the lattice, it can easily accept the photogenerated hole and transfer it to a cysteine molecule. Indeed, we found that at 200K, the electron transfer process occurs, the holes are transferred from the TiO2 particle to a cysteine molecule, and a sulfur-centered radical is formed:

h+ + (TiO2)nTi(IV)-O2C-CH(NH3+)CH2SH

(TiO2)nTi(IV)-O2C-CH(NH3+)CH2S +H+ Eq. (3)

The EPR signal of the TiO2 colloid itself at 200K was not observed (21). The REDOX potential for the oxidation of cysteine into a sulfur radical intermediate requires the potential of the hole to be greater than +0.92 V vs. NHE (22). The sulfur-centered cysteine radicals most probably undergo dimerization with free cysteine molecules and form the cystine radical (RSSR-; E(RSSR-/2RS-) = +0.65 V vs. NHE) (23) at room temperature. Illumination of a cysteine-modified TiO2 colloid thus results in oxidation of cysteine molecules into cystine and accumulation of trapped electrons.

Photodeposition of Lead

Upon addition of lead ions into solutions with surface-modified TiO2 colloid, a new complex of cysteine with heavy metal was observed with IR spectroscopy. Lead ions bind with the cysteine molecule in a strong 1:1 complex (pK=11.6), in which cysteine acts as a tridentate ligand (24). IR spectroscopy of the cysteine-modified TiO2 colloid containing lead ions also suggests that lead is chelated with cysteine ligand, with only the carboxyl and mercapto groups. The carboxyl group bridges Ti and Pb ions (Ti-O-C-O-Pb), and in this way Pb becomes covalently linked to the particle surface as a continuation of the particle lattice. Illumination of this system did not result in the formation of a sulfur-centered radical at 200K, probably because the lone pair of electrons from sulfur that participate in oxidation are bound to the lead ion. However, upon increasing the temperature to room temperature for several minutes, all photogenerated electrons were scavenged by metal ions,

Eq. (4)

and the metal lead was observed to precipitate.

As the reduction of Pb2+ ions in TiO2 aqueous suspensions was not observed previously (25,26), our results suggest that surface modification of TiO2 particles with cysteine molecules is responsible for lead reduction. There are four ways that cysteine can modify the system properties that would lead to the reduction of Pb2+ ions: 1) electron accumulation, 2) strong adsorption of lead ions, 3) modification of lead ion reduction potentials after complexation, and 4) the modification of the REDOX properties of TiO2 itself. Our results indicate that all four factors are responsible for enhanced reduction properties of the TiO2 colloid.

We have found that the yield of trapped electrons is further enhanced after addition of methanol, which is an effective hole scavenger (E(CH3OH/CH2OH)= +1.2 V) (27). It has been shown previously that electrochemical oxidation of methanol results in formation of electron donating species (E(CH2OH/CH2O) = -0.95 V) (23). The large negative potential of the methanol radical induces electron injection into colloidal TiO2 with formation of surface trapped electrons:

(TiO2)n Ti(IV)-O...HOCH2 (TiO2)n Ti(III)-O + OCH2 + H+ Eq. (5)

The net effect is that from one photon, two electrons are formed, and consequently the yield of electrons is doubled. Trapped electrons in TiO2 have enough potential to reduce lead ions in two electron reduction processes. It should be noted that direct reduction of Pb2+ ions was not observed in homogeneous solutions due to the negative potential of one-electron reduction of lead ions. Direct reduction of Pb2+ by CH2OH on colloidal TiO2 was not observed.

EXPERIMENTAL SECTION

Lead acetate (Pb[C2H3O2] 2) were selected as the representative inorganic contaminant to be tested while naphthalene and phenol were chosen as the target organic compounds to be treated. All of the chemicals used in the studies were reagent grade (obtained from Fisher Scientific) and were used as received. The sample solutions were prepared fresh before conducting the experiments using laboratory deionized water. All of the experiments were conducted with a quartz reactor having a total capacity of 250 mL.

The photochemical reactor (Rayonet Model RMR-600, Branford, Conn.) used in the studies had a reactor chamber 10" in diameter and 10 1/2" high, equipped with eight UV light sources surrounding the chamber. The eight UV light sources provided a

maximum of 32 watts (four watts for each UV lamp) of UV energy at a wavelength of 254 nm to the reactor. During a typical experiment, a 50-mL sample solution containing a known amount of contaminant(s) and photocatalyst were placed in the center of the reactor chamber and irradiated for a desired period of time with the UV lights. The irradiated solutions were well stirred throughout the experiment. After irradiation, the photocatalyst and elemental metals were separated from the solution by filtration. The organic compound was analyzed by using a gas chromatograph (HP 5890 series II, Hewlett Packard, Wilmington, DE) equipped with an FID detector; the lead concentration in the solution was analyzed by using an atomic absorption (AA) spectrophotometer (model 200 A, Buck Scientific, East Norwalk, Conn.). The sample solutions were preserved in a 1% nitric acid solution (pH<2) before being analyzed.

Adsorption studies for the target contaminants were carried out in the laboratory; a shaker table (Eberbach Co., Ann Arbor, Mich.) was used to provide sufficient mixing of the sample solutions. A 30-mL vial sealed with a Teflon cap was used for each sample solution. During the experiments, the sample solutions and the vials were covered with aluminum foil to avoid any exposure to light.

RESULTS AND DISCUSSION

Adsorption Rate and Adsorption Capacity of TiO2 Photocatalyst

The adsorption rate and adsorption capacity of lead, as well as the target organic compounds, over either treated or untreated TiO2 photocatalysts were investigated before any UV irradiation had been performed. Adsorption is the first reaction that occurs when the photocatalyst is contacted with contaminants. This process is reversible, does not require light, and is very sensitive to the pH. The pH of the irradiated solutions was adjusted to about four. Changing the pH value of the solution changes the surface charge of TiO2, as well as the extent of hydrolysis and species distribution of the metal ions, and as a result the adsorption capacity of the photocatalysts to metal ions changes. It has been reported that there was no adsorption of Pb2+ ions on TiO2 photocatalyst semiconductor particles in the dark and at pH 1.4. If another chemical compound, such as naphthalene or phenol, is present in the solution, the lead ions will compete with the added chemical compound for the adsorption sites on the surface of the photocatalyst, which may result in a lower adsorption capacity for the target compound.

Adsorption equilibrium between the target compounds and the photocatalysts was assumed to be reached after 72 h of contact, although it was reported that adsorption equilibrium between pyridine and TiO2 photocatalyst could be reached within one hour of contact time (28). The adsorption capacities of the two photocatalysts appear to be linearly proportional to the lead concentrations in the liquid phase. The adsorption capacity of the treated TiO2 photocatalyst is appreciably higher than that of the untreated photocatalyst. Adsorption data on lead ions also reveal that the adsorption rate of the treated photocatalyst is much faster than that of the untreated photocatalyst. The coated cysteine compound behaves as a strong active site for capturing the dissolved metal ions in solution. The adsorption rate and adsorption capacity may have significant effects on the reaction rates of the photo-induced REDOX reactions. During a typical UV irradiation with a photocatalyst in solution, the electrons (e-) and holes (h+) formed on the surface of the photocatalyst would preferentially recombine on the surface sites in the absence of surface-adsorbed lead ions or other electron acceptors. If this happens, the lead ions have to diffuse from the bulk solution to the interface where the REDOX reaction occurs. The diffusion rate, in this case, may become a significant factor in the REDOX efficiency.

In the experiments, the initial lead concentration in solution was about 91 mg/L. After mixing with the photocatalysts, the concentration decreased to about 60 mg/L and 15 mg/L within 60 min of adsorption for untreated TiO2 and cysteine-modified TiO2, respectively. Adsorption rates of the lead ions in the system using treated TiO2 photocatalyst were about three times faster than those in that using untreated TiO2 photocatalyst. The adsorption rates of TiO2 photocatalysts (either treated or untreated) remained constant within this lead concentration range.

Photocatalytic REDOX Reaction

UV-irradiation of organic and inorganic compounds in the aqueous solution results in the oxidation/degradation of organic compounds and reduction of inorganic compounds. The disappearance of the introduced lead ion and naphthalene in the irradiated aqueous solution is represented in Figs. 1 and 2, respectively. The degradation of

phenol compound with or without the presence of lead ions is not shown here but is presented in a separate poster session. However, the phenol results are discussed below.
Fig. 1. Effect of Irradiation Time - Lead Only.
Fig. 2. Effect of Irradiation Time - Naphthalene Only.
The removal of lead ions in solution was verified from the residual lead analysis (using AA) of the irradiated solution, along with the observation of black particulates (believed to be metallic lead) generated in the solution. From an the initial concentration of about 120 mg/L, lead ion concentration slowly dropped down to about 30 mg/L with 60 min of irradiation, using the untreated TiO2 photocatalyst. In other experiments, the use of treated TiO2 photocatalyst significantly enhanced the concentration-decreasing rate, down to about 5 mg/L with 25 min of irradiation; more than 95% of dissolved lead ions were removed from the irradiated solution. The removal rate of lead ions in the system using treated TiO2 photocatalysts was about two to three times faster than that using untreated TiO2 photocatalysts.
During the UV irradiation, the lead ions were recognized to be adsorbed onto the surface of TiO2 photocatalyst and then reduced to elemental lead. However, it is uncertain how many lead ions were removed from the solution through photoreduction to their metallic form and how many were removed only by adsorption on the TiO2 photocatalysts.
Figure 2 shows that naphthalene concentration decreased with increasing irradiation time. Concentrations of less than 2 mg/L of naphthalene (initial naphthalene concentration was about 11 mg/L) were obtained within 30 min of irradiation in both cases. The difference in the degradation rate between the use of treated and untreated TiO2 photocatalysts was statistically insignificant. The introduced naphthalene may be degraded through direct adsorption of UV energy or through oxidization by the radicals generated by the excited TiO2 photocatalysts or by the photocatalysts themselves.
UV irradiation of phenol compound in aqueous solution using the two photocatalysts exhibited similar results. Initial phenol concentrations of about 100 mg/L decreased to less than 20 mg/L within 30 min of irradiation and leveled out over irradiation times of 30 to 60 min. Approximately 80% of the phenol was removed within the first 30 min of irradiation. The phenol degradation rate using treated TiO2 photocatalyst was somewhat faster than that with untreated photocatalyst. With lead ions present in the irradiated solution, the phenol degradation rate decreased slightly with the use of untreated photocatalyst in the solution, but the change was insignificant. It appeared that the phenol degradation rates were unchanged when using treated TiO2 as the photocatalyst in the experiments.
Simultaneous Removal of Lead and Organic Compounds
Experiments were also carried out in which lead ions and organic compounds (such as naphthalene and phenol) were simultaneously treated with the UV-TiO2 photocatalyst. When organic compounds, such as naphthalene and phenol are present, they may compete with lead ions for the adsorption sites on the surface of TiO2 photocatalyst during UV irradiation, resulting in a decrease in the lead removal rate, or serve as additional electron donors and enhance the photoreduction rate of lead ions. Under our experimental conditions, the removal rate of lead ion in the irradiated solution seems to have a minor effect on the existing phenol compounds. The decay in lead concentration remained unchanged in this case. However, noticeable differences were obtained when naphthalene was added to the solution. As shown in Fig. 3, the presence of naphthalene resulted in a "lag-time" effect on the photoreduction of lead from the irradiated solution. The removal rate of lead ions decreased significantly within the first 30 min of UV irradiation. In both cases (using untreated and treated TiO2 photocatalysts), the use of cysteine-modified TiO2 photocatalysts resulted in faster and more effective removal/recovery than was obtained for the untreated TiO2 system.
Fig. 3. Combined Naphthalene - Lead System - Lead Concentration.
With inorganic and organic compounds in solution in the same system, the presence of lead ions would provide additional electron-acceptors, resulting in an increased removal/degradation rate for the organic compounds. However, probably due to the low organic concentrations in the irradiated solution, the experimental results (as shown in Fig. 4) showed that the presence of lead ions had little effect on the removal/degradation of naphthalene from solution. The presence of lead ions also had an insignificant effect on the photooxidation of phenol compound. The degradation

rate remained unchanged with or without the presence of lead ions in the solution.
Fig. 4. Effect of Irradiation Time - Naphthalene only
SUMMARY AND CONCLUSION
The experimental results indicate that simultaneous removal of organic compounds (such as naphthalene and phenol) and inorganic compounds (such as lead ions) in aqueous solution can be achieved by using a UV-irradiated TiO2 photocatalyst system. The removal rates of organic and inorganic compounds can be enhanced through surface modification of the TiO2 photocatalyst using an organic substance such as cysteine. The cysteine-modified TiO2 photocatalyst, enhanced the oxidation rates of organics as well as the reduction rates of heavy metals in the irradiated solution, resulting in improved treatment efficiencies for combined organic/inorganic wastestreams. The photoreduction rate of lead ions were significantly affected by the presence of some organic compounds, such as naphthalene, but had little effect on the presence of other organic compounds such as phenol. The photodegradation rates of organic compounds were not significantly affected by the presence of metal ions.

A PORTABLE SYSTEM FOR THE TREATMENT OF WATER-REACTIVE MIXED WASTE

Jacek Dziewinski
Los Alamos National Laboratory
David Munger
Santa Fe Engineering, Ltd.

ABSTRACT

Los Alamos National Laboratory and other locations in the complex of experimental and production facilities operated by the United States Department of Energy (DOE) have generated an appreciable quantity of hazardous and radioactive wastes. The Resource Conservation and Recovery Act (RCRA) enacted by the United States Congress in 1976 and subsequently amended in 1984, 1986, and 1988 requires that every hazardous waste must be rendered nonhazardous before disposal. Many of the wastes generated by the DOE complex are both hazardous and radioactive. These wastes, called mixed wastes, require applying appropriate regulations for radioactive waste disposal and the regulations under RCRA. Mixed wastes must be treated to remove the hazardous waste component before they are disposed as radioactive waste.

This paper discusses the development of a treatment process for mixed wastes that exhibit the reactive hazardous characteristic. Specifically, these wastes react readily and violently with water. Wastes such as lithium hydride (LiH), sodium metal, and potassium metal are the primary wastes in this category. Besides their tendency to react with water, the wastes also produce alkaline hydroxides and hydrogen gas as products of the reactions.

$$LiH + H_2O \rightarrow LiOH + H_2 \quad (1)$$

$$2Na + 2H_2O \rightarrow 2NaOH + H_2 \quad (2)$$

$$2K + 2H_2O \rightarrow 2KOH + H_2 \quad (3)$$

If in aqueous form and if the pH exceeds 12.5, the alkaline hydroxides must be further processed to lower the pH to the range of 2-12.5 to remove the corrosive hazardous characteristic. The hydrogen gas formed during treatment is not considered a RCRA hazardous waste, but the hydrogen poses a substantial safety hazard because it can form explosive mixtures with air. Tritium may also be substituted for hydrogen in the LiH. If tritium is present, special processing may be necessary to avoid exhausting tritium into the environment.

Because of the requirement to control environmental exposure to radioactivity contained in the wastes, the process design requires a reaction within enclosed vessels. These vessels require inert gas purging with subsequent off-gas scrubbing and high-efficiency particulate air (HEPA) filtration before discharge to the atmosphere. If tritium is present in the reaction gases, a better system to capture the tritium is necessary. The hydrogen-containing off-gas could be vented, flared, oxidized to water by combustion or electrochemical oxidation, or separated from the nitrogen purge and collected in gas cylinders or thermally regenerable hydride substrates. Any alkaline hydroxide reaction products would be neutralized and further treated for disposal.

PROCESS DEVELOPMENT

Initial process development investigations centered around the idea that a stream of humidified nitrogen could be used. This approach has many apparent advantages including

- the ability to control the reaction rate by limiting the humidity level in the nitrogen purge gas;
- the nitrogen provides a carrier for the water vapor and acts as the purge blanket; and
- the possibility to control the hydrogen content in the off-gas to below explosive

limits by maintaining +96% N2 by hydrogen/nitrogen separation and nitrogen recycle. An experimental program focused on the humidified nitrogen process. In the experiment, nitrogen was passed through a humidifier and then contacted with the water-reactive substance in a reactor. The reaction kinetics were determined for LiH by measuring the gas flows and the amount of hydrogen exiting the reactor. The primary investigation variables were temperature, percent of humidity, and particle size of the water-reactive substance. Specific results of these tests have been previously presented (1). Essentially, the results showed that the reaction follows the Unreacted Shrinking Core Model (2). Acceptable control and reaction rates were achieved with finely divided powders. Rates were prohibitively slow for larger pieces of LiH.

The humidified nitrogen process was abandoned because of these factors.

The formation of an alkaline hydroxide layer on the particle surface slowed the reaction appreciably. Therefore, there was no foolproof way to ensure that the reaction had gone to completion.

Heat removal from the reacting solid is critical because melting can occur at relatively low temperatures. Because melting would quickly plug most reactor designs, operation would be below the maximum saturated temperature. Table I shows that for LiH, operation would be fairly reasonable because saturated nitrogen at 50C would carry enough water to the reaction without consuming too much nitrogen. Sodium and potassium metals would require recycling the reactor off-gas or would consume excessive nitrogen.

The reaction rate for large particles was too slow to be practical. Grinding would be necessary to ensure complete and reasonable reaction rate.

Controlling a large volume of a dusty reactant within a reactor while contacting with a moving gas stream would be a difficult design task. This task is made even more difficult because LiH has a very low density.

An alternate contacting method was developed. This process involves directly immersing the water-reactive waste in a volume of water. Reaction rate is controlled by the rate of addition of the waste to the reactor. In this system, a nominal amount of nitrogen is introduced as purge gas, but there is no attempt to maintain the hydrogen content 4%. The possibility of explosion is avoided by excluding oxygen. All off-gas is scrubbed, filtered, and discharged. During processing, the liquid volume charged gradually accumulates alkaline hydroxide strength. After pH adjustment, the waste water is sent to a wastewater processing plant. Figure 1 shows the basic process block floor diagram.

Fig. 1.

The advantages of this approach are the following:

Either powdered or large solid pieces of water-reactive waste can be fed, with acceptable reaction rates. Simple solids introduction methods can be used.

Extraneous materials can be processed with the water-reactive waste. For instance, if lithium hydride is bonded to another non-water-reactive substance, the whole mass can be introduced to the reaction system to reliably remove the water-reactive waste from the nonreactive substrate.

The volume of water in the reaction system provides an effective heat sink for the exothermic reaction. The reaction system is sized to limit the temperature rise to 20C if the cooling system fails.

Accumulations of solid alkaline hydroxide layers that could stop the reaction are minimized because the excess water dissolves the accumulations. This factor also eliminates the need for separate dissolution and rinse procedures.

The amount of water-reactive waste treated per run is limited only by the liquid volume in the reaction system and the solubility of the alkaline hydroxide or neutralized hydroxide, and not by the volume of the reactor itself.

Experiments were performed to determine reaction characteristics and to validate the process concept. Details about the results of this experimentation are not within the scope of this paper, however, these generalizations are made.

1. Water-reactive solids larger than 1/4 in. tend to complete reaction in a reasonable time and do not react instantaneously. Tests on 1/4-in. pieces of LiH resulted in reaction times between 20 and 40 seconds.
2. Finally divided water-reactive material tends to react very quickly. Tests on LiH powders showed that reaction rates equivalent to 50% reaction within 0.5 seconds

were attainable.

3. Attempts to regulate the reaction rate of powders showed some success:

Raising the solution strength to saturation of LiOH or LiSO4 had little effect on reaction rate for small samples.

Forcing water to access the LiH through orifices controlled the reaction rate. The mechanism for control is the rate of water accessing the LiH, which is controlled by the escaping hydrogen gas. With fine orifices in metal bombs or cloth bags, the reaction rate was relatively steady for several minutes. An attendant problem is plugging the orifices with undissolved LiOH. Tuning the powder containers in the process unit will be necessary. An additional advantage of using a rate-controlling container or bag is that a delivery method controlling the powder rate is possible.

Water-soluble bags were tried as a delivery method and as a rate-controlling method. Although the soluble bags contained powders well, the rate controlling aspect did not work well. Once a spot on the bag dissolved, the whole bag would quickly empty because of hydrogen pressure buildup. Another problem encountered with the bags was they lost their ability to dissolve as the ionic strength increased in the reaction liquor. Suppression began as the concentration approached 20% of saturation of LiOH.

PROCESS DESIGN

A process design was completed in early 1995. The water-reactive waste treatment system will remove the RCRA reactive characteristic by contacting the solid waste with water. The treatment process is a skid-mounted system designed with maximum flexibility to treat the anticipated water-reactive wastes. The treatment skid consists of individual modules. Each module weights a maximum of 4000 pounds and has maximum dimensions of 5 feet wide x 10 feet long x 12 feet high. The structural system is designed so that it can be easily cleaned for removal to storage. This requirement necessitates welded stainless steel construction that greatly minimizes cracks, crevices, and corrosion products such as rust. All reasonable effort has been given to meeting this goal with standard industrial equipment. When stainless construction is not possible, epoxy painting for nonstainless metal parts is specified. Figure 2 shows a simplified process flow diagram of the process.

Fig. 2.

The skid design conforms to the standards of the National Electrical Code for explosion-proof operations in Class 1 Division 2 or Class 1 Division 1 Group B (3). Explosion-proof design uses a combination of explosion-proof enclosures, purging, and intrinsic safety barriers. The instrument and control portion of the skid design allows local and remote control of all critical portions of the process. Further, the skid system is mobile for use outside the Hazardous Waste Treatment Facility (HWTF) at Los Alamos National Laboratory or can interface with the central control system of the HWTF.

The process equipment is designed as several transportable modules that will be connected together to form an integrated skid. This allows moving of the equipment to various locations at the laboratory, including movement of the skid in and out of the HWTF. Figure 3 shows the overall appearance of the skid. The four main process modules are on the lower level. A fifth module, which holds the processing glovebox, is on the second level.

Fig. 3.

Several design features are noteworthy because of the requirements of the process:

Every attempt is made to minimize the complexity of the design.

Multiple layers of operator and process protection are provided. For example, the preliminary safety analysis has determined that no single failure of equipment or procedure can lead to a catastrophic event. Much attention has been paid to ensure that water cannot accidentally contact water-reactive waste during handing operations; operators will not be exposed to water-reactive waste; explosive mixtures cannot form within the reaction or venting vessels; and radioactive materials are not released to the environment.

A computer-based process control system is specified. This control system provides maximum flexibility for necessary future changes, simplicity in operation and design, explosion-proof design, capability for logging data, and capability for remote operation. Control system components are compatible with those used in the previously designed process skids for depleted uranium treatment (4) and chemical plating waste treatment (5).

Every attempt was made to specify 304L, 316L, or higher alloy. This specification

is for corrosion control and easy decontamination. Exterior surfaces not constructed of stainless steel or other material that cannot be decontaminated will be painted with approved epoxy paint.

Because of the explosion-proof requirement and the size and weight limitations, the number of electrical devices is minimized. For example, to avoid electric motors on the main process skids, pumps driven by nitrogen gas will be specified. The processing skids adhere to NEC Class 1 Division 2 design code for explosion protection in the liquid-handling area. Twater tohe gas-handling areas adhere to the NEC Class 1 Division 1 Group B code.

Careful component selection results in a long term operation assuming normal maintenance. The ASME piping specifications (ASME 31.3-1993) call for a 20-year piping life.

A separate utility skid (6) is provided to supply chilled water to remove the heat generated during reaction. The utility skid is designed to be set up outside potentially contaminated process areas. The utility skid also provides heated water to desaturate scrubber off-gas for HEPA protection.

Operating flexibility is incorporated into the design. Examples of this flexibility are:

Some flow directions can be changed to enable the operator flexibility. For instance, the operator can change the reactor circulation/cooling loop flow to clear inlet restrictions.

The control software is capable of supporting various operating modes such as normal interlocking or bypass selected interlocks, etc.

Three is spare capacity for additional control and monitoring equipment. The unit has at least 20% analog I/O, discrete I/O and wiring spares.

All interlocking and control functions are done within the software of the control system. With the exception of new equipment additions, any control logic changes can be accomplished by programming changes with no need for hard-wiring modifications.

TREATMENT SYSTEM OPERATION

Figure 4 below presents the simplified operating sequence for treating water-reactive mixed waste. Each step represents a unit operation or series of operations in the treatment of a generic water-reactive waste. Some steps depend on the nature of the specific waste being treated. For instance, the hydrogen treatment step is necessary only if appreciable amounts of tritium are present.

The water-reactive waste treatment system is designed to receive an inspected, sampled and sorted drum of waste. These operations are performed in a sample/sorting glovebox separate from the process. The waste drum is introduced into the nitrogen purged, sample glovebox where it is opened and inspected. If further inspection, sampling, sorting, repacking or consolidation is required, the sample glovebox is equipped with multiple ports for these operations. Once introduced into the sample glovebox, the waste drum is isolated from the atmosphere until it is empty and clean. The drum with the prepared waste is placed into a transporter vessel. The transporter is designed to transfer the waste drum between the sample glovebox and the process glovebox while maintaining a nitrogen blanket for the waste drum. The transporter is designed to survive a fall from 20 feet without rupture and subsequent release of waste.

Fig. 4.

Operators receive the waste into the process glovebox, sort the waste according to size and load the feeding device. The feeding device is an air powered bucket conveyor. The buckets on the conveyor are first manually loaded and then an automatic, interlocked system feeds one bucket every five minutes. The buckets place the feed material on a check weigh scale. If the weight is greater than 1000 grams for large solids or 250 grams for powders, the system is stopped while the operator reloads the feeder with the proper weighed feed. This system provides a check against feeding the reaction system at too high a rate.

The nitrogen purged reactor vessel is fed directly from the glovebox. Isolation valves are placed between the glovebox and the reactor. These valves are sequenced for minimum open time and to never to open simultaneously. This avoids the potential for a broken glove causing air intrusion into the reaction system sufficient to cause ignition. Additionally, the valve positions are sensed. If correct valve position is not maintained, the feeding operation ceases until the operator corrects the problem. Mechanical barriers and control system interlocking are used to assure separation of glovebox and reactor atmospheres. For instance, feeding operations

cannot commence before the nitrogen purge totalizer has reached a minimum value, the oxygen meters (4 total) all confirm the elimination of oxygen to less than 0.5% O2, all doors and valves are positioned correctly and the process itself is functioning correctly.
The reaction produces hydrogen gas and an alkaline metal hydroxide solution which is continuously neutralized with sulfuric acid. Cooling water is applied to the reactor and scrubber cooling exchangers using an intermediate heat-transfer loop. An intermediate cooling loop is used to prevent environmental contamination by insuring isolation of the main cooling system. All waste water is collected and processed at the Los Alamos National Laboratory's Waste Water Treatment Plant.
Reactor vent-off gases are scrubbed with water in a venturi-eductor scrubber before passing through a HEPA filter to the stack. The nitrogen-hydrogen mixture is vented to atmosphere after passing through water seal device. The water seal, which is located adjacent to the vent stack, is designed to allow the process gasses to exit while preventing the backflow of air into the reaction system which could potentially lead to ignition of hydrogen.
Any debris separated in the glovebox such as plastic bags, filter media, tools, etc. is stored in air-right containers until sufficient accumulations require processing of this material to remove trace amounts of water-reactive waste. This debris is processed by reintroducing to the container contents into the glovebox for "washing." Protection against ignition of any hydrogen generated includes elevated nitrogen purge rates, standard interlocking and relative trace amounts of water-reactive waste present. All transfers make use of the transporters and the sample glovebox. Any bagout operation uses the bagout port on the sample glovebox. Debris items such as depleted uranium, tools, metal pieces, reaction containers, etc. that were introduced to the reactor with the water-reactive waste, is removed from the base of the reactor after reactor draining and rinsing. This operation is done under a nitrogen blanket to prevent the potential ignition of depleted uranium. The debris is placed directly into a plastic bagout bag for immediate transport to the sampling glovebox for repacking if necessary. Any recovered depleted uranium is packed under fuel oil for later treatment.

ABSTRACT
This paper documents the treatment of a characteristic mixed waste using a combination of magnetic separation to achieve waste volume reduction and thermal

desorption to treat the hazardous organic constituent. The waste was generated during the course of performing remedial activities at a fuel fabrication facility. During the dewatering and packaging of waste from an area know to contain low levels of PCE contamination, PCE was inadvertently concentrated because of the heterogeneous nature of the contamination. With further examination, the physical properties of the fraction of waste containing the organic contamination was determined to consist chiefly of ferrous material. Using grate type magnetic separator, the PCE was removed and concentrated. The separation reduced the volume of hazardous waste by a factor of approximately 100. Following separation, the PCE was removed from the ferrous material by low temperature thermal desorption. The entire process from waste generation through treatment and disposal required less than 90 days. The paper emphasizes the need to examine the nature of contamination present in a characteristic mixed waste. Relatively simple and readily available technologies are often available to minimize the volume of waste requiring treatment.

INTRODUCTION

Decommissioning of unused facilities and surface impoundments containing mixed wastes is ongoing at a nuclear fuel fabrication facility. The decommissioning activities generate soils and sediments which must be treated to remove or stabilize RCRA constituents, dewatered, and then packaged for burial at a licensed low-level radioactive waste (LLRW) disposal site. To date over 9,000 cubic feet of sediments have been processed through on-site mixed waste treatment operations. Characteristic wastes per 40CFR261.24, Table I, D006 (cadmium) and D039 (tetrachloroethylene) have been routinely treated and disposed of at a LLRW disposal facility. The predominant radiological contaminants are isotopes of uranium and thorium.

WASTE GENERATION

One of the facilities which required demolition was a contaminated underground vault known as the scale pit. The scale pit had previously contained scales for weighting UF6 cylinders. During the removal operation, soils and rainwater were pumped from the excavation to an on-site treatment operation. This procedure generated approximately 80 drums (16,654 liters) of water, soil, and debris which could not be packaged for burial without treatment and dewatering.

An on-site mixed waste treatment process was selected as the best means for safely dewatering and packaging this material. This treatment operation is used to treat sediments and soils generated during remediation of on-site sediment ponds. The pond remediation activities are presented in a separate paper (1). The treatment process consists of four principal steps:

1. coarse material removal (knock-out tank)
2. air sparging in treatment tank
3. magnesium hydroxide stabilization
4. solids dewatering and packaging

The first processing step, the knock-out tank, is used to remove coarse and heavy material from the stream being treated. These materials are generally abrasive and the removal is primarily intended to extend the life of the in-line shredder and pumps used with the treatment and dewatering operations. It consists of a tank containing a low velocity settling section and overflow weir. Water and fines flow over the weir and are then pumped to the next processing step. Coarse material, usually greater than 200 mesh, is collected in the bottom of the tank while water and fines flow over the weir to the treatment process. The coarse material generally consists of sand, gravel, and occasionally metal debris such as wire and fasteners. During the treatment of the scale pit waste, 15 drums (3,123 liters) of coarse material was collected from the knock-out tank. This material was primarily sand. Past experience with sand indicated that flushing water through the material to remove fines would be an effective treatment since the sand typically did not retain any of the RCRA constituents requiring treatment. Following flushing, the sand was allowed to drain and then transferred into 55 gallon drums for disposal. A moisture absorbent was added to each drum to insure that no free liquid was generated during transportation and storage prior to burial.

WASTE CHARACTERIZATION

Routine sampling and analysis of the sands was performed in order to confirm that the waste did not contain any RCRA constituents. The results indicated that the flushing had not been effective in this instance. In fact the PCE in the TCLP extract was higher than other fractions of the waste tested indicating the PCE was

concentrated in the coarse material
Upon visual inspection of sample taken from the drum, three distinct material types could be identified:
1. moisture absorbent
2. sand
3. ferrous magnetic (iron oxide)
Each fraction was assayed for PCE by the TCLP extract procedure. The results are provided in Fig. 1 along with three sample results from material before separation.
Fig. 1. Knock-out Tank TCLP PCE.
From the results it was concluded that the ferrous portion of the waste from the settling tank contained levels of PCE above the regulatory limit of 0.7 ppm. Due to the large particle size, this material was not amenable to the existing air stripping process. It was also observed that the ferrous material represented less than 1% of the total waste volume. The investigation concluded the settling tank had concentrated ferrous waste along with the sand fraction. The ferrous waste also contained high levels of oil and grease.

WASTE TREATMENT

Whenever possible, mixed wastes generated during remedial activities are treated within 90 days following their generation. This procedure is consistent with 40CFR265 and greatly minimizes permitting and storage costs.
Considering the nature of the waste, thermal treatment appeared to be the most effective form of treatment. However, no form of thermal treatment was available on-site with the exception of a small oven in a permitted exhaust hood which was used for routine laboratory operations. This oven had a capacity of less than 56 liters.
Installing additional thermal treatment capacity would have resulted in additional costs and would have generated a significant delay. Such a delay could have resulted in exceeding the 90 day treatment window.
Size reduction combined with stabilization was considered, but was rejected due to the large volume increase which would have resulted.
Since the ferrous waste had been readily separated during the waste characterization effort, it was elected to duplicate this procedure on a larger scale capable of treating all 15 drums. A loading chute routinely used to fill drums was modified by securing a standard 16 cm by 16 cm magnetic grating into the discharge. A standard ceramic magnet was selected over a stronger rare earth magnet. The ceramic magnet was less expensive and provided satisfactory separation based on laboratory observations.
With this system in place, the material was poured into the chute and allowed to fall through the grate into a second drum. A photograph of the operation is shown in Fig. 2. Figure 3 is a photograph of the loaded magnet after processing one drum of waste. After each drum was processed, the grating was removed and cleaned. After one pass through the grating approximately 24 liters of ferrous material and tramp iron was collected from the 15 drums processed (approximately 2.3 metric tons).
Fig. 2. Processing waste using magnetic separator.
Fig. 3. View looking down into chute showing magnetic grating and ferrous waste.

RESULTS

All 15 drums were processed in approximately one day. Samples were taken and analyzed for PCE in the TCLP extract. The results of the analysis showed an average PCE concentration in the TCLP extract of 0.357 ppm. This value was below the limit of 0.7 ppm and the material could have been disposed of at this point. However, a close examination of the treated material revealed a small amount of ferrous material was still present.
To insure that the maximum amount of PCE bearing material was removed, the drums were passed through the magnetic grate a second time. Approximately 3 liters of ferrous waste was collected on the second pass.
Following the second pass, the material was resampled. The TCLP extract contained only 0.09 ppm PCE after the second pass. At this point the sands were sent to LLRW disposal. Figure 4 shows the initial PCE values and the values following the first and second run through the magnetic separator. A block diagram of the on-site sediment treatment process and the magnetic separation process is also shown in Fig. 4.
Fig. 4.
The 21 liters of ferrous waste were placed into trays and the trays were placed into

the laboratory oven. This material was held at 180o C for 24 hours. Samples of the material were tested and no detectable PCE was observed in the TCLP extract.

CONCLUSION

The treatment operations developed for this waste served not only as an effective and efficient process, but also saved enormous costs associated with installing on-site treatment capacity or locating off-site treatment capacity. This project demonstrates the successful implementation of magnetic separation to provide a significant volume reduction during the course of treatment. Without such volume reduction, the entire volume of the material would have remained a characteristic mixed waste. Due to the success of the separation, the amount of labor and capital equipment required for treatment was greatly reduced.

CEMENTATION OF INORGANIC NITRATE-CHLORIDE SALT, A LOW LEVEL MIXED WASTE

J. Michael Connell
Steven C. Jorgensen
Rocky Flats Environmental Technology Site
P.O. Box 464
Golden, CO 80402-0464

ABSTRACT

Aqueous low level mixed waste is solidified with Portland cement to immobilize hazardous metals at Rocky Flats. The waste is a caustic brine solution containing 40 wt% solids with low concentrations of hazardous metals. Problems such as mixing difficulties and waste form expansion can be encountered when the waste is solidified. The cause of the expansion problems are thought to be the formation of darapskite, a nitrate sulfate hydrate [Na3 (NO3 SO4) . H2O]. This report contains a description of the existing process and a discussion of the methods used to analyze the problems. Based on this study, a formulation of 30 wt% water, 30 wt% salt and 40 wt% salt is recommended as the optimum formulation.

INTRODUCTION

The Rocky Flats Environmental Technology Site (Rocky Flats) has a variety of waste streams that must be treated to meet the Resource Conservation and Recovery Act (RCRA) land disposal restriction (LDR), universal treatment standards (UTS) promulgated by the US Environmental Protection Agency (EPA). This paper discusses the cementation of an aqueous nitrate-chloride salt waste. This waste is generated from various sources, including laboratories, laundry, production operations, and incidental waters from runoff, and solar evaporation ponds. A brief history and a description of the process follow.

The cementation process was developed in the early 1980s as a short term corrective action to meet Department of Transportation (DOT) regulations for shipping waste. The original process went into use with a formulation of 55 wt% salt, 18 wt% cement, and 27 wt% water which resulted in a pourable waste form which met the Nevada Test Site waste acceptance criteria for disposal in effect during the mid 1980s. At that time, the waste mainly consisted of neutralized nitric acid. The cementation process consistently produced a certifiable product until late 1988 when shipping delays necessitated extended outdoor storage unprotected from the weather. During this period, the waste forms were packaged in corrugated paper containers. Subsequently, some of the containers degraded and some of the waste forms expanded, crumbled, or broke.

In June 1989, the cementation formulation was changed to 51 wt% salt, 22 wt% cement and 27 wt% water to obtain a waste form with a higher compressive strength. Improved containers were also used to reduce the expansion problems. For several months, the improved boxes and lower waste loading appeared to alleviate the swelling problems. In December 1989, the composition of the waste changed. Plutonium production was suspended at Rocky Flats, and subsequently the plant stopped producing large quantities of neutralized acid wastes. However, large quantities of waste from other areas on the plant site continued to be processed, resulting in waste containing much lower concentrations of nitrates.

In June 1990, some of the crates of cemented waste began swelling while still in the temporary storage areas. Visual inspections of these blocks revealed light and dark swirling patterns, indicating that the salt blocks were poorly mixed and not homogeneous. Bench-scale mixing tests indicated that formulations that mixed easily prior to the production curtailment were now more viscous and more difficult to mix apparently due to changes in the waste composition. To compensate for the increased viscosity, operators began adding additional brine to the formulation.
The mixing and expansion problems appeared to be solved in September 1990 as a result of a lab-scale mixability study which recommended a 30 wt% waste loading formulation. However, this waste form was not certified for disposal because of a lack of waste characterization data. It was thought that all of the waste forms would have to be reprocessed to meet EPA regulations. The waste loading was increased to 35 wt% during the fall of 1992 to help conserve storage space. Three months later, some of the newly produced waste forms began to expand and damage the containers. Concerns over how the waste forms would behave in a permanent repository and/or long storage led to the decision to determine the cause of the expansion. Historical production records were statistically analyzed and existing cemented waste in inventory was examined for clues to the cause of the expansion. A review of the production records found that the expansion was less likely when the waste loading was below 30 wt%. However, it was not possible to correlate the expansion to chemical composition of the waste. An examination of the 700 cemented waste forms in inventory revealed that approximately 15% of the waste forms expanded enough to bulge or damage the plywood containers. The bulging occurred most frequently on only one end of the 2.1 m long X 1.2 m wide X 0.6 m high containers.
The process waste water at Rocky Flats is treated to remove most of the highly radioactive constituents and is then concentrated by distillation. The aqueous stream is treated by flocculation and precipitation to remove the actinides and then it is sent to a clarifier to be concentrated. The under-flow from the clarifier goes to radioactive sludge treatment, and the overflow is sent to a holding tank where it is mixed with low specific activity wastes prior to concentration in a quadruple effect evaporator. The distillate is recycled for use as process water while the concentrated brine is waste that must be treated for disposal. This waste is a 35 to 40 wt% solids brine solution with a pH of 10.5. A portion of the brine is spray-dried to fully dry the solids in order to increase the waste loading in the final waste form. The spray-dried salt consists of hollow spherical particles with a diameter of approximately 10 micrometers and a bulk density of 0.4 g/ml to 0.7 g/ml. The spray-dried salt and the brine are then mixed together to form a salt slurry. Portland cement is mixed with the salt slurry to produce the final waste form.
The waste is batch-mixed in a fiberglass tank to produce a cemented waste form using a formulation of 35 wt% salt, 30 wt% water and 35 wt% cement. The cementation equipment consists of a 350 rpm Lightning mixer with two 35-cm A-310 impellers concentrically mounted in a cylindrical tank with a conical bottom. The impellers are evenly spaced along the vertical axis. Load cells on the tank are used to determine the amount of each component as it is added to the mixing tank. The tank is equipped with a vacuum system to remove dust and an inspection hatch for rinsing the walls of the tank and for inspecting the mixture in the tank.
To prepare the cemented waste, the tank is sequentially charged with 225 kg brine, 100 kg salt, and 220 kg cement while being continuously mixed. Initially, the tank is tared then the brine is added to the desired set point. Next, salt is pneumatically transferred to the mixing tank. After salt addition, cement is pneumatically transferred to the tank until the desired amount has been added. All of the set points are based on the total weight of the mixing tank.

EXPERIMENTAL APPROACH

The steps to solving the expansion problem were to:
1. determine the waste acceptance criteria for disposal,
2. characterize the uncemented waste,
3. analyze the cemented waste,
4. determine the limitations and capabilities of the existing process,
5. simulate the cementation process on a laboratory-scale,
6. optimize the formulation of the cemented waste form on a laboratory-scale,
7. implement the formulation of the cemented waste form at full-scale.

The rest of this report represents the efforts to solve the expansion problem.
The cemented waste form should meet the waste acceptance criteria (WAC) for a low

level mixed waste (LLMW). Since the waste form is destined for disposal at Envirocare of Utah, Inc. or the Nevada Test Site (NTS), WAC for both sites should be satisfied so that the waste can be disposed at either site. Waste bound for either site must meet the EPA treatment standards in order to be buried and the DOT standards in order to be transported. The EPA standards are based on the Toxicity Characteristic Leaching Procedure (TCLP) test, which is designed to test how well hazardous chemicals are immobilized in a treated waste form. The DOT standards pertaining to waste with less than 2 nCi/gram (the activity of the untreated waste is less than 1 nCi/gram) radioactivity state that the waste must be shipped in a "strong, tight" container. A summary of the combined WAC is given below.

TABLE I

To characterize the uncemented waste, samples of brine and spray-dried salt were analyzed for metals regulated by RCRA, common cations, common anions, and organic chemicals. A summary of the analysis (Tables II and III) shows that the waste consists primarily of nitrates and chlorides of sodium and calcium. No hazardous organic waste is allowed into the aqueous process waste by administrative control. The analytical results revealed that no organics were in the waste. Some nonhazardous organic material is present in the waste probably due to processing laundry and runoff water. A TCLP test on the uncemented spray-dried salt indicates that the untreated waste nearly meets the EPA treatment standards (Table IV).

TABLE II

TABLE III

TABLE IV

Samples of the cemented waste containing 35 wt% salt were analyzed for total concentrations of RCRA regulated metals and common anions. The TCLP was performed for comparison to the treatment standards for RCRA regulated metals, and organic compounds. As the analysis indicates (Table IV), the waste form meets the EPA treatment standards. As noted earlier, the waste loading in recent years has been between 30 and 35 wt%. By demonstrating that the waste meets the treatment standards at the higher waste loading, the newly generated waste produced with lower waste loading will also be certifiable (some random sampling will be necessary to verify this). Previous analysis showed that the waste forms produced in the late 1980s meet the EPA treatment standards at 55 wt% waste loading.

Since the cementation process immobilizes the hazardous constituents at waste loadings up to 55 wt%, the problem was to determine the cause of the waste form expansion. An examination of the historical production records and the waste forms in inventory indicated that the expansion was virtually eliminated during a 1 year period when the waste loading was kept below 30 wt%. Since the 30 wt% waste loading had been effective in the past, this waste loading was adopted as the maximum. What remained was to determine the cement type, cement concentration, and the water concentration in the cemented waste form.

The formulation of the cemented waste form was developed by simulating the process on a lab-scale, followed by testing a variety of cement types, waste loadings, and water to cement ratios. The rheological properties of typical waste and the limitations of the mixer are shown in Fig. 1. On a lab-scale, the formulations were tested for compatibility with the full-scale equipment, and subjected to durability testing in anticipation of storage in harsh weather conditions. The microstructures of the cemented lab-scale samples were examined to identify expansive crystal growth and compared to the microstructures of cemented samples produced by the full-scale process.

Fig. 1.

A variety of cement/flyash blends were tested on a lab-scale to determine whether a more durable waste form could be produced. The first objective was to find a blend that required less water because low water cements are stronger and more durable (1). In addition, excess water increases the void space in a waste form which increases the mobility of the hazardous chemicals (2). The water requirements were based on viscosity measurements for each of the blends. Type I, type I/II, and type V cements were blended 1:1 with Class F and Class C flyash. The water requirements for these blends were virtually identical. A variety of superplasticizers (dispersants for reducing water requirements) were tested, but none was able to reduce the water requirement without dramatically increasing the time-of-set. Therefore, the selection of a blend would be based on minimizing expansive tendencies of the waste form.

Lab-scale samples were subjected to freeze/thaw testing and wet/dry testing to determine which type of cement blend was least susceptible to expansion. The wet/dry tests and the freeze/thaw tests were ASTM methods modified to have fewer cycles (ASTM D 559-89, and D 560-89 respectively). The wet/dry testing consisted of placing one inch diameter by two inch long cured samples in an environmental chamber for two cycles through the following conditions: 95% relative humidity at 40 C for 48 hours followed by 20% relative humidity at 55 C for 48 hours. None of the samples expanded significantly, so it was concluded that variations in temperature and humidity were not the cause of the expansion and that no blend showed an advantage.
Other lab-scale samples were subjected to freeze/thaw testing. In this test, cured samples were placed in a freezer at -20 C for 48 hours then placed in an oven at 55 C for 48 hours. The freeze/thaw cycle was repeated. In this test, blends containing type V cement and blends containing Class F flyash did not expand but other blends expanded as much as 5% in length. At this juncture, it was thought that the expansion of the waste forms could be attributed to the formation of ettringite. Ettringite is formed when sulfate present in the waste reacts with tricalcium aluminate present in cement. Type V cement has less tricalcium aluminate than the other types of cement, which could explain why type V blends were resistant to expansion. However, ettringite was not the cause of expansion, as discussed later.
Three methods were employed to examine the microstructures of the cemented samples: optical microscopy, scanning electron microscopy (SEM), and x-ray diffraction (XRD). Optical microscopy was used to identify cement, the degree of cement hydration, porosity, homogeneity, salt crystals, and structural flaws. The SEM was used in conjunction with an energy dispersive x-ray detector (EDX) to give semi-quantitative elemental analysis of crystals observed in SEM micrographs. Cemented samples produced in the laboratory with the actual waste and cemented samples taken from full-scale waste forms were examined by these methods.
The examination of samples from the full-scale waste forms showed a correlation with the formation of darapskite and waste form expansion. Furthermore, concentrations of this mineral were higher in the bulged ends of the waste forms than in other locations. Another important discovery is that no ettringite was found in the expanded waste forms. Darapskite, a nitrate-sulfate double salt [$Na_3(NO_3)(SO_4) \cdot H_2O$], was the only chemical found in the waste forms that is known to cause expansion, although others could be present. Since darapskite is formed from chemicals that are found in the waste but not in cement, the type of cement blend does not contribute to the formation of the expansive component in the waste forms.
The lab-scale samples contained the expansive calcium aluminum chloride hydrates but did not contain darapskite or ettringite. Calcium aluminum chloride hydrates were found in the full-scale waste forms, but at low concentrations. Since the expansion in the full-scale waste forms is attributed to the formation of darapskite, but the expansion in the lab-scale samples is due to another mechanism, the lab-scale freeze/thaw testing was not a good method to predict expansion on the full-scale.
A third set of lab-scale tests were performed to determine the tolerable range of the water content in the final waste form with waste loading of 30 wt% anhydrous salt. The minimum water content is defined as the amount of water that produces a paste that is barely capable of mixing as defined by the "Mixer Limitation" line in Fig. 1. The maximum water content is defined as the highest concentration of water in the waste that will not cause free water to form on top of the waste form while it is hardening. Once the water content range was determined in the laboratory, it was tested on the full-scale equipment. The full-scale water content range was larger than determined in the laboratory. The full-scale range was found to be 28 to 30 wt% at 30 wt% anhydrous salt, and 26 to 28 wt% at 28 wt% anhydrous salt (see Fig. 2). In other words, the water to cement ratio can vary from 0.67 to 0.75 at 30 wt% waste loading, and from 0.48 to 0.64 at 28 wt% waste loading. This formulation has been successfully used on a small number of full-scale batches and will become part of the process in the future.
Fig. 2.
REMAINING ISSUES
1. Lab-scale tests to simulate the waste with reagent salts (or surrogates) were unsuccessful. The water requirements and the results of the durability testing were quite dissimilar. Simulation of the waste with "cold" material would have been convenient, but time constraints were prohibitive.
2. The time-of-set of this cemented waste form is very long and may be 10 to 25

days. A brief review of the literature and available products indicated that there is no product on the market to accelerate the set of this waste form.
3. Occasionally, the viscosity of a batch of waste will be greater than the mixer is capable of agitating, which necessitates the addition of more brine to thin the batch.

CONCLUSIONS AND RECOMMENDATIONS

1. The expansion of the full-scale cemented waste forms is due to darapskite, a nitrate-sulfate double salt.
2. Darapskite is not formed from chemicals derived from cement or flyash, so the formation of darapskite is unaffected by the type of cement/flyash blend used to solidify this waste. Type I, type I/II, and type V cements are suitable for solidifying this waste.
3. Class F flyash is a suitable admixture for this waste.
4. The expansion of cemented lab-scale samples made with actual waste (not surrogate) did not occur by the same mechanism as in the full-scale cemented waste forms.
5. The range of water content found in lab-scale simulations of the process using actual waste (not surrogate) was smaller than the range that the full-scale process could tolerate.
6. The maximum nonexpansive waste loading was determined from historical records. More thorough record keeping in the future is recommended to help solve problems that may arise.
7. The hazardous chemical constituents in this waste exist at low concentrations so meeting EPA treatment standards is fairly straightforward.
8. The waste should be treated with the following formulation for maximum waste loading and minimum expansion problems:
   28 to 30 wt% water with a waste loading of 30 wt% anhydrous salt,
   26 to 28 wt% water with a waste loading of 28 wt% anhydrous salt,
   cement or cement/flyash blend be used to make up the reminder.

THE KINETICS OF CADMIUM BIOACCUMULATION BY TWO AQUATIC MOSSES INDIGENOUS TO QUEBEC

Ghyslain Samson
Guy Vaillancourt
LeRoy Pazdernik
Universit du Qubec Trois-Rivires
Canada

ABSTRACT

One of the main problems encountered when analyzing heavy metals is their very low concentrations in the aquatic environment. In such cases it is often necessary to use bioaccumulators in order to monitor the evolution of these pollutants over space and time. The aquatic mosses selected are considered good biomonitors which can provide information on the status of the environment. In the past, a number of methods have been developed to enhance our understanding of these biological interactions; but the major impediment has always been the difficulty of maintaining the aqueous concentration constant at the desired values. The experimental system developed for the present study is a simple one: it opts for gravitational rather than a mechanical one. A manual control ensures a constant rate of input feed water in this dynamic system. Experiments were carried out at concentrations of 0,10, 25 and 50 mgL-1 both with and without "EDTA" as a chelating agent. The goal pursued was to assess the performance of two aquatic mosses -Fontinalis dalecarlica Schimp ex. B.S.G. and Platyhypnidium ripariodes (Hedw) Dix.- during the build-up of cadmium over a 28-day period. Preliminary results indicate a high level of bioaccumulation on the first day. In the absence of the chelating agent, accumulated cadmium varied between 150 and 300 mgg-1 according to the genus of bryophyta. On the basis of our results, it would seem that the mosses suffer an internal ionic imbalance if the accumulation period is too long (28 days). The use of EDTA has proven useful, 1) in maintaining a constant level of pollutant concentration, 2) in lowering the

bioavailability of the metal under study and 3) in simulating more closely the natural conditions of the environment.

INTRODUCTION

Our aquatic environment is becoming more and more stressed by the many pollutants generated by modern technology. According to Hogan and Whotton the toxic metallic substances, especially cadmium, is a potential menace for the survival of the ecosystem.

One of the main problems associated with the analysis of heavy metals is their low concentration in the aquatic milieu. Direct analysis of these metals in water is often inconclusive because their concentrations are close to the normal detection limits. In order to counter this difficulty, pertinent tracers can be used. To date a variety of bioindicators have been used and depending on the pollutant, the efficency will vary according to the type and complexity of the biocaptor chosen. Bryophyta have received much attention lately for metallic analysis (Agneta and Burton, 1990). The mosses are hardy and produce many leaves which favor their use for the monitoring of contaminants in aquatic areas (Berryman and Richards, 1992). They rapidly extract most metals by simple ionic exchange from water (Mouvet, 1987). The objectives of this laboratory study are 1) to evaluate the performance of two aquatic mosses indigenous to Quebec as potential biological indicators of cadmium, 2) to compare the accumulation kinetics of this pollutant in the presence and absence of EDTA (ethylene diamine tetraacetic acid), 3) to verify the efficiency of a semi-open dynamic system with gravitational input flow, and 4) to apply a mathematical model in order to extract the uptake constant(k1), the depuration constant (k2) and the bioconcentration factor (BCF).

MATERIAL AND METHODS

Sampling

The moss species genus Fontinalis was collected in the summer of 1993 from the River Cach, a small river in the southern part of the Laurentide Reserve. This moss lives totally submerge and is attached to the bottom rocks by their rhizoides (a type of small hook on the end of a semi-root). As for Platyhypnidium, this one was found in a small water cascade close to Loretteville. Limestone rocks dominated this habitat rich with mosses of this genus.

Once the mosses were located, they were collected by cutting the top two thirds of the plant rather than tearing them from their anchorage so as to preserve the survival of this species. A series of successive washings helped remove the unwanted debris (invertebrates, sand, etc.). Then the samples were placed on ice and transported to the laboratory for the acclimatization period. It is well known that mosses harvested during the summer season will have less difficulty adapting to laboratory temperatures (18-20C) than those collected in the fall (Saitoh et al., 1970).

The conservation of the muscinal biomass necessary for the experimental stage was done in rectangular basins made of fiber glass (1 x 2.5 meters). The temperature was controlled by a glycol filled serpentine which cooled the water in an adjacent container. This temperature adjusted water was circulated by the continuous pumping action of pressurized air in the return pipe. A "Grow Lite" Fluorescent furnished sufficient light to maintain the aquatic mosses in good health .

For the laboratory study, the cadmium concentrations had been fixed at 0, 10, 25, and 50 mgL-1. Certified standard solutions of $CdCl_2$ was used (Fisher Co). For the aquaria with EDTA, the concentration was 3 mgL-1. The ethylenediaminetetraacetic acid (EDTA) was used to simulate nature in preference to other organic materials or humic acid because of its well-known stability constants.

Experimental Design

An experimental set-up attempting to simulate natural conditions was developed. The system is simple and cheap. It uses gravitational flow rather than mechanical pumping.

Fig. 1.

A series of ten aquaria, each supplied by 220 liter reservoir, is shown in Fig. 1. Each aquaria contained 720 grams of each bryophyta initially. At each sampling time, that is 0, 1.5, 3, 6, 12, 24, 48, 96, 144, 192, 240, 288, 336, 384, 432, 480, 528, 576, 624, et 672 hours, 9 grams of each moss were retrieved per aquarium, the biomass necessary for three replicates. This sampling schedule generated a maximum of information during the rapid accumulation stage and also allowed the plant to respond over a longer period of time. In order to assure a uniform exposure to the

aqueous cadmium, each aquarium of 30 liters contained both moss species. The physico-chemical parameters (temperature, conductivity, dissolved oxygen, pH, and oxydo-reduction potential) were measured with a Hydro-Lab Surveyor II (SVR 2 model).

Chemical Analysis

Each subsample was oven-dried at 110C for 12 hours. After weighing, the samples were subjected to concentrated nitric acid (HNO3) attack for 7-8 hours until the elimination of the brown fumes; the reaction was driven to completion with 30% hydrogen peroxide (H2O2) (Berryman, 1991). When the reaction was finished, the reaction tubes were cooled and maintained at 4C. The digestions were diluted to exactly 50 mL with distilled water. They were then manually stirred to assure a completely homogeneous solution. Before proceeding to the spectroscopic analyses, it was very important to allow the solutions time to attain room temperature, otherwise a physical interference was evident in the subsequent analysis. The digested mosses were analyzed by atomic absorption spectrophotometry (Varian model AA1275) with air/acetylene flame. Certified standards for water (Standard Reference Material 1643 C) and mosses (Certified Reference Material BCR No 61) were used in the quality control scheme.

Statistical Analyses

The accumulation of metal in the byrophyta is made in two stages; a first fast stage characterized by a passive ion exchange process lasting only a few hours. The second stage requires many days and slowly reaches a plateau value of accumulated cadmium. This slow step is considered an active one where the metal penetrates to the cell interior while in the first stage, the metal is found primarily in the cell walls (Pickering and Puia, 1969; Breuer and Melzer, 1990). Since the mosses appear to accumulate in an exponential fashion, the two compartment model of van Hattum et al., (1989) was applied in an attempt to interpret our kinetic accumulation data:

Eq. (1)

Since the steady state conditions are:

Eq. (2)

eqn (1) becomes:

Ct = Css [1 - exp (- K2t)]

(3)

where

Ct = concentration in the mosses at time t (mgg-1 dry weight)

Css = concentration in the mosses at steady-state conditions (mgg-1 dry weight)

Cw = concentration in the water (mgmL-1)

K1 = rate constant for uptake from the water (hour -1)

K2 = rate constant for elimination from the mosses (hour -1)

In addition, a bioconcentration factor(BCF) can be calculated from the estimated rate constant values K1 and K2 (Walker, 1987; van Hattum et al., 1989; Tessier et al., 1994) where:

Eq. (4)

RESULTS

The original concentrations of cadmium introduced into the water in presence of the chelating agent varied very little (Fig. 2). Indeed after 96 hours, the concentration at 50 mgL-1 fluctuated around 11 mgL-1 and after that the values stabilized. The relative variations were the same for the 25 mgL-1 concentration (sample and replica) and corresponded to the same time period. No important variation was recorded at the 10 mgL-1 level and the values of the control also remained constant. In absence of EDTA, the cadmium concentrations fall radically within the first few hours. At 50 mgL-1 (both test and replica) the values dropped to 10 mgL-1 within 48 hours and varied between 15 and 20 mgL-1 during the rest of the accumulation stage. Similar radical decreases of 15 and 8 mgL-1 were noted for 25 and 10 mgL-1 respectively. The control aquaria maintained stable reference values through the experimentation.

Fig. 2. The cadmium concentration (mg L-1) in the water during the accumulation stage.

Examining the processus of cadmium accumulation of F. dalecarlica (Fig. 3) in the three environments studied(50, 25 and 10 mgL-1), the mosses in presence of EDTA shows an initial bioaccumulation of cadmium followed by a slow negative shift to an equilibrium concentrations of 20 mgg-1 (50 mgL-1) and 5 mgg-1 (10 mgl-1). In absence of EDTA, the accumulation values are much higher; the pattern is identical for the three concentrations studied: relatively fast for the first 192 hours, followed by a

slower accumulation in a discontinued manner. The highest values attained after 672 hours exposure are 350, 250 and 125 mgg-1 of cadmium when the initial concentrations were 50, 25 and 10 mgL-1 respectively. The cadmium in the controls remain constant.
Fig. 3. Accumulation pattern of cadmium by Fontinalis dalecarlica at four concentrations in the presence and absence ofEDTA complexing agent.
The accumulation of cadmium by P. ripariodes (Fig. 4) indicates that in presence of the chelating agent, accumulation is small regardless of the aqueous cadmium concentration. Indeed after 192 hours of exposition the values drop from 50 to 25 mgg-1 (50 mgL-1) and from 25 to 10 mgg-1 during the same period (25 mgL-1) (test and replicate) after which the accumulated concentration stabilized. The bioaccumulation at 10 mgL-1 is negligible. In presence of EDTA a fast bioaccumulation is evident up to 192 hours. This pattern is similar for all three concentrations of aqueous cadmium. Within the 192 hours surge, the cadmium is rapidly accumulated to attain values of 175, 125 et 100 mgg-1 for 50, 25 and 10 mgL-1 respectively. After this, the accumulation is slow with an irregular pattern which continues until the values of 275 175 and 100 mgg-1 are reached after 672 hours of accumulation. The values of the controls remain small constant.
Fig. 4. Accumulation pattern of cadmium by Platyhypnidium riparioides at four concentrations in the presence and absence of EDTA complexing agent.
The kinetic parameters of cadmium accumulation by mosses with and without a chelating agent are shown in Table I. The actual concentrations measured in water are much lower than the original values; that is 28.8, 10.1, and 3 mgL-1 instead of 50, 25 and 10 mgL-1 respectively. These lower values certainly had an impact on the equilibrium concentrations at steady-state conditions (Css). F. dalecarlica had accumulation values between 120 and 320 mgg-1while P. ripariodes was situated between 97 and 204 mgg-1. The Css values of the replicates show good repeatability of our system. The values of the elimination constant (K2) are very small for F. dalecarlica and are situated between 0.005 (10 mgL-1) and 0.010 (25 mgL-1). The calculated accumulation constants (K1) are evaluated between 194 (10 mgL-1) and 55 (50 mgL-1) for F. dalecarlica while for P. ripariodes, they attained values between 266 (10 mgL-1) and 54 mgg-1 (50 mgL-1). The highest coefficient of correlation (R2) (0,914 et 0,860) were associated with the initial concentrations of 50 mgL-1 and the lowest (0,718 et 0,733) with 10 mgL-1 for both genera. F. dalecarlica exhibited the larger bioconcentration factor values (BCF) varying from 38 800 (10 mgL-1) to 15 400 (50 mgL-1) while that of P. riparioides passed from 33 220 (10 mgL-1) to 6 750 (50 mgL-1).
TABLE I
DISCUSSION
The use of an experimental system simple and reliable has permitted the study of the bioaccumulation processus over a long period of time and to constat that the bryophyta used are good indicators which respond rapidly and perform well for the detection of cadmium.
The variations of cadmium concentration in water with and without EDTA are different. Indeed, the cadmium concentrations remained relatively stable in the aquaria where a chelating agent was used while in the solutions without EDTA, the variations were fairly large. The same phenomena was observed during the analysis of cadmium in the mosses concerning the presence and absence of EDTA. Cadmium accumulation by the bryophyta is more effective without the complexing agent. Here EDTA seriously lowers the biodisponibility of the cadmium cation to the mosses (Mouvet, 1986; 1987).
To compare the accumulation results of mosses, it seems that F. dalecarlica was a better bioaccumulator than P. ripariodes. Indeed, this is confirmed by the higher values for the equilibrium concentration at steady-state conditions (Css), the lower values for the epuration constant (K2), the larger values for the accumulation constant (K1) and a overall larger bioconcentration factor (BCF) for F. dalecarlica. Both mosses in the presence of 50 mgL-1 had smaller elimination constant values (K2) than when exposed to 25 mgL-1, this suggest the possibility of some physiological stress at higher concentrations of metal pollutant. The accumulation kinetics of cadmium in mosses in presence of EDTA indicate that here the accumulation is negligible, consequently these data do not permit the modelization of this experimental part.
The results obtained from this study confirm the special capacity of mosses to accumulate well the cadmium ion. Our observations are corroborated by Penuelas,

1984a; Berryman, 1991 and Mersch,1993 but differ with the data of Mouvet 1987 who preferred P. ripariodes over the other species.
In addition, we have conducted our experiments for a period of time twice is long as that cited in the literature thus allowing our data to attain the steady-state plateau followed by an irregular pattern of accumulation.
Our experiments have shown that because of the passive nature of metallic ionic exchange reaction with the plant cell walls, the largest part of the accumulation is accomplished rapidly in the first few hours to attain a level where the accumulation stabilizes. The major part of accumulated metal in mosses can be explain by the abundance of leaves containing negatively charged sites such as uronic, glucuronic and other carboxylic acids (Mersch, 1993). The rapid rate of accumulation constitutes a large advantage for these aquatic mosses. Consequently, they represent a good choice to use in environmental assessment of natural running water especially during an accidental discharge or spill of toxic substances.

ABSTRACT
Aquatic plants and algae are known to accumulate metals and other toxic elements from solution. Different plant and algae species, even strains of the same species, exhibit large variability in their capacity to sequester toxic elements. Bioremoval of toxic elements is also greatly affected by the presence of other ions and the physical-chemical factors during contacting. Therefore a plant/algae screening program, using simulated and actual contaminated water is the required first step in development of a bioremoval process. This paper summarizes results from a screening process used to determine the capability of sea weeds, aquatic plants and algae for adsorbing the heavy metals Cd, Zn, Pb, Ni and Cu. A successful candidate would exhibit the following characteristics: 1) Capability to reduce metal concentrations to the required regulatory levels; 2) High specific metal adsorption capability (mg metal adsorbed/kg of dry biomass); 3) Capability of removing several metal ions simultaneously; 4) High productivity in a low cost cultivation system; 5) Ease of harvesting, processing, storage and/or separating biomass from cultivation water; 6) Ability to be regenerate and recover metals.
A metal-biomass contacting protocol was established with a known amount of biomass in 50 ml de-ionized water containing the metal to be adsorbed. The mixture was shaken and then centrifuged and filtered. Both biomass and filtrate were analyzed with an atomic absorption spectrophotometer to measure metal concentration. For promising species of plants, further studies were performed to establish adsorption isotherms.
The results of the screening program demonstrated some plants had significantly higher metal uptake than others. Myriophyllum spicatum, Phormidium and Spirulina were the most promising plants, having high adsorption capability at low residual concentrations.
INTRODUCTION
Aquatic plants and algae are known to accumulate metals and other toxic elements from solution (1-7). There are very large differences in bioremoval due to species and strain differences, cultivation methodology, and the metal binding experimental procedures. Some systems have been shown to operate at low pH and may be applicable to the treatment or polishing of acid mine waste waters (8,9). However, very few commercial applications have been reported for the use of aquatic plants in bioremoval. Commercial systems developed presently (6,10) use immobilized algal biomass for the removal of U and Hg from different waste waters (11). Seaweeds also appear to have potential in bioremoval. Many metal ions can diffuse rather easily through the often rough surface area of seaweeds. However, considerable limitations to commercial application still exist, in general.
The commercially available biomass used in most studies is generally not satisfactory for specific bioremoval applications. Therefore, a plant/algae screening program, using simulated and actual contaminated waters is a required first step in development of bioremoval processes. The goal of this study was to find promising species for such a process. A successful candidate for bioremoval will bind large quantities of metal and to reduce residual metal concentration to meet USEPA water quality criteria (12) and suitable for mass cultivation.
Plants Used
The plants used for screening experiments included six different vascular plants, two macroalgae (four different strains of one genus) and five different microalgae. Gracillaria Strain G16 (red, brown, green), Ulva lactuca, and Lemna minor (Duck weed) were collected from the Aquaculture Division of Harbor Branch Oceanographic Institution (HBOI). Hydrilla verticillata (hydrilla), Pistia stratiotes (water lettuce), Myriophyllum spicatum (water milfoil), Hygrophila polysperma (hygrophyllum), Alternanthera philoxeroides (alligator weed) were collected from the University of Florida, Institute of Food and Agricultural Sciences, Agricultural Research Center, Ft. Lauderdale, FL. Duckweed (wild) and Gracillaria (wild) were collected from naturally growing areas. Spirulina was provided by Cyanotech Corp. in Hawaii, Algal Turf from the University of California, Richmond Field Station Algae Laboratory. Phormidium, Synechococcus and Nitzchia were collected from Microbial Products, Inc., culture center.
The outdoor enrichment that provided Phormidium was designed to select for attached microalgae, capable of withstanding high insolation. Resulting communities were assemblages containing single cell green algae and diatoms, mostly enmeshed in

tangles of several species of filamentous algae, both green and blue-green. The Phormidium species was by far the dominant organism.
Laboratory cultivation of Phormidium was done in glass-sided tanks with inclined planes made of roughened translucent plastic rising out of a shallow (3-5 cm) pool of media. The media was pumped over the inclined planes, starting at the top and forming a stream of flowing water. In these culture units, Phormidium sp. rapidly displaced all of the other microalgae. The loose tangles became tightly bound to each other forming a flattened mat. The cultures were grown using modified Allen media (1968).
Myriophyllum spicatum (Water milfoil) was grown both indoors and outdoors in tanks. Soil (undefined composition) was added along with the slow releasing fertilizer "Sierra" (commercially available). About 40 g of fertilizer per sq. ft. was added along with fresh water.
Contacting Experiments
Weighed amounts of biomass were added to metal solutions yielding 50 mL total volume in 125 mL Erlenmeyer flasks equipped with screw caps and incubated in a shaker for 60 minutes. All experiments were conducted in triplicate. The pH and temperature of the contact solution both before and after the experiment was measured. At the end of the experiment, the contents of the flasks were either centrifuged (microalgae) or strained (macroscopic plants) to separate the biomass from the supernatant. The supernatant was immediately analyzed with an atomic absorption spectrophotometer to measure metal concentration left in the solution. The biomass was stored for future digestion with nitric acid in a microwave digester (MDS 2100).
Phormidium was collected from the culture tank, weighed and blended at low speed for 12 sec. The blended liquid was centrifuged at 1500 rpm for 15 min. The supernatant was discarded and the remaining biomass used for the contacting experiments. The blending was necessary to disrupt the impenetrable algal mat. Water milfoil was collected from the culture tanks washed with DI water, cut into pieces (1-2 cm) and blotted dry.
Both dry weight and ash free dried weight (AFDW) analyses were performed as per AWWA Standards Methods (1993), pH of the solutions was measured using a Cole-Palmer portable pH meter and temperature was recorded with a thermometer.
Metal Analysis
All samples were analyzed using an Atomic Absorption Spectrophotometer (AAS) Perkin Elmer Model 3100 or an Inductively Coupled Argon Plasma (ICAP) Trace Analyzer Thermo Jarrell Ash Model 61E. The latter was used for determining low metal concentrations (< 0.1 ppm). Before running the samples, the instruments were optimized, and a calibration blank was run. A five point standard curve was then established. Prior to sample analysis, one of the median standards was rerun. At the end of 20 samples, the 20th sample was rerun as a duplicate. A matrix spike was also performed before starting the next run of samples. The recovery of the standards, duplicates and the matrix spikes was within 85-115%.
Data reduction and Derived Variables.
The mean values from triplicate runs of both initial and final metal concentration were used to calculate the following parameters:
  Percent metal remaining in solution
  Percent metal removed by biomass
  Specific adsorption capability (mg of metal adsorbed/kg of AFDW biomass). Specific adsorption was computed in two ways. The amount of metal adsorbed was calculated from the difference in metal concentration before and after contacting. It was also determined from the metal content measured in the separated biomass.
A linearized form of the Langmuir adsorption isotherm equation was plotted:
Eq.
where,
Ym = the maximum specific adsorption;
k = equilibrium constant; and
Y = specific adsorption at residual metal concentration C.
From a plot of C/Y vs. C, the slope (S=1/Ym) gives Ym and the intercept (I=1/kYm) gives k.
Scale up Experiments
A large quantity (kg) of biomass was used in metal contacting experiments (10 L metal solution). Specific adsorption capability obtained from both small and large scale experiments were compared to determine the value of the 50 mL small scale

experiments in predicting bioremoval when both biomass and metal densities are much higher.

Results

A total of 187 small scale (<100 mg biomass) and 6 kg quantities of contacting experiments were performed to screen 16 biomass for their metal adsorption capability. These sixteen biomass species were screened with an initial metal concentration of 1 mg/l. Most of the experiments were carried out with Zn and Cd. The time course experiments performed with Gracillaria and Hydrilla plants show no significant increase in metal adsorption by the biomass after the first 30 minutes of contact. Biomass density experiments for most plants/algal screen in this study exhibited the expected increase in metal removed as biomass density increased. The screening results show that some plants had significantly higher metal uptake than others. Phormidium exhibited specific adsorption of 1092 mg/kg Cd, and 823 mg/kg Zn, and water milfoil 532 mg/kg Cd and 823 mg/kg Zn. Both plants had higher adsorption capability than other plants when exposed to 1 mg/l of metal ion solution.

Further contacting experiments were conducted with certain plant species examined in this study. Water milfoil exhibited a low residual Cd metal concentration (<0.1 mg/l) while still adsorbing at 600 mg/kg. Specific adsorption of Cd onto Spirulina was 600 mg/kg at a residual concentration of 0.7 mg/l. Gracillaria green and red exhibited a 650 mg/kg and 300 mg/kg of adsorption at 0.5 mg/l of residual concentration. The initial screening results showed that Hydrilla, Hygrophyllum and Alligator weed had reached adsorption saturation (<300 mg/kg) at this residual concentration (0.5 mg/l). With residual concentration of 1.0 mg/l, the specific adsorption of Zn onto Spirulina was 1000 mg/kg. The highest adsorption of Zn onto Alligator weed, Hydrilla and Gracillaria red and brown was <200 mg/kg. These plants reached saturation adsorption at 0.5 mg/l. Phormidium, another filamentous blue-green algae, showed a high adsorption capability. Experimental results demonstrated the specific adsorption of Pb ranged between 1657 to 4580 mg/kg as biomass density varied from 0.001 to 0.005 kg/l. At biomass density of 0.0025 kg/l, the specific adsorption of Pb was 4580 mg/kg with residual concentration of 0.21 mg/l. These initial screening experiments demonstrate Water milfoil, Phormidium, and Spirulina were the most promising plants, having high adsorption capability at low residual concentration.

The scale-up (kg quantity) and small (<100 mg) contacting experiments were also performed. Gracillaria brown, Ulva, Hydrilla were exposed to metal solutions containing 0.25 ppm Cd, and 1.00 ppm Zn, and Spirulina was exposed to 1.25 ppm Cd and 5.00 ppm Zn solution. The results show that both kg and small scale experiments exhibited little variation on specific adsorption. The results further demonstrate that data for scale-up of the bioremoval process can be initially obtained from a small scale laboratory experiment using low biomass densities.

DEVELOPMENT OF CHEMICAL PROFILES FOR U.S. DEPARTMENT OF ENERGY LOW-LEVEL MIXED WASTES

Y.Y. Wang
B.D. Wilkins
N.K. Meshkov
D.A. Dolak
Argonne National Laboratory
Argonne, Illinois

ABSTRACT

Chemical and radiological profiles of waste streams from U.S. Department of Energy (DOE) low-level mixed wastes (LLMWs) have been developed by Argonne National Laboratory (ANL) to provide technical support information for evaluating waste management alternatives in the Office of Environmental Management Programmatic Environmental Impact Statement (EM PEIS). The chemical profiles were developed for LLMW generated from both Waste Management (WM) operations and from Environmental Restoration (ER) activities at DOE facilities. Information summarized in the 1994 DOE Mixed Waste Inventory Report (MWIR-2), the Pacific Northwest Laboratory (PNL) Automated Remedial Assessment Methodology (ARAM), and associated PNL supporting data on ER secondary waste streams that will be treated in WM treatment facilities were used as the sources for developing chemical profiles. The methodology for developing the LLMW chemical profiles is discussed, and the chemical profiles developed from data for contact-handled (CH) non-alpha LLMW are presented in this paper. The hazardous chemical composition of remote-handled (RH) LLMW and alpha LLMW follow the chemical profiles developed for CH non-alpha LLMW.

INTRODUCTION

Chemical and radiological profiles of waste streams from U.S. Department of Energy (DOE) low-level mixed wastes (LLMWs) have been developed by Argonne National Laboratory (ANL) to provide technical support information for evaluating waste management alternatives in the Office of Environmental Management Programmatic Environmental Impact Statement (EM PEIS). LLMW is material that is both a Resource Conservation and Recovery Act (RCRA)-hazardous waste and a low-level radioactive waste. DOE LLMW contains RCRA-regulated chemicals or special waste types in a form or concentration sufficient to render the waste hazardous under the guidelines of Title 40, Part 261, of the Code of Federal Regulations (CFR). Two major sources of LLMW in the DOE system are (1) inventory and operations-generated wastes (i.e., Waste Management [WM] LLMWs) and (2) wastes generated from site restoration or decontamination and decommissioning (D&D) of DOE facilities (i.e., Environmental Restoration [ER] LLMWs). The WM LLMWs include the LLMW currently (1994 inventory) in storage and the LLMW projected to be generated through 2013 at 43 sites. The ER LLMWs include the secondary LLMW streams expected to be generated from the treatment of contaminated soils and from the D&D of facilities at 14 DOE sites through approximately 2030.

Handling of LLMW is classified as either contact-handled (CH) for waste with a dose-at-waste surface <200 mrem/h or remote handled (RH) for waste with a dose-at-waste surface >200 mrem/h. The handling category determines the level of protective shielding required to safely store and process the material. LLMW is also classified as either alpha LLMW or non-alpha LLMW. The alpha LLMWs have combined activities from transuranic (TRU) radionuclides with half-lives greater than 20 years (between 10-100 nCi/g). The non-alpha LLMWs have TRU activities <10 nCi/g. Radiological profiles for DOE LLMW have been developed and are described in a

separate paper prepared by Wilkins et al. (1). Currently, the four radioactivity classifications CH non-alpha LLMW, CH alpha LLMW, RH non-alpha LLMW, and RH alpha LLMW determine the handling and routing for treatment and/or disposal of all LLMW.

WASTE STREAM CATEGORIES FOR LLMW

The most nearly complete information available on LLMW is contained in the recent update of the Mixed Waste Inventory Report database (2). This database is referred to as MWIR-2 in the EM PEIS and identifies the types of chemicals in over 2,000 waste streams of LLMW from major DOE installations. The LLMWs are grouped into nine major waste types: aqueous waste, organic liquids, solid process residues, soils, debris waste, special waste, inherently hazardous waste, unknown, and treated waste. In MWIR-2, these 2000+ waste streams within the nine major waste types are further condensed into 109 waste stream treatment codes on the basis of their physical-chemical characteristics. Many of these 109 waste stream treatment codes have similar physical-chemical compositions so that the waste streams can be treated with the same technologies to reduce or stabilize the toxic materials within the waste. For the EM PEIS, the 109 waste treatment codes have been further condensed into 32 treatment categories; the first 23 treatment categories constitute more than 90% of all LLMW. A baseline treatment flowchart for LLMW management has been developed by the Mixed Waste Treatment Project (3) to discuss the treatment technologies required for reducing or stabilizing toxic materials in these first 23 treatment categories. Descriptions of hazardous components in these 23 treatment categories are summarized in Table I.

TABLE Ia

TABLE Ib

HAZARDOUS CHEMICAL CONSTITUENTS FOR LLMW

Detailed chemical analyses of the RCRA-hazardous constituents in LLMW are available for only a limited number of LLMW streams. In MWIR-2, only about 5-10% of the 2,000+ waste streams contain quantitative data on chemical composition. Much of the information on the hazardous chemical composition of LLMW is derived from site-specific (process) operational knowledge. The composition and concentration of RCRA-hazardous chemical constituents for the first 23 waste treatment categories of CH non-alpha WM LLMW were estimated from 1) compilation of the chemical data presented in MWIR-2 and 2) an engineering assessment of the industrial processes that generated the respective LLMW streams. In the EM PEIS, chemical profiles for alpha LLMW were not developed separately because of the relatively small volume compared with non-alpha LLMW.

Hazardous chemical constituents for ER-derived LLMW have been developed on the basis of chemical concentrations for specific secondary waste streams outlined in the Automated Remedial Assessment Methodology (ARAM) database developed by Pacific Northwest Laboratory (4), as well as engineering estimates of the sources of LLMW generation. The ARAM was developed for the purpose of estimating the effects of different ER cleanup strategies on waste volumes, cost, labor, and reduction of public risk (4). In the ARAM database, the ER waste volumes are estimated on the basis of semirestricted ER alternatives. The chemical concentrations of secondary wastes are estimated from the measured concentrations of primary wastes; these secondary waste streams will be shipped to waste management facilities for treatment. It is assumed that ER wastes will be shipped to WM treatment facilities in two forms: pretreated, awaiting final treatment at WM facilities, and fully treated, awaiting final disposal. Two additional assumptions have been included in the ARAM LLMW estimates. First, radioactive, friable-asbestos-contaminated waste is included as an ER LLMW. Substantial amounts of ER friable-asbestos-contaminated radioactive waste are expected from ARAM results for the D&D of DOE facilities. Second, inadequate information exists for ARAM to distinguish between low-level waste (LLW) and LLMW during the D&D of DOE facilities. For the EM PEIS, it is estimated that 9% of the D&D waste listed as LLW in the ARAM results will be LLMW. The ARAM estimates are available for 14 major DOE sites for only 4 waste stream categories. The chemical profiles for ER-derived alpha LLMW and RH LLMW follow the profiles developed for the equivalent ER-derived CH non-alpha LLMW. Information about historical DOE site operations and industrial processes, as well as MWIR information, suggest that the waste streams of a given treatment category from different sites in the DOE complex are similar in chemical composition.

Currently, over 100 individual chemical species are identified in the MWIR-2 and ARAM databases; many of these species are either present in minute quantities,

limited to only a few waste streams, or not regulated as RCRA-hazardous chemicals. To provide a consistent assessment of chemicals that is comparable across waste treatment categories, the chemical profiles developed are condensed into 16 distinct chemicals and/or grouped into classes of chemicals that are common to most waste streams. These include six toxic metals, three inorganic chemicals, and seven classes of organic chemicals that are grouped according to important treatment parameters such as density, solubility, volatility, and degree of chlorination. Table II presents chemical profiles for WM LLMW. Chemical profiles for ER LLMW are provided in Table III.

TABLE II

TABLE III

DISCUSSION

The WM LLMW database in MWIR-2 and the ER LLMW database in the ARAM do not provide sufficient quantitative chemical characterization of LLMW streams. Several assumptions have been made to utilize the information provided in these databases, and these assumptions introduce uncertainties into the LLMW chemical profiles. A 10% reduction factor was used to convert gross waste volume to net LLMW volumes based on estimates from typical industrial waste filling practice. The estimated LLMW volumes and the ratio of specific waste stream volume to total waste volume estimated for each waste category were used to determine major waste streams and major contaminants under each waste category. The accuracy of the reduction factor used might result in uncertainty in the presence of contaminant in a particular waste category. The estimations of future waste generation volumes in these databases lead to uncertainties in developing the chemical profiles. At some DOE sites, the future waste generation rates are only projected to a single year, or to 5 or 10 years. The 20-year projection is estimated by assuming that the most recent generation rate will be continued for the remainder of the 20 years. Additional uncertainties might be introduced regarding the possible changes of future waste-generating operations. The assumption that chemical profiles are waste-stream-specific is made because insufficient data are available to develop site-specific chemical profiles. There is no justification for this assumption, and the true chemical profiles may vary from site to site. Limiting the chemical profiles to 16 chemicals may overlook an important chemical contaminant that appears only in minute quantities in the database but may be present in large quantities in a poorly characterized waste stream. Such an oversight can lead to significant errors when the developed chemical profiles are applied to estimate emissions generated from various treatment processes.

The chemical profiles developed for DOE LLMW are useful for the following tasks: 1) proposing appropriate treatment technologies for waste management and 2) estimating secondary wastes and emissions generated from various waste treatment processes. Currently, the lack of quantitative waste stream information makes the development of chemical profiles very difficult. Existing information is made useful on the basis of several assumptions; however, the uncertainties introduced by these assumptions cannot be accurately assessed with currently available data.

ELECTRICITY FROM SURPLUS MILITARY PLUTONIUM THE BEST TECHNICAL AND COMMERCIAL OPTION
D. Boyer

B. Burrows
British Nuclear Fuels plc, U.K.
ABSTRACT
Against the background of the 1995 review conference of the Nuclear Non-Proliferation Treaty and the surplus stocks of fissile material from the Former Soviet Union and US weapons programs, there is mounting interest in the available options for longer-term management of these materials.
The long-term storage of weapons components does not meet disarmament and non-proliferation objectives of all responsible bodies involved in these programs. The two most readily realizable options (1) for effective plutonium disposition are:
- fabrication into mixed plutonium and uranium oxide (MOX) fuel.
- vitrification or equivalent immobilization prior to storage and disposal as high-level waste.

The nuclear industry, for its part, fully supports the NPT (2) and is ready to bring its experience to bear. The required facilities can be implemented with confidence, drawing heavily on experience gained from US and overseas nuclear programs, although there are a number of uncertainties relating to the immobilization option which require further development. This paper describes the current facilities at Sellafield, and summarizes wider European experience in manufacture, transport and use of plutonium fuels in existing commercial LWRs together with associated waste management and transportation. The paper also briefly addresses the implications for the reactor operator loading plutonium fuels and the implications of incorporating significant quantities of plutonium in vitrified waste.
MOX fuel in LWRs is proven technology with a lifetime cost which can be predicted with confidence. In Europe, the civil nuclear industry has an established program of plutonium recycle and of vitrification of high-level wastes arising from commercial reprocessing facilities. These vitrified wastes include only trace quantities of plutonium, although the engineering skills for design of plant with higher plutonium incorporation exist.
MOX FUEL EXPERIENCE
MOX fuel loadings have been demonstrated in Europe since 1963 with the first loadings in Belgium (LWR) and the UK (gas-cooled reactor). Over 300 tons of MOX fuel have been fabricated to date, recycling 15 tons of reactor-grade plutonium. Programs to load, or investigate MOX fuel have been undertaken in the US, Canada, Euratom countries, Switzerland and Japan. It is perhaps worth restating that, from the earliest times of the commercial nuclear program, the expectation was that plutonium from reprocessing (and depleted uranium arising from enrichment plants) would feed fast reactor programs. Although fast reactor development programs survive in Europe and the Far East, dates for commercial realization are in the distant future and there has been a refocussing of plans for use of separated plutonium in existing reactors.
BNFL's MOX Demonstration Facility (8thm/y) is now operational and draws on experience of 30 years Pu fuel production in the UK. This plant has a unique "short binderless route" for blending UO2 and PuO2 powders, using a high energy attritor mill to achieve intimate missing and a spheroidiser to condition the powder before it is used for the pelleting process. BNFL is currently constructing the Sellafield MOX Plant (SMP) with a capacity of 120 thm/yr using this "short binderless route". This is the third MOX fuel plant on the Sellafield site. The fuel manufacturing process and plant design meet the highest current standards in terms of safety (including occupational dose control appropriate for plutonium from high burnup LWR fuels) and safeguards.
Great attention has been focused on criticality safety, with "safe by shape" vessels and minimal potential for hidden process hold-up. The Company requirement for occupational dose is that the average exposure of the group of works associated with the plant should not exceed 5 mSv/yr (whole body external plus internal) in addition to "As Low As Reasonably Practicable" (ALARP). To meet this stringent criteria for a plant of the scale of SMP requires significant automation and shielding.
Rapid residue recycling and the "short binderless" pellet production route reduce hold-up problems and total inventory. Passive Non-Destructive Analysis (NDA) determination of inventory coupled with the use of sophisticated statistical accounting software achieve Near Real Time Accountancy. The BNFL Plutonium Inventory Monitoring System (PIMS, derived from a Los Alamos technique) employs an array of neutron detectors distributed throughout the plutonium facility and achieves a high

degree of accuracy for measurement of the distribution of Plutonium across an extended area, delivering accurate Near Real Time inventory information. In addition to information for BNFL's management of the facilities, a separate parallel system provides inventory information direct to the international Safeguards inspectors (3).
The SMP project was approved by the BNFL Board mid-1993 and the project will be complete within fiver years of approval.
For the reactor operator, handling and loading of MOX fuel from MDF has proved straightforward and, for fuel manufactured from surplus weapons plutonium, occupational dose implications, even during fuel inspection, will be well within acceptable limits without modification to reactor facilities.
TABLE I
TABLE II
VITRIFIED/IMMOBILIZED PRODUCT
Specifications for the vitrified HLW product from reprocessing plants (and similar material from the US Defence program) have been subject to significant national or international scrutiny and commercial facilities are in operation in France and the UK. Japan is also committed to recycle and a new (second) reprocessing plant and vitrification facilities are under construction. The agreed limiting specification for plutonium in vitrified product from the European plants is more than an order of magnitude below the levels under discussion for weapons Pu disposition.
Although there would not be any fundamental engineering problems in designing a vitrification facility for 1-4% (or even 7%) Pu in glass, there would be concerns at the long-term safety/environmental implications in terms of solubility, criticality, and proliferation resistance. Costs for a large vitrification facility would be of the same order of magnitude as a MOX facility but the product would have no "value" and disposal costs would be uncertain.
PLUTONIUM STORAGE
In the UK, the International Standards for Physical Protection* have been implemented. Plutonium has been stored at the Sellafield site for over 40 years (civil material for 30 years). BNFL's pro-active policy on plutonium management demands that plutonium stocks are held in custom designed and built stores, security, material control, safeguards and accountancy requirements. PuO_2 separated in THORP is stored in strong, leak-tight, triple-walled stainless steel cans with a thermal capacity of 125 W (nominally 7 kg Pu). The current store capacity is 7020 containers (45 mt Pu). Plutonium entering the store is independently verified for international safeguards purposes and monitored thereafter by safeguards inspectors through a Containment/Surveillance system. All operations within the storage area are controlled remotely to reduce operator access to the absolute minimum. In view of the chemical reactivity of plutonium metal, storage as oxide (or a similar ceramic) is preferred to storage of metal.
PLUTONIUM TRANSPORT
BNFL and its associate companies have been transporting plutonium safely in various forms (nitrate, power, fuel) by all modes for over 30 years. In the past 16 years, there have been a number of international shipments comprising 80 deliveries of which at least 90% were as PuO_2, with the balance being as fabricated plutonium in various forms. PuO_2 powder is transported in SAFKEG 2812C packages, the design of which has been tested beyond requirements, including surviving a drop of over 500 meters. There have been no security or safety incidents during this transportation program (4) BNFL has developed a larger package for plutonium transport (1680) to carry four THORP product containers.
A SYSTEMS APPROACH?
The essential stages for implementing a satisfactory plutonium management regime are:
dismantling and short-term storage which will reduce the materials to a form with no classified features.
conversion of the "declassified" plutonium into a form suitable for interim storage and capable of being put under an independent safeguards regime. BNFL has operated such a process from 1975 to 1985.
fabrication of nuclear fuel or vitrification/immobilization of the plutonium.
irradiation of the fuel or storage of the vitrified product until disposal.
For the vitrification/immobilization option:
development of specification for glass/alternative and assessment of technical

(physical properties, short and long-term safety), safeguards and (lifetime) cost implications of storage and eventual disposal of this additional glass waste-form at a Federal facility.

technical demonstration and establishing database to support safety assessments if the proposed specification is in any respect outside the currently validated parameters.

construction/modification of vitrification/immobilization and interim storage facilities.

It is unclear to what extent the cots would displace costs for waste disposal but more than likely that the bulk of the cost would be additional. In addition to the cost of design and licensing, construction, operation and decommissioning a vitrification and storage facility, the cost of glass disposal at Yucca Mountain is also a topic of debate.

For both options:

Any handling of plutonium material on this scale will lead to plutonium contaminated wastes. These waste will vary in chemical and physical characteristics as well as contamination levels. In the US, wastes arising from Defence programs are destined for WIPP. In the UK, a new facility is being built at Sellafield to handle TRU wastes arising from past and future plutonium facility operations. The properties of encapsulated TRU waste have been extensively studied by BNFL. A systematic evaluation of encapsulation alternatives (5) including glass, ceramics, cements, polymers and bitumen has shown the best process encapsulation of TRU waste to be cementation.

This work has demonstrated a long term stable product will be achieved with high Pu loading. The limit on Pu content is assessed as being defined by criticality requirements, not by product quality. Disposal studies have also shown the use of cement to have advantages. The high pH minimizes solubility and the matrix adsorbs Pu effectively further reducing solubility by orders of magnitude.

Consideration of these waste opens up, at least in principle, an alternative approach to the optimization of the plutonium disposition process, in that it is possible that the only waste form for direct disposal could be TRU waste, with the other product being MOX fuel.

Determination of the optimal solution requires a systems approach taking into account:

current form (and location) of the surplus plutonium.

material feed specification for MOX or immobilization.

waste arisings from processing (and waste acceptance criteria).

waste storage and disposal options/viability including any facilities already in operation or development.

time to implement each option.

consideration of political and public acceptance factors.

BNFL has competed an optimization process similar in many respects to the above for new facilities currently under construction or commissioning at Sellafield for wastes (including TRU wastes) arising from reprocessing metal oxide fuels (THORP), MOX fuel fabrication and decommissioning (including TRU waste). In the UK, wastes which exceed 4 Gbq/t (108 nCi/g)a or 12 gbq/t (325 Ci/g)bg and do not generate significant heat are classified as "Intermediate Level Waste" (ILW).

BNFL has established a comprehensive strategy for managing all such wastes arising from past, present and anticipated future operations at the Sellafield complex; cement (with differing formulations according to the wastes to be incorporated) is the chosen matrix for ILW. Four major new waste treatment facilities are newly operational or under construction. These waste will be disposed of in an underground repository.

A further factor which BNFL has considered in the context of product from the commercial reprocessing plant is the extent of possible contaminants in the feed materials for MOX fuel fabrication. For the commercial reprocessors and their customers, plutonium is treated as a resource to be used efficiently, whereas the US priority is expected to be "disposition" of the surplus plutonium as quickly as possible and a number of options for increasing Pu content in MOX fuel have been proposed. What is needed to determine the optimum strategy for MOX is a clear determination of the "spent fuel standard" and, since this standard is qualitative, possibly an equivalent DHLW standard for immobilized waste.

The surplus plutonium from the Russian and US weapons programs differs in some

respects from plutonium arising from commercial reprocessing of higher burnup civil fuels from both gas-graphite and water reactors and particular consideration needs to be given to acceptance criteria both for wastes and for product material (whether glass or MOX). Although there must be no question of compromising reactor safety margins, and the reactor operator must be concerned at any reduction in availability through, for example, increased outage frequency, the need for stringent criteria for neutron poisons in the fuel or clad, for example, may be relaxed if the objective is to consume plutonium rather than to generate electricity in a fuel-efficient way. The effect on a candidate reactor operator's fuel cycle costs will clearly be key to assessing his/her view of fuel specification but this is a contractual matter between the reactor operator and DOE as the (MOX) fuel supplier. There is an opportunity for a risk-based assessment of the current condition of the surplus weapons plutonium to identify options for medium term disposition and urgent steps to take to stabilize the material at least in a manner which will not prejudice future use or immobilization. This is necessarily an adjunct to the review of some of the facilities themselves and, ideally(!) a review of material and facility needs in terms of waste arising and optimum waste forms/treatment process should be undertaken.

IN FAVOR OF MOX

The final "product" from the process of MOX use in LWRs is irradiated fuel similar in all significant respects to irradiated uranium fuel, in terms of safety, safeguards and requirements for final disposal and can be treated in the same way as other routine irradiated fuel arisings.

The principle benefits of the MOX disposition option are:

- minimization of high-level waste volume.
- earliest disposition of the surplus fissile plutonium inventory.
- avoidance of significant long-term plutonium storage costs.
- increased confidence that the principal waste form (irradiated MOX fuel) can be disposed of in the repository under evaluation at Yucca Mountain, Nevada.

IN CONCLUSION

conversion of surplus military grade plutonium metal to PuO_2 has already been demonstrated.

it is safer to store plutonium as PuO_2 than as metal.

the highest levels of safeguards, security and safety in handling, storage and recycle of plutonium in commercial reactors are already proven and available in Europe.

consumption of surplus plutonium as MOX fuel in LWRs offers the most credible and economic option for reducing the plutonium inventory and the least technical risk is terms of final disposal and hence the best means to meet disarmament and non-proliferation objectives.

ABSTRACT
One of the ways recommended by a recent National Academy of Sciences study to dispose of excess weapons-grade plutonium is to encapsulate the plutonium in a glass in combination with high-level radioactive wastes (HLW) to generate an intense radiation dose rate field. The objective is to render the plutonium as difficult to access as the plutonium contained in existing U.S. commercial spent light-water reactor (LWR) fuel until it can be disposed of in a permanent geological repository. A radiation dose rate from a sealed canister of 1000 rem/h (10 Sv/h) at 1 meter for at least 30 years after fabrication was assumed in this paper to be a radiation dose comparable to spent LWR fuel. This can be achieved by encapsulating the plutonium in a borosilicate glass with an adequate amount of a single fission product in the HLWs, namely radioactive Cs137. One hundred thousand curies of Cs137 will generate a dose rate of 1000 rem/h (10 Sv/h) at 1 meter for at least 30 years when imbedded into canisters of the size proposed for the Savannah River Site's vitrified high-level wastes . The United States has a current inventory of 54 MCi of Cs137 that has been separated from defense HLWs and is in sealed capsules. This single curie inventory is sufficient to spike 50 metric tons of excess weapons-grade plutonium if plutonium can be loaded at 5.5 wt% in glass, or 540 canisters. Additional Cs137 inventories exist in the United States' HLWs from past reprocessing operations, should additional curies be required. Using only one fission product, Cs137, rather than the multiple chemical elements and compounds in HLWs to generate a high radiation dose rate from a glass canister greatly simplifies the processing engineering requirements for encapsulating plutonium in a borosilicate glass.

INTRODUCTION AND BACKGROUND

The Clinton Administration has identified the disposition of excess plutonium and highly enriched uranium from the dismantlement of nuclear weapons as one of the most challenging problems for the U.S. Government to solve. An Interagency Working Group is to provide coordination among the multiple U.S. Government bureaus and departments involved. The U.S. Department of Energy (DOE) has a Special Fissile Materials Disposition Program Office to address the problem. Near-term activities for this office include identifying and characterizing alternative approaches to disposition of special fissile materials and completing documentation required by the National Environmental Policy Act for implementation of disposition alternatives. A recent National Academy of Sciences (NAS) study examined ways to dispose of excess plutonium and highly-enriched uranium. (1)

The three preferred disposal options in the NAS study are 1) transforming the plutonium into intensely radioactive spent fuel similar to that already produced by existing commercial reactors, 2) vitrification of the plutonium with radioactive high-level wastes (HLW) in the form of glass logs, and/or 3) direct disposal in deep boreholes.

The Lawrence Livermore National Laboratory (LLNL) has the lead responsibility for assessing immobilization of plutonium in glass or ceramic disposition forms, for assessing geological disposition, and in assisting the DOE in evaluating other disposition alternatives. This is being done using systems engineering to systematically define and evaluate the options and alternatives.

The NAS study introduced the term "spent fuel standard." Meeting a spent fuel standard means to render plutonium as inaccessible as the plutonium found in spent fuel from existing commercial reactors. The magnitude of the radiation field barrier from decay of radioactive fission products would be one crucial metric of a spent fuel standard. An important requirement for this radiation field barrier is a long life. Of the over 100 radionuclides in HLW, the most persistent gamma-ray emitter is Cs137, which has a 30-year half-life. Cesium-137 is also the dominant gamma emitter in aged spent-fuel from existing commercial light water reactors. The Cs137 gamma ray is penetrating and requires 7 cm of steel to reduce its intensity by an order of magnitude.

Further, cesium can be incorporated in a borosilicate glass matrix. Using a single chemical element as the radioactive source to generate a radiation field barrier significantly simplifies the process flowsheets for vitrifying plutonium in a glass matrix, when compared to using multiple fission products of varying concentrations as would be required for incorporation of HLW. A substantial inventory of relatively pure Cs137 was separated from the Hanford HLW and is currently stored in sealed capsules at various sites as cesium chloride. If sufficient inventories of these Cs137 capsules exist, then further extraction is not required from existing HLWs.

Cesium capsules can be readily transported to any site selected for the vitrification facility.

ASSESSMENT, ASSUMPTIONS, CHARACTERISTICS, INVENTORY, AND CALCULATIONS

This paper describes the feasibility assessment and calculational approach in the following subsections. These subsections cover 1) assessment objectives, 2) key assumptions, constraints and limitations, 3) radiological characteristics of Cs137, 4) current U.S. inventories of separated Cs137, and 5) a set of parametric calculations and sensitivity analyses making up the feasibility assessment.

Assessment Objectives

Technical feasibility is assessed for using Cs137 as the radiation barrier in canisters of plutonium encapsulated in glass. This assessment is based on the radioactive decay properties of Cs137, the current inventory of Cs137 in U.S. defense wastes, the compatibility of Cs137 with the envisioned glass vitrification process, and the expected time frame for completing disposition.

Assumptions, Constraints, and Limitations

The inventory of excess weapons-grade plutonium requiring encapsulation in glass is assumed to be 50 metric tons. Canister dimensions used for encapsulating high-level wastes at the Savannah River Site (SRS) are assumed. (2) The SRS canisters are constructed of 304L stainless steel having a 0.375-cm (3/8-in.) wall thickness, a 61-cm (24-in.) o.d., and an overall height of 3 m. Canisters are partially filled to contain some 1680 kg of glass. Glass density is taken as 2.73 g/cm3. Using these numbers, the glass radius would be 29.5 cm, and it would have an effective height of 2.2 m.

Radiological Characteristics of Cs137

Cesium-137 has a 30-year half-life. It beta-decays to Ba137 (5%) and Ba137m (95%). (3) The Ba137m then decays with a half-life of 153 seconds through an isometric transition to the stable form, Ba137. About 90% of the Ba137m decays produce the penetrating 662-keV gamma-ray. The gamma yield from metastable barium equals 85% (90% of the 95% yield) of the Cs137 activity, which is 87 Ci/g. The 30-year half-life should be adequate for the interim storage period that will be needed before permanent geologic disposal of the glass canisters can be implemented.

Current Cs137 Inventories

Most of the current U.S. inventory (some 1109 curies of all radionuclides in 397,000 m3 of HLW, as of December 1990) is the result of past DOE defense activities and is stored at the SRS, Hanford (HAN) or at the Idaho Nuclear Engineering Laboratory (INEL). A small amount (2,200 m3 containing of 3107 Ci) of commercial HLW was generated during 1966-72 commercial reprocessing operations at the West Valley Demonstation Plant (WVDP). Details of these inventories are maintained in a U.S. integrated database. (4,5) Except where noted, the inventory data and descriptions in this section are taken directly from those references.

Approximately 131,700 m3 of alkaline HLW has accumulated at the SRS during the past three to four decades. This HLW is being stored in underground, high-integrity, double-walled, carbon-steel tanks. The current inventories include alkaline liquids (61,300 m3), sludges (14,800 m3), salt cakes (55,500 m3), and precipitates (125 m3) that were generated primarily by the PUREX reprocessing of nuclear fuels and targets from production reactors. All the SRS wastes totaled 5.6108 curies (December 1990).

The 12,000 m3 of HLW stored at INEL consists of 8,500 m3 of liquid waste and 3,500 m3 of solid calcine. Liquid HLW was generated at the Idaho Chemical Processing Plant primarily by the reprocessing of spent fuel from naval propulsion reactors and reactor testing programs. This acidic liquid waste is stored in underground stainless-steel tanks that are housed in concrete vaults. Most waste was then converted to a calcine solid and store space retrievable stainless-steel bins that are housed in underground reinforced-concrete vaults. The INEL wastes total 6.3107 curies (December 1990).

Commercial reprocessing at the Nuclear Fuel Services plant was terminated in 1972, and no additional HLW has been generated since that time. As of December 1990, the 1,231 m3 of HLW stored at WVDP consists of 1,136 m3 of alkaline waste (1,090 m3 of liquid plus 46 m3 of sludge), 50 m3 of acidic waste, and 45 m3 of an inorganic ion-exchange material (a zeolite) loaded with radioactive cesium (Cs134, Cs135, and Cs137). The alkaline waste was generated by reprocessing commercial and Hanford N-Reactor spent fuels. As generated, the waste was acidic; treatment with excess sodium hydroxide resulted in the formation of an alkaline sludge. The small amount of acidic waste now in storage was generated by reprocessing a batch of

thorium-uranium fuel from the Indian Point-1 Reactor. Storage of the alkaline waste is in an underground carbon-steel tank, while the acidic waste is stored in an underground stainless-steel tank. The total curies at the West Valley site is 2.7107 (December 1990).

The 253,600 m3 of alkaline HLW stored at HAN are categorized as liquids (26,400 m3), sludges (46,000 m3), and salt cakes (93,000 m3) that are stored in underground single-shell tanks and as slurries (88,200 m3) that are stored in underground double-shell tanks. This waste, which has been accumulating since 1944, was generated by the reprocessing of production reactor fuel for the recovery of plutonium, uranium, and neptunium for defense and other national programs. In all, these HAN wastes contain a total of 3.9108 curies (December 1990).

Most of the high-heat-emitting isotopes (Sr90 and Cs137, plus their separable daughters) were removed from the old waste at HAN, converted to solids (strontium fluoride and cesium chloride), placed in double-walled capsules, and stored in a water basin. (4,6,7)

According to David Peeler of the Pacific Northwest Laboratories, some 1577 cesium-containing capsules were fabricated at the Hanford Reservation (7). Of those 1577 capsules, some 961 are stored at HAN, 371 are stored at other locations, and 245 have been cut or destroyed. The 961 at HAN and 371 at offsite locations contained an average of 4104 curies per capsule, as of April 1994. The 961 HAN capsules contain a total of 39 MCi (megacuries), and the 371 offsite capsules contain 15 MCi. In this paper, we assume that the full 54 MCi (39+15) are available for use in plutonium disposition.

Casks have been routinely used to ship the capsules to various sites for various radiologic applications. The encapsulated cesium is in the form of cesium chloride, and it contains some 2-6 wt% of impurities, which are primarily sodium, aluminum, magnesium, potassium, nickel, iron, chromium, and silicon (6).

Parametric Calculations and Sensitivity Analyses

A series of radiation shielding and other parametric studies for Cs137 in borosilicate glass canisters was performed using the commercial MicroShield point-kernel code. (8) The radioactive cesium was assumed to be uniformly distributed throughout the borosilicate glass. In turn, the glass was assumed to be inside SRS HLW canisters (0.3-m-radius by 2.2-m-high glass cylinder with a specific gravity of 2.7, surrounded by a 0.95-cm-thick steel wall). The dose point was taken to be midway down the cylinder length and 1 meter out from the steel shell. These calculations show that 1105 curies of Cs137 are required per canister to generate a radiation field of 1000 rem/h (10 Sv/h) at 1 meter some 30 years after the glass canister is filled. The 1105 curies are generated by 1.2 kg of Cs137. Within the point-kernel approximation, external gamma radiation is linear in Cs137 content, and this is illustrated in Fig. 1. Linearity means that 0.6 kg of Cs137 produces half the radiation dose of that for 1.2 kg. Figure 2 shows how the dose rate decreases with increasing distance from the canister surface. Figure 3 shows how the radiation field varies with position along the length of the glass cylinder.

The number of glass canisters must be known, if the 54 MCi of separated and encapsulated Cs137 are to be sufficient to generate a radiation barrier for 50 metric tons of plutonium. The maximum plutonium content in borosilicate glass has not been determined. Figure 3 shows a graph of the number of containers required to encapsulate 50 metric tons of plutonium for various plutonium loadings. For this study, plutonium loadings in glass logs were assumed to range between 0.1 and 10 wt%. From Fig. 4, a 0.1 wt% loading requires 30,000 canisters and a 10 wt% loading requires 300 canisters. Canister minimization is highly desirable to reduce wastes and costs associated with handling operations, material consumption, transportation, and geologic disposal. The highest tolerable loading will likely be established by nuclear criticality rather than by chemical or mechanical requirements on the glass. From the MicroShield calculations described above, 1105 curies of Cs137 are required for a single canister to generate a 1,000 rem/h dose rate at 1 meter after 30 years. Since the total inventory is 54 MCi, 540 glass canisters can be fabricated with 1105 Ci each, to meet this radiation specification. Each of the 540 glass canisters will contain about 93 kg of the 50 metric tons of excess plutonium stock. Since the glass in a canister weighs 1680 kg, this implies a plutonium-in-glass loading of 5.5 wt%. This works out to a cesium-to-plutonium weight percentage of 1.3% for the required 1.2 kg of Cs137.

A recent paper by Westinghouse-Hanford personnel proposes combining cesium-137 with

plutonium oxide in containers several centimeters in diameter and several centimeters high. (9) Their calculations show that a 10 wt% cesium-to-plutonium content is required to achieve 1,210 rem/h at 20 years. Exponentially decaying this value to 30 years yields 960 rem/h.

We modeled the hypothetical addition of cesium to plutonium oxide inside of typical DOE plutonium shipping containers. These containers have an outside diameter of 15.2 cm (6 in.) and a steel wall thickness of 0.95 cm (3/8 in.) Assuming that the 5 kg PuO_2 mass has a unity specific-gravity leads to an effective powder height of 37 cm. Modeling with MicroShield shows that 2.3104 Ci of Cs137 would be required for a 1,000 rem/h dose rate at 1 m for the DOE plutonium shipping containers after 30 years. Based on 4.5 kg of plutonium, this calculation shows a cesium-to-plutonium weight percentage of 6%, which is in approximate accord with Ref. 9. The important point here is that the ratio of required cesium to plutonium is higher for small shipping containers as compared to large glass-filled canisters (6 wt% versus 1.3 wt%). This means that the existing stock of separated Cs137 will go further in the larger glass-filled canisters. In addition, heavy glass-filled canisters are more desirable from a safeguards and security perspective.

CONCLUSIONS

This study establishes the technical feasibility of using the existing U. S. stock of separated Cs137 in cesium chloride capsules as the gamma source to provide a radiation barrier for excess weapons grade plutonium encapsulated in glass. The alternative to using a single fission product, Cs137, is to feed a highly variable HLW composition stream containing a multitude of fission products to a melter. Direct use of HLW could introduce some uncertainties in the final glass composition that could effect geologic performance. Further, the high-level wastes at HAN, SRS, and WVDP do not contain concentrations of Cs137 large enough to directly generate a 1000 rem/h radiation barrier. To increase the radiation barrier level, complex chemical recovery and cesium concentration process operations on the HLWs would have to be designed and performed prior to any glass encapsulation operations.

The use of the single fission product Cs137 for generating a gamma-radiation field offers significant advantages in developing the engineering solutions for vitrification of excess plutonium. For example since only two chemical compounds of plutonium and cesium need to be added to a borosilicate glass, the glass frit composition can be more readily tailored to make a vitrified product with optimum geologic performance. These process feed stream simplifications allows the engineering of simplified vitrification process equipment due to only three streams (Pu, Cs and glass frit) feeding a melter. The fact that the cesium is already separated also means that: (1) the Cs137 can be transported to any site capable of hosting a vitrification facility, including one that is not constrained to be located at SRS or Hanford or INEL and, (2) a sufficient inventory is available so that cesium recovery from its current dilute forms at the HLW defense wastes is not required for any vitrification process.

In addition, the cesium capsules are regarded as an unacceptable waste form issue for direct geologic disposal since cesium chloride is water soluble and the cesium isotope is fairly long lived. (10) The utilization and incorporation of Cs137 into a borosilicate glass matrix generates an acceptable waste form for geologic disposal and resolves a current DOE environmental waste management issue, should encapsulation of excess weapons-grade plutonium in glass be selected by DOE as a disposition alternative.

ACKNOWLEDGMENTS

Work performed under the auspices of the U.S. Department of Energy by LLNL under Contract W-7405-ENG-48.

ABSTRACT

As a result of nuclear disarmament activities, many thousands of nuclear weapons are being retired in the U.S. and Russia, producing a surplus of about 50 MT of weapons grade plutonium (Pu) in each country. In addition, the Department of Energy (DOE) has more than 20 MT of Pu scrap, residue, etc., and Russia is also believed to have at least as much of this type of material. The entire surplus Pu inventories in the U.S. and Russia present a clear and immediate danger to national and international security. It is important that a solution be found to secure and manage this material effectively and that such an effort be implemented as quickly as possible. One option under consideration is vitrification of Pu into a relatively safe, durable, accountable, proliferation-resistant form. As a result of decades of experience within the DOE community involving vitrification of a variety of hazardous and radioactive wastes, this existing technology can now be expanded to include immobilization of large amounts of Pu. This technology can then be implemented rapidly using the many existing resources currently available. A strategy to vitrify many different types of Pu will be discussed. In this strategy, the arsenal of vitrification tools, procedures and techniques already developed throughout the waste management community can be used in a staged Pu vitrification effort. This approach uses the flexible vitrification technology already available and can even be made portable so that it may be brought to the source and ultimately, used to produce a common, borosilicate glass form for the vitrified Pu. The final composition of this product can be made similar to nationally and internationally accepted HLW glasses.

BACKGROUND

The Committee on International Security and Arms Control (CISAC) of the National Academy of Sciences (NAS) was commissioned by General Scowcroft, National Security Advisor to President Bush, to conduct a study on disposition alternatives for management of excess plutonium resulting from disarmament activities. This charter was later confirmed by the Clinton Administration. After receiving input from many sources and evaluating the options, NAS recently issued the results of this study in a report entitled "Management and Disposition of Excess Pu" (1) in January of 1994. The treatise covered many important aspects of the Pu disposition question and with respect to long-term management of the excess Pu stated the following:

"Then two most promising alternatives for achieving these aims (long-term Pu disposition) are:

  fabrication and use as fuel, without reprocessing, in existing or modified nuclear reactors; or

  vitrification in combination with high-level radioactive waste."

A third option, which has not been studied in as much detail, burial of Pu in deep boreholes, was also mentioned as a possible consideration.

As a result of the NAS study, the vitrification option was elevated to the same level of importance as a reactor option and listed as one of two leading preferences

for ultimate disposition of weapons grade Pu.
The Savannah River Site (SRS) has been involved in vitrification of high level waste for several decades and also associated with vitrification of a variety of other types of radioactive and non-radioactive materials (2,3). As a result of over 20 years of vitrification experience and about 40 years of Pu handling and processing experience, the site has been requested to provide input into this subject by a variety of groups and agencies, including the U.S. Department of Energy. These efforts are directed at addressing a variety of Pu disposition alternatives (4-7), including management of weapons grade Pu and also Pu scrap, residues, etc. that currently exist throughout the DOE complex. An early summary of vitrification options is documented elsewhere (8).

WHY VITRIFICATION

There are many potential advantages associated with the vitrification option for long-term management of plutonium. These include the following:

Immediacy of Implementation

Many experts in the field believe it is important to act quickly to immobilize Pu for security, safeguards, safety and environmental reasons. Because of the advanced state of the art of vitrification and as a result of the existing capabilities and experience in this area, there is no other Pu option that can be implemented as rapidly.

Flexibility

The vitrification option provides a common technology for treatment of almost all forms of Pu. This includes not only weapons grade Pu, but also significant quantities of more complex Pu scrap and residue compositions, currently existing within the DOE community and posing additional problems.

Technology Availability

As a result of the High Level Waste program and associated waste management efforts, there have been decades of research on development of techniques and procedures for vitrifying radioactive and hazardous components, equipment and facilities for these tasks, and in specifying waste form qualifications to assure product quality. These efforts are directly applicable to Pu vitrification and could be piggy-backed upon. A very extensive and capable vitrification infrastructure exists containing experienced and dedicated experts throughout federal and national laboratories, academia, and industry throughout the United States as well as in other countries.

Waste Glass Performance

HLW glasses have been demonstrated to have excellent chemical durability, mechanical integrity, radiation and thermal stability. Chemical durability is considered to be the most important technical performance property of a waste glass form. It is important to note that actinide bearing glasses exhibit excellent chemical durability. The leaching of actinides is generally 10-100x better (lower leach rates) than modifiers or alkali cations contained in HLW waste glass systems.

Processing Considerations

The ability to vitrify radioactive materials is not only well developed, but also well demonstrated. In the case of HLW, actual production facilities are in operation world-wide. These include the French process in Marcoule and also La Hague, the German vitrification operation in Mol Belgium, the Sellafield facility in England and others. Construction of the first HLW vitrification facility in the United States, the Defense Waste Processing Facility (DWPF) at SRS, has recently been completed and is scheduled to be in production in about one year. Vitrification of Pu represents an extension of this already available vitrification technology and its many components.

Waste Minimization

Due to the type of equipment and buildings needed to process radioactive materials, and as a result of the vitrification facilities and equipment used to treat other types of radioactive wastes, existing contaminated and non-contaminated facilities could be modified to perform Pu vitrification. These facilities include buildings and equipment designed to receive Pu, store the material, process the Pu, and vitrify it into acceptable products. These facilities currently exist within the DOE complex and although they would require various degrees of modification, their existence would eliminate the need to build and later D&D additional buildings.

Ability to Immobilize Pu in Glass

Immobilization of Pu into borosilicate glass has already been demonstrated in HLW programs. This early work involved immobilization of 7 wt. % of plutonium oxide into

a glass matrix. Higher Pu loading is probable. Hence, there is no question whether Pu can be vitrified- the maximum amount immobilized remains to be defined and will most likely not be determined by solubility limits but by criticality considerations.

Inherent Criticality Control

Due to the composition of borosilicate glasses, boron as well as lithium, which are normally present in HLW forms, can act as poisons to assist in criticality control. This is especially important during handling and processing operations. Other poisons such as gadolinium or erbium and rare-earths could be added to further this effect, which would be especially relevant for long-term repository storage scenarios due to their insolubility. Additional work would be necessary to better assess the effects of potential poisons for criticality control in some of the final disposal options under consideration and for increasing the difficulty in reclaiming Pu from the glass matrix. Criticality control represents the most important consideration in all stages of any disposal option.

Acceptability/ Waste Form Qualifications

The only waste form which has achieved a degree of national and international acceptance for immobilizing HLW is borosilicate glass. HLW glasses already contain Pu, although in very small amounts. It took approximately ten years and thirty million dollars to qualify the SRS HLW waste glass composition. This important and necessary effort could be piggy-backed upon for the Pu vitrification option.

Proliferation Resistance

There are many ways in which Pu can be immobilized into glass to produce durable, safe, proliferation-resistant forms. These options depend on the degree of proliferation resistance required and are directly proportional to the cost and complexity of the operation. For example, simply immobilizing Pu into glass can be achieved rapidly and most easily and provides the highest degree of flexibility. The Pu-glass product produced would be more proliferation resistant that Pu in its weapons form, but could be reclaimed fairly easily by those reasonably familiar with this field. The degree of proliferation resistance could be increased significantly, however, by either initially mixing the Pu directly or by re-melting Pu-only glass, with fission products or existing HLW. The radiation field associated with the radioactive additives would considerably increase the difficulty in obtaining or handling this material and in subsequent transportation and reprocessing operations to reclaim Pu. Proliferation resistance can be further enhanced by the potential size and weight of the product and most importantly, by the safeguards that would be necessary for any undertaking of this type.

OVERVIEW OF A POTENTIAL Pu STRATEGY

Vitrification provides an important option to immobilize and dispose of not only weapons grade Pu, but also many other forms of Pu of concern within weapons producing countries. The major steps involved in a Pu vitrification strategy include the following

Pu Handling and Glass Preparation

I. Preparation (receipt, pre-storage, and pre-treatment)
II. Conversion to melter feed
III. Vitrification into intermediate or final Pu-glass products

Interim and Final Product Storage

IV. Interim product storage
V. Final product disposition

A simplified flowsheet summarizing this overall vitrification strategy is depicted in Fig. 1 followed by a brief description of each of the important phases.

Fig. 1.

Preparation

The vitrification strategy applies to Pu in metal form currently contained in weapons as well as Pu in other forms such as oxides, buttons, scrap, solutions, ash, salts, residues, etc. The other forms of Pu are contained at DOE sites including Rocky Flats, Los Alamos National Laboratory, Hanford, Argonne National Laboratory, Idaho National Engineering Laboratory, and the Savannah River Site. Preparation of these materials will involve receipt, disassembly/ separations in some cases, assaying, interim storage and pre-treatment prior to immobilization.

Conversion

There are two major options that can be used for conversion of Pu from a metallic form to a suitable melter feed. These include a) oxidation- burning it to produce

plutonium oxide powder and b) dissolution- dissolving it to yield a plutonium acid solution. Additional preparation involving Pu scrap and residues could be performed, depending on composition and subsequent melting characteristics. Vitrification can handle either liquid or oxide feeds.

Vitrification

A vast array of electric melting techniques have been developed for vitrification of radioactive wastes over the years and include indirect heating, joule heating, plasma and microwave vitrification. Many of these techniques and their tested glass melters could be used to vitrify Pu. The proposed strategy considers two main options for vitrification:

In Option A, shown in Fig. 1, the treated Pu is melted directly with fission products such as Cs-137 or HLW to produce a highly radioactive Pu glass product. This could be accomplished in several ways and provides the highest degree of proliferation resistance possible. Because of the highly radioactive wastes to be mixed with the Pu, specially contained and shielded facilities and equipment would be necessary.

In Option B, an interim Pu-only glass is first produced as an interim product. This option has the advantages of being able to use a wide range of site-specific vitrification technologies already located at sites containing the waste, can be performed by the use of relatively simple portable equipment and gloveboxes, and can be accomplished most rapidly and easily due to the relatively low levels of radioactivity involved. While the resulting Pu-only glass does not produce the most proliferation resistant glass product, it does provide the most flexibility because it can be transported to other locations that have more highly radioactive wastes, such as HLW or selected fission products, and later be re-melted with this waste to produce more proliferation resistant forms. Since specially contained facilities and equipment are necessary for this part of the operation, current facilities with other missions could be used by meshing into existing programs and schedules to produce duel missions and optimum use of existing resources.

An important concept in this strategy is that a common final waste glass form can be produced with a similar composition to HLW glass (9), which has undergone a very time consuming and expensive process to be certified and made acceptable. A resulting Pu- HLW glass compositions would be anticipated to be as good, if not better, than the already acceptable HLW glass compositions.

Interim Product Storage

A need to store Pu bearing glasses temporarily is important to the vitrification option. The design of the interim storage facility would depend on factors such as the composition and radioactive content of the products and the intended duration of storage before ultimate disposal. Among the most important considerations for this facility are worker radiation exposure, public and environmental protection from radiologic hazards, and material safeguards and accountability.

Final Product Disposition

The reference concept for ultimate disposition of HLW glass and spent fuel is to dispose of this material by deep burial in carefully selected geologic repositories. This is also being considered for Pu bearing glasses. A very significant challenge for any repository scenario is to demonstrate safe and effective performance of products out to very long time periods (1000 to 10,000 years, and longer). This challenge would be expected to be even more formidable for any immobilization alternative containing large amounts of Pu, due to criticality considerations. The waste form and waste package will be designed to prevent criticality from occurring but this must be demonstrated to a very high degree in a very complex environment. While this would not be expected to be as significant an undertaking for a "Retrievable Surface Storage Facility or RSSF", it would be expected to take much more effort to demonstrate in a geologic repository.

The final form and composition of Pu glass would be tailored for technical and political considerations, involving possible reuse or non-reuse by the weapons producer and for optimizing proliferation resistance, especially towards potential non-friendly nations.

VITRIFICATION OF Pu USING EXISTING RESOURCES

As discussed earlier, there exists an infrastructure knowledgeable on vitrification of radioactive and hazardous wastes that could be used for vitrification of Pu. Along with the developed technology, experience and experts, are existing buildings, equipment and supporting hardware and software for such an effort. While buildings

and equipment exist throughout the DOE complex, the following discussion will emphasize vitrification options and facilities associated with the Savannah River Site (SRS). These facilities are shown along with the accompanying main vitrification steps discussed earlier in Fig. 2.
Fig. 2.
At least six separate vitrification options have been identified using SRS facilities. The processing options involve three potential Pu products; a Pu-only glass (interim product), a Pu/Cs-137 glass (final product) or a Pu/HLW glass (final product). Among the main existing facilities which could be modified and are critical to these vitrification options are the following:
Plutonium Storage Facility (PSF)
The mission of the PSF was to receive Pu materials from offsite that would later be processed. The building contains a fully safequarded vault for automated transport and stacking, gloveboxes for opening drums and removing and inspecting contents, and instruments for non-destructive assay and computer accountability. The facility also contains a delivery systems for later processing of materials in an adjacent facility, the New Special Recovery (NSR).
New Special Recovery (NSR)
The mission of the NSR was to process plutonium from throughout the DOE complex. This includes dissolving Pu scrap, oxide or metal from various sources to produce purified Pu metal buttons or oxide powder. The facility contains state of the art glovebox trains for feed preparation, waste handling, dissolution processes, samples and analysis, along with a supporting remote control room. This facility also contains extra room which could be outfitted with glass melters to pursue one of the vitrification options under consideration.
F Canyon (Including the Multi-Purpose Processing Facility or MPPF)
221-F Canyon was the world's first PUREX production plant used to dissolve natural and depleted uranium targets and to recover the uranium and plutonium. It is a large, heavily shielded facility operated by remote means. The building has the potential of being refitted with a melter and used for vitrification in support of another vitrification option of immobilizing Pu directly with HLW or selected fission products. The MPPF is located within the facility and contains eight modules that are now being used for vitrification of Cm and Am using a bushing melter, and will also be used for vitrification and subsequent clean up of Pu scrap on site.
Defense Waste Processing Facility (DWPF)
The mission of the DWPF is to immobilize the 34 million gallons of HLW currently being stored at SRS into borosilicate glass. This represents the first waste vitrification facility constructed in the United States and is scheduled to be in production in about one year. All of the operations necessary to process, vitrify, containerize, seal and decontaminate HLW glass units are present, including supporting capabilities to control the process and verify product quality. This facility and its equipment could be modified to vitrify larger quantities of Pu than presently contained within HLW.
Important for DWPF options is not to adversely effect the current, important mission of the facility. This could most easily be achieved by the staged approach mentioned earlier. There are two primary ways that Pu vitrification could be conducted using the DWPF. First, during the scheduled melter change out of the DWPF, the facility and equipment could be modified and Pu bearing feed introduced either directly as a Pu feed or as a Pu bearing glass frit, to produce Pu-HLW glass forms in 304L stainless steel containers. These units would be similar to HLW glasses in canisters, 2-ft. in diameter and almost 10-ft. high. An important potential advantage of this option is that waste loading to the glass could be increased by 1-2%, which would still result in a highly durable form which could immobilize 50 MT of Pu as part of the HLW program, and without increasing the number of waste canisters produced.
The second main option involves placing the interim product, Pu-bearing glasses, into HLW canisters and pouring HLW over them in the current HLW vitrification campaign. While this option does not produce as integral a product as the Pu-HLW glass, it does produce a form with similar radiation characteristics (proliferation resistance) and is considerably easier and less expensive to implement into the current facility and schedule.
SUMMARY
Vitrification is a technically viable option to immobilize and manage Pu resulting

from disarmament activities as well as a wide range of existing Pu scrap and residue compositions. A vitrification infrastructure exists from waste management programs. This includes expertise and experience, personnel, buildings, equipment and supporting capabilities, which could be used to implement vitrification of Pu in a time expedient and cost effective manner.

COMPOSITIONS AND DURABILITIES OF GLASSES FOR IMMOBILIZATION OF PLUTONIUM AND URANIUM

William G. Ramsey

Thomas F. Meaker
Westinghouse Savannah River Company
Savannah River Technology Center

ABSTRACT

Investigations have been performed to determine the suitability of glass as a host for surplus fissile material removed from nuclear weapons. The U.S. Department of Energy - Office of Technology Development has sponsored research at the Savannah River Site to develop durable glass compositions that are compatible with high concentrations of plutonium and uranium. These investigations are also being performed to provide baseline actinide glass durability and processing data.
Two glass forming systems are being evaluated. One of the systems is a commercial borosilicate glass and the other an iron phosphate glass. Both glass systems have a very high degree of compatibility with actinide oxides and are considerably more durable than conventional high-level waste glasses. The iron phosphate glass has a melting temperature in the 1100C range and has the higher uranium and plutonium solubility. The borosilicate has a melting temperature in the 1425C range and is the more durable (on the order of fused silica) glass.

INTRODUCTION

As the nuclear weapon arsenals of the United States and the Former Soviet Union are reduced, metric tonnage quantities of fissile material must be dispositioned (1). One of the potential disposition options for U.S. weapons material is vitrification into a plutonium or uranium glass product (2). The U.S. Department of Energy - Office of Technology Development has sponsored a program at the Savanna River Technology Center (SRTC) to develop suitable glass formations for the long term safe

storage of uranium and plutonium as well as americium, neptunium and curium. These "actinide glasses" are the focus of this paper (3).
Three of the most important questions which must be answered for any actinide glass product are 1) what is the maximum actinide oxide loading, 2) what is the chemical durability, and 3) how can it be produced. The experiments described below were performed to provide a preliminary technical baseline on actinide solubility in glass and glass durability. Glass processing characteristics and limits will be discussed in subsequent publications.
This paper discusses the chemical composition and durability of two types of actinide glasses under development. One of the glasses is a commercial borosilicate composition developed in the 1930's for use as an optical glass (4). This glass, referred to as the Lffler glass, was selected for study due to the very high (55 weight percent) lanthanide oxide content (5). Lanthanides are commonly used as actinide surrogates (6). There was, therefore, a high degree of confidence that this glass would be chemically compatible with high concentrations of actinides. The other glass is an iron phosphate. This glass was selected for study due to the combination of low melting point and high durability (7,8). In the initial studies thorium and uranium were used as the actinides. Because of the low radioactivity of these elements, the glasses could be prepared and tested on the bench top.
The specific objects of the initial study were to determine:
1. maximum weight percent loading of thorium and uranium oxide in the borosilicate and phosphate glass,
2. chemical durability of the glasses as a function of actinide loading.
Data obtained were used to determine initial frit compositions and processing parameters for the plutonium melts. The first plutonium glasses have been prepared and are being tested in the shielded cell and glovebox facilities at SRTC.
EXPERIMENTAL
Glass Fabrication
The initial glass samples fabricated were made from reagent chemicals. The batches were made in high-form alumina crucibles. Water was added to all reagent chemical batches to ensure proper mixing. The batch was allowed to dry overnight at 90C prior to firing. The crucibles were then placed in a furnace and ramped to temperature no faster than 8C per minute. The appropriate melt temperature was held for a period sufficient to ensure complete melting. The glass was then cast into a graphite mold and annealed. Glass frit was produced in the same manner except the melt was cast into water and then crushed into powder.
Glass Durability Testing
Relative durability of the glasses discussed above was measured using the ASTM C-1285 standard nuclear waste glass durability test method, commonly referred to as the Product Consistency Test, or PCT (9). The PCT protocol calls for crushed glass powder to be reacted with ASTM-I deionized water in a closed vessel (10). The test conditions included:
  10 milliliters ASTM-1 H2O per gram 100-200 mesh glass powder,
  90C test temperature,
  7 day test duration.
PCT leachates were analyzed for soluble glass constituents by Inductively Coupled Plasma - Emission Spectroscopy (ICP-ES). U and Th concentrations in the leachates were determined by Inductively Coupled Plasma - Mass Spectroscopy (ICP-MS). Leachate solution pH was measured by a glass bulb electrode.
Relative glass durability was calculated from the PCT data. Normalized Loss (NL[1]), a common expression of relative glass durability was calculated for each glass tested. NL[1] is a function of the concentration of a soluble glass constituent cation in the PCT leachate solution and the concentration of the cation in the glass. NL[1] is expressed in the units grams of glass dissolved per liter of leaching solution. The following relationship is used to calculate NL[1]:
Eq.
where
c[i] = concentration of "i" in solution (mg/L).
f[i] = weight fraction of "i" in glass.
X-Ray Diffraction
X-Ray Diffraction was performed on all samples to identify any crystalline phases. Scanning Electron Microscopy was also performed as a complementary technique if crystalline phases were detected. None of the glass samples discussed above had any

discernible crystalline character.
RESULTS
Glass Production
Minor adjustments to the base Lffler glass composition were made in order to lower the melting point and liquidus temperature and raise the melt viscosity (11,12). This was accomplished by reducing the total lanthanide oxide content and increasing the alumina, lead oxide, and silica fractions of the glass composition. The compositions of one series of glasses, which bracket the expected process parameters for actinide glass production, are given in Table I. All glasses shown in Table I, with the exception of Lan-22, were melted at 1425C. Lan-22 was melted at 1460C.
TABLE I
The next series of glasses consisted of uranium and thorium oxide added to the target glass composition shown in Table I. Uranium and thorium oxide were substituted on a 1:1 molar basis for cerium and neodymium oxide. Melts containing 1, 5 and 9 mole percent (9 mole percent @ weight percent) uranium oxide (calculation basis UO2) and thoria (ThO2) were successfully processed at 1425C.
The base composition iron phosphate glass, as shown in Table II has a melting point @ 1100C. No composition adjustment was necessary to the base glass prior to adding uranium or thorium oxide. Thorium and uranium oxide were substituted on a 1:1 molar basis for Fe2O3. Melts containing 10, 14 and 17 mole percent (17 moles percent @ 30 weight percent) actinide oxide were successfully processed at 1150C.
Iron phosphate glass frits were made for plutonium processing. Frit and PuO2 were mixed together and then heated to 1100C (5 hours at temperature). Melts containing 10 and 17 mole percent PuO2 were successfully processed. A frit composition (denoted Frit + Ba) developed for the plutonium glass melts is shown in Table II.
TABLE II
Relative Glass Durability
The Lffler glasses are quite resistant to aqueous attack. The PCT experiments on the non-radioactive glasses (Table I) show very uniform results. All six Lffler glasses tested were more durable than two common durable glasses - Vycor and fused silica. This is graphically represented in Fig. 1. Table III lists the PCT leachate Si concentration for the Lffler glasses, fused silica and Vycor. Normalized Release, NR[Si] and the Glass ID's used in Fig. 1 are also shown in Table III.
Thorium and uranium bearing Lffler glasses are also quite resistant to aqueous attack. The PCT results show little or no difference between the durability of actinide bearing and non-radioactive compositions. Also, uranium and thorium oxide appear to have identical effects on glass durability. There is no difference between the durability of glasses with 1 percent and 5 percent actinide oxide content. Glasses with 9 mole percent actinide oxide were slightly less durable. These results are displayed in Fig 2. It should be noted the relative durability of the Lffler glasses is approximately 3 orders of magnitude better than the standard for high-level waste glass (13,14).
The iron phosphate glasses are also quite resistant to aqueous attack. PCT experimental results indicate the iron phosphate glass to be approximately 2 order of magnitude more durable than the standard for high-level waste glass. Thorium and uranium bearing glasses have similar PCT response up to the 20 weight percent actinide oxide concentration. Both thorium and uranium have a negative effect on the durability of the iron phosphate glass beyond 20 weight percent oxide loading. Beyond twenty weight percent, uranium glasses are appreciably less durable than thorium glasses. These data are graphically represented in Fig. 3. The leachate solutions are also significantly more acidic as the uranium oxide content increases beyond 20 weight percent. These data are graphically represented in Fig. 4.
TABLE III
Fig. 1.
Fig. 2.
Fig. 3.
Fig. 4.
DISCUSSION
The Lffler and iron-phosphate are glass compositions with high concentrations of actinides. Also, both glasses are extremely resistant to aqueous corrosion. Interestingly, the Lffler and iron phosphate glass are completely different chemically. The base compositions share no common oxides. Lffler glasses are processed at temperatures consistent with commercial borosilicate glasses. Iron

phosphates are processed at temperatures 300C lower, in the range of high-level waste glasses. It is felt, therefore, that these glasses may be used for different actinide vitrification missions - in the manner of complimentary products. The Lffler glass has been selected as the optimum glass formulation for vitrification of SRS americium and curium (11). This glass is compatible with existing commercial melters and appears well suited for mass production. It is completely compatible with lanthanide neutron poisons (Gd, Sm, Eu), and certainly, boron. The use of dual neutron poisons in the frit and glass compositions has obvious safety benefits. The iron phosphate does not have the same degree of compatibility with lanthanide neutron poisons as the Lffler glass, but is easily processed in low temperature furnaces. Moreover, the glass appears to be fairly tolerant of fluoride and reducing agents. For this reason, the iron phosphate is being proposed for disposition of heterogeneous, sub-critical masses of plutonium by direct vitrification. This should significantly lessen the number of pretreatment processes which must be developed to handle U.S. plutonium inventories.

CONCLUSIONS

There are four principle conclusions.

1. The solubility of thorium and uranium oxide in a representative Lffler borosilicate glass is approximately 9 mole percent (20 weight percent).
2. The durability of the Lffler borosilicate glass is extremely high, equivalent or better than fused silica. Thorium and uranium oxides have identical effects on Lffler glass durability.
3. The solubility of plutonium, uranium, and thorium oxide in the iron phosphate glass is approximately 17 mole percent (30 weight percent).
4. The durability of the iron-phosphate glass is considerably better than the standard for high-level waste glass. Glasses with high concentrations of uranium are slightly less durable than corresponding thorium bearing glasses.

The Lffler composition is the recommended glass composition for vitrification of SRS Am and Cm. The original composition has been tailored to be more compatible with the tetravalent actinide oxides and existing commercial melter systems. Based on the processability and extremely high chemical durability, it is concluded that this glass should also be considered for vitrification of metric tonnage quantities of weapons plutonium and uranium.

The iron phosphate glass has extremely high chemical compatibility with actinide oxides. It also has a high chemical durability and can be easily processed on the crucible scale. Based on these data, this glass should be considered suitable for disposition of small, heterogeneous sources of plutonium and uranium.

ACKNOWLEDGMENT

This work was performed in connection with work done under contract No. AC09-89SR18035 with the U.S. Department of Energy and under Task Technial Plan SR14-20-08 sponsored by the U.S. Department of Energy - Office of Technology Development.

Nez Perce Tribe
Department of Environmental
Restoration and Waste Management
ABSTRACT
Tribal governments are affected by a variety of environmental challenges. The legal doctrine of federal trust responsibility provides an avenue for tribal governments to build their infrastructure and human resources to handle these environmental challenges. Federal support for the development of tribal expertise, however, is limited by the increasingly tight federal budget. The Nez Perce Tribe proposes that building the necessary internal expertise is vital to strengthening its sovereignty and protecting the health and welfare of its members and neighboring jurisdictions. The Nez Perce Tribe in an effort to accelerate the development of its expertise and promote a clear, more comprehensive national environmental protection regime seeks to expand its long-term strategic education partnerships to include industry at work in the environmental restoration and waste management fields. The legal and political nature of environmental protection issues requires full consideration and stronger partnerships between all parties involved.
INTRODUCTION TO NEZ PERCE TRIBE AND WASTE MANAGEMENT
In a set of promises between two sovereign nations, the Nez Perce Tribe exchanged vast territorial holdings for protection, material aid, a relationship with the United States. This set of promises is contained in the Treaty of 1855. The Treaty of 1855 established a federal trust responsibility that requires federal agencies to act in the best interests of the Nez Perce Tribe when the Nez Perce Tribe does not have the capability to act in its own best interests.
For example, in the area of environmental protection, the Nez Perce Tribe has an understanding of what a healthy environment is and how to maintain that environment. This knowledge is based on traditional knowledge and cultural practices. While there is a lot to be gained by the United States and other non-Indian societies from an equitable and fair exchange of ideas and practices, the larger non-Indian society has been busy in developing more complex industrial processes along with their associated externalities (pollution). Accompanying the technical difficulty of addressing the industrial externalities is the politically and legally tortuous task of understanding and operating within the environmental arena. The Nez Perce Tribe is aware of the complexity of the environmental problems, however, within the national context it is next to impossible to negotiate these waters without assistance. Obtaining this necessary assistance while maintaining and nourishing the traditional Nez Perce knowledge and practices is the goal of Nez Perce ERWM Department's internship program.

The Nez Perce Tribe has environmental concerns, jurisdiction, and activities in three geographic areas: on reservation, in ceded territory and in possessory rights areas. "On reservation" is an area seen on most maps as the Nez Perce Reservation. "Ceded territory" is land beyond the exterior boundaries of the Nez Perce reservation that once encompassed the land claimed exclusively by the Nez Perce Tribe. "Possessory rights areas" are locations beyond ceded territory traditionally used the Nez Perce Tribe in common with other tribes. These possessory rights areas are in three states and in the ceded territories of other Indian nations. The possessory rights areas are guaranteed by the US government and are acknowledged by all other jurisdictions.

The US Department of Energy's Hanford Reservation and its related environmental management challenges affect the Nez Perce possessory rights areas most immediately along the Columbia River. Since the focus of this paper is on building strategic partnerships through internships, it is not necessary to focus on the well-documented problems at Hanford.

The Nez Perce Tribe has entered into a cooperative agreement with the Department of Energy as the mechanism for Nez Perce involvement at Hanford. The Nez Perce/DOE cooperative agreement covers the following main areas: policy and planning; clean-up and technology development; education and human resources development; public involvement; cultural resources; data management; transportation and emergency response; and health studies. Each of these areas has deliverables assigned to both the Department of Energy and the Nez Perce Tribe. The spirit of the cooperative agreement is based on a government-to-government relationship of mutual respect and as the name implies, cooperation. The Nez Perce Tribe has an on-going effort to educate the Department of Energy to its federal trust responsibility and the roles and levels of interaction that can be appropriate vis--vis the Nez Perce Tribe. Building strategic partnerships through internships can expand this education effort to other environmental management organizations.

Nez Perce Education: Historical Background

Traditionally, Nez Perce Tribal members went from being children to adults. There was no "adolescence" as we recognize the term today, with all of the implications that go with that stage of life. Children were traditionally taught by three main methods--by example, storytelling and experience. The adults of the Tribe were responsible for being role models and teachers, setting examples for the young to emulate. Although all members of the Tribe had this responsibility, the grandparents were normally the primary teachers and mentors of the children. By virtue of their age and experience, grandparents were equipped with the knowledge and the wisdom to provide role modeling, values, and behavior that would be learned by the children. Grandparents and certain other tribal elders were also "storytellers." The oral tradition of the Nez Perce people includes many stories and legends that on the face, appear to be humorous and many times even "off color." Coyote, "Its-iyaya" is the main character of many Nez Perce legends and plays many roles: the trickster, the wise one, the clown and the leader depending on the legend. The stories and legends always have a moral and this is the reason for their telling. Storytelling also passed down from grandparents and elders to children the history of the Tribe. By the time children were 12 or 13 they had been taught the necessary values and history to be considered adult. About the same time they were expected to get their "Wyakin," their guardian spirit who would remain with them for their lifetime as a guide and helper. The Wyakin was always a living thing. Usually an animal or bird and was received after praying and fasting in a remote mountain area.

Education for Nez Perce children was traditionally a process that was so interwoven into the culture that it was "painless" compared to the educational process today. There may have been tests, in that young men were expected to demonstrate what they had learned by showing their horsemanship, hunting prowess, fishing skills, tool making, and living the values they had learned. Similarly, young women were expected to demonstrate weaving, cooking, sewing and other skills they had been taught.

The education of Nez Perce children on nature; and environment, was an integral part of the culture and of their spiritual development. Since life depended on water, fish, meat, plants, herbs and medicines, there was spiritual recognition of these things and was extended to such objects as rocks. Anything related to nature was a part of the spirituality and culture of the Nez Perce people and was treated with respect. An example of this is when a deer was killed by a hunter, the hunter knocked out the deer's eyes so that thanks was given to the deer for the meat and

hide he would provide for the people.
Contemporary Indian Education
With the onslaught of European contact, the Nez Perce people were conquered physically, but never spiritually or culturally. Missionary schools were established on the reservation in the mid 1800's. The schools endeavored to teach Anglo ways and meted out harsh physical punishment to children who spoke the Nez Perce language, participated in dances or ceremonies or refused to comply with rules of English standards and protocol. Presbyterian missionaries were particularly harsh with children who attempted to practice Nez Perce customs or speak the language and were physically whipped as punishment. Anything Nez Perce was considered by the missionaries to be "heathen". The English language was picked up quickly by children and the forced imposition of European ways was eventually adopted by the majority of children in these schools as well. During this time period, the conversion of the Nez Perce to Christianity was the overriding purpose of the schools and although other subjects were taught, the missionaries were successful in accomplishing this conversion, mainly to the Presbyterian and Catholic faiths, causing factions in the Tribe that played a major part in the Nez Perce War of 1977 and continue to brew today.
European teaching methods have never been completely successful with Nez Perce students. Teaching methods differed so drastically from the traditional ways of learning that the adaptation was extremely difficult for most students and continues to be difficult today. In 1992, the public school on the Nez Perce Reservation with the highest Nez Perce enrollment aggregated test scores to see how groups were accomplishing in the system. The test scores were aggregated by race and sex and the results showed that the highest scores were earned by white females, followed by white males, Indian females, then Indian males. It became apparent that the educational system for the most part is failing Nez Perce students. The school located in Lapwai, Idaho, has a 70% Indian enrollment and has some Nez Perce teachers and administrators within the system. The school district is struggling to find ways to teach Nez Perce students so that they can successfully accomplish in school and be prepared to go on to college. Of course, there are exceptions among the Indian students with some earning high grades and not experiencing problems with learning. An interesting facet of the study, showed that Indian students accomplished on an equal level with white students until about grades 6 and 7. One theory is that once Indian students must deal with abstract concepts, learning takes a drastic dip on the scale. Math, science, and English are the areas of biggest impact and are of concern to the Nez Perce Tribe since Fisheries, Forestry, Water Resources, wildlife and Environmental Restoration, particularly in respect to the Hanford Nuclear Reservation cleanup are all in need of Nez Perce scientists and professionals. This trend appears to be true nationwide and educators currently struggle with the answers to this problematic situation.
Introduction to the Nez Perce ERWM Internship Program
The Nez Perce Tribe is implementing an internship program based on a model developed by the Council Of Energy Resource Tribes (CERT). This program identified interns as young as recent high school graduates and provides them career counseling and internship opportunities throughout their college years and beyond. The Nez Perce ERWM Department currently has seven interns, and is currently in the process of hiring a full-time education programs specialist. The ERWM Department is intent on providing opportunities to interns that best meet student, ERWM, and intern-host needs.
The Nez Perce ERWM
Department plans to develop qualified professionals with a wide variety of work experience based in a sound understanding of traditional Nez Perce culture and values. The students begin with some introductory level opportunities and as the student's interests experience and professional contacts increase, they can begin to take more control over the direction of their placements. Some students see the internships as a possibility to gain a broad-based view of their fields. Students with engineering internships have the option to experience policy and planning internships as well.
Inception of the Nez Perce ERWM Internship Program
In 1992, when the Nez Perce Tribe received funding from the US Department of Energy to participate in the Hanford cleanup, it became painfully apparent that the Tribal membership did not include scientists qualified to work in this area. Nez Perce

students who had been able to get through the public school system, were just beginning to graduate from universities, but had taken up fisheries biology or forestry, knowing that those Tribal departments were also desperately in need of scientific expertise from Tribal membership. The ERWM Department and the Nez Perce Trial Executive Committee (Tribal Council) agreed that the best approach to develop in-house expertise for this Department was to immediately start a strong on-going internship program to develop Nez Perce scientists and professionals.

An attractive aspect of the Tribal internship program is its innovative and pragmatic approach to education and training. If a student, for example, began in his or her first year of college and went through a graduate program, he or she could spend at least six summers rotating through employers such as the Nez Perce ERWM Department, the US Department of Energy (including headquarters, sites, labs, and contractors), universities and other companies dealing with environmental management and related activities. In some cases if a student is willing to take a year off from school, an annual internship can be arranged, in certain instances with companies and/or agencies providing technology development internships. The possible sites are endless and interest has even been expressed by international companies.

Nez Perce ERWM Internship Program Mechanics

The ERWM Department began its internship program by seeking out college students who were in science areas and had experienced some degree of success in these programs. Students were asked to submit letters of reference, college transcripts and a letter outlining their interest in the ERWM internship program. Five students were selected initially who were at various levels in college and had a variety of majors or goals all in the science areas, pre-medicine, civil engineering, geology, botany, and environmental engineering. The program allows for students to work during the summer, Christmas and spring breaks and in special instances we look forward to accessing year long internships with especially attractive companies or agencies. Universities and colleges attended by the interns were also varied geographically and otherwise and include the University of Idaho, Lewis Clark State College, Boston University, Brigham Young University and Colorado State University. All interns quickly developed an interest in Hanford and the particular technological and health problems presented there. Interns the first and second years were placed with the Nez Perce Tribal ERWM Department, the Council of Energy Resource Tribes (CERT) in Denver, and the US Department of Energy and its contractors, Battelle, Westinghouse, Bechtel, Kaiser, with DOE labs and with other companies and agencies dealing with technology development and health issues.

Each intern is assigned a specific project. Projects have included risk assessment; GIS mapping; botanical identification of traditional plants and herbs; and research on a wild and scenic river designation for the Hanford Reach stretch of the Columbia River, the last free-flowing section of the River. Each project concluded with recommendations for the Nez Perce Tribal Executive Committee to consider in taking an official position. The projects are not make-work type projects but have all produced quality research and/or work which have been used by the ERWM Department and the agencies providing the internship sites.

In the summer of 1994 two high school seniors were added to the program and interned at US DOE headquarters in Washington, DC, one working in the Office of Science Education and Technical Information and one in the Office of Environmental Management's Office of Public Accountability. One of these students has dropped out of the program but the other continues to participate. It has been determined that selecting students who have already begun college and have demonstrated some success is more efficient and effective for the Tribe and for the students.

Success of the Nez Perce ERWM Internship Program

We believe the primary reason for the success of the ERWM internship program is the holistic approach in dealing with the interns. The Nez Perce ERWM Department has endeavored to combine science and culture; a circle of learning that provides the interns contemporary scientific facts and knowledge, and concurrently, provides confirmation of the Nez Perce value system and culture. The fact that the Hanford Nuclear Reservation is situated on Indian lands and is rich in cultural and natural resources has driven home the importance of combining the scientific and cultural knowledge. The finding of burial grounds during the construction of the Environmental and Molecular Sciences Laboratory in 1994 made it abundantly clear that American Indians with a tribal value system need access to decision-making

roles in order to deal with instances that present problems to tribes that are both scientific and cultural. The appreciation and respect which is applied to all living things especially cultural and natural resources by Tribal peoples, unfortunately was not, and still is not, applied decision-makers in the field of environmental management. Accompanying the career counseling and educational support, the ERWM staff subtly encourage interns to investigate the cultural and spiritual aspects of their being such as traditional dancing, drumming, crafts and the language. Most interns have embraced one or more cultural areas. Not only do these activities assist them in exploring their past and present culture, but it enhances self-esteem and well-being. Identity is important to any student and these students are fortunate to have a rich and living culture with which to identify.

Another aspect of the program is a strong staff monitoring effort of all interns. There is a tribal saying that it "takes a whole village to raise a child". this is very similar to the Nez Perce Tribe's philosophy. The ERWM Department staff have endeavored not only to provide the employment and training opportunities to interns but to also provide as a whole, staff mentorship which includes friendship, personal support, counseling, gentle discipline and financial support. There is intense involvement between the individual ERWM staff and the ERWM interns. The staff is there in many of the same aspects as parents, grandparents and teachers. A mutual respect between the staff and interns has developed during the time the program has been in operation. To understand completely the type of mentorship which exists, it is important to understand that the Nez Perce Tribe numbers about 4,000 members with about 1900 living on the Nez Perce Reservation. This provides a very small cohesive group which shares many interests, sorrows, successes and failures. Everyone knows everyone else and so between the Nez Perce staff members and the Nez Perce interns, relationships already existed. In all cases, the relationships,, however, have become much closer and much more trusting.

Summary and Plans for the Future

The internship program in the ERWM Department of the Nez Perce Tribe is replicable, however at this time it is being aggressively pursued by only one Tribe. It is a program which we hope to develop and share with other tribes interested in development of their own technical expertise. It is a program which may also prove to be of great value to mainstream America.

The Nez Perce Tribe also proposes to developed education support programs with the public schools on the Nez Perce reservation. These support programs are being developed with the schools principals and student identified needs. Beyond the in-school support the Nez Perce ERWM is identifying after-school, hands-on educational opportunities aimed at enrolled Nez Perce Tribal members students.

The Nez Perce ERWM places a strong emphasis on educating Nez Perce youth because for the Nez Perce Tribe to remain a sovereign people, it must be Nez Perce people who make decisions for the Nez Perce Tribe. The more abundant and powerful tools that the Nez Perce people can learn and use to promote Nez Perce values and traditional knowledge within the national context the more equitable future exchanges, and more fruitful future partnerships will become.

OPPORTUNITIES FOR STRATEGIC PARTNERSHIPS

Opportunities to build strategic partnerships with the Nez Perce Tribe, through its ERWM Department education programs exist for industry, government and other organizations that focus on building tribal capacity, address environment justice concerns, emphasize science and engineering education, or wish to establish relations with a tribal government located in the Northwest United States with a variety of concerns affected by US DOE activities related to Hanford. The opportunities are limited by ERWM staff and resource constraints.

The ERWM Department has begun strategic partnerships with: the US Department of Energy Office of Environmental Management in Washington, D.C. and at its Richland Operations Office; and the Council of Energy Resource Tribes in Denver. Other partners in the Nez Perce education efforts are being approached with the hope of fulfilling the stated goals of the Nez Perce Tribe.

CONCLUSIONS

The Nez Perce Tribe has historically supported education for its members. Gaining the necessary knowledge of scientific and engineering disciplines is crucial to protection of Nez Perce treaty rights along the Columbia River and elsewhere. The Nez Perce ERWM internship program supports the acquisition of this knowledge and practice of these skills within the context of traditional Nez Perce culture and

values. In an effort to maintain the high quality of its program, the Nez Perce ERWM Department has identified the need to encourage strategic partnerships with government, industry, and other institutions involved in the environmental management and related fields. The technical nature of radioactive and hazardous waste management and the national political climate of greater accountability and cost-effectiveness should encourage all participants in environmental management related activities to focus on long-term, strategic partnerships. The Nez Perce Department of Environmental Restoration and Waste Management recognizes this situation and has begun to forge these new partnerships through its internship program.

Policy and Public Involvement Program
Environmental Management Program
Los Alamos National Laboratory
Louis Naranjo, Jr.
EES-13
Los Alamos National Laboratory
ABSTRACT
In this paper, we review the history of the relationship between Los Alamos National Laboratory and neighboring pueblo communities and identify recent successes in improving that relationship. In particular, we discuss an initiative undertaken in connection with the Laboratory's Environmental Restoration Project. During the course of this initiative, Laboratory staff and San Ildefonso Pueblo officials have established channels of communications that have yielded significant dividends, both in terms of the quality of government-to-government interactions between the two entities and in terms of cooperative efforts that promote environmental investigation and characterization activities, both on Laboratory and Pueblo lands. Among the specific accomplishments this initiative has fostered is representation by tribal members on Laboratory technical teams, to sensitize team members to the cultural and religious significance of sites where samples are collected.
HISTORY
Los Alamos National Laboratory, located in the mountains of northern New Mexico approximately 32 miles northwest of Santa Fe, occupies a unique position in the US Department of Energy's nuclear complex. It was in Los Alamos, during the "Manhattan Project" years that scientists from Europe and the United Stated worked together to develop and test the first atomic bomb, thus heralding the beginning of the nuclear age.
Development of nuclear weapons has left a legacy of radioactive and hazardous waste. Although the dangers of acute radiation exposure were known at the time of the earliest work at Los Alamos, no one knew with any certainty what problems would arise if waste products were buried for long periods or released to the environment. Nevertheless, waste was buried in material disposal areas situated around the Laboratory site. Liquid waste also was disposed in a few of the canyons that drain the Pajarito Plateau, where the town of Los Alamos is located.
Los Alamos National Laboratory and the town of Los Alamos are surrounded by the communities of Santa Fe, Espaola, and several smaller, predominantly Hispanic, villages. A number of Indian pueblos, the closest of which are San Ildefonso, Santa Clara, San Juan, and Cochiti, are also the Laboratory's neighbors.
The area surrounding the Laboratory is steeped in pueblo history. According to oral tradition, some of the Anasazi, or "old ones," who inhabited Mesa Verde (in the four corners area of Colorado) migrated to Chaco Canyon in New Mexico. In the early 1200s, some of these Chacoan Anasazi established themselves on the Pajarito Plateau. During the 1500s, many of the inhabitants of the plateau moved to the pueblo villages that now are located along, or near, the Rio Grande. Among their descendants are the residents of San Ildefonso, Santa Clara, San Juan, and Cochiti pueblos.
Many archeological sites are located on the Pajarito Plateau and in the canyons that dissect the plateau. For instance, Bandelier National Monument contains several

beautiful ruins that have been excavated, stabilized, and opened to the public. Ceremonial rooms ("kivas"), great houses, and cliff dwellingsexcellent examples of passive solar engineeringat Longhouse, Tyuonyi, and Tsankawi ruins afford the visitor a glimpse into Anasazi village life of the 1300s.

The entire Pajarito Plateau is rich in prehistoric cultural materials. The area of the plateau occupied by the Laboratory contains many archeological sites, and over the years most of these sites have been surveyed, documented and numbered. These sites range from simple field houses to large pueblo villages.

Pueblo residents claim the Pajarito Plateau as their ancestral lands. Although they value the Laboratory as a provider of well-paid jobs, the institution is still viewed by pueblo peoples as an foreign presence. Indeed, Laboratory operations have had a major impact on the plateauecologically, culturally, and economically. Of all the modern pueblos, San Ildefonso, whose western boundary adjoins the Laboratory's, has felt the greatest impact.

The Environmental Restoration (ER) Project at the Laboratory, therefore, considered it important to establish a way for the pueblos to become involved in environmental restoration activities, especially those targeting the canyons that drain the Pajarito Plateau.

ER PROJECT GOALS

The ER Project was established in its present form at the Laboratory in 1989. The project has three goals:

Protect human health and the environment from exposure to releases of hazardous, radioactive, and mixed wastes from historical treatment, storage, and disposal practices at the Laboratory.

Meet the environmental cleanup requirements of the Laboratory's permit to operate under the Resource Conservation and Recovery Act (RCRA), specifically, under Module VIII (known as the Hazardous and Solid Waste Amendment Module, which governs ER Project activities). (1) The Environmental Protection Agency issued Module VIII in May 1990 and modified it in May 1994.

Perform these activities faster, better, and cheaper.

REGULATORY PROCESS

The ER Project follows a complex regulatory process for investigation and characterization activities:

1. A potential release site, or group of sites, is the subject of a work plan, which sets forth the sampling methodology necessary to implement the RCRA facility investigation (see step 2). The Environmental Protection Agency must approve the work plan.
2. The RCRA facility investigation identifies the nature and extent of contamination that could lead to exposure among human and environmental receptors. When the need is identified, the Laboratory may initiate an expedited cleanup, i.e., a voluntary corrective action that reduces time to completion. The Laboratory may also adopt a more formal approach involving the next two steps in the process.
3. The corrective measures study evaluates cleanup alternatives to reduce risks to human and environmental health and safety in a cost-effective manner. A corrective measures study is performed only if the RCRA facility investigation indicates that corrective measures are needed.
4. The corrective measures implementation applies the chosen remedy, verifies its effectiveness, and establishes ongoing control and monitoring measures.

LABORATORY IMPACT ON THE PUEBLOS

Figure 1 shows a map of Los Alamos National Laboratory and the surrounding communities. Many communities in the area surrounding Los Alamos are very concerned about the environmental impact that past and present Laboratory operations have on their communities. Their main concerns are the effects of releases of contaminants from the Laboratory on water, soil, and air, as well as the effects of waste stored or disposed on Laboratory property.

Environmental surveillance results (2) show that contamination may have migrated offsite through the canyons of the Pajarito Plateau to the Rio Grande. San Ildefonso and Cochiti pueblos are located downstream from the canyons that drain the Los Alamos town site and Laboratory lands. Several other pueblos are also located downstream from the Laboratory. Pueblo dwellers located downstream of the Laboratory are primarily concerned about contamination in surface water and ground water. In the pueblos located upstream of the Laboratory, residents have indicated that contamination of the air and of the meat in animals they hunt for food is their

primary concern.
Fig. 1.
THE BUREAU OF INDIAN AFFAIRS, U.S. DEPARTMENT OF ENERGY, AND SAN ILDEFONSO PUEBLO MEMORANDUM OF AGREEMENT
The Bureau of Indian Affairs, U.S. Department of Energy, and the Pueblo of San Ildefonso signed a memorandum of understanding (MOU) in the early part of 1987 (3). This MOU addressed some of the concerns of the tribal government and the pueblo community regarding contamination of air, water, soil, and ceremonially significant plants. Additional tribal concerns related to the possible effects of contamination on deer and elk populations.
The MOU established a formal protocol for sampling soil, foodstuffs, air, and water at the pueblo. The Laboratory agreed to collect and analyze material taken from vegetable gardens and the meat of cattle raised on the reservation. The Laboratory agreed to share the results of the sampling activities with the tribal council.
RECENT CONTACTS WITH SAN ILDEFONSO PUEBLO
ER Project investigations for Field Unit 1 which includes the canyons, are trying to identify movement of contaminants through the canyon systems to offsite. These canyons are the subject of a single, unified set of ER work plans. Some of these canyons run through San Ildefonso lands. It was appropriate, therefore, to involve tribal officials from this pueblo to participate in the formulation of the work plans, especially with respect to sampling activities that might directly affect cultural and religious sites.
The ER Project staff was invited to make a presentation to a meeting at San Ildefonso Pueblo in March 1994. The governor of San Ildefonso and members of the tribal council were favorably impressed with the prospect of active participation in ER activities, as was an observer from Santa Clara Pueblo. In June, the ER Project received a recommendation that the ER technical team working on the canyons be joined by a knowledgeable member of the tribe. This representative's function would be to inform team members about San Ildefonso residents' concern for their environment and about religious and cultural issues that might be raised during the preparation of the workplan and characterization activities. The tribal representative joined the team in July, and the process of familiarizing the technical team with the Pueblos' concerns have already been incorporated in the draft work plan's first four chapters. Our tribal representative received all the appropriate radiological and waste operations training he would need to work in the field, as well as training in site-specific safety procedures.
At the beginning of August 1994, ER Project staff met with the pueblo governor and received permission to do an ecological survey of lower Los Alamos Canyon, which runs through San Ildefonso lands. This was a major breakthrough for the ER Project. ER staff now had direct access to areas within pueblo boundaries if accompanied by a tribal representative. Without such access, sampling work in Los Alamos Canyon could only have been performed up to, but not beyond, the Laboratory boundary. Now, technical teams would be able to characterize the entire drainage up to its confluence with the Rio Grande, thereby allowing ER Project staff to investigate relationships between contamination on Laboratory property and that found in the most important New Mexico river.
In September and the early part of October 1994, the San Ildefonso tribal government gave permission to the Environmental Assessment/Resource Evaluation Group at the Laboratory to perform the first phase of a biological characterization survey on San Ildefonso lands in Los Alamos and Pueblo canyons. The purpose of the survey was to identify habitat types and their potential for harboring threatened and endangered species. The area to be surveyed borders the Rio Grande and extends west to Basalt Springs on the eastern boundary of the Laboratory.
Our tribal representative accompanied the team members conducting the survey. The first phase of the biological survey consisted mainly of identifying different types of vegetation in the canyon area. Members of the biological survey team laid out seven vegetation transects consisting of a series of 20-x-50-cm quadrates. The canopy cover and diameter at breast height of trees over 3 ft. high were measured in circular plots with a radius of 30 ft. The team sampled plant communities on the banks of the Rio Grande, on canyon slopes, and in the bosques (wooded areas). Percentages of grass, forb, and litter cover were determined for each quadrate. The team also identified different plant species and prepared herbarium specimens.
When the survey was completed in the beginning of October, 1994, the team

established a total of 10 to 15 transects, which should yield a clear picture of the plant communities inhabiting the canyon. These transects will be monitored every five years. Both Laboratory researchers and San Ildefonso officials will have solid baseline data with which to gauge how the canyon environment is affected by Laboratory operationsinformation that will prove useful to the tribe as it formulates its own environmental policy and program.

MILESTONES IN THE LABORATORY-SAN ILDEFONSO RELATIONSHIP

So far, collaboration with San Ildefonso has greatly benefitted the ER Project. We have been able to

establish a positive working relationship with the Pueblo of San Ildefonso;

begin developing work plans for characterizing stretches of Los Alamos and Pueblo canyons running through San Ildefonso lands to the Rio Grande;

raise ER Project and subcontractor staff's consciousness concerning the pueblo's cultural and religious concerns;

provide opportunities for training so that tribal representatives can function as part of field teams.

San Ildefonso tribal leaders acknowledge the benefits of a more open and positive relationship with the ER Project and the Laboratory. The governor has now designated an additional tribal environmental representative who regularly attends meetings of the Canyons technical team. In February, a Santa Clara tribal member will be joining the ER Project.

WIDENING THE SCOPE OF LABORATORY-PUEBLO INTERACTIONS

In November 1994, the Laboratory signed cooperative agreements with three pueblosSan Ildefonso, Jemez, and Cochiti (4). These agreements, witnessed by Charles Curtis, Undersecretary for the Department of Energy, complement a 1992 accord between the pueblos and the Department of Energy and promise to build confidence and a positive working relationship between the pueblos and the Laboratory. It also establishes a Los Alamos Pueblos Project that will carry out the objectives of the agreement.

The cooperative agreement formalizes the government-to-government relationship between the pueblos and the Laboratory. Accordingly, all interactions between the ER Project and the pueblos will henceforth follow clearly defined channels. The agreement establishes the tribal government liaison in the Laboratory's Stakeholder Involvement Office as the facilitator for any activities involving the ER Project and the pueblos.

DEVELOPING THE ENVIRONMENTAL RESTORATION PROJECT KNOWLEDGE BASE OF THE TRIBAL REPRESENTATIVE

As a member of the technical team for the Canyons, our tribal representative has learned and continues to learn more about the unique geology of the Pajarito Plateau, the distribution of the perched aquifers across the plateau, and the possible pathways along which contaminants could spread through the environment. Because his cultural background has proven to be so valuable to the ER Project, our tribal representative has also been involved in working with a second field unit. This field unit includes Bayo Canyon, which adjoins San Ildefonso lands. This canyon was the location of past Laboratory experiments which involved detonating high explosives to determine the effects on small quantities of radioactive materials. He has joined the Bayo Canyon field team to help team members take into account the unique cultural and religious significance of Bayo Canyon to San Ildefonso Pueblo. He also communicates relevant information to the Pueblos.

THE FUTURE OF LABORATORY-TRIBAL RELATIONS

A near-term goal of the ER Project is to train students from the different Pueblos in sampling techniques, and general field work during summer vacations. This can be accomplished in cooperation with the existing Undergraduate Student Program at the Laboratory. Instruction would be accomplished through course work and on-the-job training. If sampling needs to be done on pueblo lands, the ER Project could have a ready pool of field technicians available either to accompany ER staff or for trained students to take samples if the land is not accessible to non-tribal members. The students are likely to acquire job skills that make them very valuable to the Pueblos' environmental programs which are now being established. In addition, they would be employable by the Laboratory or its subcontractors.

Other pueblos that have heard about the ER Project's initiative have indicated an interest in the ER Project's work on the canyons. Hopefully, the Laboratory will be able to accommodate their participation in the future.

The ultimate success of this initiative will be measured by whether the pueblos are

confident that the chosen cleanup remedy for the canyons is the most beneficial for their people. For the Laboratory's ER Project, the ultimate success will be that the cleanup has been accomplished faster, better, and cheaper and that we have developed a mutually trusting, respectful relationship with the pueblos.

ACKNOWLEDGMENTS

This partnership with San Ildefonso Pueblo would not have been possible without the assistance of the tribal government liaison in the Stakeholder Involvement Office at the Laboratory. Gilbert Suazo was instrumental in providing access to the tribal leadership and made us aware of the unique government-to-government relationship the Laboratory has with our pueblo neighbors.

Without the vision and support of Laboratory EES-15 Deputy Group Leader Everett Springer and Principal Investigator Pat Longmire, this partnership effort would not have come to fruition. Both of them, as well as Laboratory Field Project Leader Allyn Pratt, continue to provide their support and technical knowledge.

ABSTRACT

The Risk-Based Systems Analysis Model was designed to establish funding priorities among competing technologies for tank waste remediation. The model addresses a gap in the Department of Energy's (DOE's)* "toolkit" for establishing funding priorities among emerging technologies by providing disciplined risk and cost assessments of candidate technologies within the context of a complete remediation system. The model is comprised of a risk and cost assessment and a decision interface. The former assesses the potential reductions in risk and cost offered by new technology relative to the baseline risk and cost of an entire system. The latter places this critical information in context of other values articulated by decision-makers and stakeholders in the DOE system. The risk assessment portion of the model is demonstrated for two candidate technologies for tank waste retrieval (arm-based mechanical retrieval - the "long reach arm") and subsurface barriers (close-coupled chemical barriers). Relative changes from the base case in cost and risk are presented for these two technologies to illustrate how the model works. The model and associated software build on previous work performed for DOE's Office of Technology Development and the former Underground Storage Tank Integrated Demonstration, and complement a decision-making tool presented at Waste Management 1994 for integrating technical judgments and non-technical (stakeholder) values when making technology funding decisions.

INTRODUCTION

Because of the extraordinary uncertainty inherent in research and development (R&D) activities, decision-makers must choose among still undeveloped or partially developed products for roles in large and complex technical systems, such as for high-level waste tank remediations for the U.S. Department of Energy (DOE). They must attempt to make funding decisions about appropriate technologies within tight timeframes. Decision-makers who have fiscal responsibility for program budgets have difficulty in determining whether the technology provides sufficient benefit to the overall system to warrant its development. Unfortunately, the tools to accomplish these tasks have proven cumbersome. Current systems engineering or environmental impact statement analyses that address entire systems are larger and more costly than is practical for the multiple, highly detailed decisions required to guide a technology development program. Also, these more complex models are not typically amenable to online sensitivity analyses, which are required when there are expert disagreements in predictions of a new technology's performance under varying conditions. In addition, a number of good activities are underway to improve stakeholder involvement in the decision-making process for choosing technologies, which adds the dimension of increased inputs into the process.

Because of this complexity and uncertainty, the current decision-making processes often suffer from a lack of disciplined assessment of the factors, particularly of the potentials for risk and for cost-reduction, which are usually considered by all parties to be critical. The current processes can lead to biased judgements because the technologies are rarely evaluated in a systems context.

The Risk-based Systems Analysis Model, a computer-based model for assessing emerging technologies, addresses these gaps in the decision-making tools available for selecting what technologies to fund when those technologies must function as part of a large and complex system. It provides a simplified systems perspective that is more practical for technology decisions than are the more complicated systems engineering models. It combats biases in judgment by summarizing system-level information that is difficult for experts to consider when assessing individual technologies. It accommodates differences of opinion in assumptions or predicted performance through sensitivity analysis. Finally, the interface is easy to display and understand, which makes this model useable online in forums involving multiple decision-makers, including public stakeholders and regulators who want to see (or have the opportunity to assess and differentially weight) how a technology performs on a broad range of variables.

RISK-BASED SYSTEMS ANALYSIS MODEL DESCRIPTION

The model uses a structured systems methodology for estimating the risks and the costs of new technologies for remediating DOE underground storage tanks (UST) relative to a base case. Figure 1 describes the envisioned decision-making process underlying the model. The base case establishes a flowsheet and material balance for all stages of a baseline UST remediation (the Hanford technical strategy is currently modeled). The model incorporates new technologies (test cases) into this complete remediation system to allow a disciplined assessment of changes in the risk and cost of specific functions as well as overall system risk and cost. The values for each module are summed to provide total system values. Potential risks to workers and to the public associated with both routine and failure conditions are currently represented. These data are combined with additional decision variables (e.g., program schedule) and stakeholder values (e.g., economic impacts, final land use) to ensure that risk factors are placed in a broader decision context. Where data are not available, risk and cost analyses are performed for each module using available data, expert judgment, and simplifying assumptions.

Fig. 1.

The assessment methods selected had to be:

- comprehensive and "cradle to grave" in scope;
- easy to apply early in the technology evaluation process (when limited information is available); and,
- amenable to changes in assumptions or estimates to facilitate discussion among users.

System Characterization

System characterization requires that all of the major processes and process streams be identified and that an overall material balance be established. First, the major processes are labeled as unit operations. Each unit operation is described in terms

of the information categories listed in Table I.
It is particularly important that all process streams discharging to the environment (vapor or liquid transport) be characterized, as these are the primary contributors to the public risk values. This information is used to estimate routine worker radiation exposure and potential for and severity of accidents associated with each unit operation, under both routine and nonroutine conditions.
TABLE I
The unit operations are grouped into functional groups labeled as modules. The model's baseline risk assessment consists of 13 modules that encompass the complete set of tank remediation functions, including waste retrieval, treatment, disposal, and tank and facility decontamination and decommissioning. Each module is a group of similar or related process steps linked to a specific technology and is comprised of one or more unit operations or major components. The modular format allows users to add or replace modules to define the test cases and provides a practical breakdown of overall system risk and cost. Figure 2 shows the process flow defined by the modules for the base case. The model's modular format provides a mechanism by which new modules can be added or modules can be modified to form test cases. This facilitates the incorporation and comparison of the impacts of new technologies with the baseline.
Following organization of the modules into an overall flow diagram, stream flows between modules are identified and labeled. Then, a material balance is completed for all critical streams entering and leaving each module in terms of the total liquid mass, total solids mass, total water mass, and mass of contaminants of concern.
Risk Evaluations
The objective of the model's risk calculation is to provide a consistent basis for qualitatively evaluating the potential influence that alternative technical modules may have on overall health risks associated with the remediation system. The specific steps involved in the risk assessment portion of the model are shown in Fig. 3. The risk assessment spans both operational and post-operational phases of remediation and addresses all potentially significant sources of contamination and all potential contaminant receptors. Potential risks associated with both routine and failure conditions affecting both workers and the public are addressed.*
Fig. 2.
Fig. 3.
Calculational methods were selected that are consistent with the fact that they will be applied early in the technology evaluation process, when limited or only qualitative information will be available regarding technology characteristics. The specific methods selected for demonstrating the model were chosen for their ease of application and familiarity; they may (and, in some cases, should) be further reviewed and modified. See Peters et al. (3) for the detailed calculations.
Health risks are calculated for six variables:
  workers and the general public,
  routine and failure events, and
  two timeframes:
- near-term exposures associated with the active installation and operational phases, and
- future public exposures associated with residual contamination and disposed wastes following completion of the active operations.
In the case of workers, health-related impact is evaluated in terms of radiation dose to individual members of the work force. In the case of the public, health-related impact is addressed in the context of a maximally exposed individual's (MEI) (1) incremental increase in risk (probability) of death from cancer and (2) hazard index (HI), which is the ratio of calculated toxic material exposure to the toxic material reference doses. Public health risks associated with past and future UST leaks and routine facility environmental releases are currently estimated using the Multimedia Environmental Pollution Assessment System (MEPAS) computer code (Droppo et al., 1989). For identifying and evaluating potential failure events, standard safety analyses exist, but they require a minimum level of facility and process information that is not available for these technology evaluations. Thus, a subjective approach was selected that relies on expert judgement: risks to workers and failure risks are determined using a Priority Planning Grid (PPG), developed under DOE funding and commonly used at the Hanford

Site. This process uses qualitative frequency consequence values (unitless) that have been derived from selected elements of the relative ranking system implemented in the PPG. The PPG has established eight levels of consequence (ranks), within which nine impact attributes are compared. The attributes of interest for the model risk evaluation are public safety, worker safety, environmental contamination, and cost.

Results generated by the risk calculations, while given as discrete numerical quantities, should not be viewed as estimates of actual or potential human health risk associated with the tank waste remediation technologies. The calculation results are intended to support consistent comparative evaluations of the influence that alternative technologies may have on overall system risk, and should be viewed as qualitative estimates only.

Cost Calculations

Cost information is required to provide a basis for direct comparisons of alternatives in terms of overall cost and cost-benefit. The model measures benefit in terms of risk reduction. Given the high uncertainties in risk and cost data available for emerging technologies, costs were appropriately estimated using relatively simple cost estimating software and best engineering judgement. All costs are converted into Total Net Present Worth (TNPW) in 1994 dollars. The complete waste retrieval, treatment, and decontamination and decommissioning (D&D) process is assumed to take 13 years (10 years processing and 3 years D&D).

The following costs are calculated:

capital (facility design, purchase and construction, and equipment purchase and installation),

labor (exempt, nonexempt, and bargaining unit personnel),

utilities (steam and electricity),

CENRTC and GPP (capital equipment not related to construction and general plant process),

disposal (for low-level and high-level waste only), and

D&D (decontamination and decommissioning of all tanks and facilities when remediation is complete).

System Analysis Model Software

The System Analysis Model Software is a linked system of Microsoft Excel 4.0 spreadsheets that provide the user with a computerized directory of the flow processes being evaluated by the model. By using the mouse to click on a series of buttons or menu items, the user can call up a particular case (i.e., the Base Case, Test Case I, or Test Case II), display a complete flow diagram of any module within the given case, and then find out more information about the module and any unit operation within the module. Available information also includes the set of assumptions used to characterize the module, the details of the mass balance at that point in the model, and the results of the risk analysis and the cost analysis. This layered information system, which displays only as much information as required by the user, allows the user to easily compare modules, unit operations, and risk/cost analyses results for different system configurations. It also provides access to any of the critical assumptions or parameters, making the process transparent. This serves both educational and negotiation purposes: non-experts can view the critical parameters throughout the model and experts can test alternative assumptions or judgements of performance.

EXAMPLE RISK ASSESSMENT RESULTS

The model has been demonstrated using the Hanford Tank Waste Remediation System as a base case, with two retrieval technologies for test cases: an arm-based retrieval system and close-coupled chemical sub-surface barriers. Complete descriptions of these test technologies are provided in Peters et al. (3).

Table II shows the relative contributions of each module to the base case systems and costs. Comparisons of the base case to each of the test cases is presented in relative terms in Table III. Table III shows, for example, that Test Case I (a close-coupled barrier) promises to reduce by 41% the chance that the MEI will get cancer, reduce by 47% the chance that the MEI will be harmed by toxicants, increase by <1% the accident risk, and increase by 2% the collective routine worker radiation dose. These reductions are achieved at a 24% increase in cost, or an addition of $3,300,000,000. In contrast, at slightly less cost increase (19%, or $2,500,000,000), Test Case II (robotic sluicing) may provide relatively greater risk reductions to the public. We cannot confidently conclude from the level of analysis

in the model that a test case will reduce the incidence of cancer by a specific amount, only that it will do so to a greater or lesser extent than will the baseline.

APPLICATION

The ultimate value of a technology decision tool is to provide decision-makers with a way to identify development efforts that, if successful, would provide significant overall benefit as related to cost. Health risk and cost are two critical components of overall benefit, but they are not the only relevant factors. McCabe et al. (2) have argued that decision-makers and stakeholders wish to consider environmental impacts, programmatic risks (e.g., schedule), socio-political issues (e.g., positive economic impact), other aspects of technical performance (e.g., ease of implementation), and regulatory compliance when assessing new technology. Stakeholders at the Hanford Site, which has the biggest UST remediation problem, have identified a core set of 14 values that they want to guide remediation decisions. Other stakeholder involvement exercises have uncovered additional values that may be discriminators for technology development decisions (1).

The decision process that is envisioned for application with the Risk-Based Systems Analysis Model involves the following basic steps:

Identify criteria. Decision-makers and stakeholders would agree on the criteria against which technologies should be evaluated; if this includes risks other than those currently modeled here, the data and calculations used to measure risk may be adapted to make the model more relevant (e.g., to address such things as environmental risk, schedule, and regulatory compliance).

TABLE II

TABLE III

Evaluate criteria. The Risk-Based Systems Analysis Model provides direct input to relevant risk and cost criteria; experts may use the output from the model to make holistic judgments or the output can be used to directly measure system performance for different technologies; other criteria may be evaluated using expert or stakeholder judgment.*

Apply weights. In typical decision environments, there is not single decision-maker or set of value functions to, for example, weigh cost against amount of risk reduction. We envision using a number of alternate weighting schemes to analyze how sensitive overall benefit scores are to each criterion. Decision- makers would look for those technologies that perform well regardless of weighting scheme.

Feedback. Decision-makers, stakeholders, experts, and modelers would engage in a dialogue to address outstanding questions or issues; this may result in some redefinition of the risk assessment model or its parameters.

Recommend. The final step is a recommendation to higher-level decision makers that a technology be funded or not, either as is or reconfigured to minimize outstanding risks or to maximize other performance criteria.

The model generates disciplined assessments of two of the most complex and heavily weighted variables in most funding decisions: risk and cost. However, the decision interface software also allows decision-makers to consider additional criteria, have those evaluated by multiple stakeholders, weight them using alternate value sets, and produce rankings of candidate tank technologies under each weighting scheme. Additional criteria that stakeholders may hold in evaluating technologies include System Performance, Socio-Political Interests such as protecting land use and tribal rights, and Regulatory Compliance.

SUMMARY AND CONCLUSIONS

The Risk-Based System Analysis Model provides a framework for evaluating the risk and cost of new technologies relative to a baseline remediation plan. The general approach incorporates new technologies into complete remediation systems to allow a disciplined assessment of overall system risk and cost. Risk and cost data can then be combined with additional decision variables, and evaluated from multiple perspectives (stakeholders, technologists, etc.) to produce a disciplined assessment of emerging technologies.

Application of this model will ensure that funding priorities reflect the risk/cost tradeoffs, stakeholders can understand the basis for risk/cost assessments, the final recommendation will consider risk and cost in the context of additional stakeholder/user concerns, and the decision process itself will enhance the dialogue and understanding of the different parties (technical experts, stakeholders, users, etc.). In that way, it is a practical tool for building consensus among users,

technologists, stakeholders, and final decision-makers.

DEVELOPING PROTOTYPE INDICATORS OF VALUE AND COSTS ADDED THROUGH PUBLIC INVOLVEMENT PROGRAMS

ABSTRACT

Although the use of public involvement continues to grow at the Department of Energy (DOE) and other federal agencies, our understanding of public involvement remains relatively rudimentary. Information about public involvement for managers, practitioners, and stakeholders is typically restricted to descriptions of the types of public involvement strategies or activities available for use or case histories of single efforts. The documented attempts at evaluating public involvement activities are limited to attitude surveys of participants or self-referential assessments of whether objectives have been met. To date, no methods or indicators of public involvement effectiveness have been developed. This research project moves beyond this descriptive stage by identifying dimensions that public involvement participants believe add or subtract value to their projects. Face-to-face interviews were conducted with public involvement participants--managers, practitioners, regulators, and other stakeholders--to ascertain dimensions of value. These dimensions were operationalized as a series of social indicators that make tangible the abstract values expressed by respondents. Indicator metrics were also identified and are being tested for reliability and validity across a wide range of public involvement efforts.

INTRODUCTION

There is a pressing need to document the value and costs of public involvement for the participants in these processes--the stakeholders--and to present this information to decision makers in a way that helps them assess the value and costs of managing public input through a public involvement program.

This research effort was designed to develop prototype indicators of the value and costs added to projects by public involvement efforts. The first step towards this goal was to identify the various dimensions of value and costs and to assess how those dimensions are distributed among different participants. Of critical importance during this phase of the research was the documentation of how participants characterize the value and costs of public involvement. Next, we used the identified dimensions of value and cost to draft a set of indicators. Indicators of the value added or subtracted by public involvement fall into three categories--process, outcome, and cost. Finally, we developed potential metrics for the indicators to be used to validate the prototype indicators.

Our review of the literature suggests that empirical analysis of public involvement processes is in its formative stages. The current literature fits generally into one

of two categories: 1) case studies or 2) normative prescriptions of how and why to do public involvement. Case studies generally provide assessments that examine the effectiveness of a public involvement process in achieving program goals and objectives. This type of research is primarily self-referential and as a result does not facilitate comparison across public involvement processes. The second type of public involvement research focuses on the reasons why and how public involvement processes should be implemented. Consensus building and the fulfillment of democratic principles are often cited as support for public involvement processes. As expected, little documentation of the value or costs actually added through public involvement exists. Nevertheless, the review of existing literature did highlight some of the dimensions of value that appear to be important to stakeholders. Issues of public acceptability, accessibility, good decision making, education and learning, time commitments, and trust were commonly discussed themes in the extant literature. This information was used to assess the validity of the indicators that were developed through the analysis of data collected in the interviews.

METHODS

The first phase of this research was to identify the various dimensions of value or cost added through public involvement processes. The data used to identify the dimensions were obtained through interviews with the participants of three different DOE-sponsored public involvement processes. These projects were selected on the basis of three criterion:

1. A wide range of stakeholders participated in the public involvement processes. Stakeholders included managers, public involvement practitioners, regulatory agency representatives, technology developers, and public interest group representatives.
2. The public involvement processes were in different stages of completion when this research was conducted. This variation facilitated the thorough examination of process versus outcome value responses.
3. The public involvement processes are perceived as successful. Past research indicates that participants of successful processes are more likely to articulate benefits as well as disadvantages of the process in which they were involved than are participants of less successful programs.

Several caveats must be noted about the generalizability of the project results to other circumstances. All three DOE projects involved the same or similar types of stakeholders. In fact, many of the respondents interviewed for this project have participated on more than one of the three projects. Most of the respondents were experienced public involvement participants and very familiar with the issues surrounding the individual projects. All three DOE projects involved the same site, although the problems addressed in the projects were slightly different. In addition, the problems addressed in the projects have not typically elicited passionate responses or involvement from stakeholders, although respondents consider the problems addressed by the projects to be serious and long-standing. All three projects were viewed by participants and observers as successful, yet none of the projects have implemented any decisions informed by the public involvement process as of the writing of this report.

While project similarity facilitated the analysis of the data collected for this report, it must be remembered that many types of public involvement exist. The dimensions of value identified by participants in these three projects may be limited by the circumstances described above. Care must be taken in generalizing the results from this limited sample to the larger population of public involvement efforts.

The sampling strategy for this project was not randomized or standardized. The key sampling criteria were diversity and representativeness. Our objective was to represent the full range of stakeholders--managers, practitioners, regulatory agency representatives, technology developers, and public interest groups--in our sample. Informed participants helped identify potential respondents.

An interview protocol was designed to elicit information from respondents about three main topics: 1) expectations of what participants wanted to accomplish during the process; 2) benefits and costs of the involvement process; and 3) the effect of the public involvement process on decision making.

In an attempt to identify the multiple dimensions of value, the respondents were asked to answer each question in reference to themselves personally, to their organizations, to the project with which they were involved, and to the community.

The essence of several questions was quite similar, although the wording of the questions was different. This method of multiple questioning was used in order to ensure that all facets of the different issues were explored.

Interviews were semi-structured, a format which allowed the interviewer to probe for both process responses (articulation of values or costs experienced as a result of participating in the public involvement process) and outcome responses (articulation of values or costs experienced as a result of the specific outcome(s) of the public involvement process). The flexibility of the semi-structured format also helped avoid undue repetition of questions. Interviews were conducted with teams of two interviewers. Audio equipment was not used, however notes were taken during the interviews.

Once the data were collected, the dimensions valued by respondents were identified through analytic coding--the process of categorizing and sorting the data. The coding was a two-phase process. In the initial coding phase, the data were sorted into discrete categories for which we developed conceptual labels that described the values and costs reported by respondents. For example, in this first round of sorting, many respondents talked about "improving the project." We used this as a conceptual label for all those values related to making the project better. The responses to each question were analyzed individually using these conceptual labels to identify the values reported by each respondent. After the individual questions were analyzed, the values were then compared across questions.

The conceptual labels developed in the first phase constitute the dimensions of value from which the indicators were developed in the second phase of focused coding. During this phase, the value dimensions (the conceptual labels) were examined for similarities and differences, which often resulted in a re-sorting of the components of the value dimensions. Following this second coding, individual indicators were developed that capture the value dimension in a way that can be measured. For example, the values included in the dimension of "improving the project" were incorporated into indicators such as "project efficiency," "cost avoidance," and "decision acceptability," all of which were components of the original value dimension. The final set of indicators are not necessarily mutually exclusive in that similar value dimensions may fit into more than one conceptual category.

At this point we re-visited the public involvement literature to see if the major dimensions of public involvement were adequately represented in the selected indicators. Stakeholder accessibility to decision making was not revealed through the interviews although it is emphasized in the literature. It may be that this was not an issue for respondents because they had secured access through their successful participation. Accessibility is included as a draft indicator but should be tested through further interviews with public involvement participants.

Finally, potential metrics for each indicator were identified in order to further validate the indicators in future work. Three sources informed the construction of the metrics: 1) the public involvement literature; 2) interview data; and 3) expert judgment and experience. The list of metrics provided for each indicator is not meant to be exhaustive but to provide examples of possible ways that the indicators can be measured.

THE PROTOTYPE INDICATORS

The prototype indicators were developed to reflect the literature and the interview responses. When respondents talk about what is valuable, they use either specific and unique examples--"then manager X and regulator Y stopped talking to each other until we brought in a facilitator for each meeting"--or conceptual ideas--"having people with lots of different ideas is important." These specific and abstract dimensions were operationalized into "indicators" which can be measured through observation (and counting) of specific behaviors. For convenience, these indicators were divided into three different categories:

- process indicators that focus on the dimensions of value found in the procedures and processes used in the public involvement effort;
- outcome indicators that focus on the dimensions of value found in the outcomes of the public involvement effort; and
- cost indicators which describe the direct and indirect costs of the public involvement effort.

Each of the prototype indicators is described briefly below. Tables I, II, and III describe examples of potential metrics for each prototype indicator.

Process Indicators

Five process-related indicators are discussed below. Potential indicators of process-related indicators are arrayed in Table I.

1. Accessibility to decision making process: The ability to participate in any given public involvement process is dependent on several variables which can be grouped together as accessibility issues. These variables emphasize decision makers willingness to meaningfully involve stakeholders in decision processes. This issue was not commonly mentioned by respondents although the literature on public involvement considers it fundamental.
2. Diversity of views represented in public involvement process: The organization and maintenance of any public involvement program depends on the identification and selection of participants who represent the range of public interests, positions, and values. Almost all respondents reported that the diversity of views represented not only the community and its interests, but enhanced and improved discussion.
3. Opportunities for participation: While public involvement participants bring their own needs and desires to the process, they all expect to participate in the process in some meaningful way. Respondents reported that participation provided the opportunity to voice their concerns and views not only to the decision makers, but to other participants as well.
4. Integration of concerns: Public involvement is enhanced for most participants by the identification and integration of stakeholder concerns. "Getting all the issues on the table," "showing respect for our point of view," and "improving and guiding" the project were all common refrains from respondents about the value of identifying stakeholder concerns. "Affecting the test plans," "prioritizing project activities," and "providing vision and direction" were common responses of how stakeholder concerns were integrated into project activities. Interviewees from all three programs were particularly satisfied with the agency's willingness to hear and respond to their concerns.
5. Information exchange: The two-way exchange of information is at the heart of public involvement programs. Every respondent reported that the process(es) they were involved in allowed information to flow and understanding to develop on both sides of the table. Information of value to participants included technical, regulatory, and public acceptability.

Outcome Indicators

Five outcome-related indicators are discussed below. Potential metrics for outcome-related indicators are arrayed in Table II.

1. Project efficiency: Public involvement is frequently claimed to reduce the amount of time required to complete a project. Public involvement activities are likely to add time "up front," especially in identifying stakeholders, educating participants about public involvement, and developing procedures that identify and integrate stakeholder concerns. Respondents claimed that regardless of these additional time requirements, time was saved on their projects in terms of faster decisions, fewer work stoppages, fewer lawsuits, and quicker implementation of decisions.
2. Cost avoidance: Many of the project "savings" reported in public involvement efforts are actually an avoidance of potential costs. These avoided costs are notoriously difficult to measure and document. However, respondents perceive these "savings" to be substantial in some cases and important in all projects. Respondents reported that typical "savings" include avoided litigation and additional studies or investigations, regulatory streamlining, and acceleration of the decision process.
3. Project/decision acceptability: Underlying all of public involvement is the desire to improve chances that decisions will be acceptable to the widest range of stakeholders, including agency staff. The majority of respondents reported that the public involvement process they were involved in enhanced project acceptability. From a manager's perspective this can mean avoiding unanticipated conflict in the future, accelerating regulatory processes, and justifying continued funding. Other stakeholders are likely to view acceptability as the point or goal of all public involvement efforts.
4. Mutual learning: Learning is the supposed outcome of education as a process and mutual learning occurs when all stakeholders learn from their participation in public involvement efforts. Mutual learning suggests that all stakeholders see themselves as responsible for finding a solution, rather than defending a particular cause or agency. Respondents told us that when stakeholders put their personal agendas aside, focused on the problem(s) at hand, and worked together to develop

solutions, mutual learning was occurring.
5. Mutual respect: Participation in public involvement processes allows stakeholders to work, talk, and solve problems with individuals who are often perceived as the "enemy." If successful, this opportunity results in an increase in respect for other people, their perspectives, and positions they take on issues. Respondents report that other participants are usually "de-demonized;" they are no longer seen as the enemy. For mangers, this often translates into viewing the input of stakeholders as valuable to resolving problems. Other stakeholders begin to see agency staff as individuals they can talk with and who listen to concerns.

Cost Indicators

Seven direct cost indicators and four indirect cost indicators are discussed. Potential metrics for direct and indirect costs are arrayed in Table III.

1. Direct costs: Direct Costs can usually be measured through traditional accounting practices once the indicators have been selected. The following direct cost indicators have been identified:
  staff labor or reimbursement for participation
  time
  facilitation services
  facilities
  materials
  travel
  specialists/experts
2. Indirect costs: Indirect Costs cannot usually be measured through traditional accounting practices, although participants are likely to recognize that they are "paying" these expenses. The following indirect cost indicators have been identified:
  Time: 1) cumulative: many stakeholders participate in more than one public involvement process. Their sense of time requirements may reflect the number of projects they participate in or a ratio of the current project to total projects time commitment. 2) perceptions: many stakeholders perceive their public involvement activities as painful or distasteful. This may be reflected in a distortion of the memory of how much time is required for public involvement participation. 3) attention: decision making efforts are frequently stretched out over many months, with actual public involvement required only sporadically. However, stakeholders are required to attend to the progress of the decision making which may be reflected in a perception that time requirements are heavy.
  Opportunity: Participation in, funding of, and commitment to public involvement efforts often requires foregoing other resource-dependent activities. These "lost opportunity" costs are notoriously difficult to measure, but the consequences are apparent to most stakeholders and agencies.
  Authority and influence: Participation in public involvement efforts is perceived by some stakeholders as a diminution of their decision making authority or influence. Respondents told us that they not only feared a loss of their decision making authority, but also a loss of credibility within their organization, a fear that information they shared would be used against them in the future, and peer pressure in the public involvement effort that was difficult to justify outside the effort.
  Emotional: Many respondents reported that they paid a heavy emotional cost for participation in public involvement activities. They report personal verbal attacks, demands that cannot be met, lack of institutional support, and general frustration as common side effects of public involvement.

Discussion of the Findings

While this research project was designed to develop a series of prototype indicators of value and cost added through public involvement, several findings from the research methods, interviews, and analysis are worth noting.

Public involvement participants were able to articulate specific dimensions of value, both positive and negative, brought to a project by public involvement activities. However, we only spoke with participants in effective programs and it may be possible that respondents from less effective efforts may have difficulty in identifying dimensions of positive value or may reveal somewhat different dimensions of value.

No participants discussed the value of accessibility to decision making although this issue is considered fundamental in the existing literature. This may be due to

the successful nature of the participants' access to programs which they considered effective. Or, people who have been actively involved for a longer time and with more projects may articulate different values. We may find that participants with less effective access or in less successful programs value and articulate concerns about accessibility (or lack thereof) to public involvement.

Almost without exception, respondents identified having a wide diversity of views represented in the public involvement process as valuable and important to them. Almost all respondents also reported that accommodating the different values and needs of this diverse group of stakeholders was difficult, if not impossible, to accomplish within the public involvement effort. Integrating input from stakeholders was attempted through allowing stakeholders to change the agenda as required, flexibility in defining problems, providing feedback on the use of input, and having stakeholders evaluate the public involvement effort.

Several respondents discussed project "savings" resulting from public involvement programs. These "savings" typically take the form of costs avoided such as avoided litigation, additional investigations, and program components. When asked to assess the monetary value of these avoided costs, respondents typically provided large, rounded-off figures such as $100 million or $45 million, which suggests that the "savings" are estimates. While avoiding litigation, new research, and schedule project components can save a large amount of money, these "savings" are hypothetical in nature. While the perception of stakeholders "saving" large amounts of money should not be denied, relying on these numbers for indicators of value added through public involvement poses both ethical and methodological questions. For example, how can one assess the amount of money saved by avoiding a hypothetical lawsuit on a hypothetical issue brought by hypothetical stakeholders? These types of "savings" can only be evaluated through a rigorous and comparative evaluation of completed projects.

Measuring the direct costs of public involvement should be relatively easy using traditional accounting practices. Indicators of direct costs also serve as metrics. One indicator of cost that will be interesting to track is change in costs over time. As public involvement becomes more efficient, costs should decrease or, at least, not increase for projects of similar magnitude. These changes will need to be measured against a "baseline" of current costs. Measuring indirect costs will present problems similar to measuring process and outcome dimensions. This does not mean that indirect costs should not be tracked. Respondents' perceptions that they are "paying" the price for participating in public involvement efforts are often indicated in how they feel about indirect costs such as lost opportunity, loss of authority and influence, and emotional wear and tear.

When asked how much time is required to participate in public involvement efforts, most respondents believe that their time commitment is quite large. When pressed to document the time spent on preparation, participation, and follow-up, however, the tallies turned out to be quite modest. We try to capture this discrepancy between actual amount of time and perceived amount of time in the indicators of indirect costs of cumulative time, perceptions of time, and length of attention required (as described in Section 5.4). Actual time commitment to public involvement needs to be tracked carefully and completely while exploration of these indirect time costs proceeds to determine what contributes to the idea that public involvement "takes a lot of time."

CONCLUSIONS

This first step of the effort to develop prototype indicators of the value added through public involvement identified those dimensions of public involvement that were valued, either positively or negatively, by participants in three different public involvement efforts sponsored by the Department of Energy. The dimensions were operationalized into indicators which could be measured and potential metrics for such measurement. However, this is only the first step in a series of steps that are necessary to develop useful indicators.

The next step is to take these prototype indicators back to a sample of the initial respondents to determine whether these indicators truly capture the dimensions of value they identified in their interviews. Validation of the indicators will also benefit from talking with public involvement participants beyond these three projects, outside of DOE, in different stages, and with more varied outcomes. Participants from different types of public involvement efforts are likely to accept the proposed indicators but will probably suggest others that reflect their own

programs and experiences. The indicators can be refined using all validation sources.
After this validation and refinement process, the indicators will need to be tested in ongoing and completed public involvement programs. Procedures for obtaining data on the metrics will need to be developed. And then, baseline data collection will be necessary. The indicators should be tested on programs that are considered successful as well as unsuccessful. If possible, the indicators should also be tested on public involvement efforts sponsored by DOE and other federal agencies such as the Department of Defense as well as state-level efforts such as those sponsored by the Washington State Department of Ecology. It is only through testing the indicators on a wide array of programs that their general usefulness will be assessed.
In the short term, the indicators can be used as a discussion point with Hanford and PNL managers currently sponsoring public involvement activities as well as those managers who have yet to do so. Hanford and PNL managers who sponsor or participate in public involvement activities can help in the validation of the indicators. They can be asked to review this report and to provide input based on their own positive and negative experiences. These managers may also have pragmatic suggestions for metrics for the indicators. Their participation in any future testing phases can also be solicited at this point.
For those Hanford and PNL managers who have yet to sponsor or participate in public involvement activities, the prototype indicators can be used to discuss common costs and benefits of using public involvement to manage public input to benefit projects. The indicators are likely to identify many of their fears of participation, particularly the indirect costs and time commitments. The discussions can also be used to validate the prototype indicators and to ensure that no major dimensions have been overlooked in this process. The indicators (and report) can begin an iterative discussion process with these managers as they begin to think about public involvement.

A NON-LINEAR PROCESS FOR MULTI-STAKEHOLDER INVOLVEMENT IN ENVIRONMENTAL MANAGEMENT ACTIVITIES
Mary Harper
Center For Changing Systems
William Kastenberg
University of California
ABSTRACT
Governmental and industrial institutions involved in radioactive waste management are now entering a new era in which they must significantly expand public involvement. Thus, the decision making process formerly utilized to direct and guide these institutions must now be shifted to take into consideration the needs of many more stakeholders than ever before. To meet this challenge, these institutions now have the job of establishing an entirely new set of accurate, sufficient and continuous information pathways between themselves and many divergent stakeholder groups in order to create lasting relationships built on trust and mutual respect. In this paper we outline the necessary considerations for establishing the pathways for successful multi-stakeholder decision making, based upon a non-linear, cognitive-linguistic grid that has demonstrated a high degree of effectiveness in human interaction. Such effectiveness occurs because human beings are non-linear open systems, and require decision making strategies that reflect our very nature.
   The world that we have made as a result of the level of thinking that we have done so far, has created problems we cannot solve at the level of thinking at which we created them.
   -Albert Einstein
INTRODUCTION
The international industrial and governmental community involved in radioactive waste management and environmental remediation are now entering a new era of greater public involvement. Thus the decision making processes formerly utilized to direct and guide these institutions must now be shifted to take into consideration the needs of many more stakeholders than ever before. To meet this seemingly difficult challenge, these institutions will likely need to adopt new strategies for interaction that provide accurate, sufficient and continuous information pathways

between themselves and the many divergent stakeholder groups. These strategies would provide the means to establish trust and mutual respect, as well as serve as a vehicle for staying open and responsive to the needs of all internal and external stakeholders: industrial partners, governments, including the various federal, state and local regulatory agencies, and all related community groups. In this paper we present a process for creating such a strategy.

BACKGROUND

Throughout the history of Western civilization, the methods humankind has devised for problem solving have tended to be very linear in nature. As noted by Davies (1), the greater part of Western science has been founded on the method of "reductionism", whereby the properties of a complicated system are understood by studying the behavior of its component parts. To give a simple example of such linear thinking, Davies states, "there is probably nobody who understands all the systems of a Boeing 747 airliner, but every part of it is understood by somebody. We are happy to say that the airliner's behavior as a whole is understood, because we believe that an airliner is just the sum of its parts."

The first Western scientists were preoccupied with linear physical systems which are especially amenable to a reductionist approach. Indeed, Isaac Newton, whose laws of motion and gravitation gave birth to the age of science, also gave rise to the philosophical and social underpinnings of reason. If simple cause and effect relationships could describe the gravitational force on a falling apple, they could describe everything else in nature as well.

In recent years scientists have come to recognize more and more systems that must be understood holistically or not at all. These systems are described mathematically by equations known as "non-linear." Poincar, the 19th century mathematician and physicist, was among the first to recognize the problems associated with reductionism in his examination of "closed" systems, i.e. a system made up of just a few interacting bodies sealed off from the outside world.

Briggs and Peat (2) describe the problem of Poincar as follows. For a system containing only two bodies, such as the sun and earth, or earth and moon, Newton's equations can be solved exactly, and the orbits obtained are stable. Add a third body and the equations cannot be solved, the orbits only approximated by a technique called perturbation theory. To the ideal two-body system, Poincar added a term that increased the non-linear complexity (feedback) that corresponded to the small effect of the movement of the third body. Although most of the possible orbits for the two bodies are only slightly altered by the motion of the third body, Poincar discovered that with even the very smallest perturbation, some orbits behaved in an erratic, even chaotic way. "His calculations showed that a minute gravitational pull from a third body might cause a planet to wobble and weave drunkenly in its orbit and even fly out of the solar system altogether."

As noted above, modern science has focused more and more on systems whose description is considered holistic. Chaos theory, fractals, and the advent of the hologram are examples of this way thinking. David Bohm (3) perhaps summarizes it best when he theorizes that the universe must be fundamentally indivisible, in which the observer cannot be separated from the observed.

As a result of Newtonian thinking, and other conventions of dualistic thought, many human decision making strategies have become/are linear in nature. They tend to impose arbitrary limitations as well as positing simple cause and effect relationships rather than considering the myriad of constantly changing factors that come into play in each and every moment, and their mutual effect on one another. In organizations or systems where the articulated needs are relatively uniform, or homogeneous, there may be fewer disparate variables to consider. As a result, the levels of complexity they face seem, for the moment, to be manageable within the limits of what linear decision making strategies can solve.

In order for decision makers to keep a system manageable when faced with increasing numbers of variables, they tend, over time, to fix external boundaries and limit external feedbackcreating a closed system. For example, since its inception, the nuclear enterprise has a history of operating in this closed systems manner. In it formative years, the Joint Committee on Atomic Energy, a small elect group of United States Senators and Representatives, with little or no external feedback, made decisions regarding the development and deployment of both civilian and military applications of nuclear energy. In the name of national security, both the decision making, and the resultant programs, were not only kept from public view, they were

kept from other governmental review, except on a "need to know" basis. Hence a homogeneous viewpoint, coupled with fixed boundaries and little or no feedback, characterized the dawn of the nuclear age.

Such a reductionist stance gives rise to strategies which create an atmosphere susceptible to intractable conflicts with other "outside" systems that may not necessarily agree that they are outside the boundary that has been internally established. Moreover, allowing such an outside system to merely perturb the closed system, can, as observed in numerous public forums regarding nuclear issues, render the closed system chaotic and unstable, as is the case with natural phenomena.

Now as industrial and governmental institutions are challenged to open their formerly fixed boundaries to include increasingly varying viewpoints from the outside, the levels of complexity are increasing many fold. The difficulties in using linear, closed systems decision making strategies are likely to become more evident at the interface between internal and external stakeholder groups.

THE NEED FOR A NON-LINEAR MODEL

Our attempts, as decision makers, to recognize, sort, and track seemingly disparate views around the represented multiple categories of human need in what are labeled "intractable" circumstances can often seem like an impossible task. In fact, and in experience, this task often is impossible when decision makers use linear strategies for decision making. Linear problem solving methods, such as compromise, trade-offs, settlements and win/lose scenarios are likely to ignore significant relevant needs. Even win/win scenarios, which may take into account certain relevant needs, differs from our approach in that "win/win" seems to imply that there is something to winstill one-half of a polarized concept. We strive to eliminate any concepts like "winning" or "losing" that could lead to possible fragmentation of the whole. Rather we continually pay attention to the interaction between needs and the context out of which those needs arise. Without this level of attention we will likely delay or deny a final suitable resolution in which all sides recognize and agree that the best solutionbased upon present evidence and current resourceshas been attained.

The central problem we must address, as we search for resolution, is that human communication has been predicated on a set of linear and closed system assumptions, partially deriving from the fact that language itself is sequential and linear. Yet, as human beings, we are open living system organisms, continually adapting to the feedback from the environment in which we live. This constant reorganizing and transforming ourselves is the essence of living or staying alive. Using a closed systems paradigm for languaging our experience is at best inappositea category errorand, at worst, creates a dissonant distortion in experience which often fuels individual discomfort and potential conflict.

Our open systems model can be thought of as a "map" or "guidance system" which facilitates the translation of closed systems conventions in language into an open systems language which allows a more seamless movement through the ideation and decision making process. When skillfully utilized, this model helps to break the cycle of this closed systems taint in our experience. It provides a means to establish a new level of congruence in thought formation and interaction which can significantly increase understanding and cooperation in decision making processeseven between people who previously viewed their positions as intractable.

TOWARDS NON-LINEARITY

Essentially, life is non-linear, teeming with variables, all interacting, all interinfluencing and thereby yielding what we refer to as change. This seems to be an accurate view of living transactions, whether at the molecular level, cellular level, level of the organism, groups of organisms, and the subset of organisms called "human," as well as the collections of activities, organizations and institutions we create.

As we shift our decision making strategies to be more congruent with an open living systems paradigm, our ability as decision makers to recognize the consequences of the pattern of perception we are applying to the definition of our need, or the situation, is critical in the non-linear decision making realm. Accurately identifying if there are any closed systems elements in any transactions that may lead to conflict, mismanagement, or insufficiency of need gratification is essential, as is accurately and completely tracking ourselves and with others at any given moment. Further, we must be able to recognize and understand the consequences of the organization of the pattern of information that we are holding as we participate in a decision making process.

To help us do this, it might be useful to describe the landscape or backdrop on which this phenomena called human experience is being played out. From David Bohm's point of view, "physical reality is not a collection of separate objects" as we might perceive it, "but more an undivided whole that is in perpetual dynamic flux." In his view, "mind and matter are not separate substances. Rather they are different aspects of one whole and unbroken movement." He refers to this flow as "holomovement""holo" indicating that the manner in which perceived reality is structured can be likened to holography, and "movement" referring to the flux and constant state of change. This perspective is correlated with our approach borne out in this non-linear decision making modela language of holomovement.

ACCURATE AND COMPLETE INFORMATION

We as human beings are attempting to strategize sufficient means for meeting our needs. Yet, most of us do not have accurate or complete information about the essential functional elements of how to do so. Therefore, when we run into the limits of our knowledge we often create some scenario that fits for the limits of our knowledge and try to act on it to the best of our ability.

Both the nuclear industrial/governmental community and the public have been prone to finding "solutions" without having complete and accurate information. In addition to a lack of technical information regarding the magnitude and the extent of environmental degradation and its effects, both sides have failed to find the means to provide the other with the sufficient information necessary for informed decision making. In the absence of sufficient information we suffer the consequences of the limits of the information we possess. Any living system deprived of or depriving itself of information will, in all probability, function in a diminished capacity. The variations of these diminished capacities lead to a critical level of chaos and confusion, with many observers believing that the situation is impossible to remedy. Yet, when given sufficient and accurate information, the open system organism begins to course correct and bring itself back into balance.

As the environmental legacy of the weapons complex continues to come to light, greater and greater public awareness has placed even greater pressures to open the system. The public no longer wishes to become informed after the fact; rather the public wishes to become an active participant in the decision making regarding the environmental, economic and health impacts on their communities and on themselves.

FROM COMPLEX TO SIMPLE

Oftentimes, professionals in leadership positions have access to information and choose to withhold or partially disclose it. This is a behavior calculated to exclude, borne out of fear that some important need is threatened.

The continued development and production of nuclear weapons has been tightly controlled by the Department of Energy, which has been solely responsible for the various decisions regarding the development of new weapons systems, the construction of new facilities, and particularly the allocation of resources regarding production versus safety and the environment. In the name of "national security," the DOE was able to make "unilateral" decisions, a closed system strategy that ignores the interconnected, undivided wholeness by excluding from the decision making process most members of the set of what we call our "nation"with jarring consequences. This process of exclusion is a form of fragmentationthe major culprit in creating the phenomena referred to as complexity.

Complexity usually exists when we do not readily have a means to unravel and understand some new phenomena we face which do not resemble something we have handled before, something we might refer to as a puzzle. Yet, if we possess the informational grid to deal with the puzzle phenomena, we may, all of a sudden, be able to refer to the puzzling experience as simple rather than complex.

Experiencing complexity is an indicator of insufficient and/or inaccurate information in a system at the individual or group level. "Complexity" is relative to the organization of the organism labeling or describing their experience as such. Our non-linear pattern of languaging serves as a grid of manageable scale to identify the differences that make a difference in reducing complexity and intractability in human interaction and decision making. It simultaneously identifies the markers that are essential ingredients to hold in mind in order to course correct when you perceive that you may be moving toward an unstable, closed systems position. Reporting experience from this defined grid of interactive focal pointsrepresenting open system transactionsindividuals or groups of decision makers are able to begin to experience openness, wholeness, movement (emerging

cooperation), and simplicity (clarity) in each moment.
When we have such a precise reflecting surface in which to see a moment to moment view of our complete position with ourselves internally, as well as the interactive interface between our position and the position of those with whom we participate in the decision making process, something important happens. Information is now being managed in an open systems frame as it is being formed by all of the participants in the decision making process. When individuals understand this open systems non-linear frame, and apply it, the arena of complex and intractable conflict can move into the domain of simpleprovided everyone involved in the decision making process is willing to play the game by participating with the self-organizing principles of this open systems strategy.

NON-LINEAR OUTCOMES

As we align ourselves with these principles, we are likely to begin to experience many levels of internal conflict and confusion evaporating, replaced by an evolving calm, order, and balance that facilitates fuller understanding and acceptance of our own needs and position. This can be evidenced in fuller attention and enjoyment of the process we are engaged in, and more effective and satisfying relations with the other participants in the "conflict."
Further, in the realm of decision making, many of the so-called impediments related to differences seem to blend, while boundaries that once separated are now seen as boundaries that connect. The sometimes stubborn and demanding threats of loss of power, influence, money, position, and overall well-being inherent in closed systems approaches can finally become pass_ as part of the human condition. In using our non-linear grid to restore the perceptual capability for experiencing essential wholeness and interconnection, the strategies for resolving differences result in cooperative outcomes.
In circumstances that have been defined as complexintractable, multi-stake holder group conflictswe refer to the team of individuals working with the multiplicity of positions as open systems translators. As translators, we are dealing with phenomena from the position of reminding that-which-is-whole that it is whole. This translating encourages us to stop treating ourselves and the world around us as if it is fractured, fragmented and closed off rather than ultimately interconnected with every other element of alivenessthus restoring us as decision makers to our perception of wholeness within our own process of ourselves. As we participate in decision making with others (who are also being reminded through translation of their wholeness) we are able to fractally replicate the pattern of wholeness in all levels of complexity and intractability. Creating and acting as a self-healing system eliminates the so-called stubbornness of difference, and brings the possibility of unity back into direct individual and collective experience.

OUR MAPPING PROCESS

In discussing this model we cannot simply intellectually transfer it as a fixed entity to each of you, so that you can map it onto your existing definitions and beliefs about yourself and the on-going transactions around you. In one sense, this is not a "model" at all, nor is it simply a piece of knowledge to be understood and added to your existing data base. Instead, it is a mapping process to constantly order and rearrange your data base in each moment as new bits of data, or signals, come into your systemyour awareness. This essential constant rearranging is necessary in order to understand the meaning you are creating and are part of in the relative unfolding of all processes in which you find yourself. In fact, this moment to moment observing and shifting and reporting the shifting is the core of decision making.
How we identify and report this shifting is central in solving the problem of intractable conflict in human decision making. If we use a linear construct to report our experience to ourselves, we will likely perceive and report ourselves as separate from the phenomena we are observing and interacting with, thus seeing the outside world as colliding with us, as if it were doing something to us. This is the recipe for victimization, and potential conflict arising from the perception of victimizationthe creation of an "enemy."
In using this mapping process we are able to skillfully focus upon and report the fact that we are moment to moment creating meaning as it emerges from the sea of mutual arising contingenciesthe multiplicity of events we call signals and which we arrange into what we call information. In this non-linear living system which is us, there can be no victims and no enemies. In fact, the arbitrary boundaries we draw to

create meaning are simply the distinctions we provide to signal where we are focusing in the flux of variables and where we would like to influence someone else to focus with us. We are, in fact, asking for connection and cooperationnot divisiveness and separation.
To the degree that any of us have relied upon linear descriptors and descriptions to understand our experience of ourselves, we are misguiding ourselves about the nature of the transactions we are in with ourselves, particularly in the realm of decision makingwhether with ourselves or someone else. Of course, the more "someone elses" there are, the more trouble we will be in if we are using linear descriptors for a non-linear event. It is a matter of scale, in that we are in some trouble when we are in conflict with ourselves individually, yet we are in great trouble when we are in conflict with ourselves collectively, be it interpersonal hatred of difference, gang or family violence, ethnic cleansing, or degradation and pollution of the planet. Unfriendly competition and fear of limited resources, which can lead to the hoarding of information or other things essential for the common benefit, are all consequences of using linear organizing principles for non-linear eventsour lives!
What we have to offer here is a perceptual course correction for translating our linear closed systems strategies for human interaction into non-linear open systems strategies for ultimate restoration of the possibility of connection and cooperation. A means to collectively experience confluence of need and the marshaling of resources to met those needs in ways that do not unilaterally exclude any one. The illusion that we could exclude anyone is fueled by the delusion that we could possibly transact business together as non-linear organisms through the means of linear strategies and languaging.
The mislabeling of events, whether it be ourselves or elements in the universe around us, is the crux of our problem in intractable conflicts. Mistaking our definition/label of events for the experience of the event itself is our category error. To treat that which is moving (holomovement) as if it were static is our basic mistake. Therefore, the more we get into describing events between us as if they are "real," rather than just a momentary description of the pattern of information we are in with ourselves, and projecting that "realness" onto the rest of the events around us, the more we can get into trouble. These types of strategies will inevitably lead to some type of break down in our process of relating to one another, regardless of the task or function in which we are involved.
In fact, when using linear descriptors for non-linear events we are setting an inaccurate pattern in motion that will be borne out in all levels of relating: intrapersonally, interpersonally, intra-group, inter-group, intra-organizationally, inter-organizationally, intra-regionally , inter-regionally, intra-globally, inter-globally, on into infinity. The essence of our fractal universe is set in motion from the pattern we create, be it accurate or inaccurate. The consequences of inaccuracy are inordinately grave. Making the choice to shift the habit of identifying and patterning ourselves as closed linear systems, closed off from the rest of the world and, therefore, vulnerable to it, is essential for sustaining life.

CONCLUDING COMMENTS

In every corporate or institutional setting where I have applied the model in the past 20 years, it has been at the request of the "people in charge" who recognize that they are not achieving what they hoped or thought possible to achieve and, much to their dismay, things are breaking downalarm and crisis are at the doorcredibility, effectiveness, and profitability are threatened.
Whether in the corporate boardroom, the laboratory, or the production line, the problem is always the samemislabeling events leads to the breakdown of the system which eventually effects something or someone adversely, be it profits or the satisfaction of the work force. The solution process is ultimately always the same as wellto translate the configuration of events and the language describing the events, and the policies and regulations governing the events, from a closed systems linear motif into an open systems non-linear pattern of understanding and operation. This usually involves helping the players involved find the thread of how they lost and are losing themselves, defining the differences that truly make a difference in sustaining the non-linear pattern, and thereby, through apposite (negative) feedback restore the clarity and balance necessary to keep the system functioning in a salubrious fashion where each person involved can have their personal and professional needs met. I introduce them to the living exercise of decision making

by noticing the change they are in constantly and beginning to feel accord with this change and skillfully track themselves in the change, rather than straining to resist the change.
This non-linear model can be a standard of possibility for human decision making. Decision makers choosing to use this methodology will likely need in vivo coaching to unlearn the linear assumptive conventions in language and thought as they simultaneously learn the skill of applying non-linear strategies. The model provides a means for an entire individual, cultural and cross cultural course correction from adversarial to cooperative strategies in any setting provided the participants are willing to choose to use it.

ABSTRACT
Challenged with doing more with less, the U.S. Department of Energy (DOE) Environmental Management (EM) program is placing strong emphasis on achieving significant productivity improvements in environmental data operations (i.e., sampling and analysis) through better front-end project planning. An important tool for helping achieve this objective is the Data Quality Objectives (DQO) process. Initially defined by the U.S. Environmental Protection Agency (EPA) and adopted as EM policy, DQO planning of environmental data collection is beginning to take a strong foothold at a number of DOE field sites. To accelerate the spread of DQO planning throughout the EM program, the EM Office of Compliance and Program Coordination Analytical Services Division is well within the second phase of a three-phase approach in working with DOE field sites to introduce and integrate the DQO process into field environmental data operations. This phased approach combines the strategies of technical assistance and training, creating DQO case study "success stories," field assessments, and formation of an EM Headquarters and Field Focus Group on Data Quality Objectives and Data Management. Highlighted in this paper are eight DQO case studies initiated in FY 1995 that demonstrate a broad range of applications for the DQO process, including environmental restoration, decontamination and decommissioning, waste characterization, and innovative technology demonstration.
INTRODUCTION
The U.S. Department of Energy Environmental Management program is challenged with accomplishing more in a time of shrinking budgets. As EM drives toward "early action on the ground," (1) new emphasis is focused on better planning and management of activities. One area in which EM can demonstrate significant productivity improvement is environmental data operations (i.e., sampling and analysis). Recognizing this potential, Assistant Secretary of EM, Thomas P. Grumbly took an

important step in this direction by issuing his September 7, 1995 EM policy statement that the Data Quality Objectives process be used in all environmental projects where there may be a need to collect significant environmental data.
The DQO process is a series of logical planning steps to identify and design more efficient and timely data collection efforts. This process is defined by the U.S. Environmental Protection Agency in its September 1994 final Guidance for the Data Quality Objectives Process (EPA QA/G-4), and it is a requirement for EPA Superfund projects. The DQO process has several notable strengths. It brings together the right players (managers, technical staff, regulators, and other stakeholders) early in the planning process to gain consensus and commitment about the drivers and scope of the project. This interaction leads to a clear understanding of the problem and issues, the actions needed to address the problem, and the acceptable level of uncertainty in the data for making decisions. Through this planning process, data collection and analysis are optimized so only those data needed to address the appropriate questions are collected. This saves time in planning and decision acceptance and resources by eliminating unnecessary data collection.
The DQO process has most often been applied to site remediation projects and to some extent, to waste characterization (e.g., Hanford tanks HLW waste characterization). However, DQO planning has a much wider application for designing sampling and analysis activities. The types of questions answered by environmental data cut across all of the EM program. These questions and their applications include:

What, where, and how much contamination? When is it clean or safe?

- Site remediation
- Facility deactivation
- Decontamination and decommissioning (D&D)
- Environmental monitoring (groundwater, surface water, air)

What process knowledge is appropriate and how much sampling and analysis is needed?

- Waste characterization
- Site remediation
- D&D

What existing information can be used and what new data are needed to verify facility acceptance into the EM program?

- Facility transition

What determines technology effectiveness and how is it demonstrated?

- Technology development

The DQO process also forms the basis for a related approach created by DOE. In FY 1992, DOE enhanced the DQO process as applied to environmental restoration sites by merging it with remedy selection and implementation to address all facets of an environmental restoration project. This enhanced process, called the Streamlined Approach for Environmental Restoration (SAFER) combines DQO planning and the Observational Approach operational framework, balancing the reduction of uncertainty for decision making by collecting new data with managing uncertainty through contingency actions. Descriptions of SAFER and DOE's applications are the subject of another paper in this session of the WM95 Proceedings (2).

STEPS TOWARD IMPLEMENTING DQO PLANNING ACROSS THE EM PROGRAM

Over the last three years, the Analytical Services Division (ASD), now within the DOE Office of Compliance and Program Coordination (EM-20), has been working in a phased approach with DOE field sites to introduce and integrate DQO planning into EM environmental data operations. ASD began its initial phase with a Complex-wide training program and early technical assistance to a few high profile sites (i.e., Hanford, Oak Ridge, and Savannah River). These sites have achieved resource savings and improved relationships with regulators and other stakeholders on several projects. Some specific examples are provided in another paper in this session of the WM95 Proceedings (3). Indicative of the recognized benefits of the DQO process, the initial sites are now expanding DQO planning sitewide to many of their projects and supporting it with line management funding.
After this early demonstration phase, ASD moved into phase two, stepping up its activities to enhance wider use of DQO planning in EM. In August of 1994, ASD sponsored a widely attended workshop on Applications of Data Quality Objectives Planning to EM-Wide Environmental Data Operations, where candidates for DQO case studies were solicited from around the DOE Complex. The objectives of these case studies are to:

provide hands-on training of site personnel while helping them achieve savings on their own projects;

help new sites get started in using DQO planning on their projects; and

provide documented templates on a range of DQO applications for use by the Complex.

Eight DQO case studies have been initiated in FY 1995 so far. These case study projects include waste characterization, evaluation of innovative waste characterization technology for regulatory approval, environmental remediation, and reactor and building D&D. Each of these case studies and the progress to date are described in the next section.

Phase three of implementing DQO planning across all EM environmental data operations is expected to begin in late FY 1995 to early FY 1996. The DQO/SAFER training program will continue, as it has through all phases, providing classroom instruction to sites where requested. ASD also plans to continue its technical assistance through DQO facilitation and statistical support to the field for four to six new case studies, targeting sites where DQO planning has not yet been used and new types of applications for the DQO process. Finally in phase three, ASD will initiate a program of field assessments. The intent of these assessments is to: (1) help sites evaluate their environmental data collection processes and procedures, including the planning aspects, for effectiveness in generating credible and cost effective data for environmental decision making, and (2) give them advice on how to make improvements.

Since the time DQO planning was first introduced into DOE, a number of field sites have made strides in adopting this process, both with and without ASD's technical assistance. However, there is significant room for more experience and broader use around the Complex. With the objective of facilitating and enhancing wider field implementation of DQO planning to achieve productivity savings, a new Quality Improvement Team Focus Group on Data Quality Objectives and Data Management, led by ASD, has been formed in EM. This group is comprised of representatives from all of the EM Headquarters line management organizations and several of the field offices to provide a cross section of perspectives and lessons learned on integrating DQO planning into EM field operations. The Focus Group will champion improving communication to increase awareness and understanding about the benefits of DQO planning throughout the program and promote ways to help field sites identify projects and activities where DQO planning could effectively improve operations.

DQO CASE STUDY PROJECTS

Following is a brief discussion of the eight DQO case study projects and their status as of January 30, 1995. The DQO planning phase on these projects is in varying stages of completion at this time, ranging from early discussion to near completion. In all cases where planning is underway, the DQO process has significantly helped the project teams in focusing the questions to be addressed and has often resulted in critical scope changes in response to identification of new issues not considered initially.

Waste Characterization: Hanford Ion Exchange Modules

Ion exchange modules (IXM) used to remove radioactive ions from Hanford storage basins have been stored at the K-Basins (105-KW, 105-KE, and 183-KW chlorine vault storage area) for a number of years. During this time, varying amounts of hydrogen and other potentially explosive gases have accumulated in the module chambers. The IXMs need to be stabilized and moved to more permanent storage locations, but there is a potential environmental and safety concern in moving them without testing their potential for explosion first. An action level for hydrogen of greater than 1 percent by volume within the IXM chambers is considered to be protective of human health and the environment and will minimize worker exposure during the stabilization process. Testing will be used to categorize the IXMs in one of three categories: 1) safe to move as is; 2) requires purging before it can be safely moved; or 3) requires purging and reconfiguration before it can be safely moved. DQO planning, which is complete, has been used to design a sampling program to make these determinations. Because there are no historical hydrogen data from IXMs at K-Basin, preliminary sampling and analysis of one or two IXMs is necessary to complete a statistically defensible design for making decisions with the appropriate level of certainty. The DQO process was used to 1) design this preliminary sampling and 2) produce alternative options for the number of samples required from subsequent IXMs in the complete sampling design based on probable results from the

preliminary sampling.
Through the DQO process, another issue was identified by the DOE and site contractor project team. The concern is how quickly the concentrations of potentially explosive gases in the IXM chambers are changing so that subsequent samples would be required to adequately represent the gas concentrations. This aspect of the sampling design will be addressed using a hydrogen generation and breathing model. The DQO process also helped refocus some of the initial project decisions. For example, it was realized that IXMs do not have to be monitored after their receipt for storage or disposal at the Hanford Central Waste Complex, as previously thought. This enabled the team to narrow their focus to the safety concerns surrounding the hydrogen gas concentrations in the IXM before moving or purging them. DQO planning also resulted in avoiding duplication of efforts. The IXMs in the trench at the 200-W Burial Ground became a priority and through the DQO process, it was decided that they could be moved from the trench directly to their final destination, rather than to an intermediate storage location after sampling/purging, as originally planned. By including the IXMs in the trench as a related issue in the modified scope of the initial DQO case study project, considerable planning time was saved overall.
Innovative Technology Evaluation: Fourier Transform Infrared (FTIR) Spectroscopy
Waste drums containing plutonium contaminated material that are designated to be sent to the Waste Isolation Pilot Plant (WIPP) in New Mexico for disposal must undergo head space gas testing and analysis for volatile organic compounds as part of the WIPP waste acceptance criteria and Land Disposal Restriction requirements imposed by the EPA. Analysis of head space gas has been performed using a method approved by the EPA, consisting of taking a sample of gas and analyzing it by conventional gas chromatography/mass spectrometry (GC/MS). Considering the large estimated volume of waste to be sent to the WIPP, this sample collection and analysis method is anticipated to be prohibitively expensive and time consuming (approximately $1,000+ per drum with a two day turnaround). An alternative technology, FTIR Spectroscopy has been proposed to test the head space gas. FTIR spectroscopy analysis can be performed in minutes rather than hours. This method is anticipated to be far less expensive than conventional testing because it will allow on-line analysis of waste streams.
The requirements set by the EPA for the GC/MS method in the No Migration Determination for WIPP are 25 percent precision and 30 percent accuracy. The decisions to be addressed by this case study are: 1) Does FTIR spectroscopy perform as effectively as GC/MS, and 2) can FTIR spectroscopy support decisions about whether waste drums meet WIPP waste acceptance criteria or other applicable criteria for head space gas. Two aspects of this case study make the application of the DQO process somewhat unique. First, the DQO process is usually applied to identify error tolerance for the uncertainties associated with making remedial decisions. In this case, the process is being used to make decisions about the performance of a new technology. Secondly, DQOs are being used to evaluate and compare experimental test GC/MS and FTIR spectroscopy data sets, rather than design a sampling and analysis program for collecting new data. Because most of the FTIR data are already available, DQOs will be used to assess whether further tests are required and to perform data quality assessment on the already existing test data.
Many of the steps of the DQO process have been worked through with the project team and specifications for some new data are being determined. To help with the final data quality assessment, DOE plans to assemble a panel of experts in the technology and type of measurements made to evaluate how comparable the FTIR spectroscopy results are to GC/MS and how well they meet the DQOs. This data quality assessment will form the defensible basis for presenting a case to the EPA for their approval to use FTIR spectroscopy.
Site Characterization: Paducah Waste Area Grouping (WAG) 22 Burial Grounds
The Paducah WAG 22 Burial Grounds began as a RCRA site but became a CERCLA site after it was placed on the EPA National Priorities List (NPL). Two solid waste management units in the WAG were identified as targets for field sampling to support a risk assessment and possible remediation. It appears that groundwater has been contaminated with radionuclides, metals, and chlorinated hydrocarbons. Some offsite contamination has also occurred. Although the two waste management units may be a source, all of the sources of offsite contamination have not been identified. The purpose of the sampling and analysis is to provide additional data for identifying the nature and extent of releases of hazardous waste constituents from the two

areas. The data will be used to formulate a Feasibility Study or to support the "no action" alternative.
Originally, the purpose of the investigation was to fill "data gaps" identified in the existing database. The DQO process emphasizes that data should be collected only to answer specific questions identified during planning, rather than to fill apparent data gaps. After applying the DQO process, it became clear that "data gaps" and "data needs" are not the same thing. This focused the project team better and allowed them to formulate a conceptual model of the site, identifying sources, pathways, and receptors. At that point, the site contractor was independently able to complete the process and design the sampling and analysis plan. Recognizing the value of DQO planning, Paducah will be applying the process to additional projects at the site.
Environmental Restoration: Nevada Test Site (NTS) Underground Testing Area (UGTA)
The NTS UGTA was used for nuclear testing over a wide area, with one-third of the 825 tests performed below the water table. Based on the physical characteristics of the site, vast quantities of soil and groundwater could have been adversely affected by this testing. The problem is compounded because groundwater, with the exception of some perched zones, is an average of 500 meters below the land surface. There are no clear external regulatory drivers to investigate or remediate this site and there appears to be no immediate endangerment to human health or the environment posed by the UGTA. However, DOE is committed to address the UGTA location as part of their effort to restore the environment from radioactive contamination. The State of Nevada follows a "non-degradation" of groundwater policy but has not defined what "degradation" standards might be imposed. Therefore, the objective of this DQO case study is to identify what further site characterization is required before a decision on future actions can be made. This will be based on reaching consensus with the regulators about decision drivers, such as groundwater non-degradation. If remedial action is required, decisions will include what remedies are feasible, practical, cost effective and capable of reducing risk to acceptable levels now and in the future. Discussions with the State on alternative future actions are in the early stages.
Environmental Restoration: Nevada Test Site (NTS) Double Tracks (Tonopah Test Range)
The NTS Double Tracks was a nuclear detonation area where soils have been contaminated by radionuclides and fission products, particularly plutonium. In the short term, the Air Force would like to continue using the Double Tracks area as a conventional bombing training range. This creates a risk from resuspension of plutonium contaminated soil. Long term future land use of the area could range from continued bombing to agricultural. Although no RCRA constituents have been identified at the site and thus, no clear external regulatory driver for an investigation/remediation, DOE has undertaken this investigation because of its commitment to state and federal regulators and to the public to address the radioactive contamination.
The scale of the decision making is unclear at this point; is the contamination at Double Tracks confined to soil hot spots or is it widespread across the area? The DQO process will be used to focus planning on what needs to be characterized, how remedial actions will be evaluated, and what are the ultimate disposition of the waste and waste acceptance criteria. Specific concerns stem from a question of whether field testing or screening techniques can be used to characterize the soils rather than conventional laboratory analysis. An additional aspect to this project is that the Nevada Test Site has many locations with problems similar to the Double Tracks. The process used to evaluate and remediate this location may be used as a template to apply to other NTS areas under consideration.
Environmental Restoration: Savannah River Site (SRS) R-Reactor Seepage Basins/108-R Overflow Basin
Six seepage basins associated with the R reactor operated at this location between 1957 and 1964. They have been capped with clay, and subsequently sprayed with asphalt. The R reactor area has been designated a CERCLA site, and remedial options will be evaluated once a site investigation has been completed. Monitoring wells installed in the 1960s have detected some groundwater contamination in the area, and there is evidence that radionuclides continue to be present in the soils. The main concern identified to date appears to be ecologically related rather than human

health risk. However, the site decisions defining contaminant thresholds for considering remedial action are now being developed to determine whether ecological impacts or human health will drive risk. Several project issues need to be resolved: 1) whether groundwater contamination is a result of releases from the seepage basins and should be addressed in the seepage basin remedial investigation/feasibility study (RI/FS) or whether it is part of a more complex, multi-plume contamination problem from R reactor, itself, requiring an independent study; and 2) whether the RI/FS can or should be integrated into the R Reactor D&D operation.

A characterization work plan written in 1992 was found unacceptable by some of the stakeholders, and will be redone using DQO planning. The regulators are familiar with the DQO process, having successfully applied it with SRS staff on other site projects, and were anxious to use it for this study. To date, the DQO process has been used to help design preliminary data collection to get a better idea of whether the plume is isolated or attributed to additional sources. Based on the preliminary information, broader characterization will be designed.

Integrated D&D and Site Remediation: Oak Ridge K-1410 Area Complex Demolition Project

The Oak Ridge K-1410 Area Complex Demolition Project consists of two contaminated buildings and concrete pads, a neutralization pit, associated underground power lines, and the grounds surrounding the buildings. The objectives of the project are to perform applicable CERCLA actions to protect human health and the environment and D&D actions for the most cost effective way to deal with the facilities. This project is being planned as an integration of D&D decisions (such as possible decontamination, removal, and disposal of the buildings, concrete pads, and power lines) and remediation decisions (such as removal of hot spots and remediation of soil, groundwater, and surface water). Project activities to be accomplished that are defined so far include: 1) detailed characterization of the area, 2) building demolition feasibility study, 3) removal of transferable radiological contamination, 4) removal of hazardous waste materials, 5) either demolition or stabilization and isolation of the facilities (depending on D&D decisions), and 6) closeout of the project. The DQO process will be used to identify data requirements within each project activity.

EPA and state concurrence is required on all CERCLA decisions and actions but concurrence is not required for D&D decisions. However, it is necessary for regulators to see both sets of decisions because the project is integrated. Recognizing that the project team did not have a clear picture of the process relating the logic and actions of CERCLA decisions to D&D decisions, the DQO process is being used initially with the regulators to define a model linking the CERCLA and D&D decisions so it is understood where regulator decision making authority rests and where it does not.

Reactor D&D: Argonne National Laboratory East CP5 Reactor

The Argonne CP5 was a heavy water graphite research reactor built in 1952 and abandoned in 1979. The fuel and a substantial portion of the ancillary research equipment have already been removed from the reactor building. However, tritium contamination is still a major concern. Characterization, removal, and disposal of the reactor core structure are the primary technical activities to be addressed. An environmental assessment and initial D&D work scope were prepared in 1982. This work scope needs to be reviewed and revised as appropriate based on current standards and information. Argonne would also like to use the CP5 D&D project to help develop a general model approach to management of facility D&D that can be applied to other projects.

During the initial steps of the DQO process, the DOE, site contractor, and independent experts planning team identified a number of higher level management issues to be resolved before D&D could commence. Central to these are which D&D activities should be performed by the site contractor and which should be subcontracted to outside contractors. Deciding on options for the organizational and reporting structure of the D&D project team was another key issue. Also discussed was whether to use the CP5 D&D project to demonstrate innovate technologies. Based on these discussions, the project team was able to prepare: 1) a proposed organization and reporting responsibility matrix for the CP5 project team; 2) a scheme for the planning and implementation phases of the project and content lists for the associated planning documents; and 3) recommendations to DOE for subcontracting. While working through these issues, the next step will be to

assemble a technical planning team that will apply the DQO process to developing a current day approach to D&D of the reactor core structure.

CONCLUSION

The DQO process has gained a strong foothold at a number of DOE field sites. Early successes and demonstrated benefits have stimulated these sites to expand its use to their other EM projects. Lessons learned have also filtered to other DOE sites where DQO planning is being initiated. While progress to date is favorable, DOE is still a long way from institutionalizing this front-end planning tool as a routine part of its environmental data operations. In the current world of ever increasing fiscal constraints, generating credible decision making data in a more cost effective manner is the only option. DOE can no longer afford old practices of repeating data collection over and over until we get it right. It must be the right data the first time. The DQO process is an effective tool for helping achieve this objective. With the combination of this significant fiscal driver, the recognition of DQO "success stories," and continued facilitation and technical assistance from ASD and the Quality Improvement Team Focus Group on Data Quality Objectives and Data Management, we anticipate an accelerated spread of DQO planning across the Complex over the next few years.

ABSTRACT

The cost of collecting and analyzing data to address U.S. Department of Energy (DOE) remediation problems comprises a major portion of the total DOE annual budget. Lessons Learned have shown that many past sampling efforts were not essential for reaching interim or final solutions. Sampling design approaches, such as the data quality objectives (DQO) process and the streamlined approach for environmental restoration (SAFER), are now available and provide proven methods to "get to the bottom line" on the essential elements of making a remediation decision. Given the impending major cuts in DOE spending, we cannot afford not to use the DQO and SAFER processes for all future remediation efforts.

This paper outlines the history of the DQO process implementation for the Oak Ridge Environmental Restoration (ER) Program, describes problems associated with past planning efforts that resulted in less than adequate sampling program designs, provides examples of program improvements that have occurred during 1993 and 1994 because of DQO process implementation, and discusses the future direction for improved integration of data collection and decision making.

INTRODUCTION

A major portion of the total DOE annual budget is earmarked for the collection and analysis of environmental data to address DOE remediation problems. Our "Lessons Learned" records indicate that many of the past sampling efforts have not contributed significantly to decisions about interim or final solutions. Sampling

design approaches such as the data quality objectives (DQO) process and the streamlined approach for environmental restoration (SAFER) provide proven methods to "get to the bottom line" on the essential data necessary for remediation decision making. Given the impending major DOE spending cuts, we cannot afford not to use the DQO and SAFER processes for all future remediation efforts.

The goal of an efficient environmental restoration (ER) program should be to locate areas of unacceptable contamination and remediate them to levels defined as acceptable by the principal decision makers (or stakeholders). The sooner and more cost-effectively this is accomplished, the better it is for both DOE and the public. Data collection programs serve as effective tools for gathering the information we need to make sound decisions but cannot, by themselves, lead us to the best answers for remediation questions.

Selection and implementation of the best remedial decision requires the development of a conceptual model that can be used to make decisions that will address the problem at hand with an acceptable level of certainty. A conceptual model is generally a series of interconnected mathematical models and statistical descriptions of the site that are built out of data. There is no clearly defined "level" of quality that data must meet before it can be used to build a conceptual model. The only requirement is that the model have sufficient integrity, on the whole, to yield reliable results that are within the tolerance for error as defined by the stakeholders. In order to understand the uncertainty of the conceptual model, we must understand (if not measure) and prioritize the major sources of sampling error.

The following sections describe the design weaknesses of past sampling programs in the Oak Ridge ER Program, discusses improvements currently being made, and indicates the direction in which DOE Oak Ridge Operations would like to see the program move.

BACKGROUND OF DQO PROCESS IMPLEMENTATION IN OAK RIDGE

Over the last two years, the design of the ER Program's data collection processes has changed from focusing on complete characterization to focusing on the collection of data sufficient for decision making. The motivations for this change were the need for improved cost effectiveness, the desire to accelerate schedules, and information from "Lessons Learned" that showed us when too much, too little, or inappropriate data had been collected to be useful in remediation decision making. Quality Assurance staff in both DOE Headquarters and the regulatory agencies have served as catalysts for this shift by providing improved policies and direction to field elements and by backing up this direction with sound technical leadership and on-site assistance.

The ER Program was created in 1984, when Resource Conservation and Recovery Act (RCRA) corrective measures and closure regulations were the principal drivers for the mitigation of contaminant releases from disposal areas that had received hazardous and mixed wastes. While planning for these early efforts was conducted with the assistance of technical experts and involved mutual agreement between DOE and the regulators [the U.S. Environmental Protection Agency (EPA) and the State of Tennessee], the main emphasis was on schedules and reduction of regulatory compliance issues; the technical rationale for data collection often took a secondary role.

These conditions sometimes created sampling program designs that lacked a technical rationale and were inefficient in terms of cost control and scheduling. Some of the major weaknesses in past programs include the following.

Lack of adequate involvement by DOE and regulators in the design of sampling plans. Before 1993, sampling programs were often designed by DOE management and operations contractors and their subcontractors with minimal initial involvement by DOE and the regulators. DOE technical staff often did not conduct focused review of the sampling strategy until time for draft work plans to be reviewed. Because schedules were often tight, these reviews were performed to quickly to ensure data adequacy, sound technical rationale, or proper linkage to actual feasible decisions. This method of planning resulted in an unnecessarily high risk of collecting too much, too little, or inappropriate data.

Inadequate statistical design. Sampling program designs often lacked a sound statistical basis. In most cases, the statistical certainty that the sampling program provided was not based on an allowable tolerance for decision error established by the decision makers. Thus, demonstrating that the conceptual model

based on the data would meet the needs of the decision maker needs was difficult. Also, the numbers of samples to be collected were often driven by the schedule and the budget rather than by the quantities needed to make statistically reliable decisions.

A disproportionate emphasis was placed on analytical laboratory quality control. Until recently, there has been a misconception that tight lab quality control and lab data validation will ensure that the quality of the data collected will be acceptable for decision making. Unfortunately, decisions are not based on the actual data. Rather, they are based on the conceptual model that is developed from the data collected. Perfectly good analytical data, unless it is sufficiently representative of the remediation problem, may not yield a quality conceptual model. A representative conceptual model requires:

a sufficient number of samples to ensure that the statistical sampling error is within decision tolerance,

a quality control program emphasis on all major sources of sampling error and not just the analytical lab, and

appropriate data validation and assessment methods that check to ensure that all sources of sampling error are considered in proportion to their importance.

Inadequate use of historical data in building final conceptual models. For many contaminated sites on the Oak Ridge Reservation, there is a base level of historical and current knowledge regarding the nature and extent of contamination that is present and the potential exposure routes that present human health and ecological risks. Past remedial investigation planning efforts have sometimes placed improper emphasis on this invaluable source of information for decision making. There was a tendency to collect new data that repeated existing data from past studies and current data from sources not related to the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA). This was done because the sampling program planners did not consider the data collected in their survey to be of sufficient quality for reliable decision making. The yardstick that the sampling program designers were using to measure data quality, however, was not performance based. They were too focused on the quality of individual data points (e.g., whether or not the data were associated with a Level IV analytical data package) rather than on whether the data, on the whole, yielded a reasonable conceptual model of the site.

Lack of adequate public input in sampling design planning and decision making processes. In some cases, public participation in the selection of feasible remedial decisions was not given proper emphasis until the time of the CERCLA-mandated proposed plan. In one case, a large data collection program was built around obtaining data to support an interim decision about the isolation of hydrologic waste (i.e., waste capping) for a large land-waste disposal area. The regulators and DOE thought the capping action was the best course to minimize releases and achieve regulatory compliance. However, when the capping decision was proposed to the public, they rejected it because they considered the proposed expenditures too large and not warranted, given the relatively low risk that the site posed to the off-site environment (the site contributed less that 2% of the total radiological releases from the plant site). A minimum level of sampling may have been sufficient to ascertain that the contaminant loading from this waste site was very small, and CERCLA-driven priorities could have been assigned to sites where risk-based decisions were more appropriate.

As is true of most problems, elaborating on cause and effect from a retrospective position is easy. The true test of the value of the conclusions reached, however, is whether the "Lessons Learned" can be applied within a program and produce quality improvement. As discussed in the next section, we in the ER Program feel that we are in the process of significant quality improvement.

IMPROVEMENTS IN PLANNING

Despite past weaknesses in sample program planning, several recent improvements have resulted in cost and schedule savings and have provided for a sounder technical rationale for remedial investigations. These improvements include development of policies and procedures that institutionalize the DQO and SAFER processes into everyday business; provision of program-wide training to educate DOE, the regulators, and contractor staff about the DQO and SAFER processes; modification of the Oak Ridge Federal Facility Agreement to require the use of DQO-based scoping meetings during CERCLA sampling program planning, and the use of headquarters-assisted pilot projects to demonstrate technical successes and train

staff.
Two pilot projects where extensive improvements were realized include the Clinch River Remedial Investigation Program and the Oak Ridge National Laboratory (ORNL) Waste Area Grouping 1 Impoundments Remedial Investigation. The first of these was specifically designated to use the DQO process, while the latter used SAFER. The logistics of each of these pilot programs and the associated improvements are described briefly below.

Clinch River Remedial Investigation

A DQO pilot project was conducted for Phase II of the Clinch River Remedial Investigation during 1993 and 1994. This pilot provided a means for substantially reducing the number of samples needed for decision making and accelerated the schedule for a Record of Decision.

The Clinch River is the main surface water receiving stream for the Oak Ridge Reservation (see Fig. 1). The history of DOE-associated contamination of the Clinch River extends back to 1943, when the Atomic Energy Commission began operations in Oak Ridge. The most significant contaminant releases occurred during the 1950s and early 1960s, and the main contaminants of current relevance were mercury from the Y-12 Plant and Cesium-137 from ORNL (other major releases of short-lived nuclides occurred, but these have long since decayed). Because of these releases, there is now widespread sediment contamination in Watts Bar Reservoir downstream of the Oak Ridge Reservation.

The principal area of concern includes mid-channel sediments for approximately 23 river miles of the Clinch River (Upper Watts Bar Reservoir) and 38 river miles on the Tennessee River downstream of the Clinch River confluence (Lower Watts Bar Reservoir). Substantial reservoir sedimentation has occurred since the period of major DOE releases, so the main inventory of contamination is now covered by two or more feet of cleaner sediment, as well as by the reservoir water column. Numerous other nonradiological contaminants have also been detected in the deep and surface sediments and waters of the Clinch River, including other metals and organics. Most of these, however, are common to industrialized watersheds, and their presence is probably only partially attributable to DOE Operations. Of these other contaminants, the PCBs are of greatest public concern; fishing advisories have been issued to limit fish consumption.

To address the current contamination concerns, a two-phase CERCLA remedial investigation was initiated in 1989. Phase I, completed in 1993, was focused on obtaining data for confirmation of past contamination studies and for conducting preliminary site characterization and screening-level risk analyses (human health and ecological). The Phase II sampling program, for which the pilot DQO project was conducted, was focused on completing characterization of the nature and extent of contamination and on providing data for final risk analyses. Although the Phase II work plan had been approved by DOE and EPA before the DQO scoping meetings began, DOE technical and management staff felt that there was sufficient opportunity for scope reductions through application of the DQO process. Thus, they coordinated with the regulators to revisit the planning stage for the Phase II work.

DQO scoping meetings for the Phase II Remedial Investigation were held from fall 1993 through winter 1994 and culminated in the issuance of a revised Phase II Sampling and Analysis plan that substantially reduced the number of samples required for decision making. Most of the sampling program reductions were achieved by improving regulator, DOE, and contractor understanding of the nature of the problems in the Clinch River, the feasible options for addressing these problems, and the general level of error tolerance allowable in these decisions.

Some of the major agreements reached, along with their associated impacts to the sampling and analysis plan, are listed in Table I. An additional benefit of the DQO process for the Clinch River Phase II Remedial Investigation was that it provided a route for communicating with the regulators about accelerating the schedule for remedial decisions. The original scheduled date for a Record of Decision was 1999. During the DQO Process, it was decided that separate remedial decisions could be made for Lower and Upper Watts Bar Reservoir, with the decision for the Lower Reservoir to be made in 1995 (a four-year acceleration), and for the Upper Reservoir in 1998 (a one-year acceleration). These schedule accelerations result in both cost savings and public relations improvements. One valuable Lesson Learned for the Clinch River DQO Process is that decision makers are uncomfortable with establishing quantitative limits on uncertainty (i.e., Step 6 of the DQO Process). For the Clinch

River, these limits were established only in a qualitative manner. Although this prevented realization of the full power of the DQO process, the use of qualitative limits provided sufficient comfort to the decision makers and still resulted in substantial improvements.
Fig. 1.
TABLE I
In summary, the DQO process for the Clinch River allowed DOE and the regulators:
to better understand the specific risk issues associated with Clinch River contamination,
to focus on attainable remedial options, and
to qualitatively evaluate how much data actually is needed to build a conceptual model for making comfortable decisions about these feasible options. The end result was substantial savings in cost and time. Table I lists documented cost savings in sample collection logistics; these, however, are only a portion of the cost savings realized. Schedule reductions and associated program size reductions will also lead to large reductions in program management costs.
Oak Ridge National Laboratory Surface Impoundments
During 1994, in cooperation with DOE Headquarters, the ER Program began performing a pilot project using SAFER to address remediation of two contaminated unlined surface impoundments at ORNL. The implementation of the SAFER process which combines the observational approach and the DQO process, resulted in a focused remedial investigation and feasibility study (RI/FS) work plan that explicitly linked data collection needs to stakeholder-defined remediation decisions. As a result, substantial data collection savings were realized by gathering the minimum data sufficient to evaluate possible remedial actions and to implement the selected action. The ORNL surface impoundments (Fig. 2) were constructed in 1945, and served through the mid 1960s as settling or equalization basins for low-level radioactive and process waste water as part of ORNL waste treatment systems. The impoundments were identified for rapid remedial action under CERCLA because their sediments were releasing contaminants to the groundwater and to adjacent surface water. Administrative controls protect current ORNL workers from exposure to contaminants; however, there is a potential risk for future site occupants. And, should an impoundment berm fail, large quantities of contaminant would be released to an adjacent surface stream (White Oak Creek), hence to the off-site environment.
At the onset of the SAFER process, much data collected as a result of various sampling efforts throughout the years existed for the impoundments. These data were gathered and assessed to develop a conceptual model that focused on hydrologic fluxes and contaminant movement. This model was presented and discussed in project scoping meetings with stakeholders that included DOE, EPA Region IV, and the State of Tennessee. During these meetings, the model was used to obtain stakeholder agreement on both the contamination problem and future exposure scenarios. Project scoping meetings resulted in several stakeholder agreements that provided for a well-defined project focus and a streamlined plan for remediation. Two key agreements were:
Remediation should be focused on risk reduction for an industrial land use. Because the site is currently industrial and is likely to be an industrial site for the foreseeable future, it was agreed that any acceptable remedial action must be sufficiently protective for industrial use. If, however, a partial cleanup protected an industrial use of a site, additional cleanup activities may be required if the site use changed in the future.
Feasible remedial decisions should be evaluated for implementation. Several possible remedial solutions were identified that would address potential health and environmental concerns in an industrial use scenario. These alternatives included simply filling and capping the impoundments, hydrologic isolation or immobilization of contaminants, consolidation of sediment into containment structures, and sediment removal for off-site disposal.
With these agreements, the project team was able to develop a series of questions that needed to be addressed to:
confirm the applicability of the conceptual model to selecting feasible remedies,
evaluate possible remedial actions, and
implement the selected action.
The questions were laid out to focus on the most likely alternatives. Specific data requirements to address the questions (i.e., to address risk assessment, ARARs,

effectiveness, cost, etc.) were identified, along with the uncertainty acceptable in those answers. Representatives of contractors responsible for the data collection, alternatives selection, remedial design, and remedial construction participated with the stakeholders in this process to be sure that data collected during field investigations would support their specific tasks.

This planning approach resulted in a relatively simple set of data requirements that considered acceptable error in characterization. Little additional data were required to support the RI/FS, and data collection was accomplished within a few weeks. This focused data collection resulted in substantial cost and time savings for sample collection and analytical work.

In summary, the SAFER process focused data collection on simply confirming an existing site conceptual model needed for evaluating and selecting among a defined set of remedial actions for future industrial land use. Without benefit of the DQO approach, extensive data might have been collected that were neither needed nor required to support remedial decision making. The linkage of data collection needs to actual decisions during this project also greatly accelerated the schedule and efficiency of producing the feasibility study because the data needed for alternative evaluation were available and much of the combined RI/FS document could be written while data were being collected and evaluated. The end result was that the project schedule was shortened from 24 months (the original baseline estimate) to 15 months for the period between the scoping workshop and delivery of an RI/FS report. This saved several hundred thousand dollars. Collecting only the data needed for decision-making also provided additional, although undocumented, cost savings. The substantial economies gained for this relatively simple project indicate that much more substantial cost savings could be gained for more complex projects.

Fig. 2.

FUTURE DIRECTIONS

Despite the progress that has been made, much remains to be done. When conscientiously applied, the DQO and SAFER processes provide substantial savings in time and dollars. Since the present culture has not, however, shifted completely to decision-based data collection planning, it is imperative that program managers (DOE, regulator, and contractor) continue to strengthen the role of the DQO/SAFER processes in routine planning.

In response to the need for improvement, DOE Oak Ridge will continue to focus on the DQO/SAFER processes as important management tools. Some of the specific areas that DOE Oak Ridge intends to focus on in coming months include:

Extending DQO/SAFER processes to remedial design and remedial construction. The pre-Record of Decision component of the cleanup process is small fraction of total cleanup costs; however, it has been given the most emphasis in the DQO process. The challenge, therefore, is to not only to streamline the process for arriving at remedial decisions, but also to more rapidly and cost-effectively design and implement remedial actions. The DQO process can be effectively employed to specify data needed for safe and effective design and construction of feasible remedial alternatives. These data can, in turn, be collected during the remedial investigation planning phase, saving time and effort. Obtaining stakeholder agreements on allowable uncertainties in remedial action performance may also prevent over-designing and, thus, provide substantial cost savings.

Using DQO/SAFER processes for decontamination and decommissioning planning. The decontamination and decommissioning process closely mirrors the CERCLA process, although the level of regulatory involvement has not been as intense. Several current decontamination and decommissioning planning efforts are being conducted using the DQO process for project scoping. Preliminary results are positive.

Improving quantitative specification of decision-error tolerance for improved sampling plans. Decision makers are uncomfortable discussing acceptable decision errors in quantitative terms. Because the quantity of data collected depends directly on the statistical uncertainty that can be accepted in the data-related decisions, it is critical that this issue be addressed. It should be made clear from the start at all DQO scoping meetings that establishment of quantitative error tolerances will be given high priority.

Increasing the use of field analytical laboratory methods and performance-based data validation/data assessment. Requested analytical methods and data validation and assessment processes are often not closely aligned with the actual data quality objectives of the project. This is due in part to an improper understanding of the

uncertainties associated with the analytical measurement process in relation to overall sampling program uncertainty and the tolerable level of decision error for the project. In some cases, a better conceptual model can be developed by using available funding to perform a larger number of field lab analyses in lieu of costly offsite lab services. Data validation can also be streamlined by concentrating efforts on those analyses where the consequences of decision error are greater and by eliminating reviews of redundant quality indicators. Data assessment should also become a routine practice to ensure that the overall dataset is suitable for use in the conceptual model.
In conclusion, the funding for DOE cleanup programs is shrinking and, unfortunately, remediation of many of our major sources of contamination has only recently been initiated. Based on previous spending patterns, it will be difficult to sustain a viable and effective remediation program if we follow the rigid and exhaustive CERCLA path of the recent pastit is simply too costly. Fortunately, the DQO and SAFER processes offer a proven method of cost and schedule reduction. The success in realizing their benefits, however, is up to us.

ABSTRACT
The Department of Energy (DOE) developed the Streamlined Approach for Environmental Restoration (SAFER) as a tool to effectively recognize and manage the uncertainties inherent in the environmental restoration process. The SAFER approach integrates the Data Quality Objective (DQO) process with the Observational Approach. DOE and the Environmental Protection Agency (EPA) agreed to jointly test SAFER on a pilot project scale. In January, 1994, DOE selected four facilities to host SAFER Pilot Projects: Hanford in Washington, Mound Plant in Ohio, Oak Ridge National Laboratory (ORNL) in Tennessee, and Savannah River Site (SRS) in South Carolina. The Hanford Pilot focuses on remedial design and remedial action at a reactor area. At the Mound Plant, two of the three SAFER projects involve removal actions. The third Mound project involves property transfer to the City of Miamisburg. The ORNL SAFER pilot project addresses the remedial investigation (RI) / feasibility study (FS) for a series of surface impoundments. SRS hosted two pilot projects, both of which were in the RI planning stage. The success of the pilot projects is being measured both quantitatively and qualitatively by an independent performance measurement team. Although the SAFER Pilot Projects are only 75 percent through the allotted time, significant accomplishments can already be credited to applying SAFER.

INTRODUCTION
The Department of Energy (DOE) developed the Streamlined Approach for Environmental Restoration (SAFER) as a tool to facilitate focused identification and management of key uncertainties inherent in the environmental restoration process (1,2). SAFER embodies the strengths of the Data Quality Objectives (DQO) process and the Observational Approach, which are integrated to form a comprehensive methodology, applicable to all stages in the life of an environmental restoration project. The primary features of the SAFER process include: 1) emphasis on up-front planning to ensure that only data required to make a decision about the site are collected; 2) management of uncertainties whenever possible by contingency plans, allowing remediation to progress; and 3) stakeholder involvement throughout the process. Planning using the SAFER approach incorporates and enhances the DQO process, which

was developed by the Environmental Protection Agency (EPA) (3,4,5,6). This process begins with the participation of stakeholders to develop a conceptual model that summarizes the existing site knowledge and to explicitly state the problems at the site that need to be resolved. Decisions that must be made in order to resolve the problems are the basis for formulating data needs. With stakeholders involved, the balance between the acceptable uncertainty in the resultant data and the cost of the data can be established early to optimize the sampling plan.

The Observational Approach, a basic geotechnical engineering technique (7,8,9), is integrated with the DQO process effectively using the conceptual model to identify probable conditions and reasonable deviations. Reasonable deviations are addressed in a contingency matrix that specifies a contingency plan. Monitoring protocols trigger implementation if the deviation is detected. If realistic contingency plans cannot be developed for a deviation, then additional data collection may be warranted to reduce or eliminate the uncertainty about that condition.

Formulation and implementation of SAFER has been a collaborative effort by four different offices within DOE: Office of Program Integration (EM-43), Office of Transportation, Emergency Management, and Analytical Services (EM-26), Office of Environmental Activities (EM-22) and Office of Environmental Guidance (EH-23). The DOE SAFER team has worked for several years to develop and refine the SAFER process. This includes providing workshops to disseminate the concepts and helping to implement the process.

In 1992, DOE approached the EPA with the idea of testing SAFER on a pilot project scale. The primary objectives of the pilot study were to: (1) measure the effectiveness of the SAFER process as implemented at several sites, and (2) identify reactions by participants, both positive and negative, to implementing SAFER broadly throughout the DOE complex. EPA supported the idea of piloting the SAFER process at sites within the DOE complex, but requested that DOE stipulate the nominated sites for the pilot study satisfy three criteria: 1) projects must be part of National Priority List (NPL) sites; 2) DOE, EPA, and cognizant State authorities must jointly nominate the candidate projects; and 3) the local DOE Project Manager must have signature authority for the primary deliverables on the project. In January 1994, the DOE Deputy Assistant Secretary for Environmental Restoration and Waste Management selected four DOE facilities to host SAFER Pilot Projects: Hanford in Washington, Mound Plant in Ohio, Oak Ridge National Laboratory (ORNL) in Tennessee, and Savannah River Site (SRS) in South Carolina. SAFER team support to the pilot projects will continue through the summer of 1995.

Of particular importance during the pilots is how the effectiveness of SAFER in these projects can be measured. An independent performance measures team is developing qualitative and quantitative measures that will be applied to the pilots. A final report will be released in the Fall of 1995 that describes the sites, how SAFER was applied, and the measures of success. This paper serves as an interim report on the progress and success of the SAFER pilot projects.

PILOT PROJECT PROGRESS

When the pilots started, the subject projects were at different stages in the remedial process: Hanford's pilot project is in Remedial Design/Remedial Action (RD/RA); at Mound, two of the pilot project sites are interim removal actions and one site is a land transfer associated with an ongoing RI; at Savannah River the 2 projects are in the Remedial Investigation (RI) planning stage; and the ORNL project is planning the Feasibility Study (FS). The following is a brief description of each site and the progress through December 1994; measures of success are discussed in the next section.

Hanford Pilot Project

The Hanford Pilot focuses on Operable Unit (OU) 100-BC-1 contained within the 100-BC Reactor Area. OU 100-BC-1 is a source overlying a groundwater OU, which flows directly into the Columbia River. The 100-BC-1 OU contains 44 waste sites, all resulting from managing 183 million liters of liquid and 40 cubic meters of solid effluents from B Reactor operations. The waste sites include cribs, trenches, retention basins, burial grounds, pipelines, river outfalls, and septic tanks. Contaminants of concern include fission products (primarily Cs-137, Co-60, Sr-90, Eu-152, and Eu-154) and chromium.

DOE, EPA, and State regulators, through a tri-party agreement, have determined that a single Interim Action Record of Decision (ROD) will be applied to the entire 100-BC Reactor Area. The Proposed Plan is scheduled to be signed in February 1995;

the ROD and Design Report are scheduled for June 1995. Following signature of the ROD, remediation of at least one waste site must begin prior to October 1, 1995, with other waste sites following thereafter. The SAFER pilot is focusing on assisting DOE/Richland Operations in meeting the goal of completing the design and beginning remediation of one waste site, following ROD signature in June.
The SAFER process is being used in the following aspects of the pilot project:

To identify a process that will be used to develop remediation levels (i.e. cleanup goals) for incorporation in the 100-BC ROD and to translate final remediation levels established in the ROD into stopping rules for the waste site remediation.

To establish priorities for waste sites within the 100-BC-1 OU. Criteria are being developed to determine the order in which different waste sites within the OU will be selected for remediation, and to identify the waste site that will be the focus of the first interim action at 100-BC-1.

To develop conceptual design criteria for the selected waste site, including identification of data needs for the remedial design and development of monitoring plans and contingency plans to manage uncertainties.

Mound Plant Pilot Project

Two of the three SAFER projects at the Mound Plant are removal actions: 1) B Building Solvent Storage Shed and 2) Area 7 soil remediation. The third project involves determining that property is not contaminated and can be transferred to the City of Miamisburg.
The B Building solvent storage shed pilot addressed a 33- by 15-meter area of soil contamination beneath a solvent storage shed. Historically, the B Building storage shed was used to store waste and product-grade solvents from B Building. Before the shed was constructed, drums of solvents were stored in an outdoor storage area adjacent to the present shed location. Prior to SAFER team involvement, the removal action called for complete site characterization, removal of the shed, and use of soil vapor extraction (SVE) to remove contaminants from the soil. The objective of the site characterization was to determine depth to bedrock in order to evaluate the feasibility of using SVE.
For the B Building Storage Shed, SAFER team assistance and recommendations were applied to the following:

A conceptual model and matrix of probable conditions, possible deviations, and contingencies were used to show the project team that there was no need for a complete site characterization prior to beginning the SVE. A simple and cost-effective contingency plan was identified that could be implemented quickly in the field if it was determined that the depth to bedrock was insufficient for the SVE system to operate effectively at certain wellheads.

The conceptual model also helped the project team to separate demolition of the shed from remediation of the soil. This separation allowed on-site staff to demolish the shed, eliminating the need for a separate contract. Thus the removal action could focus on remediation of the soil.

The second SAFER pilot site at Mound was the Area 7 Soil Removal. Area 7 was historically used to deposit construction debris, thorium drums, and other wastes. In 1959, 3 dump truck loads of soil contaminated with Ac-227 and Ra-226 were deposited in or near an abandoned septic tank in the northeast section of Area 7. The septic tank historically had received only sanitary waste from the administrative buildings at the Mound Plant between 1946 and 1952, when it was abandoned. The exact location of the septic tank is unknown. Results from previous sampling efforts have shown elevated levels of Ac-227 and Ra-226 in the soil near the suspected location of the septic tank and elevated levels of Ra-226 in the soil downslope. Prior to the commencement of the SAFER pilot, the response action was focused on removing the septic tank, including a full site characterization to find the tank.
SAFER involvement in the project had the following effects:

The conceptual model helped focus the team on the contaminated soil rather than the tank. This re-focusing made a significant difference in the nature and scope of the removal action and formed the basis of the revised work plan.

SAFER processes were used extensively to develop the basic design approach, removal goals, and preliminary decision rules.

The third SAFER project at Mound was a property transfer action. The property involved is land purchased in 1981 as a buffer area around the Mound Plant. No DOE

operations were conducted in the area. Prior to DOE ownership, the land was used primarily for agriculture. DOE wants to release the property to the City of Miamisburg for industrial development. Although no DOE operations took place in the immediate vicinity, thorium re-drumming (including handling and disposal of thorium) was done in an adjacent area. Previous sampling efforts indicated a potential for migration of thorium onto the area considered for transfer. No other potential releases of hazardous substances have been identified.

SAFER was introduced in the project in the following ways:

Developed a land transfer strategy for the New Property and identified a formal method of approval (i.e., an "intent to transfer" letter) that would ultimately lead to formal EPA approval of the transfer. The strategy used a phased approach wherein the clean areas (based on distance from operations) would be transferred first, followed by sampling of potentially contaminated areas to determine whether they could be transferred with no remedial action.

Applied decision rule logic to the analytical results from the "clean" area to document the absence of contamination, thereby supporting the transfer. The same decision rule logic was used to develop the sampling plan for the potentially contaminated area.

Oak Ridge National Laboratory (ORNL)

The ORNL SAFER pilot project began in the RI report and FS work plan stage of a CERCLA remedial action. The focus of the project is the four Waste Area Group (WAG) 1 surface impoundments. There are two lined and two unlined impoundments located adjacent to a stream in the highly industrialized main plant area of ORNL. The surface impoundments were used to store low-level mixed liquid wastes that were generated by ORNL operations from 1945 through 1976.

Since the remedial investigation had been completed, substantial historical and sampling data was available. These data included historical operational activities and analytical results from samples of groundwater, soil, and sediments in the vicinity of the impoundments. Based on these data, the impoundments are cut into or are very close to bedrock, which is fractured limestone aquifer. Groundwater beneath the impoundments is known to be contaminated and continued release of contaminants from the unlined impoundments to groundwater and surface water is a virtual certainty.

Sludges in the impoundments contain radionuclides (Sr-90, tritium, Pu-239, Pu-240, Cs-137, and possibly U-233), metals, pesticides, and polychlorinated biphenyls (PCBs). The Sr-90 and tritium are of particular concern because of their mobility in groundwater.

SAFER influenced the direction, schedule, and cost of the pilot project in the following ways:

Encouraged the Tennessee state regulators to become fully integrated members of the project team. A State regulator now attends all pilot project meetings, and provides valuable insight into the specific types of information the State wants to see in an RI/FS in order to evaluate the remedial alternatives under consideration.

The conceptual model helped focus the RI/FS document on key issues and decisions, resulting in a smaller, clearer, and more concise document. The conceptual model also was instrumental in establishing a common understanding of the goal through early development of the problem statement and remedial objectives, and continual reevaluation of the model in response to changing information.

Use of decision rules enabled the site project team to identify a limited set of data needed to analyze the feasibility of remedial alternatives, and to eliminate collection of all other data or to postpone data collection to the remedial design stage of the remediation.

Savannah River Site (SRS)

SRS is hosting two pilot projects, the F- and H-Area Retention Basins and the D-Area Oil Seepage Basin, both were started at the RI planning stage. Although both sites were used for liquid waste disposal, the similarity ends there. SAFER has been applied to both sites with success.

The F- and H-Area Retention Basins were unlined surface impoundments designed to receive contaminated cooling water discharged when leaks in the cooling system caused operational upsets. The contaminated liquid was delivered to the basins via large diameter (24- to 36-inch) process pipelines. However, only the F-Area Retention Basin had inactive pipelines that were included in the pilot project. The two retention basins were operational for more than three decades, up to the

late 1970s. Releases to the environment occurred via infiltration from the basins themselves and potentially from leaks along the pipeline. Additionally, both basins had historically overflowed into adjacent streams, contaminating the overflow areas. Based on RESRAD modeling outputs, the primary contaminants of concern are Cs-137 and Sr-90, because these are predicted to be the most mobile.
When the retention basins were taken out of service, the F-Area basin was remediated to the standards of the 1970s, but the H-Area basin was fenced and left as is. At the F-Area basin, the contaminated soils and sludge were excavated down to the original bottom of the basin and disposed of. Analyses of samples collected at the bottom of the excavation indicated that Sr-90 and Cs-137 had migrated into the soil underlying the basin. Sr-90, the more mobile of the two, was present 2 meters below the basin bottom. However, the threat to groundwater appears to be minimal because groundwater is 16-20 meters below ground surface. The excavation was filled with clean soil and revegetated.
Access to the H-Area Retention Basin and the overflow area is restricted to minimize exposure to high radionuclide concentration, estimated to be greater than 10 mrem/hr at several locations. The fenced area, which includes the basin and surrounding berm, is covered with vegetation, including numerous trees. The vegetation is part of the problem at this site, because it is too radioactive to dispose of in a solid waste landfill. At times, the basin contains standing water, reflecting the high groundwater level (i.e., 3 to 4 meters below the surface).
The SAFER process has been applied to the F- and H-Area Retention Basins project in the following ways:

Facilitated the use, and stakeholder acceptance, of the RESRAD model to estimate the migration of radioactive contaminants through soil. Through use of RESRAD, DOE was able to significantly reduce the number to contaminants of concern to the two most mobile.

SAFER consensus building and integration of the stakeholders as members of the project team facilitated the use of innovative technology, including a robotic pipecrawler and hydropunch. The pipecrawler remotely videotaped the process pipeline, and the videotape was used to identify potentially contaminated areas (i.e. cracks or joints). The hydropunch facilitated collection of soil and water samples. The regulators were willing to consider use of these innovative approaches because they were integrated into the project team, they were excited about SAFER, and SRS agreed to confirm the information derived from the pipecrawler.

Both EPA and State regulators were active participants in the early decision-making stages of this pilot. They often provided timely and valuable insights into their issues and concerns, allowing the project team to re-focus their activities and eliminate false starts.

The second SAFER pilot project hosted by SRS is the D-Area Oil Seepage Basin. Prior to acceptance of the D-Area Oil Seepage Basin as a SAFER Project, there was an interim action planned that will remove the source material (drums and sludge) and replace the disturbed soil back into the trenches. The RI will focus on the soil remaining after the interim action and the groundwater. This site was constructed in 1952 as a series of 2-meter deep unlined trenches for disposal of waste oils and other fluids not suitable for burning in powerhouse boilers, general office, and cafeteria waste. Until 1973 the waste in the trenches was periodically burned. After 1973 open burning ceased, but disposal in the trenches continued until 1975 when the trenches were backfilled with soil, burying an unknown number of drums.
The trenches are in recent fluvial sediments of the Savannah River floodplain which consist of sand, silt, and clay. Alluvial groundwater level fluctuates seasonally between 1 and 5 meters below the ground surface. Thus, during periods of high water level, groundwater is within the trenches and in periods of low water, the trenches are in the vadose zone. Groundwater flow is to the southwest towards a wetland area located about 60 meters from the basin. The alluvial aquifer is separated from the underlying aquifer unit by a clay layer.
Soil in the trenches was sampled and analyzed in 1984 and 1993. Based on comparisons between maximum observed values and Preliminary Remediation Goals (PRGs), the contaminants of concern are a dioxin congener, arsenic, and dieldrin. In groundwater, trichloroethylene and its degradation products have been detected and floating free product was bailed from a borehole.
SAFER has influenced the RI portion of remedial action at the D-Area Oil Seepage Basin in the following ways:

Regulatory stakeholders had early input into the development of the conceptual model, problem statements and decision rules that form the basis of the RI work plan.

The problem statements and decisions needed to resolve the problems focused the scope of the RI. In particular, only the top 1 meter of soil will be considered for its potential to expose a human receptor by direct contact. Soil deeper than 1 meter will only be considered for its potential to continue to impact groundwater.

For the RI work plan, a phased sampling and analysis plan was developed for saturated zone soils with the objective of assessing the potential effects on groundwater. The first phase will focus on determining retardation factors for the contaminants present in the saturated zone soils. If contaminants are not highly retarded, the objective of the second phase will be to assess whether the saturated zone soils will continue to be a source of contamination that poses an unacceptable risk to human health or the environment.

MEASURES OF SUCCESS

The success of the pilot projects will be measured in two ways -- quantitatively and qualitatively. The quantitative measurements will be savings in time and money that can be attributed to SAFER. Comparisons will be made between previous baselines, regulatory milestones, and comparable projects and the actual expenditures on the projects. These kinds of measurements cannot be made until action that SAFER was applied to is complete.

Qualitative measurements are how the participants view the SAFER process and their satisfaction with how it was applied. These measures come from interviewing the participants of each pilot project, including representatives from DOE, the DOE contractor, any subcontractors, State regulators, and EPA. A site-specific survey instrument is developed for each hosting facility, and all interviews are conducted by the same two interviewers to maintain consistency. Through December, only the interviews at the Mound Plant had been completed. Interviews at ORNL and SRS have started and these will be completed in January 1995. Hanford interviews will be conducted in the spring of 1995. Notable measures of success through December 1994 are:

Mound: B Building Solvent Storage Shed - the uncertainty analysis eliminated the planned site characterization, resulting in a 40 percent cost savings and completion of the project 6 months earlier than planned.

Mound: Area 7 Soil Removal - the uncertainty analysis eliminated the planned site characterization, saving close to $300,000 and implementing the field response earlier than planned. Mound personnel felt that the technical quality of the work plan was significantly improved with the SAFER input.

Mound: New Property Transfer - developed decision rule logic that demonstrated the sufficiency of available data to make the decision that the property was "clean" and could be transferred; no additional data were required.

ORNL: WAG 1 Surface Impoundments - (1) developed a focused work plan, (2) facilitated early field work, (3) RI field work and RI/FS report will be completed within 7 quarters, half of the time originally estimated, resulting in significant savings, and (4) State regulator attendance in project meetings has been extended formally to all restoration projects at ORNL.

SRS: F- and H-Area Retention Basins - (1) facilitated the use of innovative technologies, resulting in reduced sampling locations and avoided costs of $750,000; (2) State regulator participation increased State confidence in using RESRAD modeling to limit the contaminants of concern and avoided $450,000 in additional analytical costs; and (3) State and EPA regulators attending monthly scoping meetings on all SRS restoration projects.

SRS: D-Area Oil Seepage Basin - (1) the conceptual model effectively focused the RI on the impact on groundwater and recognized the minimal potential for deeply buried soils to directly contact human receptors, thereby limiting human health risk assessment to the top four feet of soil and (2) decision rule logic produced a bifurcated soil sampling plan that considers the risk posed by the vadose zone (top 4 feet of soil) differently than the risk posed by the saturated zone; this is expected to result in substantial cost and time savings in the remedial action phase of the project.

CONCLUSIONS

Although the SAFER Pilot Projects are only 75 percent through the allotted time, significant accomplishments can be credited to applying SAFER. At each site, there

has been nearly universal acceptance and enthusiasm for the SAFER process by DOE, contractors, and regulatory stakeholders. SAFER has changed basic ways of doing business at these sites; for example, at ORNL and SRS regulator involvement has been formalized in scoping meeting attendance much earlier in the process than in the past. Gone are the days of submitting a work plan that is completely new material to the regulators and waiting for comments. Now, before the work plan is drafted, the site team and the regulators have jointly looked at what is known about the site and made some preliminary decisions about how the site should be approached. Another example of change in practice is at Mound where removal actions will not automatically be scheduled and costed for a site characterization; instead an uncertainty analysis will be done to determine the need for further characterization.

What DOE hopes to demonstrate with the SAFER pilot projects is that the SAFER process should be the standard way of doing environmental restoration business. When it does, the SAFER acronym can disappear from use, because there will be no difference between environmental restoration and SAFER. When that comes to pass, the ultimate goal of the SAFER Pilot Projects will have been realized.

ABSTRACT

The comprehensive Remedial Investigation (RI) Feasibility Study (FS) Remedial Design (RD) and Remedial Action (RA) is not the only route through which site remediation can be achieved. A phased approach to remediation integrates early actions and final actions to achieve early cleanup of selected site problems while at the same time contributing to the most logical and efficient solution for achieving remediation at an Operable Unit (OU). By aggressively planning and implementing early cleanup opportunities offered by CERCLA removal and remedial authorities, a phased approach can expedite remediation, reduce risks, reduce costs, demonstrate progress, and respond to stakeholder and other priorities while moving the OU most quickly to final remediation. However, early actions have not been widespread because their

usefulness and advantages are not fully understood and methods for combining these actions into a phased approach have not been articulated.
Since a comprehensive RI/FS culminating in a final Record of Decision (ROD) is essentially the only process by which a site can be removed from the National Priorities List (NPL), phased approach actions must be integrated with final cleanup. This is accomplished through development of a phased approach strategy and a consensus memorandum. A phased approach strategy guides application of a phased approach. Basic elements of the phased approach strategy include identification of the site problems and specific candidates for early actions. A consensus memorandum is based on the phased approach strategy and actually initiates an early action. A consensus memorandum is a brief statement of intent that describes specific scope and approach for each early action. Both a phased approach strategy and consensus memorandum are developed jointly by the Department of Energy (DOE), Environmental Protection Agency (EPA), and State agencies at the OU level.
DOE has developed a Phased Approach/Early Action Guidance (in draft) to support use of a phased approach for remediation. DOE based the guidance on current EPA and DOE guidance and initiatives. The purpose of this paper is to provide the basis for DOE's Phased Approach, identify advantages of using a phased approach, describe the relationship of DOE's phased approach to other EPA/DOE streamlining initiatives, and describe development and implementation of a phased approach strategy
PHASED APPROACH BASIS
The use of early actions during environmental restoration is not a new concept. Statutory authority is provided in the Comprehensive Environmental Response Compensation and Liability Act (CERCLA) that gives considerable discretion is determining appropriate actions for quickly reducing risks. In addition, EPA and DOE have established policies that encourage the use of early actions. The National Oil and Hazardous Substances Pollution Contingency Plan's (NCP's) bias for action and the discussions found in EPA guidance (EPA 1993) contain extensive direction for expediting cleanups and maximizing reduction in risks to human health and the environment. The DOE's RI/FS guidance (DOE 1994) also describes how early actions can be taken during and RI/FS.
CERCLA Authority
Authorization for early actions comes from two sections of CERCLA: removal authority from Section 104 and remedial authority from Section 106. The distinction between these two authorities is not greatly significant in the DOE Environmental Restoration (ER) program since DOE is the lead agency the same DOE funds are used regardless of which authority is selected and the same EPA and State regulatory staff are generally involved in the oversight function. However, a necessary step under CERCLA is to declare which authority is being used. Many site problems can be addressed by either authority, although some Federal Facilities Agreements (FFAs) may restrict this flexibility. Procedural and documentation differences exist depending on which authority is used. Where flexibility among authorities exists, site managers need to consider the advantages of each authority in making decisions.
NCP Support
The regulations promulgated by EPA in the NCP state that sites should be remediated using early actions as necessary or appropriate to achieve significant risk reduction quickly, streamline analysis commensurate with the scope and complexity of the problem being addressed, or expedite the completion of total site cleanup. Using this bias for action and streamlining principles help effectively manage site problems and expedite the reduction of risk posed by the site. EPA links the phasing of actions as part of the ongoing strategic planning at a given site with the ultimate goal of implementing final remedies. Phasing actions support the strategic planning process by helping determine the types of actions and analyses necessary or appropriate and the optimal timing of those actions.
EPA Guidance
A cornerstone of the EPA's streamlining philosophy is an approach described in Guidance for Evaluating Technical Impracticability of Ground Water Remediation (OSWER Directive 9234.2-24) and Considerations in Ground-Water Remediation at Superfund Sites and RCRA Facilities (OSWER Directive 9283.1-06). These documents encourage "early actions to control plume migration and remove contaminant sources, reducing risks and providing information useful in identifying the restoration potential of the site." EPA also notes that "phasing of activities does not lengthen or deter the remediation process; rather if approached properly, phasing of

activities should expedite the process by reducing risk and by bringing final cleanup levels closer to completion of the RI/FS." DOE Guidance
The DOE's RI/FS Guidance (1993) extended the "bias for action" encouraged in the NCP to RI/FS activities. Specifically, the guidance addresses the using limited field investigations (LFIs) to support early actions. The Phased Approach/Early Action (draft) guidance now extends the use early actions from the discussion in the DOE RI/FS Guidance.
PHASED APPROACH ADVANTAGES
Several advantages of using a phases approach have already been mentioned such as expediting the process, reducing risks promptly, and moving final cleanup levels closer to completion of the RI/FS (i.e., demonstrate progress). Other advantages include reducing costs and responding to stakeholder and other priorities. This section further describes how these benefits are realized by using the phased approach and may be used a basis for measuring success of the approach.
Expedite Action
A phased approach can result in actions that overall are quicker and more efficient (thereby expediting the process in two ways). Implementing actions quickly reduces the time to affect risk reduction and lower overall restoration costs. More efficient use of resources (e.g., less data collection, less alternatives development, and better tailoring of the action to the site problems) also allows the final RI/FS to be focused on the more complex problems that remain after the early actions are completed.
A phased approach also emphasizes opportunities for parallel or concurrent conduct of several activities that are historically carried out sequentially (e.g., investigation, decision, design). A particular emphasis of the phased approach is to complete preliminary remedial design documents during planning. By using data and documents to serve multiple purposes, a phased approach can reduce the overall time needed to move through an investigation and begin actual remediation.
Reduce Risks
Early actions can limit exposure and halt migration of contamination quicker than comprehensive RI/FS/RD/RA approaches. This directly supports the main intent of CERCLA and the NCP. Early protectiveness is usually the strongest justification for developing or implementing a phased approach strategy. A phased approach should always identify opportunities for early risk reduction.
An additional advantage of a phased approach exists where final technologies for a site problem are not yet available but where wastes pose a current (or near-term future) risk to the environment, workers, or other receptors. DOE faces many such situations (e.g., Weldon Spring Quarry). Where such situations exist (e.g., surficial radiation hot spots), a final ROD would likely require delay of a solution until the technology was developed or constructed or until a final waste management decision was made. The phased approach facilitates interim risk reduction through such activities as removal and storage. Although a phased approach may result in implementability issues such as the need for interim storage capacity, and may result in additional Operations and Maintenance (O&M) costs to maintain compliance, careful definition of the problems to be addressed with an early action (e.g., a priori agreements about the definitions of contaminant concentrations that constitute hot spots or unacceptable risks and the amount of wastes that will be excavated) can offset these problems and improve the overall effectiveness of the entire environmental restoration program for the OU.
Reduce Costs
A phased approach leads to cost reduction similar to the ways in which it contributes to expediting an action. Three primary methods exist. First, a phased approach leads to better focused studies of reduced scope (i.e., not final) that generally require fewer data to support decisions. Second, by selecting the most appropriate authority, actions are commensurate with the complexity of the problem. That is, a comprehensive RI/FS is not needed to select a remedy for a problem with a relatively obvious solution. Third, by allowing for the concurrent preparation of remedial design documents, the overall amount of time for preparing documents and conducting actions can be reduced. This results in lower overall program costs.
Demonstrate Progress
Phased approaches show earlier progress (e.g., implementing actions) to the stakeholders than the comprehensive CERCLA approach because they result in the early cleanup of actual problems. Demonstrating early progress alone may be enough reason

to implement a phased approach. If progress can be coupled with the other advantages (e.g., early risk reduction), a clear benefit of a phased approach is the ability to accomplish needed cleanup earlier than planned.

Another advantage of a phased approach is building momentum leading to an improved overall process for conducting environmental restoration. Even small accomplishments achieved under a phased approach can build momentum for additional progress, in many instances leading to a new or even more logical approach to addressing whole OU or facility-wide environmental remediation challenges.

A phased approach also can show progress by providing an avenue for testing new techniques, management approaches, or even technologies. CERCLA already encourages the use of treatability studies for trying new technologies. In some instances, a treatability study can be incorporated as part of a phased approach. If a technology proves useful and effective, the phased approach also provides a forum for continuing the technology (as an early action) before a final remediation decision is made.

Respond to stakeholder and Other Priorities

Integrating stakeholder concerns and incorporating new information learned during a phased approach may lead to changes in the priorities for addressing site problems. A phased approach process provides a forum for responding to stakeholder concerns. For example, on the basis of stakeholder concerns, several DOE sites have made significant changes in the priority given under original plans to remediate certain site problems most amenable to early transfer for public or other non-DOE uses. A phased approach provides the flexibility to address these changing priorities quickly and efficiently.

RELATIONSHIP TO EPA/DOE STREAMLINING INITIATIVES

Several streamlining initiatives have been developed that demonstrate EPA and DOE's commitment to achieve cleanup with the most practical, efficient, and quickest means possible. These initiatives provide structured approaches to achieve early risk reduction and streamline the process. Two of these initiatives, Superfund Accelerated Cleanup Model (SACM) and Resource Conservation and Recovery Act (RCRA) Stabilization Initiative were developed by EPA. A third, the Streamlined Approach for Environmental Restoration was developed and is being used by DOE.

SACM

EPA has initiated a CERCLA streamlining initiative, the Superfund Accelerated Cleanup Model (SACM) program, which utilizes removal authorities at remedial sites to achieve earlier risk reduction and to increase the efficiency of actions. Principles of the SACM program are as follows:

- Provide an ongoing process for evaluating site-specific conditions and need for action.
- Allow for cross-program coordination of response planning.
- Facilitate prompt risk reduction through early action.
- Ensure appropriate cleanup of long-tern environmental problems.
- Ensure early public notification and participation.
- Define conditions where removal actions are appropriate.

SACM principles are met through the phased approach developed by DOE. For example, DOE's phased approach emphasizes prompt risk reduction through early action, public notification and participation, and defining conditions where removal actions are appropriate.

RCRA Stabilization Initiative

EPA has developed a stabilization initiative that is similar to SACM but relies on different statutory and regulatory preferences for action. Stabilization initiatives generally rely on well-understood technologies to limit the migration of contaminants, to reduce immediate threats, and to contribute to understanding the range of existing problems. DOE is preparing a separate guidance on developing a phased approach for RCRA actions, however, principles discussed in this paper are generally applicable for phasing RCRA actions as well.

SAFER

DOE has developed the Streamlined Approach for Environmental Restoration (SAFER) as its own streamlining initiative. SAFER specifically addresses management of uncertainties during remediation at DOE sites. SAFER uses the concepts of probable conditions, deviations, decision, and contingency plans to achieve enhanced planning, focused investigations, and aggressive alternative assessment and remedy selections. SAFER streamlines the CERCLA process by providing a framework to

optimize the management of uncertainty through the use of a conceptual model, identification of site problems, incorporating new information as it is learned, and integrating the extended project team in decisions about characterization and remediation. SAFER's tenets are fully integrated into DOE's phased approach.

PHASED APPROACH STRATEGY DEVELOPMENT AND IMPLEMENTATION

Once the commitment to using early actions and developing streamlining opportunities is made, a plan for identifying and implementing those opportunities must be developed. Ideally, this would be a prospective process that begins once a site is listed on the NPL and continues through the RI/FS, the remedy selection process, remedial design, remedial action, to deletion from the NPL. Even if opportunities have been missed, advantages can still be realized by integrating phased approach principles into what has already been accomplished.

A strategy is necessary to ensure a coordinated approach is taken by DOE, EPA, and the State. This common vision of what and how problems will be addressed ensure proper phased analysis and response is taken that doesn't preclude implementation of the expected final remedy. Specifically, a phased approach strategy (see strategy outline in Table I) should contain the following elements:

A statement identifying site problems included in the OU and briefly summarizing what is known about each (i.e. site problems).

A description of which site problems will be addressed using early actions and which will be addressed through an RI/FS and final record of decision (ROD) (i.e. candidates for early action).

A list of the type of early action (e.g. time-critical removal, early remedial action) that will be used to address each site problem amenable to early action and authority (i.e. removal or remedial).

The primary objectives that each early action will achieve (i.e. strategic objectives).

Brief text explaining the rationale for each assignment (i.e. consensus of the phased approach strategy).

A preliminary schedule, through the final remedial action(s) (i.e. implementing an action).

Each of these elements is discussed in this section.

Table I

Site Problems

Understanding of site problems will vary depending on how much information is currently available. Regardless of current understanding, definition of site problems is necessary to develop a phased approach around an agreed upon list of problems being addressed within the OU. Description of the problems must be technically based commensurate with available information. Then as increased understanding of the OU is achieved, new information can be technically linked to refine problem definitions.

In general, site problems are discrete aspects of an OU that may require remediation. Problems should be definable in terms of an environmental medium, geographic features, the types of waste present or suspected, or the types of waste units that exist. Identification of problems should begin by analyzing existing site data, including results of any removal actions, preliminary assessment and site investigations, and the NPL listing process. Consistent with the phased approach principles advocated by EPA and DOE, additional data collection and analysis should be focused and limited to narrow site problems, accelerate response actions, and identify additional information needed to scope complex problems.

The most logical place to begin identifying phasing opportunities is with the conceptual site model (see Fig. 1). This model is developed as soon as initial site understanding is achieved and revised as further understanding is gained. The conceptual site model is the primary tool for presenting the known or suspected source-pathway-receptor connections. Since site problems are most often developed in terms of sources and pathways and these are the most appropriate for taking early actions (e.g., by removing or containing a source or by eliminating a pathway).

Fig. 1.

Candidates for Early Action

Working from the agreed upon list of problems for an OU, several factors must be applied to help determine whether or not early actions can be successfully implemented. These factors include the early actions appropriateness, feasibility, and potential for achieving benefits. Laying out potential early actions identified

in the conceptual site model and balancing them against all these factors will help prioritize where to begin taking early action.
Basic criteria for determining when early actions are appropriate include complexity, urgency, and potential responses. Site problems that are less complex and straightforward do not justify development of a full range of alternatives. These obvious solutions may create opportunities to take actions quickly affording significant risk reduction. When the need to protect human health and the environment outweighs the need to examine all alternatives, prompt action can usually be justified. Finally, when the choice of alternatives is limited by requirements, program precedence, guidance, or practicality, the remedies can be implemented without studying the few remaining alternatives in detail.
Sufficient site understanding is required to understand how site conditions and configurations influence selection of early actions. Certain situations exist when the ability to perform early actions is impossible. For example, an early action to remove drums may be infeasible because adequate storage, treatment, or disposal capacity is not readily available. This emphasizes the need for thorough planning to ensure time and resources are not wasted pursuing infeasible early actions.
Ultimately, the ability to demonstrate the success of early actions by achieving ER benefits will provide the strongest most quantifiable rationale for taking early action (e.g., expediting actions, reducing risks, achieving remediation progress quicker, reducing costs, and responding to stakeholder priorities). By balancing all these benefits among potential early actions, a means for prioritizing where to begin taking early action can be developed based on greatest chances for success.
Type of Action/Authority
As discussed in the phased approach basis section, a necessary step under CERCLA is to declare which authority is being used to justify an early action. The actions that can be taken under CERCLA removal (104) authority include emergency, time-critical, and non-time-critical removal actions. The actions that can be taken under CERCLA remedial (106) authority include early, interim, and final remedial actions. Other variations exist among EPA regions and Federal Facility Agreements (FFA) (e.g., expedited response action, removal) in how these actions are termed or can be used. However, differences should not prohibit a broad use of the phased approach.
These various authorities can be placed into two groups with the exception of final remedial actions which must be addressed through the complete RI/FS process. The first group, emergency and time-critical removal actions, generally focus on the critical interventions need to address imminent threats. Actions within this group can be taken with minimal time for investigation, public involvement, evaluation of alternatives, and design. The second group, non-time critical removal actions and early/interim remedial actions, require near term action due to risks that warrant response prior to a detailed investigation. These actions should be most amenable to remediation, unhampered by lack of site information, least encumbered by requirements, and avoid controversial remediation decisions. This group requires a more complex sequence of planning and decision activities and can allow for more investigation, planning, documentation, and stakeholder involvement.
From a practical standpoint, the applicable authority will not significantly affect the opportunities to streamline, reduce risk, save time, and save money. The differences are related to administrative requirement (e.g., documentation required) and/or procedural (e.g., requirement to comply with applicable or relevant and appropriate requirements (ARARs)). Decision on what authority to use should be based on the advantages of each authority. Again, this relies on sound strategic planning to understand the influences of these decision on all site problems, candidates for early actions, and overall benefits that can be achieved.
Strategic Objectives
Early actions are appropriate where the need for action is obvious and the nature of the required action is relatively clear. Because of this, objectives for early actions can be established more clearly that is generally possible at the beginning of a comprehensive RI/FS. These objectives should specify contaminants and media of concern, potential exposure pathways and receptors, remediation goals, and contribution to the overall remedy.
Early actions are not required to achieve final remediation levels, achieve all ARARs, or even provide final protectiveness of human health and the environment. Therefore, early action strategic objections should detail site problems to be

addressed and the actions to be taken as well as the problems that will not be addressed. This will provide focus for planning early actions and evaluating the remaining actions required for final remediation.

Consensus on the Phased Approach Strategy

Due to differing interests in remediating a site among the various stakeholders, agreement on the tentative actions and objectives much be reached. Any unresolved issues can weaken the strategy and eventually result in delays or abandonment of early action efforts. This consensus should be worked out in three phases:

- Confirming that an action is required, deciding on the specific scope, and committing to begin early stages of the remedy design process.
- Agreeing on how to ensure early actions are consistent with future, full-scale remedial actions.
- Reaching common understanding and resolution of regulatory and other issues that could hinder or prevent early action.

By design early actions focus on specific activities that can be taken immediately to mitigate obvious and dangerous threats. In order for coordinated work to begin among all involved parties, they must commit to begin acting on a specific scope of work. In the DOE Phased Approach Guidance, this consensus is documented in a consensus memorandum (see outline in Table II) . After this consensus is reached, agreement on design and implementation issues must be worked out as follows:

- Appropriateness of a phased approach for the OU.
- Identification of some site problems that are candidates for early actions.
- Identification of site problems deferred to a comprehensive RI/FS/RD/RA.
- Identification of the steps and schedule for implementing a phased approach.

Table II

An early action must contribute to the overall objectives of the comprehensive RI/FS. The NCP also requires early actions to be consistent with the final remedial action. Therefore, consensus should also be obtained on:

- Whether the early action will interfere with any future, full-scale remedial actions.
- Where potential interferences might occur, the risks, and how they can be avoided or mitigated.
- The follow-up actions needed as part of the comprehensive RI/FS to prepare a final ROD.

Understanding and agreement between all involved parties must be reached on issues fundamental to implementing an early action. Resolution of these issues will drive what needs to be accomplished, operating conditions, and approaches. Consensus must be reached on at least the following issues:

- Interim cleanup levels.
- ARARs and waivers.
- Risk assessment methodology.
- Use of innovative technologies.
- Treatment/storage/disposal of remediation-derived wastes
- Land use
- Use of institutional controls

SUMMARY

Use of early and final actions in an integrated, phased approach offers several advantages to DOE facilities implementing environmental restoration activities under CERCLA. These advantages include expediting progress, reducing costs, reducing risks, demonstrating progress, and responding to stakeholder priorities. Development of a phased approach strategy with regulators is critical to effective implementation of a phased approach. DOE is finalizing guidance on developing a phased approach strategy and early actions that will be available in mid-1995. Similar approaches are appropriate for RCRA corrective actions.

ABSTRACT

The U.S. Department of Energy (DOE) is involved in the remediation of environmental contamination at many of its facilities under the Resource Conservation and Recovery Act (RCRA). RCRA's corrective action provisions were established by the Hazardous and Solid Waste Amendments of 1984 (HSWA). These provisions provided a broad mandate for the U.S. Environmental Protection Agency (EPA) and the States to require corrective action at hazardous waste treatment, storage, and disposal facilities (TSDFs). The goal of RCRA corrective action is the cleanup of releases of hazardous waste or hazardous constituents from solid waste management units (SWMUs) at TSDFs. In response to the HSWA mandate, EPA established a program for the conduct of RCRA corrective action that was similar to that established under the Comprehensive Environmental Response Compensation and Liability Act (CERCLA). In addition, EPA developed and implemented its "stabilization" initiative as a means of quickly addressing immediate risks posed by releases until long-term solutions can be applied. Progress toward environmental restoration under the RCRA corrective action program has improved since EPA implemented its stabilization initiative, but remains slow.

To improve the efficiency of environmental restoration at its facilities, DOE is developing guidance and training programs on accelerated environmental restoration under RCRA. A RCRA guidance document, entitled "Accelerating RCRA Corrective Action at DOE Facilities," is currently being developed by DOE's Office of Environmental Policy and Assistance. The new guidance document will outline a decision-making process for determining if acceleration is appropriate for individual facilities, for identifying, evaluating, and selecting options for program acceleration, and for implementing selected acceleration options. The document will also discuss management and planning strategies that provide a firm foundation for accelerating RCRA corrective action. These strategies include a number of very basic principles that have proven effective at DOE and other federal facilities, as well as some new approaches.

The purpose of this paper is to introduce DOE's new guidance document, discuss the general approach presented in the guidance for accelerating RCRA corrective action, and to emphasize some of the more important principles of effective management and planning.

INTRODUCTION

The U.S. Department of Energy (DOE or Department) is currently involved in the remediation of environmental contamination at many of its facilities under the Resource Conservation and Recovery Act (RCRA). RCRA's corrective action provisions were established by the Hazardous and Solid Waste Amendments of 1984, commonly referred to as HSWA. HSWA provided a broad mandate for the U.S. Environmental Protection Agency (EPA) and the States to require corrective action at hazardous waste treatment, storage, and disposal facilities (TSDFs). The goal of RCRA corrective action is the cleanup of releases of hazardous waste or hazardous constituents from solid waste management units (SWMUs) at TSDFs. The term SWMU includes both units used to manage hazardous waste and units used to manage nonhazardous waste.

In response to the HSWA mandate, EPA established a program for the conduct of RCRA corrective action that was similar to that established under the Comprehensive Environmental Response Compensation and Liability Act (CERCLA). The RCRA program was initially implemented through a series of guidance documents. Then, on July 27, 1990, EPA issued a proposed rule that outlined the RCRA corrective action program (55 FR 30798). Although a portion of the proposed rule has been finalized

[Corrective Action Management Units (CAMUs) and Temporary Units (TUs) - 58 FR 8658, February 16, 1993], the bulk of the rule remains proposed and EPA continues to use the proposed rule as guidance. In addition, in 1991, EPA implemented its "stabilization" initiative, as a means of taking interim measures at RCRA sites to address immediate risks posed by releases until long-term solutions can be applied (U.S. EPA. Managing the Corrective Action Program for Environmental Results: The RCRA Facility Stabilization Effort. October 25, 1991).

Overall, EPA estimates that about 100,000 SWMUs at 5,800 facilities are potentially subject to RCRA corrective action requirements, and that 15,000 SWMUs at 2,600 of the 5,800 facilities may actually require remediation (Draft Regulatory Impact Analysis. March, 1993). Current sources conflict regarding the number of SWMUs that have actually been remediated to date, partly because much of the progress that has been accomplished is due to stabilization activities. It is clear, however, that progress toward environmental restoration under RCRA corrective action is slow.

To improve the efficiency of environmental restoration at its facilities, DOE has placed environmental restoration initiatives on a "fast-track." DOE continues to emphasize taking remedial action based on sound scientific and engineering data, but is placing a new focus on accelerated, cost-effective remediation, in partnership between the Department and stakeholders. In achievement of its mandate to provide relevant and effective environmental guidance to Departmental program and field elements, the DOE Office of Environmental Policy and Assistance (EH-23), is developing guidance and training programs on accelerated environmental restoration under RCRA and CERCLA. A RCRA guidance document, entitled "Accelerating RCRA Corrective Action at DOE Facilities," is under development.

One key element of DOE's approach to accelerating RCRA corrective action that is being incorporated into the new guidance document is effective management and planning. Effective management and planning is a prerequisite for compliance with any complex regulatory program, but is especially important for environmental restoration. The new guidance document will identify management and planning strategies that will help to provide a firm foundation for accelerating RCRA corrective action. These strategies include a number of very basic principles that have proven effective at DOE and other facilities, as well as some new approaches. The purpose of this paper is to introduce DOE's new guidance document, discuss the general approach presented in the guidance for accelerating RCRA corrective action, and to emphasize some of the more important principles of effective management and planning.

WHAT IS ACCELERATED RCRA CORRECTIVE ACTION

In order to define what accelerated RCRA corrective action is, it is first necessary to examine the conventional RCRA corrective action process. The conventional RCRA corrective action process is depicted in Fig. 1 (adapted from EPA's May 31, 1994 RCRA Corrective Action Plan - Directive No. 9902.3-2A). The process consists of four basic phases; the RCRA Facility Assessment (RFA), the RCRA Facility Investigation (RFI), the Corrective Measures Study (CMS), and Corrective Measures Implementation (CMI). During the RFA, SWMUs are identified and the potential for release determined. RFAs at most TSDFs were completed during the late 1980's and early 1990's. RFA's are typically conducted by the regulator; the subsequent phases are conducted by the facility with regulator oversight. If SWMUs are determined to have the potential for a release, the requirement to conduct an RFI is incorporated into the facility's RCRA permit or into an enforceable order, and the facility conducts the RFI. A CMS is then conducted to evaluate remedial technologies for those releases determined to be significant. The requirement to conduct remediation is then incorporated into the facility's RCRA permit (or enforceable order) and implemented during the CMI. Corrective action ends at a facility when remediation has been completed at all SWMUs, and is also implemented through the RCRA permit or order. Finally, interim measures, which include primarily short-term actions intended to stabilize releases, may be implemented at any time during the process, but are most likely to be implemented prior to or during the RFI phase.

For a typical small or medium sized facility, it may take up to five years or more to reach the CMI phase. For larger facilities, including many DOE facilities, the time required to reach the CMI phase can be in excess of ten years or more. While much of this time is spent meeting requirements as spelled out in the statute and regulations, and coordinating activities with other laws, primarily CERCLA, there exists a number of opportunities for accelerating the process. The main objective of

the new DOE guidance being developed is to outline a decision-making process for determining if acceleration is appropriate for individual facilities, for identifying, evaluating, and selecting options for program acceleration, and for implementing selected acceleration options.

Acceleration for DOE facilities is being examined with two major objectives. DOE's first objective is to reduce risks and prevent further release migration in a faster time frame, pending long-term solutions. This objective is comparable to EPA's stabilization initiative. The second objective is to complete remediation at all SWMUs on a facility-wide basis, also in a faster time frame. Once remediation is completed at the facility, the regulator would proceed with a permit or order modification, resulting in a release from RCRA corrective action requirements.

APPROACH TO ACCELERATING RCRA CORRECTIVE ACTION

An overview of the process being developed by DOE to achieve acceleration is depicted in Fig. 2. Most facilities are in the RFI or CMS phase and many have implemented interim measures at individual SWMUs. Therefore, the new guidance document will present a decision-making process that considers where the facility is in the corrective action process at the time accelerated alternatives are being considered.

Fig. 1.

Fig. 2.

The decision-making process under development within the new guidance will consist of four basic steps. In the first step, the facility will determine if acceleration is feasible at the facility at that particular point in time. Factors to be considered here include the status of permits, orders or agreements, relationship with the regulator and stakeholders, and funding and resources. For example, if a permit requiring corrective action was recently issued, it may be advisable to refrain from suggesting changes in requirements so soon.

If acceleration is determined to be an option, the facility will examine its operations and makes changes as necessary to facilitate identification, evaluation, selection, and implementation of acceleration alternatives. The facility also examines facility-wide considerations, such as waste management capacity and need for new units. This is the second step of the process. It is at this point where the principles of effective management and planning, which are the focus of this paper, are examined. More information on these principles is provided below.

During the third step, specific options for acceleration are examined and selected for individual SWMUs or SWMU groupings. These options will be referred to within the new guidance as "tools" for accelerating RCRA corrective action. Tools that may be applicable are dependent on the phase of RCRA corrective action that the SWMU or SWMU grouping is currently in. Referring back to Fig. 1, for example, many SWMUs at DOE facilities are currently in the RFI stage. Tools that may be considered during the RFI stage to help accelerate the process include streamlining data collection activities, conducting a preliminary or focused CMS, and conducting voluntary corrective action, among others. The new guidance will provide facilities with a systematic process for identifying, evaluating, and selecting options for program acceleration at SWMUs or SWMU groupings.

During the fourth step of the process, selected acceleration alternatives are implemented, monitored, and completed. The new guidance also discusses interaction with other laws and includes many examples illustrating application of the principles, as well as the tools. The guidance is currently under development and assuming that resources remain available, is expected to be released by the end of the calendar year.

PRINCIPLES OF EFFECTIVE MANAGEMENT AND PLANNING FOR RCRA CORRECTIVE ACTION

Effective management and planning is a prerequisite for compliance with any complex regulatory program. While there are certain principles of effective management and planning that are recommended components of an adequate environmental restoration program, these principles become essential if the facility is to be successful in accelerating RCRA corrective action. These include a number of very basic principles that have proven effective at DOE and other federal facilities. These principles will be discussed within the new DOE guidance, and as indicated above, are examined as part of the second step of the acceleration process. The most important of these principles are summarized below, with specific reference to how they can be used to promote acceleration.

Prevent Releases/Minimize Waste - If future releases can be prevented, facilities

can devote resources to addressing past releases. The most important principle of accelerating RCRA corrective action is to prevent future releases. The prevention principle pretty much goes without saying with respect to new releases. What is not so obvious is preventing further releases at existing SWMUs. Release prevention will be especially important as facilities proceed under RCRA corrective action, from investigation to remediation. Active remediation provides many opportunities for additional releases. Examples include overflow of drums used to collect contaminated groundwater, leaking pipes from ground-water extraction and treatment systems, and transfer of contaminated soil from one area to another from improperly cleaned remediation equipment. Facilities should develop proactive programs to: 1) Prevent future releases; 2) Detect releases quickly if they do occur; 3) Take corrective action quickly to stop the release and prevent (further) release migration and conduct cleanup; and 4) Continually monitor the effectiveness of ongoing prevention programs and modify these programs when they are not working.

An important facet of release prevention is waste minimization. Simply put, the less waste created, the fewer opportunities for releases and environmental contamination. During RCRA corrective action activities, waste minimization can be practiced by: 1) Carefully delineating areas requiring active remediation; 2) Segregating hazardous waste from non-hazardous (solid) waste; 3) Treating or otherwise managing contaminated media in-situ, where possible; and 4) Judiciously using water or detergents to rinse equipment, such as drilling rigs.

Determine Regulator and Facility Priorities - Because most RCRA corrective action activities must be approved or imposed at TSDFs through the RCRA permit or an enforceable order, the priorities of the regulator can strongly influence the feasibility of accelerating corrective action at a particular facility. Therefore, DOE should assess regulatory agency and facility priority as they examine their prospects for acceleration. By targeting scarce resources to address the most pressing problems, overall risk reduction at facilities can be achieved in a faster time frame.

Regulatory agency resources are not available to take immediate corrective action at all of the facilities that warrant corrective action. In recognition of this fact, in 1992 EPA established the National Corrective Action Prioritization System (NCAPS). NCAPS is a computer program that EPA uses to rank facilities for corrective action purposes. Using NCAPS, EPA evaluates SWMUs at a facility for actual and potential releases. A facility ranking of high, medium, or low is then assigned by EPA based on an estimation of the environmental benefit that would be realized from accelerated cleanup. NCAPS is intended to be a life-cycle prioritization system, where facilities are continually re-assessed to determine priority. As of the end of calendar year 1993, EPA had determined the priority for corrective action for most major RCRA facilities. Nearly 40 percent of all facilities were ranked by EPA as high priority; approximately 30 percent were ranked as medium priority, and 30 percent were ranked as low priority.

The new guidance document will encourage DOE facilities to learn their NCAPS ranking and EPA's justification for the ranking, including the contribution of individual SWMUs to the ranking. In most cases, the NCAPS ranking of a facility can be learned by contacting the regulator. This information is important for determining if acceleration of corrective action is feasible on a facility-wide basis, and for prioritizing individual units for action.

Generally, facilities with high NCAPS rankings will be the first to receive attention from the regulator. In this case, it is likely that the regulator will have initiated development of permit conditions or an enforceable order, and in some cases, permit conditions or an enforceable order may already be in-place. There may be less of an incentive for the regulator to consider other alternatives in this situation because of limited resources. Nevertheless, viable acceleration alternatives can be proposed to the regulator, especially if the alternative would be expected to achieve risk reduction in a shorter time frame. High-ranked facilities are therefore encouraged to identify the options available for accelerating RCRA corrective action, and to work with regulators and stakeholders to implement feasible options, even if permit conditions or orders are under development or already in place. More important, if a permit or order has not been established, facilities can suggest accelerated alternatives during the negotiation period. In addition, facilities can work with the regulator to structure the permit or order to maintain flexibility, such that better ideas do not require a formal

permit or order modification prior to implementation.
Facilities ranked as medium or low priority are not as likely to receive immediate regulator attention. If medium or low priority facilities are already subject to permit conditions or orders, these facilities are likely to experience a reduction in regulatory oversight. At the least, the schedule for completion of milestones, such as RFI work plans, may be drawn-out over a longer period of time. At these facilities, and especially at facilities that do not have permit conditions or orders in place, there may be more opportunities for undertaking specific types of accelerated actions, such as voluntary corrective actions. In fact, EPA is encouraging lower-ranked facilities to consider voluntary actions.
The DOE facility should also consider developing a facility-specific ranking for individual SWMUs or for SWMU groupings. Developing a facility-specific ranking is important, because, like EPA, DOE also lacks the resources to do everything at once. Equally important, facilities may have reasons that regulators would be reluctant to consider for wanting to take action at certain SWMUs earlier than others. For example, some facilities may wish to remediate certain portions of their facility earlier than others considering future activities (e.g., new construction). Based on the facility-specific priority ranking, the facility can identify acceleration options for implementation at SWMUs or SWMU groupings and discuss feasibility with the regulator and stakeholders.
Understand the Regulatory Program and the Regulator - Understanding the regulatory program and the regulator is one of the keys to successful acceleration of the RCRA corrective action process. Following is an example that illustrates the importance of understanding the regulatory program and the regulator.
In the early days of RCRA corrective action, many facilities were directed by regulators to conduct comprehensive investigations, including analyses for all RCRA 40 CFR Part 261 Appendix VIII constituents. Some facilities resisted conducting unnecessarily broad and costly investigations and negotiated a more reasonable scope for their facility investigations. At the same time, other facilities blindly accepted these requirements, not realizing that there were opportunities for negotiation. It didn't take these facilities long to realize the costs associated with overly broad investigations, however. These facilities then went through a painful process of working with their regulator to modify their permit or order to focus on a more reasonable investigation. Meanwhile, time and resources were wasted. The point is to underscore the importance of understanding the regulatory program. It is important for facilities to understand all the options available to them for conducting and accelerating RCRA corrective action. Most important, facilities must understand that RCRA, and corrective action in particular, is for the most part a negotiated program. While ultimately, the regulator is responsible for issuing permits, orders, or agreements that compel the facility to conduct RCRA corrective action, the facility can influence requirements and schedules through negotiation. Equally important to knowing the regulatory program, is knowing the regulator(s), both organizationally and individually. Each EPA Region and State has its own goals, objectives, policies, and procedures. Hence, the program is inconsistently implemented by the Regions and States; what "works" in one location, will not necessarily work in another. Also, the preference of the individual corrective action official may influence how corrective action is imposed at a particular facility. It is, therefore, important for facilities to understand the regulatory program as well as the individual regulator. Facilities should: 1) Employ or contract with personnel that have experience with the regulator; 2) Learn as much as possible about the program and the regulator through training courses, guidance documents, symposia, conferences, trade journals, peers, etc.; 3) Keep open the lines of communication through status and similar meetings; and 4) Research decisions made regarding other facilities (public and private) located within the Region or State.
Remain Current With New Developments - RCRA in general, and the RCRA corrective action program in particular, are evolving programs. Programs evolve as a result of public opinion, political pressure, new technological developments, court decisions, fiscal limitations, and many other factors. EPA's stabilization initiative, which put new focus on implementing interim measures as a means of early risk reduction, is a prime example of program evolution. The CAMU and TU rule is another good example of program evolution. Knowing that the CAMU and TU rule was in the process of being finalized, many facilities urged their regulator to delay decisions on

corrective measures pending promulgation of this final rule, because of the new waste management options it was expected to provide. More recently, EPA published for comment a draft list of screening levels for 107 of the most common contaminants found in soil (59 FR 67706, December 30, 1994). These levels are concentrations below which cleanup would not be required. Concentrations above these levels mean that further study would be required prior to determining the need for cleanup. This is a particularly important development in the context of corrective action acceleration because many SWMUs may now qualify for determinations of no further action.

RCRA corrective action is particularly vulnerable to evolution because the bulk of the regulations that would formally implement the program have yet to be promulgated. New developments will also occur in related programs that will directly affect RCRA corrective action. For example, the pending CERCLA reauthorization is expected to define risk goals, remedy cleanup standards, consideration of land use, and other issues that will affect RCRA corrective action. RCRA is also up for reauthorization, which provides more opportunity for program evolution.

It is important to remain current with these new developments. DOE facilities should: 1) Designate one or more individuals with the responsibility of maintaining currency with new developments and upcoming events, and communicating with the rest of the organization; 2) Maintain subscriptions with major and local environmental newsletters; 3) Establish contacts with individuals in DOE's Office of Environmental Policy and Assistance; 4) Obtain relevant DOE and EPA guidance materials and attend training programs, conferences and symposia and other information transfer events; 5) Communicate frequently with the regulator; and 6) Communicate frequently with peers, and especially other DOE facilities.

Establish a Good Rapport With the Regulator - Early relations between DOE facilities and their RCRA regulators can be characterized by a mutual distrust and lack of cooperation. DOE facilities have more recently begun to establish better relationships with their regulators. The advantages of establishing a good relationship with regulators are significant. Most important, regulators are more receptive to new ideas and new approaches, such as those put forth in the new DOE guidance being prepared. In addition, a good rapport facilitates the establishment of a team approach to problem-solving, which can be critical when innovative solutions are being examined.

It takes time and a concerted effort to establish a good relationship with the regulator. DOE facilities should: 1) Be open to new ideas and approaches put forth by the regulator; 2) Be cooperative rather than antagonistic; 3) Invite the regulator on frequent site tours to show progress or accomplishments 4) Establish an onsite location for the regulator (larger facilities only); and 5) Hold regular meetings with the regulator where progress and problems can be discussed in an team setting.

Establish a Strong Public Participation Program - DOE management has long recognized the importance of public participation in decision-making associated with environmental restoration activities. In 1991, guidance on this subject was published by DOE's Office of Environmental Guidance, entitled "Public Participation in Environmental Restoration Activities" (DOE/EH-0221, November 1991). Then in October 1992, DOE's Assistant Secretary for Environmental Restoration and Waste Management (EM) issued a statement of policy on public participation, declaring that the overall goal is "to create an open and accessible decision-making process that results in decisions that are technically and economically feasible, environmentally sound, health and safety conscious, address public values and concerns, and can be implemented." This policy statement was followed by DOE's "Public Participation Guidance for Environmental Restoration and Waste Management (March, 1993), which advocated public participation planning.

Due in part to these concerted efforts, many DOE facilities have made significant progress in improving relations with their local communities. DOE facilities are making a genuine effort to educate the public on site remediation activities and to involve the public in actual decision-making. Public participation for accelerated actions needs to be considered, therefore, in light of the facility's existing structure for public participation and community relations. Most DOE facilities will have facility-wide community relations plans for RCRA and CERCLA activities. These plans specify, in general terms, the community relations activities that will be appropriate for environmental restoration activities. However, each specific

accelerated undertaking may have additional needs and/or create additional demands for public involvement. Another activity that the DOE facility should consider, therefore, is conducting a strategic analysis of the need for, and implications of, developing a specific and more detailed public involvement plan as part of the initial strategy for acceleration.
Regulators, the public, and other stakeholders must be provided with the opportunity to take an active role in the decision-making process. However, all parties need to realize first that compromise is not always easily achieved, second that decisions are subject to funding limitations, and most important, that decision-making regarding RCRA corrective action is not a democratic process. While DOE has substantial opportunities for suggesting courses of action, and stakeholders have significant opportunities for input into the decision-making process, ultimately, the decision regarding available options under RCRA lies with the regulatory authority. All parties to the decision need to be flexible to the extent possible and compromise where necessary.
Consolidate SWMUs Into Groupings - Another important principle is to establish (or re-establish) SWMU groupings. SWMU groupings can be established based on a number of factors, including unit type, unit age, unit design, physical (3-dimensional) location, waste type and constituent content, release characteristics, regulator priority, facility priority, relative risk to human health and the environment, and many other factors.
Individual SWMUs should be organized into major categories, subcategories, and even smaller categories if appropriate. In essence, the smallest SWMU grouping should be established based on the least common denominator concept. Only those SWMUs with the same type of problem, the same release characteristics, and that may potentially be subject to the same corrective action (accelerated or not) at the same time, should be in the lowest subcategory.
SWMU consolidation into SWMU groupings is especially useful for large facilities with multifaceted problems at different physical locations, as is the case with many of DOE's larger facilities. DOE facilities under the CERCLA program have been practicing consolidation of contaminated sites into what are called operable units (OUs) for years. Most often, major OU categories are established based on physical location. The contaminated sites within the OUs are then further organized into subcategories based on many of the factors listed above. DOE has taken a site-specific approach to organization of sites into OUs. A site-specific approach to similar organization of SWMUs under the RCRA program should also be taken.
During the process of SWMU consolidation into groupings, facilities are encouraged to critically examine the manner in which SWMUs should be organized. Moreover, if SWMUs are already organized into groupings, which is the more likely case, changes should be suggested if deemed appropriate. Further, SWMU groupings should be established such that future changes that may be appropriate can be implemented without having to modify permits, orders or other agreements.
The advantages of SWMU consolidation into groupings relate to ease of management and facilitated decision-making. In particular, if SWMUs are properly categorized based on the least common denominator concept, accelerated options will be easier to evaluate, easier to implement, and cost less from an administrative standpoint.
Delegate Authority - One of the less obvious but nevertheless important principles of accelerating RCRA corrective action is delegation of authority. The DOE field organization should delegate decision-making to the lowest level possible, preferably to the SWMU or SWMU grouping (operable unit) manager. While decisions that have significant funding or policy implications need to be approved at a fairly high level within the DOE organization (often with headquarters approval and oversight), there are many decisions that can be approved at a much lower level. The less approvals required for any one decision, the less time it will take to implement that decision. Delegation of authority to the lowest level possible can have a significant effect on accelerating the process. In accordance with this principle, DOE facilities should carefully evaluate all the decisions that need to be made during the corrective action process, and categorize these decisions. Each category of decision can then be delegated to the lowest level possible within the DOE organization.
Obtain Expert Assistance - Remediation programs like RCRA corrective action and CERCLA are among the most complex regulatory programs. Successful implementation of these programs requires many different technical and non-technical fields of

expertise. In addition, many facets of RCRA corrective action require interaction with other regulatory programs, primarily CERCLA, but including many other federal laws and state equivalents. It is virtually impossible for any one person, or for even a group of several people, to possess all the knowledge to make RCRA corrective action work. Another important principle of accelerating RCRA corrective action is to obtain expert assistance where necessary.

Perhaps the greatest potential for delay that can be introduced by the facility is the need for re-work. A good example is moving stored remediation waste from one location to another because the original location did not meet regulatory standards. These types of errors, which can also result in substantial fines and other actions, are often caused by the failure to recognize the need for expert assistance. Expert assistance can save time as well as resources. DOE facilities should maintain a standing group or panel of technical and regulatory experts for input into corrective action decisions, work plans, reports, and similar documents. DOE facilities should also seek DOE headquarters input regarding particularly innovative actions and actions that may set precedents.

REVIEW AND CONCLUSION

As the nation progresses more and more towards the goal of doing more with less, federal facilities in particular need to find innovative ways to meet their obligations under the various environmental laws. The new guidance document that DOE is developing for "Accelerating RCRA Corrective Action at DOE Facilities," including both the principles of effective management and planning, and the tools for accelerating RCRA corrective action, will provide some new ideas toward meeting this goal.

Acceleration of corrective action, however, will not always mean lower costs. On the contrary, in many cases where corrective action is accelerated, the costs will increase, at least in the short term. On the other hand, in most cases risk reduction would occur sooner. As accelerated alternatives are examined, each facility will need to evaluate cost and risk reduction associated with specific actions, considering overall available funding. It is clear that tough decisions are in our future.

EXPEDITING PROGRESS IN THE HANFORD ENVIRONMENTAL RESTORATION PROGRAM

Steven D. Liedle
Thomas F. Demmitt
Bechtel Hanford, Inc.
Richland, Washington 99352

ABSTRACT

The U.S. Department of Energy, Richland Operations Office (DOE-RL) has adopted a "project" philosophy for planning and executing the Environmental Restoration (ER) Program at Hanford. This approach centers around task specific project teams supported by highly specialized functional groups.

The newly formed Environmental Restoration Contract (ERC) Team has assembled an organization of transitioned employees from existing site contractors and personnel with private sector environmental cleanup experience. Representatives from DOE-RL have also assumed active roles within the ERC Team. Working together, the ERC Team has improved project efficiency, resulting in significant cost savings and shortened schedules.

INTRODUCTION

With the unique challenges and near term implementation of remedial action projects associated with the Hanford ER Program, DOE-RL recognized the need to pursue different approaches for managing and executing the work. Due to the magnitude of the cleanup effort, the uniqueness of the contaminants, and the associated costs, there was a need to ensure that state-of-the-art methods and technologies from environmental cleanup efforts worldwide were considered and employed, as appropriate. Conversely, because of the site's complex waste management history, the institutional memory of the existing site work force was vital for characterizing the site and planning the remedial activities. Coupled with these factors was the desire by the DOE, Congress, and local stakeholders to have a cost efficient process whereby cleanup could be expedited without an abundance of unwarranted studies, permits, and paperwork.

To proceed within this framework, DOE-RL issued an $800 million Environmental

Restoration Contract to a team consisting of four companies recognized for their expertise in environmental cleanup and overall project management: Bechtel Hanford, Inc., CH2M Hill Hanford, Inc., IT Hanford, Inc., and TMA Hanford, Inc. The scope of work included:

Remedial action in the 100, 200, and 300 Areas
Decontamination and decommissioning in the 100, 200, and 300 Areas
Design and construction of a waste disposal facility
Demonstration and implementation of innovative technologies
Deactivation of the N-Reactor Complex
Sitewide support for all ER activities

The contract was awarded in March 1994, and transition (including transfer of the work force from the existing site management and operations contractor) was complete on July 1, 1994. To stress the importance of cost efficiency, the fee for the contract was established as "performance-based" with incentives for cost/schedule improvements.

NEAR TERM CHALLENGES

To effectively execute the scope of work and meet DOE-RL's expectations, the ERC Team faces three major challenges:

Increase Efficiency - Move from operational mode to cleanup (project) practices - Streamline and focus high impact support functions, such as procurement and regulatory analysis
Incorporate Private Sector Knowledge/Experience - Are we doing the right things? - Are we doing things right?
Promote DOE/Contractor Team Concept - Develop common strategies - Encourage mutual "buy-in" to project commitments

PROJECT PHILOSOPHY

To address these challenges, the ERC Team evaluated the life cycle of a typical manufacturing complex. During the initial construction phase, activities at most facilities involve clearly defined, non-repetitive tasks, executed by specialty contractors. During the operations phase, work is usually focused on more repetitive functions, with an in-house work force, production-line procedures, and a multi-layered management structure. As a facility's operating life ends, a deactivation and restoration phase is initiated, where once again the work becomes non-repetitive and task oriented. However, the scope of work during the restoration phase is often not as clearly defined as it was in the construction phase, particularly when environmental cleanup is involved. This build/operate/restore cycle is illustrated in Fig. 1. The Hanford facility is currently transitioning from the operations phase to the restoration phase.

Fig. 1.

To effectively manage the restoration work, the ERC Team implemented a "project" approach, where specialized resources are assembled into project teams. Work is planned and executed through the teams and, after completing the work scope, these teams are disbanded and the resources reassigned. For this approach to work, costs and schedules must be based on a well-defined baseline scope so that resource loading can be predicted and balanced within the overall ERC Team. Additionally, effective project control systems are needed to track the work closely, so that progress and costs can be monitored and reported quickly.

Division of the ERC work scope among individual project managers is based on the type of work involved. These project managers are responsible for defining resource needs, obtaining the appropriate resources from functional (discipline) departments, and guiding the teams as necessary to execute their assigned scope of work. They are accountable for cost, scope, and schedule. The individual teams are responsible for completing their assigned tasks according to an overall project plan, and are accountable to their project manager. A key element to the success of this approach is having representatives from DOE-RL assume active roles within the project teams.

Several functional departments exist to support the projects. Some of these groups provide general sitewide support such as auditing, human resources, contract administration, and community relations. Other functional groups such as engineering, project controls, procurement, and field support provide specific support services, technical oversight, and resources to individual projects. These groups use skills and experience from numerous other projects to improve efficiency in high impact administrative processes such as procurement and regulatory analysis. Functional department managers are accountable for maintaining a well-trained and

experienced staff to support the projects, addressing sitewide issues in a consistent and cost-effective manner, deploying resources to the project teams on an as-needed basis, and providing technical oversight.
An organization chart indicating the relationship between the projects and the functional groups is shown in Fig. 2.
Fig. 2.
Such an approach was quite foreign to much of the transitioned work force, and orientation was needed on the new project philosophy. Also, to infuse private sector experience, many people with specialized skills in environmental remediation needed to be relocated to Hanford from the ERC Team's offsite offices. Once everyone was on board, special team building sessions were held to establish working relationships and develop specific commitments for each project area and the functional groups. Both the ERC Team and DOE-RL participated in these sessions. The result was a cohesive team with a common focus.

INCREASED EFFICIENCY

Initiating a new work process usually involves a steep learning curve. During the first few months, a decline in productivity is typical prior to seeing the gains that are ultimately anticipated. However, for the Hanford ER Program, productivity gains needed to be immediate. DOE-Headquarters was closely scrutinizing the initial efforts to assess the viability of having specialized ER contractors at other sites within the DOE Complex. Simultaneously, budgets were being tightened, as the administration looked for ways to make DOE more cost effective. The ERC Team was asked to complete the remaining fiscal year 1994 work scope with $19 million less than previously budgeted. For fiscal year 1995, $201 million was allocated for $233 million worth of work scope. Coupled with these challenges were significant regulatory and contractual milestones that had to be met and the activities associated with relocating personnel, establishing work procedures, and setting up an office for over 800 employees.
To meet this challenge, the ERC Team implemented the project approach described above. Each of the project managers were provided resources from the functional organizations consisting of transitioned and transferred staff to support the effort. The resulting teams were empowered by management to complete the work scope. Due to the project approach, the ERC Team is seeing positive results including:

Completed the fiscal year 1994 work within the reduced funding target

Reduced applicable procedures from 2400 to about 1700

Reduced turnaround time issuing documents to outside entities by as much as 75 percent

Streamlined the procurement process - 45 day bid/award cycle for multimillion dollar remedial action subcontract
- 35 day bid/award cycle for a site preparation subcontract

Met all Federal Facility Agreement and Consent Order milestones -38 on schedule
- 24 ahead of schedule

Met several project team efficiency challenges that resulted in $23 million of documented cost savings

PRIVATE SECTOR KNOWLEDGE AND EXPERIENCE

A key to the success of the ERC Team is to incorporate into the project the knowledge and experience gained from private sector construction and environmental projects. This involves questioning the way things are being done for the restoration at Hanford. After five decades of highly specialized manufacturing activities, it can be a challenge to fully align the work force with a new mission (see Fig. 1).
Many work practices used at Hanford have been developed through years of experience in handling radioactive materials and hazardous wastes. The wealth of this knowledge needs to be integrated into the cleanup process. However, there are many work practices that may no longer be applicable to the type of work being performed by the ERC Team. In addition, innovative ideas developing outside the DOE Complex may have direct applicability at Hanford. This is an area where the teaming of experienced Hanford personnel with people from the environmental cleanup industry has distinct advantages. Some things done to integrate this knowledge and experience include:

Combined Bechtel Hanford, Inc. construction/project management experience with TMA Hanford, Inc., CH2M Hill Hanford, Inc., and IT Hanford, Inc. environmental expertise on individual project teams

Integrated key individuals from ERC management team into the transitioned work force

Made "home office" resources available to support the project teams on an as needed basis - consulted on fabrication of groundwater pump and treat systems - provided input on monitoring requirements for the prototype Hanford Barrier

Evaluated and redefined waste disposal facility needs/construction from a commercial operations perspective - $92 million estimated savings in cost from the baseline estimate for construction of an Environmental Restoration Disposal Facility for waste resulting from site cleanup (see Fig. 3)

Established an independent technical advisory group to counsel the ERC Team on approaches and methodologies to implement the cleanup

Fig. 3.

DOE/ERC TEAM CONCEPT

Full support from DOE-RL was vital for the ERC Team to successfully instill the "project" philosophy. Cooperation and participation at all levels within both organizations was needed to develop an effective project team. Therefore, the DOE project manager has become a key member of the ERC project management team, and individuals from DOE-RL staff are actively participating in all of the ERC project teams.

Early during the transition, senior DOE-RL and ERC managers attended an offsite planning session where goals/objectives were discussed. The result was a common and specific commitment statement, signed by all that were present. The group also formed a "Results Management Team" to monitor progress on the commitments, make quick and informed decisions, and continually guide the project toward its mission. Several months later, another session convened with over 100 representatives from all aspects of the ER Program. At this session, the commitment statement of the DOE and ERC senior management team was explained and discussed. Project teams including both DOE and ERC members worked together to analyze their tasks, align themselves with the mission, define roles and responsibilities, identify/resolve key issues, and establish project specific commitment statements. The participants realized that the success or failure of the project would be dependent on everyone working as a team toward a common goal. The session resulted in additional alignment and focus on the ER cleanup mission at Hanford.

SUMMARY

Establishing a "project approach" to the ER Program is already paying dividends. Overall project improvement has been directly reflected through reduced costs and shortened schedules. Private sector knowledge and skills are being integrated with the expertise of the existing work force to improve products, focus on specific problem areas, and question the scope/purpose of things that are being done. A strong partnership between DOE-RL and the ERC Team is being developed and is proving successful in directing the work towards a common mission. This partnership, along with the project approach to work planning and execution, will help retain focus and improve efficiency, both of which are essential during a period of declining budgets.

LESSONS LEARNED FROM EXPEDITING REMEDIATION PROJECTS THROUGH INTEGRATING REGULATORY AGENCIES INTO REMEDIATION DESIGN AND PERMITTING TEAMS

Philip A. Nixon
Parsons Engineering Science
James A. Ledford
EG&G Rocky Flats, Inc.

ABSTRACT

The Department of Energy, Colorado Department of Public Health and the Environment, and the Environmental Protection Agency established a joint working group which worked together closely during the planning, permitting, and design phases of a project to close/remediate five Solar Evaporation Ponds at the Rocky Flats Environmental Technology Site. The joint working group was a new strategy established to expedite the schedule on this technically complex project. Results from implementing the joint working group indicate that the integration of the regulatory agencies as an up-front stakeholder can be a successful method of expediting a regulatory-based remedial action project. This paper presents the

successes and lessons learned through integrating the regulatory agencies into the design and permitting team. In addition, the paper recommends methods to enhance the success of this strategy. Conditions will be presented to help identify the types of projects that could benefit from this new approach.

INTRODUCTION

The Department of Energy (DOE) operated five lined Solar Evaporation Ponds (SEPs) at the Rocky Flats Environmental Technology Site (RFETS) in Jefferson County, Colorado, from 1953 until 1986. Figure 1 presents a location map of the RFETS with respect to the surrounding region.

Fig. 1.

The SEPs which are identified as individual hazardous substance site (IHSS) Number 101 are included in the RFETS Operable Unit 4 (OU4). The SEPs were used primarily to store and evaporate low-level radioactive process wastes and neutralized acidic wastes containing aluminum hydroxide with high levels of nitrate. Operation of the SEPs has resulted in contamination of the surrounding soils and may be a potential source of ground water contamination.

Under an Interagency Agreement (IAG) with the Colorado Department of Public Health and the Environment (CDPHE) and the U.S. Environmental Protection Agency (EPA), DOE is required to close and remediate OU4 in accordance with an approved Interim Measures/Interim Remedial Action (IM/IRA) program. The IAG integrates the Resource Conservation and Recovery Act (40 CFR 265) and Comprehensive Environmental Response, Compensation and Liability Act requirements for surface impoundment closure and environmental restoration.

As a measure to expedite the closure/remediation of the SEPs to meet aggressive IAG milestone dates, the DOE, CDPHE, and EPA agreed to work together closely throughout the planning, permitting, and design phases of the project. The goal of this new strategy was to involve the regulatory agencies throughout the design and permitting processes so that the DOE, CDPHE, and EPA could jointly present and defend the IM/IRA to the public.

A joint working group was formed with a member from each regulatory agency to provide input throughout the project. The joint working group met on a weekly basis to identify and resolve issues. In this capacity, the regulatory agencies were cognizant with respect to the development of technical details and provided concurrent review as the project progressed. The RFETS operator (EG&G) and their permitting/design subcontractor were also members of the joint working group.

This paper presents the successes and lessons learned through integrating the regulatory agencies into the design and permitting teams on the OU4 IM/IRA. In addition, the paper recommends methods to enhance the success of this strategy. Conditions will be presented to help identify the types of projects that could benefit from this new approach.

JOINT WORKING GROUP COMPOSITION AND MEETING CONDUCT

A joint working group was formed with a member from the CDPHE, EPA, and members from the DOE, EG&G, and the permitting/design subcontractor. This joint working group met on a weekly basis to identify and resolve issues. The meetings were conducted informally with participation by all group members. However, the primary participants were the DOE, CDPHE, and EPA. The DOE representative was typically the meeting chairperson. Detailed meeting minutes were kept for the project administrative record.

BENEFITS FROM THE JOINT WORKING GROUP INTEGRATION

The establishment of an integrated joint working group provides numerous potential benefits to a project. One of the most significant benefits is that issues which could impede permit/design approval are identified early so that they can be addressed and resolved prior to the formal submittal of the permit application and design documentation for regulatory review. Early identification and resolution of issues reduces the potential to have to re-work aspects of the permit/design due to a denial from the regulatory agencies. The joint working group concept therefore has the potential to save the cost of permit/design re-work. In addition, the project schedule may not be impacted by re-work.

A second major benefit is the ability to reach agreement upon methodologies that will be used to screen and manipulate data. For example, the joint working group debated the methodologies with respect to:

1. Statistical manipulation of data,
2. Calculation of preliminary remediation goals,

3. Risk assessment, and
4. Computer modeling to demonstrate protectiveness to human health and the environment.

By working together, the DOE, EPA, and CDPHE established methodologies to process data in a manner acceptable to all three organizations. Early agreement with respect to methodologies can save budget and schedule since a reworking of data should not be required upon formal submittal of the permit document. The potential cost and schedule savings are significant because data manipulation methodologies are early project activities that provide the basis for important project decisions. Re-working data manipulation activities has significant cost and schedule impacts and jeopardizes all project decisions.

A third benefit of the joint working group interactions is the early identification and agreement on Applicable, Relevant, and Appropriate Regulations (ARARs). Early identification of ARARs allows the project to design and strategize appropriate measures to meet the regulatory requirements.

A fourth benefit of the joint working group is the ability to identify and resolve technical issues and design details prior to formal agency review and approval. The interactions of the joint working group allow DOE to design a project that has a high probability of acceptance by the regulatory agencies. The regulatory agencies benefit by being cognizant of many details of the project prior to the formal review process.

LESSONS LEARNED THROUGH JOINT WORKING GROUP INTERACTIONS

Several lessons have been learned through the interactions of the joint working group. Cognizance of these issues may help enhance the success of future joint working groups. The first lesson learned is that the opinions and positions that a team member brings to the joint working group may not reflect the position and policies that the individual's organization endorses. Different subgroups and departments of the various organizations do not always agree among themselves. It is therefore important that the members of the joint working group routinely brief their management. Meeting minutes should be widely distributed to the joint working group members as well as their respective colleagues and managers.

The second lesson learned is that it is often difficult to reach final closure/agreement on issues. In general, the more controversial an issue is, the more difficult it is to reach closure. Difficult issues typically involve disputes with respect to regulatory interpretation. Resolution of these issues takes time because the members of the joint working group often need to consult with regulatory/legal experts within their own organizations. It is important to identify issues as early as possible and schedule adequate time for the various organizations to research and develop a position/solution on the issue. Many issues require re-evaluation as a project evolves and becomes increasingly complex. Therefore, not all closures/agreements are final.

A third lesson learned is that the joint working group meetings can be long and tangential issues may interfere with accomplishing the meeting agenda. This is a potential problem with any meeting situation. The best way to keep a meeting on track is to:

1. Establish the agenda prior to the meeting by soliciting input from the different representatives.
2. Publish the agenda prior to the meeting.
3. Have a strong meeting facilitator to ensure that the agenda is followed.

It is best to use the meetings to establish the project criteria rather than design the project details by committee. This typically reduces the number of time consuming tangential issues. An effective process is to use the joint working group to establish and agree on performance criteria. The DOE and their subcontractors then design a solution or method to meet the criteria. A presentation of the findings/results is made to the joint working group at a subsequent meeting. This strategy is effective because the regulatory agencies are involved in establishing the performance requirements that must be accomplished. The DOE and their subcontractors are able to investigate alternatives to meet or exceed the requirements in the most cost effective and technically feasible manner.

The joint working group should maintain a list of open issues which is reviewed at each meeting. This will ensure that an issue does not get neglected. A list of previous agreements should be maintained. This list captures the significant decisions and provides an easy reference document to identify which decisions may

change as the project evolves and/or becomes increasingly complex.

METHODS TO MAXIMIZE THE EFFECTIVENESS OF JOINT WORKING GROUPS

This section is intended to provide advice on how to maximize the benefits that can result from close interaction between the DOE and the regulatory agencies throughout the planning, design, and permitting phases of a project.

Joint working group members should be empowered by their organizations to make decisions representative of the organization's policies. Therefore, senior members of an organization should be involved in the joint working group. The individual members of the joint working group should have primary responsibility for permit approval and/or implementation of the project.

The joint working group should keep a list of the open issues so that they will not be neglected. The issues list should be reviewed at each team meeting to see if any group member has further information that may help resolve any open issue. In addition, an action items list should be maintained so that each member of the joint working group is cognizant of their responsibilities to support future meetings and decisions. The actions item list should be reviewed and updated at each joint working group meeting.

It is important that detailed meeting minutes are taken at each meeting. These minutes are likely to become part of the project's administrative record. The minutes should record the decisions and agreements made at each meeting, and capture the viewpoints of the various organizations on issues that are discussed, but not resolved. The members of the joint working group should be allowed to review and ratify the meeting minutes prior to their formal issuance. The meeting minutes provide an excellent means for others who are involved in the project (but not members of the joint working group) to remain cognizant with respect to the decisions that are being made.

TYPES OF PROJECTS WHERE A JOINT WORKING GROUP MAY BE SUCCESSFUL

The establishment of a joint working group is not necessary for all projects. Projects with the following characteristics are candidates for the implementation of a joint working group.

1. Projects with a regulatory driven expedited schedule
2. Large projects involving numerous constraints and complex technical/regulatory issues.
3. Projects involving the use of proposed or newly promulgated regulations
4. Projects that may involve public controversy.

The establishment of a joint working group is important for projects that are expedited due to an agreement with regulatory agencies because it requires the agencies to participate in the expedited schedule. The agencies will be cognizant and partly responsible for schedule adherence. The agencies will therefore understand and may contribute to a situation where a schedule extension is requested.

Projects involving numerous constraints and/or complex technical and regulatory issues are candidates for establishing a joint working group because regulatory agency involvement will be useful in solving the complex issues within the project constraints. Interactions of a joint working group will be beneficial for early identification and resolution of the issues which could impact schedule and budget when the permit and/or design package is submitted for formal review and approval.

If a project will require the implementation of proposed or newly promulgated regulation, then it is appropriate to create a joint working group so that the regulators can provide direction and interpretation on how to best implement a new regulation.

If the implementation of a project may spark public controversy, then the establishment of a joint working group should be considered. The potential for the facility owner and the regulatory agencies to jointly propose and defend a project to the public can ease the public review period, and increase the potential to implement the project with few modifications.

CONCLUSION

The conclusion drawn through the establishment of a joint DOE, CDPHE, and EPA working group for the RFETS OU4 Solar Evaporation Pond Closure project is that the strategy was effective at identifying and resolving technical/regulatory issues to allow the project to proceed on an agency driven expedited schedule. The integration of the regulatory agencies as an up-front stakeholder can be a successful method of expediting a regulatory-based remedial action project.

LAND DISPOSAL RESTRICTIONS PHASE II-UNIVERSAL TREATMENT STANDARDS FINAL RULE: IMPACTS ON MIXED WASTE TREATMENT

Jay Farr
Carla Rellergert

Mona Williams
Department of Energy
WMD
Albuquerque, NM

ABSTRACT

The Environmental Protection Agency (EPA) published the Land Disposal Restrictions (LDR) Phase II Rulemaking in the Federal Register on 19 September 1994 (59 FR 47982). This rule establishes the universal treatment standards, promulgates treatment standards for newly identified toxicity characteristic organic wastes, and requires that underlying hazardous constituents be addressed in certain characteristic wastes. Phase II also clarifies the regulation of debris treated by immobilization technologies, the applicability of treatability variances, and the treatment standards for lab packs. Most of the impacts of the Phase II rule are not unique to mixed waste; they are applicable to hazardous wastes regulated only by the Resource Conservation and Recovery Act. The Department of Energy (DOE) waste managers who have recently issued Site Treatment Plans as a requirement of the Federal Facility Compliance Act will benefit from an examination of changes brought about by the Phase II rule that includes applicability of universal treatment standards, newly identified waste treatment standards, underlying hazardous constituents, and other mixed waste management issues. This paper provides an overview of LDR Phase II rule changes, and gives examples that illustrate how Phase II rule changes may affect how mixed wastes are managed at DOE facilities. Also, a summary of the expected changes in Phase III, Phase IV, and Phase V proposed rules is given.

INTRODUCTION

The Environmental Protection Agency (EPA) published the Land Disposal Restrictions (LDR) Phase II Rulemaking in the Federal Register on 19 September 1994 (59 FR 47982).* In the Phase II rule, EPA establishes the universal treatment standards, promulgates treatment standards for newly identified toxicity characteristic (TC) organic wastes, and requires that underlying hazardous constituents be addressed in certain characteristic wastes. EPA also clarifies other issues related to LDR in the Phase II rule, such as the regulation of debris treated by immobilization technologies, the applicability of treatability variances, and the treatment standards for lab packs.

Most of the changes and clarifications to LDR provided in the Phase II rule affect the management of mixed waste. This paper will provide an overview of LDR, elaborate on the Phase II rule, discuss the ramifications of the rule on mixed waste management, and then provide examples.

LAND DISPOSAL RESTRICTIONS OVERVIEW

In the Hazardous and Solid Waste Amendments (HSWA) to the Resource Conservation and Recovery Act (RCRA), Congress specifies that hazardous waste must be treated prior to land disposal in a manner that substantially diminishes the toxicity of the waste or substantially reduces the likelihood of migration of hazardous constituents from the waste. To accomplish this, Congress requires EPA to promulgate regulations specifying levels or methods of treatment of hazardous waste. In response, EPA promulgated the Land Disposal Restrictions for Title 40 of the Code of Federal Regulations Part 268 (40 CFR 268).

As required by HSWA, the regulations in 40 CFR 268 contain "treatment standards" that identify levels or methods of treatment for hazardous waste. The standards apply to all hazardous waste for which a treatment standard has been promulgated unless a variance, extension, or exemption applies. The standards must be met prior to land disposal of the waste. Land disposal includes, but is not limited to, placement of hazardous waste in any of the following:

Landfill
Surface impoundment
Waste pile
Injection well
Land treatment facility
Salt dome or salt bed formation
Underground mine or cave
Concrete vault or bunker intended for disposal

Many requirements contained in LDR apply prior to disposal, such as the dilution prohibition, storage prohibition, testing requirement, and recordkeeping requirement. To further understand LDR, this section will provide information on LDR treatment standards, the applicability of LDR, prohibitions contained in LDR, and requirements for testing and recordkeeping identified in LDR.

Treatment Standards

In 40 CFR 268, EPA identifies treatment standards for all hazardous waste codes that existed at the time HSWA was enacted. EPA identifies treatment standards for a number of waste codes identified as hazardous after HSWA was enacted (newly-identified wastes). Treatment standards are established by evaluating the best demonstrated available technology (BDAT) for the treatment of a waste. The standards are normally identified by waste code, divided into wastewater and nonwastewater categories, and identified as either a specified technology or a constituent concentration level. If a specified technology is identified as a treatment standard, that technology must be used to treat the waste or a treatability variance must be obtained. If constituent levels are specified, the waste must be treated by an appropriate technology until all identified constituents reach or fall below the designated level. The BDAT is used to determine the constituent level, but another treatment technology may be used to treat the waste to that level. Each waste code may have a number of constituents to treat to a specified level. In the past, the treatment level for a particular constituent could vary from one waste code listing to another.

Prior to the Phase II rule, the treatment standards were listed in 40 CFR 268.42 for specified technologies, and in 40 CFR 268.41 and 268.43 for constituent concentration levels. The levels listed in 40 CFR 268.41 were based on constituent concentration in an extract of the waste after using the Toxicity Characteristic Leaching Procedure (TCLP). The levels listed in 40 CFR 268.43 were based on total concentrations of the hazardous constituents.

For hazardous waste debris, the treatment standards can also be based on the matrix of the waste. These standards are identified in 40 CFR 268.45 as a specified technology and include extraction, destruction, and immobilization treatment processes. The appropriate technology to treat the debris depends on the type of debris and type of contaminant(s) present. If debris is treated by an extraction or destruction technology, it is not regulated as a hazardous waste after it is treated.

Applicability

The LDR requirements of 40 CFR 268 apply to all generators and transporters of hazardous waste with a treatment standard, as well as all owners and operators of treatment, storage, and disposal facilities (TSDFs) that handle the waste. A newly identified waste is not subject to 40 CFR 268 until a treatment standard has been promulgated. In addition, the effective date of LDR may be delayed, a variance may be obtained, or an exemption may apply. These delays, variances, and exemptions are in the form of a national capacity variance, case-by-case exemption, treatability variance, equivalent method variance, no-migration petition, or surface impoundment exemption.

The effective date of a treatment standard for a particular waste code may be delayed by a national capacity variance or a case-by-case extension. A national capacity variance is provided when EPA determines that sufficient treatment capacity for certain hazardous waste codes is not available nationwide. The effective date for a treatment standard is extended until treatment capacity for the waste is available. (Other requirements such as analysis and recordkeeping may still apply.) A case-by-case extension may be obtained from EPA for 1 year and extended for 1 more year if treatment capacity for a specific waste cannot be made reasonably available. To obtain the extension, the petitioner must demonstrate certain information identified in 40 CFR 268.5.

Variance from an established treatment standard can be obtained in the form of a treatability variance or an equivalent method variance. A treatability variance may be granted by EPA for a unique waste stream where the existing treatment standard, expressed as a concentration or specified technology, is not applicable. EPA will establish a new treatability group for that waste stream if the variance is granted. If a specific method is identified as the treatment standard, an equivalent method variance enables EPA to approve another process as the treatment standard if performance of the alternative process is equivalent.

Exemptions from meeting treatment standards may be granted if a no-migration petition is approved or the surface impoundment exemption applies. A no-migration petition can be granted by EPA for specific waste disposed at a specific site if it can be demonstrated that no migration of hazardous constituents from the disposal unit will occur for as long as the waste remains hazardous. Hazardous waste that does not meet treatment standards can be treated in a surface impoundment pursuant to the surface impoundment exemption if certain conditions are met.

Prohibitions

In addition to the prohibition on land disposal of waste that does not meet treatment standards, LDR contains two other significant prohibitions. These are the dilution prohibition and the storage prohibition. The dilution prohibition states that hazardous waste subject to a treatment standard cannot be diluted as a substitute for legitimate treatment unless it is a necessary part of the treatment process. The storage prohibition states that in most situations hazardous waste subject to a treatment standard cannot be stored unless it is to accumulate sufficient quantities of waste to facilitate proper recovery, treatment, or disposal.

Testing and Recordkeeping

All generators and TSDFs managing hazardous waste with a treatment standard are subject to waste analysis, notification, and recordkeeping requirements contained in the LDR. Hazardous waste generators must determine if the waste meets applicable treatment standards and present their findings to hazardous waste facilities that will receive the waste. A generator may determine if the waste meets applicable treatment standards based on knowledge of the waste or by conducting analysis. Treatment and storage facilities must test hazardous waste according to a waste analysis plan to determine if the waste meets applicable treatment standards and present their findings to hazardous waste facilities that will receive the waste. Disposal facilities must also test hazardous waste prior to disposal according to a waste analysis plan to ensure that it meets applicable treatment standards. All hazardous waste facilities must maintain on-site records of these activities.

Changes to the Land Disposal Restrictions Program

Since the first statutory deadline (i.e., hard hammer) addressing LDR (Solvents and Dioxins Rule) in 1986, there have been changes regarding the technologies available to treat hazardous wastes, as well as the availability of data regarding the treatability of certain constituents. As a result, EPA has taken the initiative to take actions to reform the LDR program, to update, clarify, and facilitate implementation of already existing requirements. EPA's first RCRA Reform Initiative (Phase I) was the Hazardous Debris Rule promulgated on 18 August 1992 (57 FR 37194), which modified treatment option for debris contaminated with hazardous waste. Additional modifications to the LDR program are a result of the 25 September 1992 U.S. Court of Appeals decision on Chemical Waste Management v. EPA, 976 F.2d 2 (D.C. Cir. 1992) to vacate the treatment standards for ignitable and corrosive hazardous wastes. EPA has taken action to comply with this decision by promulgating an interim final rule (24 May 1993, Federal Register, 58 FR 29860) establishing revised treatment standards for ignitable and corrosive wastes. This interim final rule retains the requirement to remove the hazardous characteristic (by deactivation), and also requires that the waste be treated for any underlying hazardous constituents (approximately 216 constituents) reasonably expected to be present in the waste.

The latest action of the RCRA Reform Initiative is the promulgation of the Phase II rule.

PHASE II CHANGES TO THE LAND DISPOSAL RESTRICTIONS

Under the Phase II rule, EPA provides a number of changes and clarifications to LDR. EPA establishes universal treatment standards, promulgates treatment standards for newly identified toxicity organic wastes, and requires that underlying hazardous

constituents be addressed in certain characteristic wastes. The Phase II rule also clarifies other issues related to LDR, such as the regulation of debris treated by immobilization technologies, the applicability of treatability variances, and the treatment standards for lab packs.

Universal Treatment Standards

Under the Phase II rule, EPA promulgates a single universal treatment standard (UTS) for each organic, metal, and cyanide constituent in wastewater and nonwastewater form. The constituent concentration treatment level is the same regardless of the hazardous waste code that identifies the constituent. This eliminates the variation in concentration levels that existed from one waste code listing to another. The UTSs are established for all hazardous wastes for which treatment standards have been promulgated, except for the following:

- TC metal wastes (Waste Codes D004-D011)
- Most hazardous wastes with a specified technology identified as the treatment standard

Implementation of the UTSs will change some of the standards identified as constituent concentration levels. More specifically, 59 percent of the previous constituent levels will remain the same, 33 percent will change within a factor of 10, and 8 percent will change more substantially. (Three percent will become significantly more stringent.) However, the adjustment in constituent treatment levels should not require a change in the technologies used to treat the waste. The technology basis for establishing the new constituent levels is primarily the same as the basis for the old levels.

For organic nonwastewaters, the BDAT for determining UTS constituent levels is combustion. The BDAT for determining UTS constituent levels in organic wastewaters is the same as that identified for the hazardous waste code: F039 multisource leachate. The BDAT for the F039 wastewaters is biological treatment followed by chemical precipitation, or wet-air oxidation followed by carbon adsorption followed by chemical precipitation. The BDAT for determining 12 of the 14 nonwastewater metal UTS constituent levels (which excludes TC metals) is high-temperature metal recovery or stabilization. The two other BDATs are vitrification for arsenic, and recovery by roasting or retorting for high concentrations of mercury. The BDAT for determining metal wastewater UTS constituent levels is chemical precipitation. For metal wastewater treatment, operating conditions such as flocculating agents, reagent concentrations, retention time, and mixing may need to be adjusted to comply with the new standards. The UTS levels for cyanide wastewaters and nonwastewaters are based on alkaline chlorination as the BDAT.

The universal treatment standards became effective on 19 December 1994. In states that have authority to implement RCRA but not LDR, EPA will enforce the new standards until the states incorporate the modifications. States authorized to implement LDR for some or all waste streams will continue to implement these treatment standards. The new UTSs will not apply to those waste streams until the state has incorporated them into state law.

Treatment Standards for Newly Identified Wastes

Under the Phase II rule, EPA promulgates treatment standards for newly identified TC organic wastes, TC pesticide wastes, coke by-product wastes, and chlorotoluene wastes. Because these wastes were identified as hazardous after the enactment date of HSWA in 1984, they are "newly identified wastes" for the purposes of the LDR program. (On 29 March 1990, EPA promulgated a rule that identified organic constituents [in addition to existing EP metals and pesticide constituents] and levels at which a waste is considered hazardous based on the characteristic of toxicity.)

The TC organic wastes (hazardous waste codes D018-D043) and the TC pesticide wastes (hazardous waste codes D012-D017) are determined to be hazardous through application of the TCLP. The coke by-product and chlorotoluene wastes are generated by specific industrial processes.

The new treatment standards for TC organic wastes are based on incineration for nonwastewaters. For wastewaters, the standards are based on existing data and technologies identified for treatment of these constituents in other wastes. The treatment standards for TC pesticide wastes already existed based on Extraction Procedure (EP) constituent levels, not TCLP levels. The Phase II rule establishes treatment standards based on constituent levels from the TCLP. The new standards are based on the same technologies used to establish the EP standards. The treatment

standards for the TC organic and the TC pesticide wastes are equivalent to the UTSs. The Phase II rule applies to those TC organic wastes that are managed in systems other than those regulated under the Clean Water Act (CWA), those engaged in CWA-equivalent treatment prior to land disposal, and those injecting into Class I deep injection wells. In addition, TC wastes rendered noncharacteristic are still within the scope of the Phase II rule.

Underlying Hazardous Constituents

The UTSs also apply to all underlying hazardous constituents in TC pesticide and organic wastes (D012-D043), as well as the constituent responsible for the TC designation. The Phase II rule also modifies the applicability of underlying hazardous constituents to D001 and D002 characteristic hazardous wastes. An underlying hazardous constituent is defined as any constituent listed in the universal treatment table, except zinc and vanadium, that can reasonably be expected to be present at the point of generation of the hazardous waste at a concentration above the constituent-specific treatment standard.

The compliance monitoring and notification requirements contained in LDR were modified to minimize the amount of information that must be placed on the LDR notification in certain circumstances. In addition, the certification and notification requirements were modified where necessary to address underlying hazardous constituents present in TC organic or pesticide wastes. A generator must identify all underlying hazardous constituents in TC organic or pesticide wastes. Generators may base this determination on their knowledge of the raw materials used, the process they operate, and the potential reaction products of the process, or upon the results of analysis. The generator also must notify TSDFs receiving the waste of the constituents, when required.

Other Issues Addressed in the Phase II Rule

Additional issues related to LDR that the Phase II rule clarifies include the possibility of removing immobilized hazardous debris from under Subtitle C regulation, the applicability of treatability variances, and the treatment standards for lab packs.

EPA decided in the Phase II rule to revisit the issue of whether immobilized hazardous debris, if treated in certain ways or treated to meet certain limits, would be excluded from Subtitle C regulation. Several issues were discussed including the inappropriateness of the TCLP for debris, the use of a 50 psi (pounds per square inch) structural test as a performance standard, and the use of a leach test performed on intact debris. Although industry supported the idea of removing immobilized hazardous debris from regulation under Subtitle C, there was no supporting data or other information submitted to EPA to support these claims. Therefore, the Phase II rule did not modify the debris rule and EPA will reassess this determination in the future. This reassessment will include evaluation of exclusions as part of the Hazardous Waste Identification Rule (HWIR) process.

Existing LDR regulations (40 CFR 268.44(a)) allow for variances from treatment standards if a waste cannot be treated to specified treatment standards or if the treatment technology on which the standard is based is inappropriate for the waste. Guidance on obtaining LDR treatability variances is provided in the Phase II rule as is guidance on treatability variances for soil, including site-specific, non-rulemaking variances. The preamble to the Phase II rule provides clarification on the applicability of the variance, the necessary data required, and the proper procedure for obtaining a variance.

Appendices IV and V of Part 268, which promulgated alternative treatment standards for hazardous wastes placed in lab packs, are replaced with a new Appendix IV. Appendix IV now identifies which hazardous wastes cannot be placed into lab packs. Prior to Phase II, Appendices IV and V listed the hazardous wastes that could be placed into lab packs. The specified method of treatment is still incineration, combined with the requirements of 268.42 (c)(4) (ash residues from lab packs containing D004-D008, D010 and D011 are treated to meet the characteristic metals treatment standards), will ensure that all underlying hazardous constituents present in characteristic wastes will be treated.

IMPACTS ON MIXED WASTE MANAGEMENT

Most of the effects of the Phase II rule on mixed waste management are not unique to mixed waste. The same effects exist for hazardous waste that is regulated only by RCRA. However, this section identifies the specific changes to mixed waste management brought about by the Phase II rule.

Applicability of Universal Treatment Standards
In several previous cases associated with mixed wastes (as well as hazardous wastes), a constituent regulated under a treatment standard for one mixed waste was also regulated in another waste at different concentration levels. Under the Phase II rule, EPA eliminates these differences in concentration limits for the same constituent to provide a better assessment of treatability and to reduce confusion. Although the Phase II rule does not require treatment for additional hazardous constituent concentrations, treatment levels are for some constituents lower. In most cases, these changes should not require technologies identified in site-specific treatment plans to be modified, since the new treatment standards are based on existing technologies. The site-specific treatment plans are also based on existing technologies.
In situations where constituent concentration treatment levels are lowered and the applicability of a treatment technology must be demonstrated, treatability studies will become an important step. Treatability studies will be used to determine the optimal process conditions needed to achieve the desired treatment standard. If, based upon the results of the treatability study, a technology cannot achieve the required constituent concentration treatment level, the technology will have to be redeveloped or redesigned.
Newly Identified Waste Treatment Standards
Under the Phase II rule, EPA promulgated treatment standards for newly identified TC organic wastes and modified treatment standards for TC pesticide waste. For hazardous waste, these treatment standards became effective on 19 December 1994. For mixed wastes, these treatment standards will become effective on 19 September 1996. EPA determined that sufficient alternative treatment capacity for mixed radioactive wastes contaminated with newly listed and identified wastes is not available and has granted a 2-year national capacity variance for these wastes.
As a result of the national capacity variance, any site that generates these newly identified mixed wastes may choose to treat the mixed waste before 19 September 1996, if treatment capacity is available or to dispose of the mixed waste without treatment if disposal capacity is available to accept these mixed wastes.
Ultimately, treatment capacity is needed for any future-generated mixed waste that exhibits only the characteristic for TC organics or TC pesticides. In addition, LDR treatment standards may already exist for other applicable listings or characteristics.
Underlying Hazardous Constituents
The requirement to treat characteristic wastes for underlying hazardous constituents does apply to mixed waste. Specifically, a mixed waste that exhibits the ignitable or corrosive characteristics must also be treated for any underlying hazardous constituents that are reasonably expected to be present in the waste. Newly identified mixed waste with a treatment standard promulgated under the Phase II rule must be treated for underlying hazardous constituents when the treatment standards become effective. For pesticide and organic treatment standards based on the TCLP, the requirement will become effective at the end of the national capacity variance.
The requirement to address underlying hazardous constituents significantly impacts the characterization of mixed waste. In addition, new treatment steps may be required for specific mixed waste streams. All ignitable, corrosive, and organic mixed waste will need to be treated for metals, thus requiring a two-step treatment process. In addition, certain corrosive wastes may require treatment for organics or metals using additional treatment technologies, where before neutralization would have been the only required treatment process to deactivate the corrosive component of the mixed waste.
The requirement for underlying hazardous constituents may also impact certain mixed wastes that are listed under 40 CFR part 261, subpart D, since any mixed waste that carries a listed hazardous waste code must also identify any applicable characteristic waste codes. This requirement was promulgated in a previous LDR final rule (Third Thirds), in which EPA established special requirements for purposes of part 268, that a waste will carry the waste code for any applicable listing under subpart D, as well as one or more waste codes under 40 CFR part 261, subpart C, where the waste exhibits a characteristic. As a result of the Phase II rule, additional characteristic hazardous wastes require treatment for underlying hazardous constituents and would therefore apply to more listed hazardous wastes.
Other Mixed Waste Management Issues

Additional issues that may impact mixed waste management from the Phase II rule include removing immobilized mixed waste debris from Subtitle C regulation, the applicability of treatability variances, and the treatment standard for lab packs. Several large volume mixed waste streams (i.e., surface contaminated or activated lead solids, and inorganic debris) could be affected by a change in the requirement for immobilized mixed waste debris to no longer be under Subtitle C control. This change would allow mixed waste debris to be disposed of in a radioactive waste management unit as opposed to a disposal unit for mixed wastes. Available disposal capacity is much greater at radioactive waste management units than at mixed waste management units. In addition, several requirements and performance standards currently exist to which immobilized mixed debris would be subject as a result of the radioactive component of the mixed waste. The treated/immobilized mixed waste would not allow toxic contaminants to remain at levels that could pose a hazard to human health and the environment absent Subtitle C regulation. Therefore, it is anticipated that existing performance standards applied to mixed waste debris treated using an immobilization technology would not have to be modified.
If mixed waste treatment technologies are unable to meet LDR treatment standards, additional guidance is provided in the Phase II rule regarding treatability variances.
For any mixed waste lab packs that contain characteristic metal wastes, the incinerator ash will require stabilization prior to land disposal.
EXAMPLE OF THE EFFECTS OF THE PHASE II RULE EFFECTS ON MIXED WASTE MANAGEMENT
Universal Treatment Standards
Before Phase II Final Rule
For mixed waste containing F001 spent solvents (trichloroethane and freon), the LDR treatment standard for the nonwastewater form was a concentration-based treatment standard. This treatment standard required compliance at or below the constituent concentration of 5.6 mg/kg in the waste for trichloroethane and 33 mg/kg in the waste for freon.
After Phase II Final Rule
For mixed waste containing F001 spent solvents (trichloroethane and freon), the LDR treatment standard for the nonwastewater form is 6.0 mg/kg for trichloroethane and 30 mg/kg for freon.
Newly Identified Treatment Standards
Before Phase II Final Rule
Mixed wastes only exhibiting the characteristic of TC organic or TC pesticide wastes were not subject to LDR and could be land-disposed with treatment.
After Phase II Final Rule
Mixed wastes only exhibiting the characteristic of TC organic or TC pesticide wastes can be land-disposed without treatment until 19 September 1996, or the mixed waste can be treated to meet the waste code specific treatment standards including underlying hazardous constituents.
Underlying Hazardous Constituents
Before Phase II Final Rule
For a treatability group that consists of aqueous liquids that exhibit only the characteristic of corrosivity and contained methanol (that was not a listed hazardous waste and did not exhibit the characteristic for TC organics) the required LDR treatment would be neutralization of the liquids. The waste would no longer be a mixed waste and could be disposed of as a low-level waste once it is solidified.
After Phase II Final Rule
Aqueous liquids (corrosive) treatability group that only exhibitS the characteristic of corrosive and contained methanol as an underlying constituent requireS an alternative treatment for the organic component of the waste. The preferred treatment option is to use evaporative oxidation for the methanol component followed by neutralization of the treated aqueous liquid and condensate. The neutralized liquids would then be stabilized. The waste would no longer be a mixed waste and could be disposed of as low-level waste.
WHAT TO EXPECT IN THE FUTURE
As a result of the U.S. Court of Appeals decision in 1992, EPA has a schedule according to which it will address the decisions in this court ruling. For example, there is an upcoming Phase III proposed rule that is expected in 1995 under which EPA will be examining treatment standards for characteristic hazardous wastes that will be managed in CWA systems, Safe Drinking Water Act (SDWA) Underground Injection

Control (UIC) class I wells, and for CWA zero-discharge facilities. The final rule of Phase III is scheduled for release in early 1996. The Phase IV proposed rule, expected in June 1995, will address treatment standards for the TC metal wastes (D004-D011). In addition, the mineral processing wastes, which were formerly excluded from RCRA Subtitle C regulation under the Bevill Amendment, are considered to be newly identified and will also be addressed in the Phase IV rule.

PROGRESS ON INTEGRATING ENVIRONMENTAL RESTORATION DATA INTO MIXED WASTE UPDATES

Marilyn Tolbert-Smith
U.S. Department of Energy
Margaret MacDonell
John Peterson
Argonne National Laboratory
Tim Kirkpatrick
Lockheed Idaho Technologies Company

ABSTRACT

The Federal Facility Compliance Act required the Department of Energy to compile specific information on the volumes, characteristics, and treatment plans for mixed wastes, and to provide this information to the Environmental Protection Agency and affected states. The initial format for reporting this information was developed largely on the basis of operations wastes. Although this format is acceptable for stored environmental restoration wastes, it was found to be poorly suited for reporting wastes that could be generated by future cleanup activities, many of which have not yet been well defined. Modifications to the process initially used to report restoration wastes were made to allow them to be reported in a manner that more accurately reflects uncertainties inherent in such estimates. This revised approach allowed for the smooth integration of data for restoration wastes with those compiled by the waste management team for mixed waste inventory updates.

BACKGROUND

For the past two years, the Department of Energy (DOE) has been involved in an intensive effort to collect and consolidate information on mixed wastes from both operating facilities and inactive sites, to satisfy reporting requirements for the Federal Facility Compliance Act (FFCA). This information is being provided to the Environmental Protection Agency (EPA) and affected states, and it includes descriptive data on both stored and anticipated wastes, as well as treatment plans for those wastes. The approach and structure of the reporting mechanisms for this mixed waste information have evolved during this time, with the goal being a comprehensive framework that can be used for future updates.

Although environmental restoration (ER) wastes account for a major portion of the total waste volume anticipated from DOE activities over the next 30 years, the initial structure for reporting mixed waste information was developed primarily on the basis of operations waste. During preparation of the mixed waste inventory report and accompanying data bases, several issues were raised with regard to incorporating ER information into that format. Most problems arise from the fact that specific ER activities that will be conducted in the future are not yet known for most sites, so waste projections (let alone mixed waste projections) are preliminary at best. Thus, considerable uncertainty is associated with the plans and costs being developed for treatment facilities based on these early estimates many of which involve conservative assignment to the mixed waste category, absent characterization data that may not be available for several years.

It is important to recognize that these wastes may not be generated at all, depending on site-specific cleanup decisions. In-place responses such as capping or access restrictions are being evaluated for certain areas at a number of ER sites, so some contaminated environmental media such as soil and groundwater at these sites may never become waste. The staged nature of the decision-making process for these sites makes it difficult to provide full information on waste volumes and characteristics, and subsequent treatment plans, prior to the establishment of formal decisions that are developed from the input of many stakeholders including EPA, the states, and affected communities.

Problems also arise in projecting information for secondary waste streams, which include personal protective equipment that will be worn by remedial action workers, as well as filters, sludges, and spent resins from the anticipated treatment of

multiple waste streams. Additional difficulties are associated with data on wastes that may be generated by decontamination and decommissioning activities, which are currently being tracked by various programs and represent a considerable source of uncertainty in the volume projections for DOE mixed wastes. A similar issue is involved in tracking the transition of wastes from environmental restoration to waste management responsibilities. Further administrative issues include the staggered timing of updates for the mixed waste data base versus the site treatment plans (conceptual, draft, and proposed), and the unavailability of specific ER contacts in the field to help coordinate with waste management (WM) counterparts. Several of these issues and their resolutions are discussed further below.

ISSUES AND RESOLUTIONS

Level of Detail. Information was collected for the mixed waste inventory report (MWIR) data base at the "waste stream" level, and completion of a 30-page questionnaire was requested by the WM team for each waste stream. This level of detail was not available for ER wastes, especially for the materials that are projected to be generated, because characterization and response planning activities are ongoing at the restoration sites.

For stored ER wastes, this issue was addressed by completing the questionnaire to the extent information was available, using standard responses in many cases (for example, with regard to treatment plans where decisions had not yet been finalized and the options were therefore still being assessed). The waste streams were defined as single containers or a group of containers with wastes of similar physical properties and contaminant conditions. Although many ER wastes consist of heterogenous mixtures of contaminated media that do not fit easily into standard categories, they were assigned to the most appropriate treatability group code that had been developed by the WM team to facilitate summary roll-ups and integrated planning. The original questionnaire has also been revised and shortened considerably, to focus on key data needs for FFCA reporting.

For projected ER wastes, a simplified profile sheet was developed to capture on a single page the information requested by the FFCA, to the extent it was available. Standard responses were provided for many entries (such as "good management practices" for the waste minimization activities). In some cases, no volume estimates could be provided yet, but a profile sheet was prepared to present other information (such as the projected source and type of waste) and also to serve as a placeholder in the event that a given waste stream is generated by a future ER activity that is currently under consideration at the site.

Stage of Site Decision-Making Process. A considerable amount of information on treatment plans and waste projections was requested by the WM team for each waste stream. To provide these data, final decisions on the remedies that affect waste generation and treatment would have to be available for each site. Comprehensive decisions have not yet been made on the remedies to be implemented at most ER sites. Thus, the eventual fate of the variety of contaminated materials typically found at a site which may or may not involve the generation of mixed waste cannot reasonably be projected prior to the evaluation of response options and the receipt of input on proposed actions from the communities, states and EPA regions involved. To do otherwise, i.e., to provide details that presume a certain course of action, might imply that the decision-making process was being circumvented at these sites, and that is not the case. This issue was addressed by caveating the information provided for ER mixed wastes as preliminary. In addition, some responses were simply noted as "unknown" or "not available" at this time, and others included standard language (see examples above) that reflected the predecisional stage of the process.

Consistency with the Site Treatment Plans. Concurrent with the collection and presentation of information for the MWIR and its updates, sites have also prepared several evolving versions of site treatment plans (STPs) for issuance to EPA and the states according to an established schedule. Issuance of the MWIR and its updates has not followed this same schedule, so data differences have occurred and the inconsistencies have been questioned.

The development of characterization and planning information at ER sites is an ongoing process, and data will change over time. To resolve the issue of apparent inconsistencies associated with different reporting periods, the schedules of the MWIR data base updates and STP revisions are being synchronized. Closer coordination between the two reporting activities is also reducing duplicative data entry

efforts. For example, information from the 1994 MWIR data base is being preloaded into the format for the 1995 update, as supplemented by information from the current STP, so field personnel need only change those entries for which new information has been developed since the most recent reporting of mixed waste data.
Integration of ER and WM Treatment Plans. Information is being collected for the FFCA on treatment plans for mixed wastes from both operating (WM) facilities and restoration (ER) sites. Using a single reporting structure developed from an operational perspective did not accommodate some of the ER considerations, such as the evaluation of bench-scale and pilot-scale facilities and the possibility of multiple feeds that have not yet been well characterized, or in some cases even identified.
To address this issue, additional clarification and flexibility have been incorporated into the treatment facility questionnaire developed by the WM team for FFCA reporting purposes. Treatment plans for mixed waste originate at the site level, whether it is an ER or WM waste. Coordination between the respective elements at sites where both are present has helped integrate the treatment planning activities for the FFCA updates.
SUMMARY
Resolutions continue to be developed for these issues, and progress is being made toward establishing a workable structure for mixed waste reporting. Successful integration of ER mixed waste data into the overall FFCA reporting framework is critical, especially given DOE's plan to provide further updates of mixed waste information to EPA and the states. Applying an approach that acknowledges the preliminary nature of ER waste projections is helping to solve some of the problems associated with earlier mixed waste reporting for the FFCA. Also, close coordination between the ER and WM teams has helped accommodate the flexibility needed to reflect differences in the two programs and has increased the consistency of information being presented for DOE mixed wastes from operations and restoration activities.

DEVELOPMENT AND STATUS OF THE AL MIXED WASTE TREATMENT PLAN
OR
I LOVE THAT MOBILE UNIT OF MINE
Larbi Bounini
Grand Junction Project Office
Mona Williams
DOE-AL
Stanley Zygmunt
Los Alamos National Laboratory
ABSTRACT
Nine Department of Energy (DOE) sites reporting to the Albuquerque Office (AL) have mixed waste, waste that is chemically hazardous and radioactive. The hazardous waste regulations require the chemical portion of mixed waste to be treated to certain standards. The total volume of low-level mixed waste at the nine sites is equivalent to 7000 drums, with individual site volumes ranging from 1 gallon of waste at the Pinellas Plant to 4500 drums at Los Alamos National Laboratory. Nearly all the sites have a diversity of wastes requiring a diversity of treatment processes. Treatment capacity does not exist for much of this waste, and it would be expensive for each site to build the diversity of treatment processes needed to treat its own wastes. DOE-AL assembled a team that developed the AL Mixed Waste Treatment Plan that uses the resources of the nine sites to treat the waste at the sites. Work on the plan started in October 1993, and the plan was finalized in March 1994. The plan uses commercial treatment, treatability studies, and mobile treatment units. The plan specifies treatment technologies that will be built as mobile treatment units to be moved from site to site. Mobile units include bench-top units for very small volumes and treatability studies, drum-size units that treat one drum per day, and skid-size units that handle multiple drum volumes. After the tools needed to treat the wastes were determined, the sites were assigned to provide part of the treatment capacity using their own resources and expertise. The sites are making progress on treatability studies, commercial treatment, and mobile treatment design and fabrication.
To date, this is the only plan for treating waste that brings the resources of several DOE sites together to treat mixed waste. It is the only program actively

planning to use mobile treatment coordinated between DOE sites.

THE PROBLEM OF MIXED WASTE AT DOE-AL SITES

In response to frustration with a lack of progress in the Department of Energy (DOE) in treating and disposing of mixed waste in accordance with the Resource Conservation and Recovery Act (RCRA), Congress passed the Federal Facilitates Compliance Act (FFCAct) in 1992. Generally, mixed wastes are wastes that have a hazardous component, as defined in the RCRA regulations, and a radioactive component. The FFCAct requires each DOE facility to negotiate a site treatment plan (STP) with the state in which the facility is located. The STP must specify how and when mixed waste will be treated.

Nine sites that have mixed waste report to the DOE Albuquerque Office (DOE-AL):

- Grand Junction Project Office; Grand Junction, Colorado;
- Inhalation Toxicology Research Institute; Albuquerque, New Mexico;
- Kansas City Plant; Kansas City, Missouri;
- Los Alamos National Laboratory; Los Alamos, New Mexico
- Mound Facility; Miamisburg, Ohio;
- Pantex Plant; Amarillo, Texas;
- Pinellas Plant; Pinellas, Florida
- Sandia National Laboratories, California; Livermore, California; and
- Sandia National Laboratories, NM; Albuquerque, New Mexico.

The level and type of radioactive contamination group the waste into different categories based on DOE definitions. The nine sites have low-level mixed waste, and a few sites have transuranic mixed waste. Transuranic mixed waste will be handled following a national program developed by the DOE. Treatment is therefore needed for only low-level mixed waste.

Waste Volumes

Approximately 7000 drums of low-level mixed wastes are at the nine sites. Volumes at individual sites range from 1 gallon at Pinellas to 4500 drums at Los Alamos. Five of the nine sites have less than 50 drums of waste, and three of those have less than 10 drums. Few waste streams are greater than 50 drums. The wastes are diversified. Even sites with small volumes have waste that requires a diversity of treatment approaches. For example, the Grand Junction Project Office has less than 10 drums of waste made up of 19 waste streams.

The Problem

The problem is that various treatment processes are needed at most of the nine sites. The treatment must be implemented quickly to meet the intent of the FFCAct. Because the activity is funded by taxpayers and there are serious competing needs for tax dollars, the treatment must be implemented as inexpensively and efficiently as possible.

THE AL MIXED WASTE TREATMENT PLAN

The purpose of the AL Mixed Waste Treatment Plan is to use the resources of the nine sites to create real treatment capacity for mixed waste that minimizes the time and cost. Each site is responsible for negotiating a site treatment plan with its state agencies. The plan offers resources outside those of the individual sites that can be used in planning the site treatment plan.

Methodology for Developing the Plan

The plan was developed by the Treatment Selection Team: four representatives of the sites, two representatives of DOE-AL, and one consultant on regulatory affairs.

The overall approach used to develop the plan is that used in the classical solution of any engineering problem:

- define the problem;
- determine what is given to work with;
- determine basis for solution; and
- solve the problem.

In defining the problem, the team took an approach different from past efforts. The team visited each site and discussed the waste, existing and planned treatment, and site capabilities. Instead of reducing the information into computer forms, the information was recorded as text wherever possible. This approach was important in characterizing the waste because it created a visual picture of the waste and allowed the team to maintain the true identity and character of the waste throughout the development of the plan. A data sheet with text describing the waste is included in the plan document for each of the 141 waste streams.

In solving an engineering problem, engineers identify givens, things that affect

decision-making. The team then prepared fact sheets for information affecting decision-making and included those in the plan document.
Each team member reviewed all the waste data sheets and fact sheets so that all team members had a common background for problem-solving.

Developing the Basis

Developing a basis bounds a problem so that an engineer can define the problem to solve it. To bound this problem, the waste streams were divided into treatability groups that were the basis for solving the problem. The 141 individual wastes found at the sites were manually separated into categories, then waste streams, and finally waste substreams that were treatability groups. Each progressive step recognized the characteristics of the waste that affect treatment. The 48 waste substreams or treatability groups were arranged on matrix sheets that include the quantity and site identification number for each waste.
A base treatment was selected for each substream. Base treatment is not the best treatment or a selected treatment, but a treatment approach the team thought could handle all the wastes in substream. Base treatments were treatment approaches that the sites recommended or that the team felt could treat all the waste in the substream.
The validity of the substreams as treatability groups was verified by ensuring that each waste included in a substream could be treated using the base treatment.

Developing the Solution

Several ground rules were established for developing the plan. The treatment options considered were directed toward the volumes and waste types found at the DOE-AL sites. Treatment options evaluated must be implementable within five years. Treatment options considered must have a realistic approach to shipping waste; that is, shipping waste to commercial facilities for treatment or shipping small volumes of waste between DOE sites for treatability studies is reasonable, but shipping between DOE sites for treatment or disposal is not practical in the short term. The ground rule on shipping waste is based on input on the states' attitudes during site visits. Finally, common sense must be used in rating and selecting alternatives. Solutions must fit the problems.
Using criteria that addressed regulatory standards, public acceptance, safety, scalability, and probability of success, alternative treatment approaches were rated against the base treatment for each of the 48 waste substreams. The top three treatment approaches were ranked as first, second, or third. If two or more approaches were rated equally, both were given the same rating. A list was made for each treatment option, which was ranked as first, second, and third choice for each substream. Matrices were prepared showing the waste that could be treated with each treatment option. These matrices are essentially client lists for the treatment approaches that rated the highest.
The matrix sheets were laid out on a table. The team assessed whether any of the treatment approaches were unavoidable, things that had to be done regardless of what other treatment approaches were used. The unavoidable treatment matrices were saved. Next, the team determined whether there were any treatment approaches for which there was no other option or for which a site was well along in design and fabrication of treatment capacity. These were also selected. The team then determined whether there were any obvious winners, treatment approaches that handle appreciable volumes of waste and that were easily implemented. These were selected. The team looked for and rejected obvious failures, treatment approaches that handle limited wastes. The selection process left nine treatment approaches on the table. The team evaluated each of these treatments individually to determine whether they fit into an overall approach.
Using the waste matrices showing the volumes and locations of waste in each treatability group, the team analyzed each selected treatment option and determining how it should be used. The actions needed to implement the options were then assigned to the sites. Distribution of assignments was based on available resources site interest and site expertise. The assignments are summarized in Table I.

Summary of the Plan

The plan makes use of treatability studies, portable treatment units in sizes ranging from bench-scale to skid-sized units, off-site treatment capacity, and the ability to survey some waste out of the radioactive designation.
The plan defines an activity for each selected treatment option and assigns a site to be project manager for that activity. The plan does not give specific direction

about how each site completes its assignments but allows each site to use its own initiative to find the most efficient approach to completing the assignment.
The plan establishes an Overall Program Manager, the Grand Junction Project Office (GJPO), to implement the plan, coordinate overall activities, and maintain a master schedule. Support working groups quickly resolve issues related to implementation of the plan.
Problem Areas
The plan presents some new concepts that create problems.
Interdependency of sites. Each site has tried to be self-sufficient in its waste management activities. The plan requires that sites depend on one another to create treatment capacity. This approach raises questions about how the concept can be incorporated into the site treatment plan negotiations and who is liable if one site fails to meet a schedule affecting other sites.
Permitting portable treatment. Permitting portable treatment units is no worse than each site's permitting multiple treatment units individually. The plan raises a question about whether there is a more efficient way of permitting portable treatment units that recognizes the individual rights of the states.
Transportation of portable treatment units. Using portable treatment units means that the units are moved to the waste, rather than the waste being moved to treatment. What are the states' concerns about moving portable treatment units?
Orphaned waste. The plan is based on the characterization data available at the time of the site visits. The treatment options selected are appropriate for a variety of wastes. Even still, some wastes are expected to be orphaned as characterization improves and the design and implementation of treatment alternative progress. The plan makes the Overall Program Manager responsible for evaluating orphaned waste and for determining whether additional treatment options are needed.
APPLICABILITY
The plan has direct applications in the Department of Energy. Using the plan, five of the nine sites can treat their low-level mixed waste in two years using off-site commercial facilities and treatability studies. Within five years, enough treatment capacity can be available to treat the wastes at the remaining sites.
The plan also has broad applications elsewhere.
Other DOE sites with similar volumes and types of waste will be interested in the possibility of expanding the use of mobile treatment units other sites.
Equipment vendors will be interested in the types of equipment they can supply to support building the mobile treatment units.
Commercial mixed waste generators will be interested in the methodology, which applies to their mixed waste problems.
Commercial waste management firms will be interested because the plan defines the types and volume of waste planned for commercial treatment, and because the plan may offer opportunities for these firms to provide packaged mobile treatment units or to operate the units.
CURRENT STATUS
Each site has prepared a project implementation plan for its assignment, and GJPO has prepared an overall schedule. The status of individual assignments is summarized in Table II. All the sites have used the AL Mixed Waste Treatment Plan as the basis for STPs.
Support working groups have prepared recommendations for approaches to permitting and preparing safety documentation for mobile treatment units. A recommendation is complete for supporting design and fabrication needs at sites needing help. A draft recommendation for using Type A containers for transporting and storing mobile treatment units is under review. Progress is being made on NEPA documentation, commonality of design issues, decontamination of units, and the feasibility of using portable enclosures.
The Portable Treatment Working Group developed a draft recommendation for maintaining and operating the mobile treatment that is being reviewed. The group strongly recommends that a central organization, either a DOE site or a commercial firm, be put in charge of all the mobile units providing treatment services to the sites.
CONCLUSIONS
Using commercial treatment and treatability studies, the AL Mixed Waste Treatment Plan can, in two years, bring five of the nine sites into compliance with the land disposal restrictions for storage under the Resource Conservation and Recovery Act.

Enough capacity will be created within five years to treat all the remaining mixed waste. The plan presents an economic alternative to treating mixed waste that can be expanded to other DOE facilities.

MEDIATED ELECTROCHEMICAL OXIDATION AS AN ALTERNATIVE TO INCINERATION FOR MIXED WASTES*

Zoher Chiba

Lawrence Livermore National Laboratory
Livermore, CA 94550

ABSTRACT
Mediated Electrochemical Oxidation (MEO) is an aqueous process which oxidizes organics electrochemically at low temperatures and ambient pressures. The process can be used to treat mixed wastes containing hazardous organics by destroying the organic components of the wastes. The radioactive components of the wastes are dissolved in the electrolyte where they can be recovered if desired, or immobilized for disposal.
The process of destroying organics is accomplished via a mediator, which is in the form of metallic ions in solution. The ions, initially at their lower valence state, are oxidized to a higher valence state at the anode surface. The oxidized ions in turn destroy organics throughout the bulk of the fluid. This results in a very efficient process, since the system can be optimized to oxidize the mediator at the anode, while the organics are dispersed at low concentrations throughout the anolyte. At Lawrence Livermore National Laboratory (LLNL) we have worked with worked with several mediators, including silver, cobalt and cerium. We have tested mediators in nitric as well as sulfuric acids.
We have recently completed extensive experimental studies on cobalt-sulfuric acid and silver-nitric acid systems for destroying the major organic components of Rocky Flats Plant combustible mixed wastes. The study was conducted on small-scale laboratory equipment and on a bench-scale facility that incorporated an industrial-sized electrochemical reactor. Organics tested were: Trimsol (a cutting oil), cellulose (including paper and cloth), rubber (latex), plastics (Tyvek, polyethylene and polyvinyl chloride) and biomass (bacteria). The process was capable of destroying almost all of the organics tested, attaining high destruction efficiencies at reasonable coulombic efficiencies. The only exception was polyvinyl chloride, which was destroyed very slowly resulting in poor coulombic efficiencies.
Besides the process development work mentioned above, we are working on the design of a pilot-plant scale integrated system to be installed in the Mixed Waste Management Facility (MWMF) at LLNL. In addition to the electrochemical process, this system will comprise the requisite secondary processes to replenish the reagents for continuous operation. These include processes for electrolyte regeneration and mediator recovery. The system will also be completely integrated with upstream and downstream processes (for example, feed preparation, off-gas and water treatment, and final forms encapsulation). The conceptual design for the MEO-MWMF system has been completed and preliminary design work has been initiated. Demonstration of the process with low-level mixed wastes is expected to commence in 1998.

INTRODUCTION
Mediated Electrochemical Oxidation (MEO) is an aqueous process which destroys hazardous organics by oxidizing a mediator at the anode of an electrochemical cell; the mediator in turn oxidizes the organics within the bulk of the electrolyte. With this process organics can be nearly completely destroyed, that is, the carbon and hydrogen present in the hydrocarbon are almost entirely mineralized to carbon dioxide and water. The MEO process is also capable of dissolving radioactive materials, including difficult-to-dissolve compounds such as transuranic oxides. Hence, this process can treat mixed wastes, by destroying the hazardous organic components of the waste, and dissolving the radioactive components. The radioactive material can be recovered if desired, or disposed of as non-mixed radioactive waste. The process is inherently safe, since the hazardous and radioactive materials are completely contained in the aqueous phase, and the system operates at low temperatures (below 80C) and at ambient pressures.

Mediated Electrochemical Oxidation was originally developed for dissolution of difficult-to-dissolve forms of transuranic oxides, but later was found to be effective for oxidizing many organic materials. Extensive development work on this technology has been carried out at PNL and at LLNL, in the United Kingdom, and in France (1-4). At LLNL, work in the past was concentrated on understanding the basic science and modeling the dissolution and destruction mechanisms. To this end, the reaction rates of water with Ag(II) were measured using spectrophotometric methods, and the diffusivity of silver ions in nitric acid was estimated using a rotating disk electrode (5). Other mediators studied were cobalt, iron and cerium. Mediators were tested in nitric and sulfuric acids. The breakdown of organics, such as ethylene glycol, was modeled in detail with the formation and eventual destruction of intermediate compounds (6-8). Dissolution of transuranic oxides was also modeled and system studies were conducted to optimize system operating parameters (9,10). Also, a full-scale system was built for transuranic oxides dissolution and tested with surrogate materials (11).

More recently work at LLNL has focused on the destruction of the organic components of major low-level mixed wastes streams at the Rocky Flats Plant (12,13). The work comprised the destruction of Trimsol, a cutting oil; various cellulosic substances, including wipes and cloth; biomass; and rubber (latex) and plastics (Tyvek, polyethylene and polyvinyl chloride). The emphasis of the work was on process development, that is, the determination of optimal process conditions for destruction of each organic. The parameters which can be controlled in the MEO process are system temperature, strength of the electrolyte, type of mediator and electrolyte, and current density at the electrodes. The destruction rates of various organics and the destruction and coulombic efficiencies were measured as a function of the process parameters which were varied in each experiment.

The destruction efficiency in this work refers to the total destruction of the organics, that is, the degree of complete mineralization of the carbon in the organics to carbon dioxide. Hence, it is a more stringent measure of destruction than the commonly used Destruction & Removal Efficiency (DRE). The DRE measures the destruction or removal of the original organics only, regardless of whether they are merely transformed into other organics, or are completely destroyed.

The coulombic efficiency refers to the theoretical amount of electric charge needed to destroy the organics versus the actual amount required. Usually the coulombic efficiency will be less than 100 percent since the total destruction of the organic requires a number of steps, some of which may be limited by homogeneous or heterogeneous (surface) kinetics. In such cases, so-called parasitic reactions of the mediator with the water in the electrolyte will consume some of the current. However, it should be noted that if the decrease in coulombic efficiency is due to operation of a cell above its limiting current, oxygen will be generated at the anode. This will not only waste current but will also require higher cell voltages. The combined effect of both will result in much higher power consumption. At LLNL great care has been taken to operate the cells at or below their limiting current. The limiting current is the maximum amount of useful current at the anode which is utilized to convert the mediating ions from their lower to their higher valence states. It depends upon the anode area and geometry, the mediator concentration, the mechanics of flow, and electrolyte properties that govern diffusion of the mediator to the electrode surface.

PROCESS CHEMISTRY

The chemical reactions given here are for a process based on silver as mediator and nitric acid as electrolyte. In addition to the electrochemical process, the secondary processes to regenerate the reagents and remove secondary wastes are discussed.

Starting with the reactions in the electrochemical reactor, silver in the form of Ag(I) is oxidized to Ag(II) at the anode:

$$Ag^{+} \rightarrow Ag^{++} + e^{-} \quad (1)$$

The redox potential for this reaction is 1.98 V with respect to a standard hydrogen electrode. The high potential allows the Ag(II) to attack organics, eventually converting the organic carbon to carbon dioxide. For example, for cellulose:

$$C_6H_{10}O_5 + 24Ag^{++} + 7H_2O \rightarrow 6CO_2 + 24Ag^{+} + 24H^{+} \quad (2)$$

The Ag(I)/Ag(II) redox potential is high enough to break down water molecules. Although this is a competing reaction which consumes Ag(II) ions, it may not be entirely parasitic since OH radicals may be formed as intermediate products. The complete reaction is written down as:

$$2H_2O + 4Ag^{++} \rightarrow O_2 + 4Ag^{+} + 4H^{+} \quad (3)$$

Ag(II) is very reactive and will dissolve many radioactive compounds which are otherwise very hard to dissolve. For example, many transuranic oxides are notoriously difficult to dissolve completely even in strong solutions of nitric and hydrofluoric acids. However, Ag(II) very efficiently dissolves the oxides converting them to ionic form:

$$MO_2 + 2Ag^{++} \rightarrow MO_2^{++} + 2Ag^{+} \text{ Eq.} \quad (4)$$

For the silver-nitric acid system, the fluids on the anode and cathode sides of the electrochemical cells must be kept separate, since nitrous acid which is produced at the cathode reduces Ag(II). The silver is introduced only at the electrolyte on the anode side (anolyte), and the electrolyte on the cathode side (catholyte) is separated by means of a porous divider or an ion selective membrane. The reactions shown above are those that occur at the anode or in the anolyte.
The hydrogen ions formed in the reactions above migrate through the divider to the cathode. There the nitric acid is reduced to nitrous acid. Hydrogen gas is not formed at the cathode unless the concentration of nitric acid there is low (below 2 M).

$$HNO_3 + 2H^{+} + 2e^{-} \rightarrow HNO_2 + H_2O \quad (5)$$

This reaction indicates the secondary processes required to support the primary electrochemical process. First, the nitrous acid generated must be converted back to nitric acid. Otherwise the nitrous acid will eventually decomposes to form NOx:

$$2HNO_2 \rightarrow H_2O + NO + NO_2 \quad (6)$$

Contacting the nitrous acid with oxygen regenerates the nitric acid, and prevents the formation of NOx:

$$2HNO_2 + O_2 \rightarrow 2HNO_3 \quad (7)$$

However, since oxygen is only very sparingly soluble in the solution, typical contactors in the form of packed bed columns would have to be very tall to attain reasonable conversion efficiencies. A turbo-aerator was developed at LLNL which achieves very high efficiencies in a small volume (14). The turbo-aerator draws the gas and the fluid together, and passes them through a row of stator blades which disperses the gas into very small bubbles. The intimate mixing and the high surface area contribute to measured efficiencies of 95 to 99%. The contactor is installed in the catholyte flow loop.
In addition to the nitrous acid, reaction 5 shows that water is generated on the cathode side. Although water is broken down on the anode side as shown in reactions 2 and 3, there is a net accumulation of water in the system when hydrocarbons are destroyed. Essentially, all the hydrogen present in the organic molecule is converted to water, which must be removed from the system. This is done using an evaporator in conjunction with a fractionation column. The electrolyte is passed through the evaporator and a small amount is evaporated off, enough to remove the extraneous water. The concentrated electrolyte is returned to the cells. The vapor from the evaporator contains both water and nitric acid, which are separated in the fractionation column. The column can be designed to produce water which is directly sewerable, while the acid is reused.
Besides the secondary systems to convert the nitrous acid and remove the water, a system is required for silver recovery. When chlorinated organics are destroyed in the anolyte, chloride ions are formed which immediately combine with silver ions to

form insoluble silver chloride. The silver chloride precipitate is removed from the electrolyte by settling or centrifuging. It is then introduced into a hot solution of sodium hydroxide and hydrogen peroxide. The silver chloride is reduced to silver:

$$AgCl + NaOH + H_2O_2 \rightarrow Ago + NaCl + H_2O + O_2 \quad (8)$$

The silver is filtered or centrifuged and dissolved in nitric acid for reuse. The chloride remaining in solution is in the form of salt (sodium chloride). It is dried and disposed of via polymer encapsulation.
Since silver chloride is almost insoluble, it affords a method for removal of silver from the electrolyte, when desired. For example, when the electrolyte becomes loaded with dissolved radionuclides and metals, they must be removed; but the silver in solution must be removed first for reuse. By adding chlorides into the electrolyte, the silver precipitates out and is separated. Then the solution is boiled off until almost dry by passing it through the thin film evaporator. The evaporator bottoms are carried out, and if desired, the radionuclides can be recovered by ion exchange. If recovery is not desired or feasible, the radioactive material is disposed of via grouting or ceramicization.
Hence, the MEO primary (electrochemical) process requires secondary processes for the conversion of nitrous acid to nitric acid, recovery of silver, and regeneration of nitric acid by removal of water. A functional flowsheet showing the relation of these processes is shown in Fig. 1. The flowsheet also shows the secondary waste generated and suggests further treatments that may be required before they are discharged or disposed. A conceptual design for the integrated MEO system based on this flowsheet has been completed for the Mixed Waste Management Facility (MWMF) at LLNL. Preliminary design for the system is currently underway.

EXPERIMENTAL WORK AND RESULTS
The experiments performed for electrochemical destruction of organics were of two types. A large number of small-scale experiments were performed where the process parameters could be easily varied. They were carried out in laboratory-sized H-cells with a capacity of destroying approximately 0.5 g of organics at a time in a batch mode. These experiments gave a preliminary assessment of the important process parameters and their influence on destruction rates. A smaller number of experiments were then carried out in a bench-scale facility containing an industrial-sized commercial electrochemical cell. This system was built with an Imperial Chemical Industries (ICI) FM-21 electrochemical reactor, which is widely employed in chlor-alkali chemical plants. The reactor presently contains a cell stack composed of two anodes and three cathodes. It has a capacity of 3000 A of limiting current at mediator concentrations of 0.5 M, and can destroy up to 0.5 kg/h of organics in either continuous or batch modes of operation. The cell voltage drop at maximum current is below 2 V. The bench-scale experiments were conducted to demonstrate organics destruction on large industrial-scale equipment so results could be confidently extrapolated to plant-sized operations.
The parameters varied in the small-scale experiments were temperature, acid concentration and acid-mediator combination. Two types of acid-mediator combinations were tested: silver in nitric acid, and cobalt in sulfuric acid. The concentration of the nitric acid was varied from 4 to 10 M, and that of sulfuric from 4 to 6 M. The temperature of the electrolyte was varied between 20 and 70 C. The concentration of the mediator in all tests was 0.5 M. In general, the results indicated that higher temperatures, higher acid concentrations and a more aggressive acid-mediator combination (silver with nitric acid) resulted in higher destruction rates. An example of the influence of these parameters is shown in Fig. 2 for destruction of cellulose. Here the initial destruction rate of cellulose is plotted as a function of temperature. Since the destruction rate is directly proportional to the limiting current in the cell it is normalized by the current. It is seen from Fig. 2 that the destruction rate rises steeply with temperature, especially for the cobalt-sulfuric acid system. The silver-nitric acid system outperforms the cobalt-sulfuric acid system, although they tend to converge at higher temperatures and acid concentrations. The effect of acid concentration is not very strong for cellulose, but that is not the case with all organics.
Fig. 2.

Fig. 2. Cellulose Destruction in Small-Scale Experiments.
Various organics of interest to Rocky Flats Plant were tested for destruction using the MEO process. These included different types of cellulosic substances (wipes and cloth), Trimsol (a cutting oil), rubber and plastics (latex, polyethylene, polyvinyl chloride and Tyvek), and biomass. A comparison of the destruction rates of the organics tested are shown in Table I. The results in the table are for the silver-nitric acid system at high acid concentrations (8-12 M) and high temperatures (70 C).It is seen that reasonable destruction rates were achieved for most organics tested except for polyvinyl chloride.
In addition to the destruction rates, the coulombic and destruction efficiencies of the process are of interest.In general, the destruction efficiency increases as more current is passed through the system, that is, with a decrease in coulombic efficiency. The results of the trade-off between destruction and coulombic efficiencies are shown in Fig. 3 for Trimsol and Fig. 4 for cellulose. These results are from experiments conducted in the bench-scale system with silver and nitric acid at acid concentrations of 8 M and temperatures of 70 C. It is seen in both cases that destruction efficiencies of 99% or higher can be achieved at coulombic efficiencies of 70%. To obtain destruction efficiencies of 99.99% requires coulombic efficiencies in the range of 40 to 50%.

CONCLUSIONS
The Mediated Electrochemical Oxidation (MEO) process is capable of destroying a wide variety of organics. Many such organics, contaminated with radioactive and RCRA-listed materials, are currently being stored at sites throughout the DOE Complex awaiting suitable means of disposal. MEO can be used as an alternative to incineration for treating these mixed wastes by destroying the organic components of the wastes. MEO mitigates some of the perceived problems with incineration, since it operates at low temperatures and pressures, and since the radioactive materials are contained in an aqueous media.
The primary electrochemical process requires a number of secondary processes to recycle the reagents. The secondary processes include removal of water and inorganics (including radionuclides) from the electrolyte, regeneration of the acid and mediator recovery. A conceptual design for the integrated process has been completed, and work has been initiated on the preliminary design to be installed in the Mixed Waste Management Facility (MWMF) at LLNL. MWMF is expected to demonstrate the treatment of low-level mixed wastes using the MEO process starting in 1998.

ABSTRACT

The Rocky Flats Environmental Technology Site produces a variety of wastes which are amenable to micro-encapsulation in cement. Portland cement is an inexpensive and readily available material for this application. The Waste Projects (WP) group at Rocky Flats evaluated cementation to determine its effectiveness in encapsulating several wastes. These included waste analytical laboratory solutions, incinerator ash, hydroxide precipitation sludge, and an acidic solution from the Delphi process (a chemical oxidation technology being evaluated as an alternative to incineration). WP prepared surrogate wastes and conducted designed experiments to optimize the cement formulation for the waste streams. These experiments used a Taguchi or factorial experimental design; interactions between the variables were also considered in the testing. Surrogate waste samples were spiked with various levels of each of six Resource Conservation and Recovery Act (RCRA) listed metals (Cd, Cr, Ba, Pb, Ni, and Ag), cemented using the optimized formulation, and analyzed for leach resistance using the Toxicity Characteristic Leaching Procedure (TCLP). The metal spike levels chosen were based on characterization data, and also based on an estimate of the highest levels of contaminants suspected in the waste.
This paper includes laboratory test results for each waste studied. These include qualitative observations as well as quantitative data from TCLP analyses and environmental cycling studies. The results from these experiments show that cement stabilization of the different wastes can produce final waste forms which meet the current RCRA Land Disposal Restriction (LDR) requirements. Formulations that resulted in LDR compliant waste forms are provided. The volume increases associated with cementation are also lower than anticipated. Future work will include verification studies with actual mixed radioactive waste as well as additional formulation development studies on other waste streams.

INTRODUCTION

The Rocky Flats Environmental Technology Site (Rocky Flats) currently generates and/or stores mixed wastes which are subject to Resource Conservation and Recovery Act (RCRA) Land Disposal Restriction (LDR) treatment requirements. Cementation is a technically viable, economic solidification treatment process for some of these wastes and is a widely accepted waste management method (1). It is one of several solidification technologies proposed to bring these wastes into compliance with

RCRA-LDR requirements. Cement is inexpensive, readily available, solidifies under ambient conditions, and is capable of immobilizing RCRA hazardous metals in the wastes. Cements have been used for approximately 2000 years and show good durability to weathering (2-4) making this an attractive technology for waste encapsulation. Cementation of low-level radioactive and mixed waste forms (wastes containing both chemically hazardous and radioactive constituents) offers long term stability at low cost. This technology has been proven for several waste streams at the Rocky Flats Site including a spray dried salt/brine waste and multiple analytical laboratory waste solutions. These low level mixed wastes (< 100 pCi/g) are currently being cemented at a production scale to produce certifiable waste forms. This report summarizes cementation studies performed on five waste streams at the Rocky Flats Environmental Technology Site in Fiscal Year 1994.

DISCUSSION

Cementation development activities focused on five waste streams: analytical laboratory solutions, silver nitrate solutions, fluidized bed incinerator (FBI) ash, hydroxide precipitation sludge, and an acidic solution from the Delphi process. Activities on each of these wastes are discussed separately below. Please note that the term "percent" or "%" refers to weight percent unless noted otherwise.

Analytical Laboratory Solutions

The analytical laboratory waste solutions at Rocky Flats are generally acidic and consist of an aqueous solution of salts with a low level of plutonium (< 100 pCi/g). They also contain various RCRA listed toxic metals including silver (Ag), nickel (Ni), cadmium (Cd), chromium (Cr), barium (Ba), and lead (Pb). The waste must be neutralized prior to cementation; the neutralization process causes the dissolved metals to precipitate as oxides or oxyhydroxides (5) which reduces the solubility and mobility of the metals in the alkaline cement matrix (6). The treated waste must be RCRA-LDR compliant and pass the Toxicity Characteristic Leaching Procedure (TCLP) test. The cement,s alkalinity further neutralizes acidic solutions which could degrade the cement structure and increase the leachability of these RCRA constituents. After the waste is neutralized, the solution is poured into a 55-gallon drum two-thirds full of type I/II cement and Ramcote 1200 and is manually stirred in a production-scale operation. Each drum is capable of treating approximately 80 to 90 liters of waste solution.

Waste Projects conducted two sets of bench-scale experiments to evaluate the effectiveness of the process. The first experiment was a TCLP evaluation of the cemented waste form prepared using a spiked surrogate waste solution. The surrogate waste was a mixture of water, sodium chloride, potassium nitrate, heavy metal compounds (Ag = 5 mg/L; Ni = 10 mg/L; Cd = 50 mg/L; Cr = 300 mg/L; Ba = 300 mg/L; and Pb = 400 mg/L) , and sodium hydroxide. The surrogate composition was based on characterization data from the actual waste. The surrogate solution was prepared by dissolving appropriate quantities of the heavy metal compounds in 500.0 grams of distilled water. Sodium chloride (90.0 grams) and potassium nitrate (80.0 grams) were then added, followed by sodium hydroxide (2.0 grams). The temperature and pH were measured at each stage. The solution was then divided into five lots and added to the cement/Ramcote mixture.

These samples were prepared using surrogate waste spiked with "worst case" levels of the metals based on characterization data from actual waste laboratory solutions. This testing was used to confirm that the production-scale process produced a waste form with adequate leach resistance (7). A second series of experiments investigated the capability of the production-scale process to treat wastes contaminated with the six RCRA listed heavy metals but at significantly higher levels. The surrogate waste solution was spiked with Ag, Ni, Cd, Cr, Ba, and Pb at levels of 1,000, 5,000, and 10,000 mg/L each, and mixed with the cement/Ramcote mixture as before.

The samples were mixed by repeatedly inserting and withdrawing a metal spatula to simulate the production process. The samples were cured for 24 hours in an oven heated to 50C, and then transferred to the Environmental Technologies (ET) group within Rocky Flats Technology Development for TCLP testing. ET prepared the samples per standard TCLP requirements with leach levels of metals measured with an Inductively Coupled Plasma (ICP) spectrometer. The numeric average (xavg) and standard deviation (s) or pooled standard deviation (sp) of the leachability for each element were calculated to determine the upper confidence limit (UCL) of the leachability at a 90% confidence level using the following equations (8,9):

xavg = xleachability/n,

(1)
where, n = number of data points,
90% UCL = avg + (1.2804 s), or (2)
90% UCL = avg + (1.2804 sp).
(3)
The 90% UCL defines the upper leachability limit assuming the leachability follows a normal distribution. The numeric average and upper limit can be directly compared to the maximum allowable limits established by the Environmental Protection Agency (EPA) (10). The Colorado Department of Public Health and the Environment (CDPHE) is responsible for enforcing RCRA in Colorado. CDPHE expects Rocky Flats to adopt the Universal Treatment Standards (UTS) as established by the EPA.
The TCLP results from the 1,000 ppm spike, 5,000 ppm spike, and 10,000 ppm spike are shown in Table I. These results show excellent leach resistance for all metals tested up to 10,000 ppm with the 90% UCL being below the treatment standard for all three experiments. Data from the initial experiment also passed the TCLP testing but have not been included.
TABLE I
Silver Nitrate Studies
At Rocky Flats, silver nitrate is a small volume waste stream which is difficult to treat. This waste consists of several bottles of radioactively contaminated solutions with silver concentrations as high as 368,000 ppm. Recovery of the silver is not feasible due to radioactive contamination. This waste is scheduled to be processed in the previously described production process for treating analytical laboratory solutions. Surrogate solutions with a similar composition as the analytical laboratory solution were prepared. These solutions were spiked solely with silver in the form of $AgNO_3$ at concentrations of 100, 1,000, 10,000, 50,000, 100,000, and 500,000 mg/L, respectively. The required quantities of silver nitrate were dissolved in 500.0 grams of distilled water after which 90.0 grams of NaCl and 80.0 grams of KNO_3 were added. Finally, 2.0 grams of NaOH were added to neutralize the solution. Each solution was added to the cement/Ramcote mixture, mixed, cured at 50C for 24 hours, and transferred to ET for TCLP testing.
The results of this TCLP testing are shown in Table II. Analysis of the data shows all samples to pass the UTS for Ag at levels up to 100,000 ppm. Samples spiked with 500,000 ppm Ag, however, failed the TCLP test. These samples had a brown interior and a metallic-like coating which was presumably silver metal from a reduction of Ag^+ ions to Ag. It is believed that the NaCl reacted with $AgNO_3$ to form AgCl which is generally less soluble (11). As the amount of $AgNO_3$ was increased to the higher levels, however, there was insufficient NaCl available in solution to form AgCl. This resulted in excess Ag being available in the 500,000 ppm spike (as a metal or soluble compound) which caused this sample to fail the TCLP test. The 90% UCL was also noted to be unusually high for samples spiked from 100 to 100,000 ppm. This was due to excessive scatter in the TCLP data which skewed the pooled standard deviation.
TABLE II
Fluidized Bed Incinerator (FBI) Ash
Rocky Flats produced a Fluidized Bed Incinerator (FBI) ash from the fluid bed incineration of compressor oils, crankcase oils, office trash, solid waste, and diesel fuel. This ash also contains a significant amount of sodium carbonate (Na_2CO_3), which was used as an acid sorbent in the bed, and spent chromia-alumina (Cr_2O_3-Al_2O_3) oxidation catalyst.
For the cementation of incinerator ash, a Taguchi experiment was designed to evaluate fly ash loading (0%, 12%, and 23%), waste loading level (20%, 25%, or 30%), water/cement ratio (0.5, 0.6, or 0.7), and cement type (type I/II or type V). These levels were based on preliminary testing with a surrogate ash which had similar physical properties to the actual ash waste. Attributes to be analyzed were mix viscosity, waste form density, waste volume increase, and resistance to degradation after freeze-thaw cycling. This experiment did not consider interactions between the variables. Nine experimental runs were required to complete this test phase.
A "best case" (low catalyst-high carbonate) and "worst case" (high catalyst-low carbonate) surrogate ash samples were prepared by the Technology Development/Waste Projects group based on process knowledge. These formulations are shown in Tables III and IV. Samples of each were prepared and spiked with heavy metal compounds of Ag, Ba, Cd, Pb, and Ni; the spike level for each was 1,000 ppm of each heavy metal.

Cr was spiked into the surrogate in the form of the chromia-alumina catalyst. These surrogate wastes were mixed into the cement using a 30% waste loading, cured at 50C, and submitted for TCLP analysis. The results from these tests showed all heavy metal concentrations, except for Cr, to be below the treatment standard limits (refer to Table V). Additional samples were prepared with only the catalyst and cemented using waste loadings of 20% and 30%. The results from these tests showed the 20% waste loading yielded a waste form which met the treatment standard of 5.0 ppm for Cr (refer to Table V). The 30% waste loading sample again failed the TCLP test for Cr. The cause for this is still being investigated. In future studies, ash will be mixed with cement using a 20% waste loading and a water/cement ratio of approximately 0.6. This work is scheduled to be conducted in mid-1995.

TABLE III

TABLE IV

TABLE V

Hydroxide Precipitation Sludge

The hydroxide precipitation sludge was created from a process in Building 374 which consisted of adding magnesium sulfate, calcium chloride, iron(III) sulfate, and diatomaceous earth to an aqueous waste stream entering the building. The waste stream originated from several diverse locations such as storm water runoff and the analytical laboratories, process aqueous waste. Potassium hydroxide was added to the waste until the pH was greater than 10.5 which created a precipitation of magnesium, calcium, and iron ions along with most other metallic cations in the waste stream. The sludge was produced at a rate of approximately 18.5 m3 per year when the process was operational (pre-1990). Because the sludge is a mixed waste, it must be treated to meet RCRA-LDR standards. Process knowledge indicated that the waste stream had no appreciable concentrations of ions except for the various nitrate salts. Therefore, a surrogate waste was developed which was based almost entirely on the chemical additions to the waste stream and represents the composition of the waste prior to any pre-treatment. The composition of the surrogate waste is shown in Table VI.

TABLE VI

For cementing the sludge, a Taguchi experiment was designed to evaluate the effect of the following independent variables: class F fly ash loading (0% or 23%), waste loading (20% or 30%), water/cement ratio (0.5 or 0.6), and cement type (type I/II or type V). Interactions between specific variables (fly ash loading-waste loading, fly ash loading-water/cement ratio, and waste loading-water/cement ratio) were also considered. Waste loading considered the waste as a dry powder. The attributes tested were mix viscosity, waste form density, waste volume increase, and sample weight change after 12 freeze-thaw cycles. Determining the effect of changing the independent variables on the attributes required calculating the degrees of freedom (DF), response total (RT), correction factor (CF), total sum of squares (SSTotal), individual factor sum of squares (SSFactor), and mean square (MS). These are defined below:

DF = n - 1 (DF= 2 for each factor and n = number of trials), (4)

RT = Summation () of the individual responses,
(5)

CF = (RT)2/n,
(6)

SSTotal = (Response2) - CF,
(7)

SSFactor = (Factor at level 1 - Factor at level 2)2/
Number of responses,
(8)

MSFactor = SSFactor/DF
(9)

The pooled error is used to calculate the F-Ratio per the following equation:

F-Ratio = MSFactor/DFPooled error
(10)

F-Table values were chosen at a pre-determined 95% confidence level.(8)

Analysis of variance (ANOVA) tables were prepared to analyze these attributes to determine the significance of the independent variables and the interactions. For viscosity, the viscometer reading at 300 revolutions per minute (rpm) was selected as the point of reference as the cement tends to gel at lower viscometer settings

thus increasing the measurement error. Freeze-thaw cycling consisted of freezing the samples at -30C for 24 hours followed by thawing the samples at 50C for 24 hours to complete one freeze-thaw cycle. This process was completed for 12 cycles for the samples. The sample weight percent change was chosen as the parameter to be evaluated during freeze-thaw cycling because the samples were kept in the plastic vials during the tests. Any dimension changes in the samples would be masked by the presence of the plastic shell. ANOVA tables for cement density, waste percent volume increase, and final percent weight change (12 completed freeze-thaw cycles) are shown in Tables VII-IX.

TABLE VII

TABLE VIII

TABLE IX

Statistical analysis showed that none of the independent variables had a significant effect on the cement mix viscosity. The variation in the viscosity was insufficient to produce a significant variable. Observations indicated that batches with higher waste loadings and lower water/cement ratios yielded a more fluid mix when fly ash was incorporated. This is due to the lubricating properties of the fly ash particles. As expected, additional water in the mix made it less viscous, while higher waste loadings caused the mixture to thicken. The only batch which did not yield a workable mixture was that with a low water/cement ratio and a high waste loading. This produced a tacky viscous mixture which had poor flow characteristics. Some variables, while not significant with respect to mix viscosity, are known to improve the mixing consistency. The water/cement ratio will be important during scaled mixing using conventional mixing equipment. The Hobart mixer used in laboratory studies is capable of adequately mixing all batches with little or no problem since it is a robust mixer which can tolerate wide ranges of viscosities. Scaling the process to a larger mixer may require compositional adjustments as the larger mixers are not usually as rugged as the Hobart. Poor mixing would result in a non-homogeneous waste form; therefore, a minimum water/cement ratio of 0.6 is recommended for future testing.

The statistical analysis of the waste form density showed three variables to be significant (refer to Table VII). These variables were fly ash addition (A), waste loading (B), and water/cement ratio (C). Cement type (D) was not significant. These results allow one to estimate and predict the waste form density based on these results. This is accomplished by averaging the density obtained for a given level 1 value and also at the level 2 value. For example, the level 1 average for the 0% fly ash was 1.91 gm/cc whereas the average value for the level 2 experiments (23% class F fly ash) was 1.83 gm/cc. These results are shown graphically in Fig. 1. One drawback to this modeling approach is that there are only two data points; therefore only linear relationships are considered. A confirmation test showed moderate agreement with the experimental results (refer to Fig. 1).

Fig. 1.

For waste loading, the average density obtained for a 20% waste loading was 1.84 gm/cc, while the average density at a 30% waste loading was 1.90 gm/cc. These results are shown graphically in Fig. 2. Confirmation tests show a linear relationship and excellent agreement between the two sets of data. Increasing the waste loading increases the waste form density, the packing efficiency, and the final weight of the waste container. The differences observed would result in a minimal increase in weight for a 55-gallon waste drum. Finally, the additional water causes the cement mix density to decrease. The average density obtained at a water/cement ratio of 0.5 was 1.91 gm/cc while the average density at a water/cement ratio of 0.6 was 1.83 gm/cc.

Fig. 2.

For waste volume, the statistical analysis of the data showed only one variable, waste loading (B), to be a significant (refer to Table VIII). Volumes were extrapolated from known quantities or calculated using density and mass measurements. These calculations were made using the following equations:

Waste Form Volume = Total Mass/Average Waste Form Density, and (11)

% Volume Change = (Final Volume - Initial Volume)/Initial Volume x 100. (12)

Increasing the waste loading from 20% to 30% substantially decreased the volume of the cemented waste form. The average volume increase at a 20% waste loading was 133% when considering the volume of the waste as a slurry (waste plus the addition of 40% water) while a 30% dry waste loading resulted in a volume increase of only 50%

(refer to Fig. 3). Data obtained during confirmation tests showed excellent confirmation of these results. These predictions can be used to minimize the volume increase of the final waste form to maximize storage space without sacrificing the durability of the waste form. The volume increases observed in this testing are sufficiently low to make cementation a viable waste stabilization technology for the sludge waste.

Fig. 3.

The statistical analysis of the waste form weight change after 12 freeze-thaw cycles showed two variables to be significant at a 95% confidence level (refer to Table IX). These variables were waste loading (B) and water/cement ratio (C). The results predict that increasing the dry powder waste loading from 20% to 30% decreases the weight loss. Data obtained during this experiment showed the weight loss to decrease from 2.76% to 1.45%. This is shown graphically in Fig. 4. The reduced weight loss is due to the reduced moisture content that results from increasing the waste loading; the weight loss was attributed primarily to evaporation from the sample and not sample degradation. Likewise, increasing the water/cement ratio caused the weight loss to increase which again was due to evaporation from the material even though efforts were made to keep the vials sealed during testing. The data obtained during this experiment showed the weight loss to increase from 1.83% to 2.53% by increasing the water/cement ratio from 0.5 to 0.6.

Fig. 4.

Visual examination of the freeze-thaw samples showed no noticeable physical degradation. These freeze-thaw samples were sealed in plastic vials during cycling to minimize evaporation. Visual examination of samples exposed to the atmosphere showed minor surface cracking on samples containing class F fly ash and a 20% dry powder waste loading. It was possible to fracture these samples by hand with some effort. This was not possible on samples prepared using cement only. This is probably due to the high fly ash loading level which lowered the cement hydration and decreased the strength of the samples. The exposure cracking should not present a problem based on current LDR requirements with the waste form sealed in a drum or crate (12). There was also significant salt migration to the top and side surfaces of samples not containing fly ash. The presence of the fly ash in the mix tends to reduce the pore pressure within the samples and thereby decrease the migration of salt and moisture to the outer surface.

As part of the evaluation of the sludge, specimens were prepared and submitted for TCLP analysis. Heavy metals (Cd, Cr, Ba, Pb, Ni, and Ag) were spiked at a level of 1,000 ppm based on an aqueous sludge waste (sludge powder with 40% added water). This represents an extreme value as no appreciable heavy metal ions are in the waste based on process knowledge. An initial set of five samples was prepared and mixed by hand using a 30% dry powder waste loading and a water/cement ratio of 0.55. The higher water/cement ratio was used to yield a more fluid mix. The results (refer to Table X) show good leach resistance for all metals but lead. Five of the six TCLP data points for lead were well below the established treatment standard. It was believed that the one non-compliant point was an anomaly, so the test was repeated and all data points were well below the treatment standard value. This test was repeated using a 20% waste loading and a 30% waste loading with fly ash partially substituted for cement (refer to Table X). When the standard deviation was pooled and the isolated data point for lead was excluded, the leachability for lead was below the allowable limit of 0.37 ppm.

TABLE X

Samples of the cemented surrogate bypass sludge waste were analyzed by x-ray diffraction (XRD) and scanning electron microscopy (SEM) to detect the possible presence of expansive crystalline phases in the cemented waste. These analyses were conducted approximately 6 months after the experiment had been completed since these phases typically require significant time to form. XRD detected the presence of a small amount of ettringite (6CaOAl2O33SO432H2O) which could be problematic if present in sufficient quantities. The use of a type V cement could minimize the expansion problems associated with the presence of this crystal phase. The quantity of the crystalline phase in the waste was determined to be insignificant at this time (12). Samples will be routinely examined (approximately every two months) so that corrective measures can be taken if the amount of ettringite increases with time.

DETOX Solution from the DELPHI Process

The final waste stream studied is a strong acidic solution used in a chemical oxidation process being developed by Delphi, Inc., of Albuquerque, NM. This technology is being tested as an alternative to incineration for the destruction of organics in various wastes. The solution, known as the DETOX solution, is prepared by adding 60% anhydrous ferric chloride (FeCl3) to a 1.5 M hydrochloric acid solution. This strong acid, in the presence of a platinum-palladium-ruthenium catalyst, oxidizes combustible waste and reduces the waste volume. This acid must be neutralized and treated as a secondary waste prior to disposal. Since it is an aqueous waste, cementation is an appropriate technology to evaluate for stabilizing and immobilizing the RCRA listed species which may be present in the waste solution. The phase I cementation evaluation was conducted using a factorial experimental design evaluating fly ash loading (0%, 14.4%, and 28.8%) and waste loading (35% and 50%). The attributes tested were mix viscosity, waste form density, waste volume increase, and freeze-thaw cycling. The DETOX solution was mixed according to instructions provided by Delphi, Inc. This yielded a highly acidic solution (pH < 0) which was neutralized with a 1.5 N NaOH solution to a pH of 7-10. The neutralized solution was estimated to have a specific gravity slightly greater than water. During neutralization, the solution generated considerable heat; in fact, the solution boiled when attempting to neutralize the solution with 5 N and 10 N NaOH. The gas coming off the solution was a mixture of HCl and water which will require a scrubber in the production process. The use of the mildly basic solution resulted in a large volume increase as approximately 3-liters of NaOH solution were required to neutralize 250 ml of DETOX (volume increase of 1200%). Cement was added to the solution and mixed using a Hobart mixer and the samples were cured in an oven at 50C for 24 hours. The results from this experiment show the waste loading to be significant for each attribute evaluated. This is not surprising as the neutralized waste was mostly water with NaOH and solids precipitated from the DETOX solution. The phase II cement evaluation was conducted to test the leach resistance of a cemented spiked solution. A sample of DETOX solution was spiked with Cd (50 ppm), Cr (150 ppm), Ba (250 ppm), Pb (2,500 ppm), Ni (150 ppm), and Hg (50 ppm). These levels were based on the anticipated waste reduction factor of 300:1 provided by Delphi. Samples were mixed with cement and cement/fly ash using a waste loading of 50%. These results have been completed on all elements but mercury but have not yet been received. All elements tested were below the EPA treatment standard limits (13).

Experimental Conclusions/Recommended Formulations

1. Based on the tests conducted with the surrogate waste, the analytical laboratory solution waste can be cemented into a monolith using the following: 42.3% type I/II cement, 22.8% Ramcote, and 35% waste solution. The waste form produced has excellent leach resistance to Ni, Ba, Cd, Cr, and Pb at concentrations up to 10,000 ppm.
2. Based on the tests conducted with the silver nitrate waste, these solutions can be cemented into a monolith using the following: 42.3% type I/II cement, 22.8% Ramcote, and 35% waste solution. This waste form has excellent leach resistance to Ag spike levels up to 100,000 ppm, but failed TCLP testing at 500,000 ppm.
3. Cementation of the incinerator ash produces an LDR compliant waste using a formulation of 20% waste, 53.3% cement, and 26.7% water based on the tests conducted with the surrogate waste and the older treatment standard which was applicable at the time of testing. Additional tests are required to further optimize the cement formulation for this waste stream.
4. Based on the tests conducted with the hydroxide precipitation sludge surrogate waste, the sludge should be cemented into a mixture consisting of the following: 30% dried sludge (50% in slurry form), 21.8% type I/II cement, 21.8% class F fly ash, and 26.25% water (water/cement ratio of 0.6). This can be mixed using standard mixing equipment and has adequate resistance to freeze-thaw cycling. This waste product has leach resistance to Cd, Cr, Ba, Pb, Ag, and Ni at concentrations up to 1000 ppm.
5. A waste loading of 30% of the sludge in cement produces a waste form which meets pertinent waste acceptance criteria. The volume increase of the waste form is only 50%, making cementation a practical waste stabilization technology for this waste stream. Increasing the waste loading to 33% further reduces the volume increase to approximately 35%.
6. Class F fly ash, partially substituted for cement in the sludge waste formulation, improves the fluidity of the cement-waste mixture and can be used to reduce the water loading requirements. The substitution of fly ash for 50% of the

cement (total loading of 23% class F fly ash) showed no noticeable degradation on the sample after 12 freeze-thaw cycling tests. The presence of fly ash in the mix also reduced salt migration to the exterior surface of the samples due to a reduced internal pore pressure.
7. In tests conducted with the surrogate sludge waste, the presence of ettringite may require the use of type V cement (versus type I/II) to improve the resistance of the waste form to sulfate degradation.
8. Based on the initial tests conducted on the surrogate DETOX waste solution, cementation appears to be an effective stabilization technology for this waste. Initial tests with the neutralized acid have demonstrated waste loadings of 50% (from a neutralized acidic waste) can be cemented to produce an acceptable waste form. Samples have been submitted for TCLP analysis to confirm this. Additional refinements in the processing (i.e., neutralizing and drying the waste) will result in a reduced overall volume increase and produce a waste similar to the hydroxide precipitation sludge.

RADIOACTIVE WASTE AND DECOMMISSIONING - PUTTING THE RECORD STRAIGHT

F.H. Passant
Nuclear Electric plc

ABSTRACT

Radioactive waste and decommissioning are often perceived as major impediments to public and political acceptance of the case for nuclear power. This is true, not only in the United Kingdom, but elsewhere. It is often argued that the issues of radioactive waste and decommissioning pose major problems for the nuclear industry which threaten public safety and the environment and which give unacceptable

financial burdens to present and future society. It is further argued that the industry does not know what to do, when to do it or how much it will cost.
This paper sets out to put the record straight on these issues by reviewing briefly the status of waste and decommissioning developments in the UK and overseas. This review covers aspects including the environmental impact, the technical and development status, economics and financing and overall strategies for the management of waste and decommissioning.
This paper shows that environmental impacts are very small and that technical solutions and strategies exist and are in place or are planned in many countries for all aspects of safe waste management and decommissioning. It goes on to show that waste and decommissioning costs are only a small fraction of nuclear electricity generating costs and that they are being provided for out of current revenues. In other words, we do know what to do, how to do it safely, when to do it, how much it costs and we are paying for it now.
It is concluded that the nuclear industry's greatest challenge in waste management and decommissioning is to bridge the gap between public perception and reality on these issues.

INTRODUCTION

Radioactive waste and decommissioning are often perceived as major impediments to public and political acceptance of the case for nuclear power. This is true, not only in the United Kingdom, but elsewhere. It is often argued that the issues of radioactive waste and decommissioning pose major problems for the nuclear industry which threaten public safety and the environment and which give unacceptable financial burdens to present and future society. It is further argued that the industry does not know what to do, when to do it or how much it will cost.
This paper sets out to put the record straight on these issues by reviewing briefly the status of waste and decommissioning developments in the UK and overseas. This review covers aspects including the environmental impact, the technical and development status, economics and financing and overall strategies for the management of waste and decommissioning.

ENVIRONMENTAL IMPACT

Gaseous and liquid radioactive wastes have been discharged to the environment from nuclear sites for many decades. Strict regulation is applied to limit the discharges and their impact, and routine environmental monitoring confirms that the risk to members of the public and to the environment is extremely small. In the case of UK power stations the annual radiation dose to the most exposed groups of the public from waste discharges is only a few percent of the natural background dose and to the general public it is negligible. From the nuclear industry as a whole, the dose to the UK population from waste discharges is less than 0.1% of natural background. A similar situation exists in other countries.
For solid radioactive wastes, storage, transport and disposal pose even smaller risks to the general public and to those living close to storage or disposal sites. The criteria set for such disposal sites in various countries, including the UK, are such that the risk to the public and to the environment will be virtually zero in practical terms.
The decommissioning of nuclear power stations and other nuclear plant is subject to the same stringent safety criteria as are in force during operation. Because the first steps in decommissioning include removal of fuel, radioactive wastes and other potentially dispersable radioactivity for safe storage or disposal, the potential risks remaining are drastically reduced. In the case of our gas-cooled power stations, for example, the removal of fuel reduces the radioactivity by more than a factor of a thousand. The remaining radioactivity is almost all in solid indispersable form as active steel, graphite and concrete contained within substantial structures. This radioactivity reduces naturally with time by many orders of magnitude. During the whole period of decommissioning including final dismantling and site clearance the radiological impact on the environment is so small that it could not be detected.

TECHNICAL AND DEVELOPMENT STATUS

All countries with nuclear industries have radioactive wastes to manage as do many countries without nuclear industries since radioactivity is used extensively in medicine and industry. Extensive international cooperation has existed for many years on the technical and engineering aspects of safe radioactive waste management. National organizations have been established in most countries to manage, store and

dispose of wastes and there is wide international agreement on the best techniques for the safe management of the many forms and types of wastes that exist.
An important factor in the ability of the industry to deal safely and economically with its radioactive wastes is that the volumes are, in industrial terms, relatively small. This can be illustrated by the fact that the total radioactive waste volume requiring storage and deep underground disposal in the UK up until the middle of the next century, and including all past accumulations from the civil and defence industries, amounts to only about 400,000 m3. This can be compared to the annual volume of toxic industrial waste arising in the UK of 4 million m3.
It is agreed internationally by various Agencies and governments that the end point of safe radioactive waste management is disposal in engineered repositories at or near the surface or deep underground depending on the type of waste and, in particular, on its longevity. Wastes containing radioactivity which reduces rapidly with time can be safely disposed of near the surface whereas those which persist for thousands of years must be isolated by geological barriers as well as engineered barriers and hence must be placed deep underground in suitable geology.
In the UK, a surface engineered repository is in operation at Drigg in Cumbria and is capable of disposing all the country's low level waste until at least the middle of the next century. Similar repositories are in operation in other countries including France, Spain, Japan and the USA. Underground repositories are operational in Sweden and Finland for similar wastes.
UK Nirex Ltd is currently investigating the suitability of a site near Sellafield for the UK's intermediate level wastes. The repository would be at a depth of about 650 meters and could be operational by about 2010. Only one deep underground repository is currently in operation, at Morsleben in Germany, but many countries plan to construct deep repositories for operation early next century. These include repositories for the disposal of high level (or heat generating) wastes and spent reactor fuel in Sweden, Germany, France, Belgium, USA and Canada.
As with radioactive waste management, decommissioning has been the subject of extensive international collaboration over many years mainly under the auspices of the IAEA, OECD and the CEC. The collaboration includes research and development, demonstration projects and studies of the costs of decommissioning. Although nuclear plants in different countries vary in design and national regulations also vary, there is agreement on the techniques and plans for dismantling and dealing with the wastes. The technology involved has been developed and demonstrated and no major research or further development is required other than for optimization of the decommissioning process.
There are some 80 power reactors around the world in various states of decommissioning. Some have been totally dismantled (e.g. Shippingport in the USA and JPDR in Japan) and others are in the process of being dismantled (e.g. WAGR in the UK, KKN and KRB in Germany and Fort St. Vrain in the USA). These 'demonstration projects' coupled with experience of major component replacement in many plants give confidence that reactor decommissioning can be carried out using today's technology. A similar situation exists with regard to other nuclear plant used in the nuclear fuel cycle such as reprocessing and enrichment plants and plutonium facilities. BNFL in the UK have significant experience of decommissioning such plant as have others in Germany, France and the USA.
This worldwide experience gives confidence in the feasibility of decommissioning. It also demonstrates the safety of decommissioning and enables reliable cost estimates of future decommissioning tasks to be made. Far from being an unsolved problem, decommissioning can be done and the techniques are available to do it safely. The challenge that remains for the industry is the optimization of the strategy for decommissioning each individual plant taking account of local factors, safety and costs.
ECONOMICS AND FINANCING
As mentioned above, international experience and exchange of information on waste management and decommissioning is extensive. In particular, information on the costs of all aspects is widely available so that nuclear plant owners are able to make estimates of their own costs and future liabilities. These estimates are made using conventional engineering project costing techniques including contingencies and risk margins as appropriate to the particular situation. Taking account of local differences in cost elements there is good international consensus on the overall costs of waste management and decommissioning. Although these costs are often high

in real terms, when levelized and discounted over the appropriate period spanning the incidence of expenditure, they represent only a small percentage of the cost of nuclear electricity.

By way of illustration, the levelized and discounted waste management and decommissioning costs for Nuclear Electric's power stations are shown in Table I. There are two main reasons why these levelized costs are small when facilities such as repositories may cost many hundreds of millions of pounds and each power station decommissioning costs a similar amount. Firstly, much of the expenditure occurs much later than collection of the revenue from electricity and future expenditure is discounted, albeit at the modest real rate of 2% per annum. Secondly, the total electricity production associated with the facilities needed and the power stations which must be decommissioned is very high. For example, the present value of the total nuclear electricity from the UK nuclear power stations' program (2.5 million million kWh) is about 150 billion retail or about 60 billion at the current Regulator-capped pool price.

Since much of the expenditure on waste management and decommissioning occurs in the future and nuclear operators accept that the 'polluter pays' principle must be applied, arrangements are made to ensure that funds are available to meet the costs when needed. In most countries, including the UK, this is done by establishing provisions to charge the costs against current revenue. The provisions are handled by slightly different methods in different countries but nearly all nuclear utilities invest the provisions in their businesses or set aside segregated funds so that all future liabilities can be met. At the present time, Nuclear Electric's provisions are partly invested in capital assets, partly in indexed linked gilts, partly as cash deposits with the Government and the remainder will be covered by the nuclear levy.

STRATEGY

UK radioactive waste management strategy conforms to the overall Government policy which sets the framework within which to operate. Simplified, Government policy is for low and intermediate level wastes to be disposed of as soon as possible and for high level waste to be vitrified and stored for at least 50 years before disposal. The industry's strategy is thus to make full use of the existing near-surface repository for low level waste at Drigg and, through UK Nirex Ltd, to develop a deep underground repository for intermediate level waste as soon as possible. Pending the availability of this repository all intermediate level waste is being accumulated safely in surface storage facilities generally on the sites of origin of the wastes. High level wastes, which arise principally at Sellafield, are currently being vitrified and stored in stainless steel containers in the air cooled store at Sellafield. The industry plans to dispose of these in a purpose built deep underground repository in the second half of the next century.

For decommissioning, each nuclear plant operator has a strategy setting out what is to be done and when for each particular installation. For example, for UK gas cooled reactor power stations, a strategy referred to as Safestore is proposed. This involves early removal of the fuel from the reactors and early dismantling of the conventional plant and buildings. Dismantling of the reactors themselves will take place around 130 years or so later in order to take advantage of the much reduced radioactive inventory at that time. The defuelling stage is already completed at Berkeley ahead of program and at a cost well below the provision set aside. At Hunterston A and Trawsfynydd the defuelling stages are progressing well.

PUBLIC PERCEPTION

Public perception of radioactive waste and the decommissioning of nuclear plants is a long way removed from the situation described in this paper. This is not just a UK phenomenon, the situation being very similar in other countries. It is widely believed that radioactive waste is a large unmanageable problem posing threats to present and future generations and to the environment. Furthermore it is perceived to be a problem which will lead to unacceptable financial burdens on future generations. Decommissioning is seen in a similar light since it is regarded as just another radioactive waste problem.

A major challenge to the nuclear industry is thus the bridging of the gap between public perception of radioactive waste and decommissioning and the true situation. To date, the efforts of the industry to inform the public of what has been achieved in waste management and of the experience of decommissioning have failed.

The industry must therefore make greater efforts to inform the public about waste

management and decommissioning. We must publicize the achievements (e.g. operating waste repositories and the demonstration decommissioning projects) by encouraging media coverage and visits. Billions of pounds are committed to the technical activities associated with waste and decommissioning -perhaps we should consider whether we are doing enough on familiarizing the public with them.

CONCLUSIONS

The risks to the public and to the environment from radioactive waste and from decommissioning are extremely small. Technical solutions for the safe management of all radioactive wastes exist and are in place in various countries. Decommissioning nuclear plant has been demonstrated to be feasible and safe. The costs are known and represent only a small fraction of the cost of electricity and money is being set aside to pay for future liabilities.

Contrary to popular belief on waste and decommissioning, the industry does know what to do, how to do it safely, when to do it, how much it costs and is paying for it now. The industry's biggest challenge on these issues in the UK and in other countries is to bridge the gap between public perception and reality.

THE DECONTAMINATION AND DECOMMISSIONING DEBATE

Anthony J. Thompson
Warren U. Lehrenbaum
Shaw, Pittman, Potts & Trowbridge

ABSTRACT

For those concerned with radioactive waste, few issues loom larger than those relating to the decontamination and decommissioning of radioactively contaminated sites. Emerging developments in this area involving the Nuclear Regulatory Commission (NRC), the Environmental Protection Agency (EPA) and other governmental entities will soon result in generic regulatory programs determining who must decontaminate, to what levels, how much radioactive waste will be generated by these activities and what will be the conditions for disposal of such waste. Currently, NRC and EPA are in the process of developing separate regulatory regimes governing decontamination and decommissioning (D&D). If these efforts are to be successful, the two agencies must avoid overlapping and inconsistent requirements, and each set of regulations must be based on sound scientific principles.

INTRODUCTION

As we approach the start of the twenty-first century, one issue that promises to assume increasing importance among those concerned with radioactive waste is the decontamination and decommissioning of radioactively contaminated sites. The sharpening focus on this issue can be linked to a number of factors. The maturing of the nuclear power industry means that a growing number of older facilities, including facilities associated with the nuclear fuel cycle, will be coming off-line or ceasing operation, which raises a number of critical questions vis-a-vis the decontamination of these facilities, the disposal of wastes generated as a result decontamination, and the ultimate disposition of these sites. Similarly, ongoing clean-up efforts at Department of Energy (DOE) and Department of Defense (DoD) facilities has sparked intense public interest and increased regulatory concern over decontamination and decommissioning (D&D) activities at federal facilities, generally. In addition, there is a heightened awareness, among both regulators and the public, of the pervasive nature of naturally occurring radioactive material (NORM). Widespread NORM contamination may profoundly effect efforts to clean up radioactively contaminated sites, and will have a substantial impact on the disposal of radioactive wastes generated through site decontamination efforts.*

The scope of the decontamination and decommissioning issue is potentially enormous. Nuclear Regulatory Commission (NRC) regulations currently define the term "decommissioning" to mean "to remove nuclear facilities safely from service and to reduce residual radioactivity to a level that permits unrestricted use and termination of the license. Decommissioning activities are initiated when a licensee decides to terminate licensed activities" (1). Decontamination is one element of the decommissioning process. It is designed to reduce or eliminate radioactive contamination of equipment, facilities and the surrounding environment, so that the facilities, equipment and sites can either be released for future unrestricted use, disposed of, or placed under controls intended to minimize risks to public health and safety.

Currently, there are approximately 22,000 licensees under the Atomic Energy Act (the AEA, 42 U.S.C. 2014 et seq.), licensed either by the NRC or by Agreement States pursuant to AEA section 274. NRC estimates that more than 2,000 of these sites will require "substantial" decontamination when their licenses are terminated (2). Overall, the Environmental Protection Agency (EPA) estimates that there are at least 5,000 radioactively contaminated sites in the United States that will potentially require D&D attention. This figure does not include the approximately 1.5 million sites that are potentially contaminated with NORM (3). According to EPA, the oil and gas and geothermal energy sectors by themselves produce more than 50 separate waste streams amounting to several billion tons of NORM waste generated each year (4). Clearly, D&D issues will become increasingly prominent as more and more radioactively contaminated sites reach the end of their productive lives and as clean-up efforts at these sites begin in earnest. Not surprisingly, given the importance of these issues, a number of state and federal agencies have moved to develop regulations governing various aspects of decommissioning and decontamination. Chief among these efforts are two regulatory initiatives currently being undertaken by NRC and EPA.

CURRENT REGULATORY INITIATIVES

As discussed below, NRC and EPA are separately developing regulations to govern D&D activities. NRC is proceeding under the authority of the AEA to develop regulations that will apply to all licensed facilities under the AEA, as well as to other facilities under NRC's jurisdiction (other than high-level and low-level waste disposal facilities and uranium mill tailings piles). EPA is also acting pursuant to AEA authority, which was transferred to it by Reorganization Plan No. 3 of 1970 (5). EPA's D&D regulations would apply to all federally owned or operated sites and sites licensed by NRC (except for high level waste disposal sites, mill tailings piles and Superfund sites with signed RODs).

Although they are proceeding separately, NRC and EPA have agreed to cooperate with one another in developing consistent regulatory regimes. Specifically, on March 16, 1992 the two agencies entered into a Memorandum of Understanding (MOU) which is intended to establish a basic "framework for the agencies to resolve issues of mutual concern" and which sets forth principles and procedures designed to avoid unnecessary duplication of regulatory requirements (6). As both agencies have acknowledged, the MOU applies to the proposed EPA and NRC decommissioning and decontamination standards. The two agencies anticipate that EPA will review the D&D standards promulgated by NRC, and if they are found sufficiently protective, EPA will not attempt to impose its own D&D requirements on NRC licensees. According to EPA, if the Agency "determines that NRC's [D&D] regulatory program achieves a sufficient level of protection . . . EPA will propose that NRC regulated sites will be exempted from EPA radiation site cleanup regulations" (7).

Nevertheless, although NRC and EPA have committed to work together to develop consistent, albeit separate, regulatory regimes governing D&D activities, it is not at all clear that the two agencies will ultimately be successful in this effort. Indeed, as discussed below, the preliminary rulemaking efforts of each agency display a disturbing degree of overlap and inconsistency. Perhaps even more troubling, however, is that, in their rush to develop regulations in this area, NRC and EPA appear to be regulating on the basis of policy judgments that have been made without solid scientific foundation.

NRC'S PROPOSED D&D RULE

In 1989, the General Accounting Office (GAO) issued a report on NRC's regulation of D&D activities. The report, titled NRC Decommissioning and Decontamination Procedures Need to be Strengthened, RCED-98-119 (May 26, 1989), was critical of NRC's failure to establish specific, enforceable D&D standards and procedures. Partly in response to that criticism, NRC initiated an "enhanced participatory rulemaking" process aimed at developing more effective D&D regulations. This enhanced participatory process, which involved numerous public workshops and "scoping" meetings, reached partial fruition in August of 1994, with NRC's publication of a proposed rule to establish radiological criteria for the decommissioning of sites licensed under the AEA (8). Briefly, NRC's proposed rule would establish numerical criteria for determining whether a site has been sufficiently decontaminated to allow termination of the license and release of the site for other uses. The Commission is proposing a risk-based limit for residual radioactivity, keyed to the total effective dose equivalent (TEDE) that an average

member of the "critical group" would receive following decommissioning. (The "critical group" is the group of individuals reasonably expected to receive the greatest exposure to residual radioactivity for any applicable set of circumstances.) This risk/dose based limit would be augmented by a requirement in the regulations that the licensee reduce residual radioactivity on the site to levels that are as low as reasonably achievable (ALARA).

Under the regulations proposed by NRC, a site would be eligible for release for unrestricted use if the TEDE for the average member of the critical group is 15 mrem/yr or less from residual radioactivity distinguishable from background. For purposes of the proposed rule, the TEDE for members of the critical group would be calculated over 1,000 years. In addition, as indicated, the proposed regulations would also require the licensee to demonstrate that residual radioactivity at the site had been reduced to ALARA levels before the site would be released. In an earlier draft of the rule, NRC staff had proposed a "goal" of 3 mrem/yr to demonstrate compliance with ALARA. In other words, under the NRC staff draft, the ALARA requirement would have been deemed satisfied in instances where the TEDE from residual radioactivity distinguishable from background had been reduced to 3 mrem/yr. This numerical "goal" of 3 mrem/yr appears to have been dropped from the proposed rule (although there is some indication in the preamble to the proposed rule that NRC still views 3 mrem/yr as the de facto "goal" for ALARA); the qualitative ALARA requirement remains in place.

Another important feature of the proposed rule is a provision which would permit a decommissioned site to be released for restricted use in instances where it would be unreasonable to remediate the site to achieve the 15 mrem/yr limit for unrestricted use. As NRC explains in the preamble to the proposed rule, "in those few cases where reducing the residual radioactivity to the levels required to comply with the 15 mrem/y TEDE limit for unrestricted use are either not technically achievable, would be prohibitively expensive, or would result in net public or environmental harm, . . . the proposed rule provides the licensee with the option of requesting release of the site with restrictions placed on its use" (9).

Under the terms of the proposed rule, a site may be released for restricted use if provisions are made for "institutional controls" on the site which provide reasonable assurance that the TEDE from residual radioactivity distinguishable from background will not exceed 15 mrem/yr for the average member of the critical group. In addition, residual radioactivity at the site would have to be remediated such that, in the event that institutional controls on the site were no longer effective, there would be reasonable assurance that the TEDE from residual radioactivity would be as low as reasonably achievable, and in any event would not exceed 100 mrem/yr. Finally, NRC is proposing that decommissioned sites may be "reopened" and that further remediation may be required if, based upon "new" information developed after a site has been decommissioned, NRC concludes that the level of residual radioactivity at the site poses a significant risk to the public (10). According to NRC, "new" information which could lead to reopening of a site under this provision includes information pertaining to additional contamination as well as information that has a bearing on the risk and/or health assumptions underlying the criteria established in the proposed rule (11).

There are a number of important weaknesses in the approach adopted by NRC. Although it is not possible, in this paper, to provide an exhaustive analysis of the proposed regulations, some of the more troubling aspects of the rule are discussed below.

Appropriateness Of NRC's Proposed Dose Limit

The central feature of NRC's D&D proposal is the dose limit that would be established for unrestricted release of a decommissioned site. Most of the significant provisions of the rule are keyed to this limit in one way or another. Despite the importance of this parameter, however, NRC has completely failed to justify, in a rigorous and scientifically valid manner, its choice of 15 mrem/yr as the proposed dose-limit.

In the first place, NRC has not demonstrated that the 15 mrem/yr limit is needed to address any real world risks to public health or the environment. The Commission offers no evidence, either factual or theoretical, to support a conclusion that 15 mrem/yr, or even higher doses, presents a significant potential health risk. Indeed, current scientific knowledge supports the contrary conclusion -- that doses at the 15 mrem/yr level do not represent a significant threat to public health or the environment. As NRC itself acknowledges, in its support documents for the D&D rule,

15 mrem/yr is at the low end of the range of doses that are received from natural background radiation, and it is an order of magnitude lower than the average background dose received in the United States. According to NRC, "[b]ackground is comprised of various sources of ionizing radiation which collectively produce an average total effective dose equivalent of about 300 mrem/yr to a U.S. resident. Radiological doses from background typically range between 100 mrem/yr and 1,000 mrem/yr in the United States. Although greater radiological doses are possible for people living in houses with very high radon concentrations, 1,000 mrem could be taken as a practical maximum . . . For comparison, the estimate of the average U.S. radiological dose from background is similar to the world average estimate of 240 mrem/yr" (12). Thus, the 15 mrem/yr limit proposed by NRC represents roughly one seventh of the dose received from low-end natural background and one twentieth of the average dose received from background radiation in the United States.

It is widely accepted that natural background levels do not pose a significant threat to human health or the environment. For example, the National Research Council's committee on the Biological Effects of Ionizing Radiation (BEIR) has concluded that "studies of populations chronically exposed to low-level radiation, such as those residing in regions of elevated natural background radiation, have not shown consistent or conclusive evidence of an associated increase in the risk of cancer" (13). Similarly, the National Council on Radiation Protection and Measurements (NCRP) has noted that because the human race has developed acceptably in an environment with ubiquitous natural background radiation, the risks (such as they are) associated with natural background can be considered a "normal factor of life" (14).

Since the available evidence indicates that exposure to natural background levels of radiation does not present a significant risk to public health, it follows that doses that are at the low end of natural background (and that are substantially lower than the average dose received from natural background) would also not pose a significant risk to public health. Indeed, according to the International Atomic Energy Agency (IAEA), " [a] level of dose which is small in comparison to natural background can be regarded as trivial" (15). In other words, NRC's proposed limit of 15 mrem/yr represents a "trivial" level of exposure; there is no indication that such a dose presents a significant risk to human health or the environment.

This raises the obvious question of whether it is appropriate for NRC to attempt, through regulation, to mitigate "risks" that are at most trivial. The answer that the law seems to provide to this question is "no;" agencies should not exercise their regulatory powers to address trivial risks. One of the seminal legal decisions in this area comes from a Supreme Court case known as the Benzene case. Industrial Union Dept. AFL-CIO v. American Petroleum Institute, 448 U.S. 607 (1980). At issue there was whether certain regulations which had been promulgated by the Occupational Safety and Health Administration (OSHA) to control workplace exposure to particular carcinogens were enforceable as a matter of law. The regulations at issue had been promulgated pursuant to OSHA's "carcinogen policy," which was predicated on the assumption that carcinogens have linear, non- threshold dose response curves (or put another way, there is no "safe" level of exposure to a carcinogen) and that, therefore, regulatory controls on carcinogens should be made as stringent as possible. In effect, OSHA took the position that because there is no "safe" level of exposure to a carcinogen, such exposure should be limited by regulation to the extent feasible, regardless of whether the levels being regulated pose a significant risk to worker health and safety. (As we discuss below, this is essentially the same position that NRC has taken in the D&D proposal with respect to exposure to residual radioactivity --namely, that it should be reduced to the maximum extent possible, regardless of the level of risk being mitigated.) The Court in the Benzene case disagreed with this approach, noting that "the government's theory would give OSHA power to impose enormous costs that might produce little, if any, discernible benefit" (16). In effect, the Court concluded that government agencies should not attempt to regulate trivial risks; instead, they should only regulate risks that are "significant." As already discussed, NRC's proposed dose-limit of 15 mrem/yr represents, at most, a trivial risk to health or the environment. Under the principles announced in the Benzene case, exposure to radioactivity at that low level should not be the subject of regulation.

NRC's approach to developing the 15 mrem/yr standard is flawed not just from a legal perspective, but also from the standpoint of sound science. In the preamble to the

proposed rule, NRC notes that the proposed standards are predicated on a linear, non-threshold dose effect model for radiation. It is widely accepted that when attempting to regulate a linear non-threshold risk, optimized decision-making requires an ALARA analysis that seeks to maximize the net benefit resulting from regulation (17). Without this type of analysis, it is impossible to determine whether the risks that are sought to be mitigated are amenable to control, and whether the controls that are imposed by regulation involve the most efficient application of resources in relation to the risk reduction benefits to be achieved. Instead of conducting a net-risk/net-benefit analysis, however, NRC proceeds from the linear non-threshold assumption directly to the conclusion that "the overall objective for decommissioning should be the return of the facility to levels approximating background" (18). There is no analysis of whether this return-to-background goal is consistent with the objective of obtaining the maximum net benefit from the controls being imposed.* Indeed, a net-risk/net-benefit analysis of the 15 mrem/yr standard would almost certainly reveal either a net benefit of zero or even a net increase in risk, since such an analysis would have to balance the trivial incremental risk reduction achieved by the 15 mrem/yr dose limit against the increased risks (both radiological and non-radiological) associated with a dose limit that approaches natural background levels -- which includes risks associated with removal, transportation, treatment and disposal of additional wastes generated in attempting to comply with the dose-limit.

The dubious validity of NRC's 15 mrem/yr dose-limit is also reflected in the fact that the standard selected by NRC is inconsistent with limits that have been developed by independent scientific organizations. For example, the NCRP and the International Commission on Radiological Protection (ICRP) have both recommended an annual effective dose limit of 100 mrem from manmade sources, excluding medical exposures. NCRP states that "[f]or continuous (or frequent) exposure, it is recommended that the annual effective dose not exceed 1 mSv [100 mrem] . . . [and] a maximum annual effective dose limit of 5 mSv [500 mrem] is recommended to provide for infrequent annual exposures" (19). Background sources of radiation are excluded from these recommended limits. Id. Similarly, the ICRP recommends that "the limit for public exposure should be expressed as an effective dose of 1 mSv in a year" (20). Neither of these organizations has suggested that general public dose limits should be set below 100 mrem/yr; however both groups take the position that the full 100 mrem dose should not be allocated to a single source. On these basic points NRC generally appears to agree; the Commission has adopted 100 mrem/yr as a general exposure limit and it has taken the position that the full 100 mrem/yr should not be allocated to a single source.

Based on the foregoing principles, it is probably appropriate, in setting a dose-limit for a single source, to establish a limit at some fraction of the full 100 mrem/yr -- which is essentially what NRC has done in the proposed D&D rule. What NRC has failed to do is provide some reasoned basis for choosing 15 mrem/yr (i.e., 15% of the annual dose) as the appropriate limit or to provide any evidence that there is even a remote possibility that the 100 mrem/yr dose limit would potentially be exceeded by a single decommissioned source. By way of comparison, NCRP suggests the following approach in attempting to address the single source issue: where the potential exists for an individual to receive greater than 25% of the annual effective dose-limit (i.e., 25 mrem) from a single site or source, the site operator should ensure that the annual exposure (excluding medical exposure) to the maximally exposed individual does not exceed 100 mrem/yr on a continuing basis (21).* This approach is almost identical to one developed by the Health Physics Society (HPS), which recommends a 100 mrem/yr dose limit with a 25 mrem/yr "screening" level. Under HPS's approach, "[i]f the mean annual TEDE to the critical group is likely to exceed 25 mrem, an evaluation should be made to ensure that no individual is likely to receive an annual TEDE exceeding 100 mrem (1 mSv) from all site-specific, nonoccupational exposures, excluding indoor radon" (22).

The wide disparity that appears to exist between the dose limit proposed by NRC and similar limits developed by the scientific community provides a further indication that NRC's proposal was not developed in a manner consistent with sound scientific principles.* If this artificially low limit is in fact adopted by the Commission as a final rule, the implications will be extraordinary -- particularly with respect to the additional amounts of radioactive waste that will be generated, treated, and disposed of in order to comply with the limit, and the risks attendant with such a

clean-up effort. Moreover, the potential economic costs associated with such a massive clean-up effort could be staggering.

Harmonization With Other Pertinent Regulatory Programs

Another fundamental difficulty with NRC's proposal is that it fails to consider in any depth whether (and to what extent) the proposed D&D regulations are consistent with requirements imposed under other radiation control programs, which has the potential to result in conflicting and overlapping regulatory requirements. One example of this is the "public participation" provision of the proposed rule.

As already discussed, the proposed D&D rule provides that a site may be released for restricted use if certain criteria are satisfied. Under the proposed rule, a licensee that requests restricted release of a site would be required to convene a "Site Specific Advisory Board" (SSAB), which is supposed to "[r]eflect the full range of interests in the affected community and region" and is to be comprised of representatives from state and local government, citizens residing in the vicinity of the site, and representatives from environmental and environmental justice groups, among others (23). The purpose of the SSAB is to provide advice and recommendations to the licensee regarding planned D&D activities at the site. Specifically, the SSAB is to consider whether residual radioactivity on the site can be reduced to permit unrestricted release, whether the institutional controls proposed by the licensee will achieve the 15 mrem/yr dose limit without imposing undue burdens on the community, and whether the licensee has provided adequate financial assurance to permit a third party to carry out any required maintenance at the site (24).

Regardless of the merits of the public participation provision, it is evident that one practical effect of the SSAB requirement will be to delay substantially the implementation of decommissioning activities. The broad representation required on SSABs and the controversial nature of the issues the Boards are directed to consider make such delays almost unavoidable. At the same time, NRC's Timeliness in Decommissioning regulation (25) sets out an accelerated schedule for decommissioning, with ambitious deadlines established for both initiation and completion of D&D activities. It is apparent that in many if not most instances in which release of a site for restricted use is sought, the delays associated with the SSAB requirement will make it literally impossible to comply with the deadlines set out in NRC's Timeliness regulations. Consequently, licensees may be placed in the untenable position of being forced to violate the provisions of the Timeliness rule in order to comply with the SSAB requirement contained in the D&D rule. This is just one example of the types of conflicts that may arise between the proposed D&D rule and other pertinent radiation control requirements.

NRC's failure to consider rigorously the interplay between the D&D rule and other radiation control programs also has the effect of undermining even further the validity of the proposed 15 mrem/yr dose-limit. As discussed previously, sound science requires that, in setting a permissible dose for the release of a decommissioned site, NRC perform an ALARA or net-risk/net-benefit analysis to determine what dose-limit is appropriate. This type of analysis involves an evaluation of both radiological and non-radiological risks, and requires that NRC factor in the real-world risks associated with D&D activities (including risks associated with transportation, demolition and disposal of wastes), to ensure that the limit established in the D&D regulations minimizes the overall risk associated with D&D activities and not merely the risks posed by residual radioactivity at a site (26). NRC's failure to consider the impacts of other pertinent regulatory programs makes it impossible for the Commission to develop an accurate assessment of the net risk posed by its D&D standards. Because NRC is not in a position to evaluate the extent to which these other regulatory programs might be implicated by the D&D rule, the Commission cannot evaluate what additional increment of risk (if any) will be associated with compliance with those other regulatory requirements. For example, EPA is currently developing regulations to govern the management of radioactive wastes, including wastes generated during site decommissioning activities. NRC, however, has not attempted to assess the extent to which those waste management regulations will be implicated by NRC's D&D requirements and, more particularly, by the large volumes of waste that would be created as a consequence of the proposed 15 mrem/yr dose-limit. Without considering how these different regulatory regimes will overlap, NRC cannot begin to assess what risks might flow from compliance with any implicated EPA waste management regulations. In other

words, it is impossible for NRC to conduct an appropriate ALARA or net-risk/net-benefit analysis for developing a dose-limit unless the Commission evaluates how the proposed D&D rule will impact other regulatory programs and requirements.

Restricted Use Provisions

There are several troubling features of the proposed restricted use provisions; two are worth examining here. First, the regulations appear to underestimate the quantities of waste that will potentially be created as a result of D&D activities. In addition, the proposed restricted use provisions fail to provide for adequate controls needed to restrict access to and limit the use of restricted use sites.

In the preamble to the proposed D&D rule, NRC indicates that release of a decommissioned site for restricted use is intended to be the exception rather than the rule under the D&D regulations. According to NRC, the option of restricted use is available "[i]n those few cases" where it would be unreasonable to reduce residual radioactivity to the 15 mrem/yr limit for unrestricted use (27). For sites where large volumes of waste would be generated as a result of D&D activities it may not be feasible -- or reasonable, in terms of net risk -- to attempt to achieve the 15 mrem/yr dose-limit required for unrestricted release. For these sites, some form of on-site disposal and stabilization coupled with restrictions on site use and access may be most appropriate. Although NRC appears to recognize this possibility, the Commission also appears to underestimate the number of sites for which this alternative may be necessary.

Because NRC's proposed dose-limit is well within the range of normal background variation, it is almost inevitable that D&D activities directed at achieving this 15 mrem/yr limit will generate large volumes of radioactive waste. This is particularly true for sites at which substantial quantities of NORM are present. Yet, it is not at all clear that the Commission has developed a realistic assessment of the number of sites that may require on-site stabilization and disposal. For example, in the preamble to the proposed rule the Commission notes that "there may be several existing licensed sites (no more than a few tens) containing large quantities of materials contaminated with low level radioactivity where health and environment are best protected by onsite stabilization and disposal" (28). Although the proposed regulations would apparently permit licensees in this position to apply for an exemption from the D&D requirements, the Commission's assumption that only a few tens of sites may require on-site disposal seems ill-founded. Indeed, it is unlikely that NRC could have performed any sort of rigorous analysis of the need for on-site disposal without considering the impacts of other pertinent radiation control programs --such as EPA's pending radioactive waste management regulations.

In addition, although NRC's proposed regulations clearly contemplate the use of institutional controls (such as land use restrictions) to achieve the 15 mrem/yr dose limit for restricted use sites, it is not clear whether, and to what extent, the regulations allow the use of passive engineering controls. For example, as currently drafted, the proposed rule provides that a licensee seeking restricted use must provide for "institutional controls that provide reasonable assurance that the [15 mrem/yr limit will be achieved];" and the "institutional controls must be enforceable by a responsible government entity or in a court of law" (29). In addition, the licensee must demonstrate that if the institutional controls fail, there is a reasonable assurance that the 100 mrem/yr limit will be achieved. However, "calculations used to show compliance with this [100 mrem/yr] provision may not assume any benefits from earthen cover or other earthen barriers unless specifically authorized by the Commission" (30).

It is unrealistic for NRC to expect that most (if not all) restricted use sites will be able to achieve the 15 mrem/yr and 100 mrem/yr standards without the use of passive engineering controls, including earthen cover and earthen barriers. Indeed, because the proposed 15 mrem/yr limit would likely result in a significant increase in the amount of waste generated at sites undergoing D&D, the use of passive engineering controls may be required at a substantial number of sites to be released for restricted use. The restricted use provisions of NRC's proposed rule seem ill-designed to address this need for engineering controls.

One final concern regarding the restricted use provisions pertains to the types of institutional controls that NRC anticipates will be implemented at restricted use sites. Although the proposed rule does not purport to require or proscribe the use of any particular type of institutional control, NRC seems to take the position in

this rulemaking that the most desirable forms of institutional control (and therefore the controls most likely to be approved by the Commission) involve private ownership of decommissioned sites, with devices such as zoning laws, deed restrictions, covenants and easements used to control access to and use of the decommissioned site (31).

What is problematic about this approach is NRC's apparent reliance on private ownership of sites following decommissioning. Private ownership puts restricted use sites in the hands of entities that are motivated by economic concerns and pressures, which may at times conflict with concerns for long-term radiological safety. Moreover, in a system of private ownership, the same entities that own a decommissioned site will also be in a position to influence political processes at the state and local level to undermine the restrictions on site use imposed by institutional controls. Finally, there can be no assurance that the private owner of a restricted use site will remain in existence over the extended time frame required for control and maintenance of the site. Thus, private ownership of restricted use sites is inherently unstable, particularly when compared to the option of government ownership. Government ownership of a restricted use site effectively eliminates any concerns over the adequacy and durability of institutional controls implemented at the site. Yet, almost without explanation, NRC has rejected the option of government ownership (32). Clearly, this issue warrants additional consideration by the Commission.

EPA'S DRAFT D&D RULE

EPA has not progressed quite as far as NRC in the development of its D&D regulations. In October of 1993, the Agency issued an advance notice of proposed rulemaking (ANPRM) on the D&D issue (33). Subsequently, on May 11, 1994 EPA released a draft notice of proposed rulemaking on radiation site clean-up regulations (the EPA "Draft Rule"); however, as of this writing, EPA has not yet published the "final" version of the proposed rule in the Federal Register. Because EPA's site clean-up rule is only in draft form, many of its specific provisions have yet to be developed by the Agency and therefore cannot be evaluated in depth here. Accordingly, our examination of the EPA rule must be limited to an assessment of the central features outlined in the Draft Rule, focusing on details of the proposal where such details have been included in the draft released by the Agency.

As indicated previously, EPA's Draft Rule would apply to all federally owned or operated sites and all sites licensed by NRC, except high-level waste disposal sites, mill tailings facilities and Superfund sites with RODs. The Draft Rule is similar to NRC's proposed D&D regulations in a number of important respects -- which is not unexpected, since each agency was an active participant in the other's rulemaking proceedings. As with NRC's proposal, the Draft Rule establishes a dose limit of 15 mrem/yr from sources other than background, calculated over 1,000 years. This limit is expressed in terms of the dose received by the "reasonably maximally exposed" (RME) individual, which EPA defines to mean an individual whose exposure falls within the 95th percentile, or above, of the population near a site (34).

In addition, the Draft Rule provides that in circumstances where it would be inappropriate to release a site for unrestricted residential use, the site may be released for restricted use if the owner or operator can demonstrate that the site will achieve the 15 mrem/yr standard through some combination of remediation and active controls. (For purposes of the draft rule, "active" controls include institutional controls such as land use restrictions, as well as engineering controls that require active maintenance (35).) As with the NRC proposal, EPA's Draft Rule does not require or proscribe any particular types of active controls. However, the Draft Rule appears to address, at least partially, two of the deficiencies contained in the NRC proposal. First, EPA's proposal admits of the possibility that institutional controls might include government ownership of the decommissioned site (although many of the sites that would be subject to EPA's rule are already government owned and/or operated sites) (36). In addition, the Draft Rule acknowledges that engineering solutions can be included in the mix of controls used to bring a restricted use site into compliance with the applicable dose-limits. Under the EPA draft, a site owner/operator seeking approval for the release of a site for restricted use is not required to convene an SSAB to provide advice and/or recommendations on the D&D effort. Instead, EPA's proposal requires that the public be notified of the proposed clean-up and allowed a chance to comment. The draft does not contain sufficient details regarding this notice and comment procedure to

evaluate whether EPA's proposal is likely to result in fewer delays in implementing D&D activities than would be caused by the SSAB approach. As with the SSAB process, however, complicated notice and comment requirements may result in substantial delays in initiating D&D activities -- which is inconsistent with the goal of achieving prompt clean-up of radioactively contaminated sites and which may directly conflict with NRC's recent Timeliness in Decommissioning rule.

Although there are a number of areas of relative congruence between the EPA and NRC proposals, in many respects EPA's Draft Rule is more restrictive than the corresponding provisions of NRC's proposed rule. It is conceivable (if not likely) that in those areas where the EPA rule is more restrictive, the Agency will conclude that NRC's requirements are not sufficiently protective. As discussed previously, this would serve as the predicate for imposing the more restrictive EPA standards on sites that would otherwise be subject to NRC jurisdiction.

One example of conflicting EPA and NRC standards is the "default" dose-limit for unrestricted sites. Under EPA's Draft Rule the owner or operator of a site that is to be released for restricted use must demonstrate that the site has been sufficiently remediated such that, in the event that active controls at the site were to become ineffective, the reasonably maximally exposed individual would not receive a dose greater than 75 mrem/yr. The corresponding "default" dose-limit under the NRC proposal is 100 mrem/yr. In this instance, NRC's standard is clearly more easily achieved than EPA's dose-limit while it is probably equally protective of human health and the environment. Because of the tension between the two standards, it is not clear, at this point, which would actually be applied to NRC-licensed sites undergoing decommissioning.

EPA's proposal, as currently drafted, also contains a potentially crippling "reopener" provision, under which decommissioned sites would be reevaluated every certain number of years following decommissioning (the specific interval is to be set out in the regulations), to determine whether the applicable dose-limits are being met, whether protective measures implemented at the site (such as active engineering controls) are still effective, and whether additional remediation activities will be required (37). This provision is troubling because it robs D&D activities of finality and inserts another layer of uncertainty into the decision-making process facing site owners and operators who are contemplating decommissioning a site. In turn, this uncertainty may lead site owners and operators to delay the initiation of decommissioning activities for as long as possible -- which is contrary to the goal of achieving prompt decontamination and decommissioning of contaminated sites. This uncertainty is compounded by the fact that Draft Rule does not specify any standards for evaluating whether further remediation efforts will be required at a site.

By contrast, the NRC proposal provides that "[a]fter a site has been decommissioned and the license terminated in accordance with the criteria in this proposed rule, the Commission will require additional cleanup only if, based on new information, it determined that residual radioactivity remaining at the site could result in significant public risk" (38). Admittedly, the Commission has not defined what constitutes "significant public risk;" however this significant risk standard provides at least some objective framework against which NRC can evaluate whether further clean-up at a decommissioned site is needed. EPA's proposal as currently drafted does not offer a clue to site owners or operators regarding the circumstances under which additional clean-up could be required. Here again, conflict between the approaches advocated by NRC and EPA lead to uncertainty regarding which standard will be applied to an NRC-licensed site which is potentially subject to the both sets of rules.

As a final example, EPA's Draft Rule would establish a separate groundwater standard that would be applied in addition to the overall 15 mrem/yr dose-limit. Specifically, sites undergoing decommissioning would have to be remediated to a level that would assure that radioactivity in any groundwater that is a current or potential source of drinking water would fall within the applicable maximum contaminant levels (MCLs) established for radionuclides under the Safe Drinking Water Act. Currently this translates to a total effective dose of 4 mrem/yr from groundwater that is or may be a source of drinking water.

According to EPA, "[w]hen MCLs for radionuclides are changed or added in the future, the Agency intends for those new MCLs to be the groundwater protection requirements used for the purposes of setting remedial objectives" (39). In other words, under

the EPA proposal, as MCLs for radionuclides are either added or modified under the Safe Drinking Water Act, those new MCLs will be incorporated into the site clean-up regulations as groundwater standards. Again, this approach tends to undermine the finality of decommissioning activities, and it creates uncertainty for owners and operators of sites -- raising the specter of the agency "reopening" the decommissioning to require compliance with modified groundwater requirements. The NRC proposal would also establish a separate groundwater dose-limit as part of the overall 15 mrem/yr standard; however, the NRC rule would simply incorporate the MCLs for radionuclides as they exist on the effective date of the D&D rule. There is no indication that NRC intends to change the site clean-up standards for groundwater whenever an MCL is added or modified under the Safe Drinking Water Act, which means less uncertainty for site owners and operators and therefore less incentive to delay the initiation of site decommissioning activities (40).

As these examples demonstrate, NRC and EPA need to work together to develop consistent regulatory regimes that are legally defensible and rooted in sound science; unfortunately, the current rulemaking efforts of the two agencies appear to fall short of these goals. Inconsistent, overlapping and open-ended regulatory programs that add complexity and uncertainty to the decommissioning process will almost certainly cause site owners and operators to delay the initiation of site decommissioning activities, which is inconsistent with the objective of achieving prompt decontamination and decommissioning of inactive sites. Indeed, to the extent that the regulatory regimes developed by the two agencies are either incompatible with one another or not supported by sound science, direct challenges to those standards can be expected, resulting in further delays in the D&D process.

U.S. DEPARTMENT OF ENERGY PROGRESS AND ACCOMPLISHMENTS IN SURPLUS FACILITY DECOMMISSIONING UNDER ENVIRONMENTAL RESTORATION

Stephen Warren
National Decommissioning Program Coordinator
U.S. Department of Energy
Office of Environmental Restoration
John Dorries
Booz, Allen & Hamilton Inc.

ABSTRACT

The mission of the U.S. Department of Energy (DOE) environmental restoration program is to ensure that risks to human health and safety and to the environment, posed by contaminated inactive waste sites and surplus facilities, are either eliminated or reduced to prescribed, safe levels. The program is concerned with all aspects of assessment and remediation activities where sites and facilities are no longer associated with active nuclear-related production or research operations. Remedial action comprises assessment and remediation of inactive waste sites and correction of a release or spill problems. Decommissioning includes assessment, decontamination, reuse, or dismantlement of surplus contaminated facilities that are no longer active.

DOE is implementing a national program, directed by the Office of Environmental Restoration (ER) within the Office of Environmental Management (EM), to ensure that all decommissioning objectives are accomplished. The national program will promote the safe and efficient decommissioning of DOE facilities and strive to achieve timely and cost-effective results, based on a reasonable set of priorities, focusing on protection of the environment, improved worker and public safety, and conservation of valued resources.

This paper describes the six components that comprise the framework for the national decommissioning program under environmental restoration. The paper also describes the scope of the program and provides descriptions of decommissioning projects that are included as decommissioning program performance measures for fiscal year (FY) 94 and FY95.

NATIONAL PROGRAM FRAMEWORK

A national decommissioning program is being established within the environmental restoration (ER) program to ensure that decommissioning projects are conducted in a safe and efficient manner, while enabling Headquarters and field personnel to share new technology applications, lessons learned and the latest regulatory and policy directions of the program. The framework for the national decommissioning program comprises: Policy framework, interface, ER decommissioning inventory, program management, technology, and communications.

Policy Framework

A policy framework is required for prioritizing, funding, and conducting decommissioning activities so that they are consistent with remediation activities. A key issue is the relationship of the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) to decommissioning activities. The U.S.

Department of Energy (DOE) and the U.S. Environmental Protection Agency (EPA) established a working group to analyze and resolve issues related to CERCLA and decommissioning and to develop a national policy for applying CERCLA to decommissioning. ER chairs the DOE/EPA working group. The working group expects to have a draft of the policy ready for EPA and DOE management review in February 1995. After that, DOE will develop an implementation framework for applying CERCLA to decommissioning projects. In addition, ER will issue and maintain the Decommissioning Resource Manual to assist field personnel in meeting requirements.

Interface

National decommissioning program staff interface with other organizations to ensure that surplus facilities are decommissioned safely and efficiently and that decommissioning projects are consistent with Departmental and external requirements. For example, ER is working jointly with the Office of Environmental Management (EM) Office of Facility Transition and Management in the development of policies and procedures for surplus facility transition. The ER program also interacts with external organizations, such as EPA, the Nuclear Regulatory Commission, and the Defense Nuclear Facilities Safety Board, to gain insight into activities of interest to, and to work towards a consistent national direction for, decommissioning. DOE actively participates in the exchange of decommissioning technology, project experience, and lessons learned at national and international forums.

ER Decommissioning Inventory

A means of identifying, documenting, and tracking the inventory of surplus facilities and decommissioning projects is needed to define the scope of effort, track progress, and ensure future accountability for their cleanup. ER is refining an inventory of decommissioning facilities and projects in the environmental restoration program. Although still in the final stages of data verification, the inventory currently contains approximately 760 facilities that are either undergoing, or require decommissioning. The inventory will be updated periodically to reflect newly identified surplus facilities and completed decommissioning projects at facilities on the inventory.

Program Management

To ensure that decommissioning activities occurring across the DOE complex are being planned and performed in an efficient and consistent manner, the national program needs an effective program management component. This component will ensure that policies for prioritizing, funding, and conducting decommissioning operations are implemented and that project managers have the tools they need. One priority for this year is a decommissioning cost benchmarking study so that managers can better project costs and review estimates. The benchmarking study is about to get underway.

Technology

The national decommissioning program is establishing a technology development and transfer initiative to meet the needs of current and future decommissioning projects. Mechanisms are also being developed to exchange beneficial decommissioning technologies and relevant project experience internally and with other government cleanup programs, the nuclear industry, and internationally. ER is participating in decommissioning technology focus groups, to identify and assess technologies in use in the private and government sectors and their potential application in the DOE complex, to implement the interface with the EM Office of Technology Development on the identification and development of needed decommissioning technologies, and to evaluate application of new technologies and their effectiveness in the private and government sectors. In addition, ER will maintain the Decommissioning Handbook to ensure that the most up-to-date information is available to the field.

Communications

Productive and continuous communications and information exchange mechanisms are being employed for transmitting lessons learned within the decommissioning community and informing interested parties of decommissioning activities and status. To help Headquarters and field personnel get to and stay at the cutting edge of decommissioning processes and techniques, for example, DOE is presenting a televideo course on decommissioning for training and education of personnel involved with decommissioning activities. This course will air six programs, beginning February 8, 1995, featuring these topics: Decommissioning overview, surveillance and maintenance, project planning, decommissioning methods and alternatives, decommissioning operations, and policies and issues.

DECOMMISSIONING PROGRAM SCOPE AND PROGRESS

DOE has identified hundreds of surplus contaminated facilities requiring decommissioning as part of environmental restoration. Approximately 760 facilities already are slated for eventual decommissioning and another 1,200 may be in the pipeline.

Of the 17 major environmental restoration projects, 14 currently are conducting or plan to conduct decommissioning activities. There are hundreds of facilities at 26 DOE installations in 13 states that are associated with these 14 major projects. To measure significant accomplishments, DOE has been developing performance measures for each fiscal year. Within the decommissioning program, ER targeted 5 project completions for fiscal year (FY) 94 and 12 project completions for FY95. The program actually completed 9 projects in FY94 and will strive to surpass its target set for FY95. The following section presents a brief background on the decommissioning projects that were completed in FY94 or are targeted for completion in FY95, grouped by DOE installation.

Santa Susana Field Laboratory

The Santa Susana Field Laboratory (SSFL) is located 29 miles northwest of downtown Los Angeles, California. Within SSFL is the Energy Technology Engineering Center (ETEC), which is operated by Rockwell International under contract to DOE. Specific programs conducted at ETEC for DOE and its predecessor agencies involved the engineering, development, testing and manufacturing operations of nuclear reactor systems and components. Decommissioning of facilities began in the late 1960s and continues as DOE phases out individual DOE-sponsored projects.

Decommissioning projects were completed at three ETEC facilities in FY94: Building 5, Building 23, and Building 64. Building 5 was used to fabricate uranium carbide fuel in the late 1960s. At the conclusion of the fuel fabrication project, uranium contaminated equipment and surfaces were either removed or decontaminated. Additional decontamination activities were initiated in 1978 and completed in phases, ending in 1992. Activities included cleaning and/or removal of contaminated floors, equipment, duct work, drain pipes and storage tanks.

Building 23 was used from 1976 to 1982 to test the transport of radiological contamination in sodium loops. Major contaminants included cesium-137 and cobalt-60. Most of the contamination identified in the building involved the radioactive liquid holdup tank and the associated drain lines and sink. Facility decontamination included the removal of the sodium loop, holdup tank, drain lines, sink, a fume hood and the ventilation exhaust system and remediation of an area of the floor where the sodium loop had been located.

Building 64 was used primarily for storage of packaged items of source material and special nuclear material of various forms and configurations. The material stored in this facility included natural uranium, depleted uranium, enriched uranium, uranium-233, thorium and plutonium. Packaged soil contaminated with cesium-137 was also stored in the facility. Interior surfaces were determined to be contaminated from the uranium repackaging process. As part of decommissioning activities at Building 64, equipment and fixtures in the building were decontaminated and/or dismantled and removed and the interior decontaminated to allow for future release to the owner after the completion of decommissioning of other Rockwell-owned buildings in the area.

Idaho National Engineering Laboratory

The Idaho National Engineering Laboratory (INEL) is located 42 miles northwest of Idaho Falls, Idaho. INEL is a multipurpose laboratory supporting the engineering and operations efforts of DOE and other federal agencies in areas of nuclear safety, reactor development, reactor operations and training, waste management and technology development, and energy technology/conversion programs. Three decommissioning projects at INEL are described below.

Test Area North (TAN) is located in the northern portion of INEL and was established in the 1950s to support the U.S. Air Force Aircraft Nuclear Propulsion Program. The TAN-607 Decontamination Shop was used for radiological decontamination of tools and small equipment from INEL and non-INEL facilities. The area began operations in 1957 and was shut down in 1987. The shop consisted of a main decontamination room, a change room, and a high energy particulate air (HEPA) filter room. Contamination consisted of low-level radioactive equipment and debris and asbestos. Decommissioning tasks included removal of all contaminated equipment, including tanks and piping, and decontamination of the space within the larger TAN-607 facility to allow for reuse of the area. Decommissioning of the TAN-607

Decontamination Shop was completed in FY94.
The Auxiliary Reactor Area III (ARA-III) facility at INEL was used by the U.S. Army from 1960 to 1965 to test gas-cooled reactors and from 1966 to 1987 as laboratory facilities for component and instrument testing. Contamination at ARA-III consisted of low-level radioactive soil, equipment, and debris (concrete and metals). Decommissioning tasks include excavation, removal, and sectioning of three wastewater tanks and associated piping; dismantling, sectioning, and disposition of ventilation/exhaust stacks and associated ducts; and reactor pit decontamination and pipe removal. Once these activities are complete, the facility will be released for unrestricted use within the INEL complex. All the buildings except one will be made available for reuse.
The Central Facilities Area-669 (CFA-669) Hot Laundry is a cinderblock building that was used as a laundry facility for both radioactive and non-radioactive contaminated clothing and contained low-level radioactive soil, equipment and debris. Decommissioning tasks include decontaminating the interior of the building, removing and disposing of equipment, excavation of underground piping, and complete demolition of the building. The ARA-III and CFA-669 decommissioning projects are scheduled to be completed in FY95.
Including the three projects described above, INEL has excessed and internally recycled or externally sold significant quantities of materials from the decommissioning activities. These materials include 363,000 pounds of scrap metal that were sold to a metals recycle vendor, 2,360 pounds of lead that were internally recycled, and 48,000 pounds of concrete debris that will be recycled on site with INEL's new concrete recycling machine.
Oak Ridge Y-12 Plant
The Alpha-4 Production Facility, designated Building 9201-4, is a 4.5 acre structure in the Oak Ridge Y-12 Plant, two miles from downtown Oak Ridge, Tennessee. It was constructed in the 1940s to house process equipment for the separation of uranium isotopes. During the 1950s and 1960s, the building was used for the separation of lithium isotopes through a mercury-solvent extraction process known as "colex." Two Building 9201-4 decommissioning projects completed in FY94 are the 9201-4 Mercury Draining project and the 9201-4 Electrochemical Machining (ECM) Area project. As a result of the mercury-solvent extraction process, piping, auxiliaries, and structural brick and mortar were contaminated with mercury. The Mercury Draining project involved the draining and storage of residual mercury from process equipment and piping for possible recycle or reuse. Decontamination of the ECM area involved the cleanup of all known sources of non-fixed contamination in the ECM Area. The project involved decontaminating more than 24,000 square feet of surface area. Primary contaminants included depleted uranium oxides, mercury, beryllium, and polychlorinated biphenyls (PCBs), as well as elevated radiation contamination levels. Nearly 350,000 pounds of material were decontaminated and the project was completed safely, ahead of schedule, and under budget.
Both projects were accomplished under Y-12's enhanced surveillance and maintenance (S&M) program. The Y-12 S&M program is characterized by aggressive removal and decontamination projects which ultimately reduce the scope and cost of long term S&M and eventual decommissioning. DOE is encouraging use of the Y-12 approach to S&M at other Oak Ridge decommissioning projects.
Decommissioning activities at Building 9201-4 planned for FY95 include steamline asbestos removal, decontamination of the ECM support systems, and comprehensive facility characterization to support final facility decommissioning activities. Complete decommissioning of 9201-4 will involve advanced mercury decontamination technologies, development and demonstration of a recycle process for aqueous solutions, and construction of a landfill for disposal of decommissioning wastes.
Oak Ridge K-25 Site
The K-25 Site, formerly known as the Oak Ridge Gaseous Diffusion Plant (ORGDP), is located 13 miles west of the city of Oak Ridge, Tennessee. The main mission of the ORGDP had been the enrichment of uranium by gaseous diffusion. In 1989, the entire site was placed under DOE's EM program. K-25 Site facilities are primarily contaminated with uranium oxides, heavy metals, organics, PCBs, and asbestos. Decommissioning of several process buildings and related facilities has been completed or is underway.
Activities completed in FY94 include the removal and storage of roughly 10,000 capacitors and transformers. All of these electrical components contain PCBs. The

storage areas, built in accordance with the Toxic Substances Control Act (TSCA), will capture and prevent the spread of any leaking fluids. K-25 PCB Electrical Compliance projects and other Phase I decommissioning activities will reduce the scope and cost of the K-25 S&M program and will provide for a safer working environment. Activities to be completed in FY95 include the packaging and shipment of non-radiologically contaminated PCB-containing capacitors for off-site disposal, the demolition of five K-25 Powerhouse auxiliary facilities, and the removal of critical uranium deposits from enrichment process piping.

The Powerhouse demolition project is being conducted as one of two EPIC (Environmental Project Integrated Contract) projects at the K-25 Site. This innovative contracting arrangement is based on a fixed price contract and provides incentives for the contractors to perform the work safely, on schedule, and under budget. The contractors will be required to absorb any cost overruns. DOE intends to accomplish more work under the EPIC model and other innovative contracting concepts. DOE is also considering several studies and pilot projects aimed at reducing the total cost of decommissioning the K-25 process buildings.

Battelle Columbus Laboratories

Various projects are undergoing decommissioning at the Battelle Columbus Laboratories King Avenue site, which is located in downtown Columbus, Ohio. Since 1943, the Battelle Memorial Institute has continuously performed energy research and development work at its Columbus Laboratories for DOE and DOE predecessor agencies. King Avenue Building 3 (KA-3) was decommissioned in FY94 while King Avenue Building 4 (KA-4) is scheduled for FY95 completion.

KA-3 was the largest and most contaminated of the nine buildings being decontaminated at the King Avenue site. KA-3 was used for various research activities involving uranium and beryllium and housed a powder metallurgy facility, a melt facility, a metallography facility, a ceramics research facility, and a uranium-235 processing facility. Work on the first nuclear submarine, the Nautilus, was conducted in this building. Decommissioning efforts involved removing contaminants from 191 rooms, involving 174,000 square feet of surfaces; 3,200 linear feet of drain lines; and 8,300 cubic feet of subfloor soil. The work entailed removing ducts, electrical conduit, water lines, and contaminated laboratory equipment. Chemicals, equipment, and other materials were removed, separated, and packaged for reuse, recycle, or off-site disposal.

KA-4 housed a radiochemistry laboratory, a metallography laboratory and an encapsulation facility for highly enriched uranium. Decontamination of only the radiochemistry laboratory was completed in 1980. Decommissioning activities include relocating staff from the building, removal of uncontaminated furniture and laboratory equipment, decontamination, disposal of radioactive waste, and final restoration of the building for release to Battelle.

Fernald Site

The Fernald Site, formerly known as the Feed Materials Production Center, is a 1,050-acre site located in a rural agricultural area about 17 miles northwest of downtown Cincinnati, Ohio. High purity uranium metal products were produced for DOE and its predecessor agencies from 1952 to 1989. All production activities at Fernald ceased in July 1989 to allow the site to concentrate on environmental cleanup and restoration. Various decommissioning projects are being completed at the Fernald Site, including Plant 7, Building 4C, and the Fire Training Facility.

Fernald Plant 7 production activities occurred from 1954 to 1956 and consisted of a uranium conversion process. The plant evolved into a storage facility for low-level radioactive materials and other debris. The majority of the process equipment was removed over time. Plant 7 was a 112 feet high, 7 floor building, consisting of a structural steel frame on a reinforced concrete base, with steel decking floors and transite siding.

A multiple stage decontamination was performed on Plant 7, consisting of a washdown for gross decontamination, followed by the application of an acrylic latex coating to "lockdown" any remaining loose surface contamination. This process significantly reduced the radioactive contamination of the structure. It was proposed that Plant 7 structural support columns be cut using controlled detonation. By using a specialized steel-cutting method of linear-shaped charges with sequential charge detonation, the weight and shape of the building was anticipated to fold within seven seconds. The steel would then be size-reduced, monitored for radiological contamination, and packaged once on the ground. Prior to Plant 7 demolition, the

walls, asbestos-contaminated materials, equipment, and elevator were removed and packaged. Plant 7 was reduced to a simple structural steel skeleton and floor decking.
In September 1994, the demolition contractor detonated 156 linear shaped, explosive charges placed in 50 locations intended to take the building down. The first two floors of the building collapsed as planned. However, splice plates that had been precut on the third and fifth floors did not separate as anticipated. The building dropped approximately 25 feet instead of the planned 78 feet. Following the partial takedown by controlled detonation, the area was secured. Following an extensive examination of the partially fallen Plant 7 structure, a decision was made to use explosive shaped charges to complete the takedown. The successful takedown occurred one week later and utilized 260 shaped charges placed in 120 locations. Even with the second explosive charge, the project will save nearly $5 million from the original decommissioning plan and will finish seven months ahead of schedule. The next objective of the project is to recycle a significant portion of the demolished material, including 700 tons of structural steel and 1.5 tons of lead flashing.
To provide sufficient open area for Plant 7 to fall, the maintenance building of adjacent Plant 4 (designated Building 4C) was removed at no additional cost to DOE. Demolition activities were conducted on this one story building in accordance with procedures approved in the Plant 7 CERCLA Work Plan. Building 4C, measuring 60 feet by 60 feet and 14 feet high, was constructed of a structural steel frame supported by a reinforced poured concrete base, with transite siding and roof panels. Building 4C housed the maintenance activities for the Green Salt Plant and other chemical process areas and was the base for asbestos removal operations at the Fernald site.
The Fire Training Facility (FTF) was constructed and operated as a training facility for the Fernald Site fire department and surrounding community fire departments from 1966 to 1990. The FTF was estimated to have been used an average of 60 days per year. During its use, various types of combustible substances were burned to practice fire fighting techniques; some of the waste solvents burned at the FTF may have been contaminated by radionuclides.
The FTF was composed of four structures. The main two-story block building consisted of first and second story floors constructed of reinforced concrete and a roof constructed of wooden joist covered with plywood and an asphalt roofing. The building was sealed after it was determined that is was no longer safe for use. A skid tank and an open top tank constructed of carbon steel were filled with waste solvents of fuel oil and set on fire to practice fire fighting techniques. The fourth structure was a cylindrical tank (former pressure vessel), constructed of 1.5-inch plate steel that was filled with smoke so that personnel could practice confined space ingress and egress under smoke-filled conditions.
The FTF was decommissioned as part of a CERCLA removal action. The project consisted of four phases: 1) demolition of the block building, 2) removal of water/liquid from associated ponds/pits, 3) removal and size reduction of tanks, and 4) excavation of contaminated soils. The building was demolished using a front end loader and a dump truck to haul the debris for packaging. Liquids were removed and containerized using a suction pump. The liquids will be sampled and processed with on-site facilities. Tank size reduction was performed with cutting torches and shears. Approximately 360 cubic yards of soil was excavated. The combined CERCLA Removal Action Final Report and the Resource Conservation and Recovery Act (RCRA) Closure Action Final Report are scheduled for submittal in July 1995.
Argonne National Laboratory-East
Decommissioning of the Experimental Boiling Water Reactor (EBWR) at the Argonne National Laboratory-East facility, 22 miles southwest of downtown Chicago, Illinois, is scheduled for completion in FY95. The EBWR was operated from 1952 to 1967 to demonstrate the use of a direct cycle boiling water reactor as a heat source for power plant steam production. After all reactor systems were flushed and drained and the water treated, the radioactive contaminants that remained at the EBWR facility were present in the reactor and the bio-shield. The primary radionuclide of concern was the activation product cobalt-60. Other contaminants included small amounts of iron-55, nickel-63 and trace quantities of miscellaneous radionuclides.
In the 1980s, asbestos insulation was removed throughout the facility, as well as all reactor system piping, components, and associated contaminated equipment. Throughout FY94, the reactor vessel internals, the reactor vessel itself, and the biological shield surrounding the reactor vessel were removed and size reduced using

a specially manufactured reactor vessel cutting machine, an underwater plasma arc torch, an electro-hydraulic remote controlled impact machine, and other specialized equipment. The components were then packaged for disposal.

Rocky Flats Plant

Several decommissioning pilot projects are being conducted at the Rocky Flats Plant, which is located 16 miles northwest of Denver, Colorado. The Plant is situated on 400 acres and, together with its buffer zone, encompass approximately 11 square miles. The Plant's primary mission prior to January 1992 was the production of nuclear weapons components fabricated from plutonium and other materials. The mission has now changed to environmental cleanup.

The first of several decommissioning pilot projects being conducted entails the removal of three 200-gallon polypropylene sodium hydroxide tanks and associated piping. Two of the three tanks are insulated with asbestos; therefore, the removal was conducted through the Rocky Flats asbestos abatement program. The tanks were connected to acid scrubbers located on the south side of Building 123. Building 123, located on the west side of the Plant within the main complex of buildings, was used for 30 years in the conduct of bioassays and environmental monitoring sample analysis. The sodium hydroxide used to scrub the acid that collected in the fume hoods was stored in the three tanks. The removal action consisted of removing the transfer lines from the tanks to the scrubbers, neutralizing the sodium hydroxide in the tanks, removing the tanks and packaging them in a waste crate, and transporting them to an approved storage facility while awaiting shipment to an approved disposal facility.

CONCLUSION

DOE is committed to the safe and cost-effective decommissioning of contaminated inactive facilities across the DOE complex. The examples described above illustrate the progress being made in this area. DOE's efforts will continue to become more efficient with the establishment, implementation and coordination of the components of the national decommissioning program.

42-4

DECOMMISSIONING OF SURPLUS FACILITIES AT LOS ALAMOS NATIONAL LABORATORY

Daniel S. Stout
Los Alamos National Laboratory
P. O. Box 1669, Mail Stop M769
Los Alamos, New Mexico 87545

ABSTRACT

Decommissioning Buildings 3 and 4 South at Technical Area 21, Los Alamos National Laboratory, involves the decontamination, dismantlement, and demolition of two enriched-uranium processing buildings containing process equipment and ductwork holdup. The Laboratory has adopted two successful management strategies to implement this project:

Rather than characterize an entire site, upfront, investigators use the "observational approach," in which they collect only enough data to begin decommissioning activities and then determine appropriate procedures for further characterization as the work progresses.

Project leaders augment work packages with task hazard analyses to fully define specific tasks and inform workers of hazards; all daily work activities are governed by specific work procedures and hazard analyses.

State-of-the-art technical strategies are also contributing to the success of the project:

Nondestructive assay methods, including the use of a long-range alpha detector, support characterization work.

A demonstration of an innovative ductwork lining technique will be undertaken.

Sampling and dismantlement techniques recently developed at Oak Ridge National Laboratory were used to treat perchlorate-contaminated items without delaying the schedule.

Together, these strategies have allowed the Laboratory to accelerate the work schedule by one year and reduce fixed costs by $1.4 million.

INTRODUCTION

The purpose of this paper is to discuss procedures for facility decommissioning at Los Alamos National Laboratory and identify lessons learned. Specifically, this paper examines the progress of several decommissioning projects currently being

carried out at Technical Area (TA) 21, where the Laboratory's plutonium processing operations were based until the late 1970s.
Many of the facilities at TA-21 were deactivated at that time and subsequently used for radiochemistry studies. Current decommissioning projects at the site involve 1) demolition of the enriched-uranium processing facility designated as Buildings 3 and 4 South and 2) characterization of plutonium-contaminated process exhaust filter buildings. The Buildings 3 and 4 South decommissioning project began remediation work on September 20, 1993. The project is one of the largest Department of Energy-sponsored decommissioning projects currently under way. The filter building characterization project began in December 1994 and will finish in May 1995. Decommissioning is scheduled to begin in July 1995.

SCOPE

Buildings 3 and 4 South Decommissioning

The first project to be discussed involves the decontamination, dismantlement, and demolition of two enriched-uranium processing buildings covering a total area of approximately 10,000 ft2. The buildings were constructed in 1945 as part of the original plutonium processing site at the Laboratory. The facility was converted from plutonium processing to enriched-uranium recovery in the late 1940s. It operated from that time until 1984 and specialized in the recovery of weapons-grade enriched uranium from scrap, unused fuel elements, and hard-to-recover items. The facility used chemical processes to convert the scrap to purified oxide or uranium metal which could be used in nuclear research programs, reactors, and nuclear weapons.

Building 3 served as the chemical concentration plant, where the scrap uranium was converted to high-quality uranyl nitrate. This building had been partially deactivated in 1987, at which time all solution tanks and associated piping were removed. Left behind were chemical dissolution hoods, a rotary calciner, a hydrofluoric acid cubicle, grinders and mills inside of gloveboxes, and a rag incinerator. An area on the north side of Building 3, Room 308, was not used for uranium chemistry; instead, it operated as a plutonium research laboratory until it was decommissioned in the late 1970s. Residual plutonium contamination was expected to range from 200,000 to 1 million disintegrations per minute per 100 cm2 in several areas.

Building 4 served as the final recovery and purification plant, where pure oxides and metal were produced. The building contains numerous furnaces, uranyl nitrate piping, collection and precipitation systems, and hydrofluorination systems (see Fig. 1).

The superstructure of each building is approximately 98 ft x 39 ft, with a height of 18 ft to the eaves and 26 ft to the center peak of the roof. The buildings are prefabricated, truss-and-purlin steel structures supported by concrete columns. Additional structures attached to Building 3 housed sitewide utilities and a nuclear material storage vault.

At the start of the project, the buildings contained surplus process equipment, approximately 300 linear feet of hoods and gloveboxes, and extensive utility systems. Ninety-three percent enriched uranium was distributed throughout major systems, as shown in Table 1 below.

TABLE I

Additional potential hazards included residual acids and bases, asbestos, and inaccessible contaminated areas such as perimeter utility tunnels.

Filter Buildings

The second project involves the filter buildings at TA-21 and associated process exhaust. They have been identified as near-term candidates for decommissioning on the basis of current facility conditions and potential risk. Prior to actual remediation, detailed information on facility condition, utilities, radioactive contamination levels, and potential chemical contaminants is required. Such information is necessary to comply with hazardous waste requirements, properly characterize waste for transportation and disposal, protect workers and the environment, and support the selection of decommissioning methods.

The filter buildings provided process exhaust to Buildings 2, 3, 4, 5, and 21 at TA-21. Exhaust is still active in Buildings 3 and 4 North; however, all but one hood has been disconnected from the system. The process exhaust filter system consists of three buildings: 21-329, the firescreen; 21-146, the filter building; and 21-324, the filter house. Figure 2 depicts the filter buildings and associated structures.

Fig. 2.

Ductwork exits Buildings 3 and 4 North and runs along elevated stanchions until it reaches the firescreen. The exhaust stream enters this structure, which is an elevated, sheet-metal-enclosed building containing screen filters and washdown equipment. A transparent glass line exits the sheet metal enclosure and discharges into a liquid waste transfer line, which runs to the onsite liquid waste treatment plant. The exhaust then enters Building 146, a concrete block building which houses a large, circular high-efficiency particulate air (HEPA) filter array and a glovebox assembly for changing out the filters. The HEPA filter array consists of a hexagonal filter bank containing six sets of three filters housed in a drum. The drum assembly rotates so that new filter faces can be presented to the airstream, thus reducing by a factor of six the downtime needed for changeout. The exhaust stream then enters Building 324, the filter house, which was added to the flow path in 1973. It contains twenty HEPA filters in parallel. Exhaust then releases through the stack at the north end of the building.

Decommissioning of the filter buildings will involve removal of the process exhaust ductwork from Buildings 3 and 4 North; the elevated ductwork which runs into Building 146; the HEPA filters and glovebox and drum assemblies in 146; the firescreen and all ductwork and stacks in 146; the HEPA filters in Building 324; and all ductwork and stacks in 324. Both buildings will then be demolished.

PROJECT ORGANIZATION AND WORK PLANNING

The Laboratory is responsible for overall project management, health physics, environmental compliance, criticality engineering, and waste management. Subcontractor oversight in the areas of engineering and health and safety also are performed by the Laboratory. Dismantlement is performed by Johnson Controls World Services, Inc., the onsite maintenance subcontractor. Johnson Controls also provides industrial hygiene services and develops work packages.

For Buildings 3 and 4 South, site characterization began in 1992 and was completed in September 1993. This effort consisted of environmental review and approvals required by the National Environmental Policy Act and radioactive air emissions standards; development of project plans, including those for project management, health and safety compliance, waste management, and quality assurance; and historical and radiological data collection.

Characterization of the entire facility was not conducted. Instead, the Laboratory follows the "observational approach" for decommissioning projects. Rather than extensively characterizing the entire project, enough data is collected to begin activities. Detailed procedures are developed as the work progresses, and additional information is collected as necessary. This process avoids efforts which can be rendered useless due to newly discovered problems, but it requires flexibility in scheduling and completing activities. The following section discusses the application of this approach to the filter buildings.

Because the emphasis is on minimizing characterization activities, the bulk of work planning is done during remediation. The removal of utility tunnel piping is a good example of this work planning process. Buildings 3 and 4 have interior, 4- x 4-ft utility tunnels which traverse the building perimeter and are located below the floor slab. The tunnels contain steam, condensate, industrial waste, and acid waste lines and are contaminated due to system leaks over the years. Access to the tunnels is through hatches outdoors; however, current safety requirements do not permit entry. Tunnel decommissioning followed a methodical process to initially identify radiological conditions and general piping configurations through visual inspections and coring samples. Work then proceeded to remove the top of the trenches using a large floor saw. Finally, the tunnels were thoroughly surveyed and dismantled.

FILTER BUILDING CHARACTERIZATION

The characterization activities necessary to support decommissioning of the filter buildings include historical records reviews and interviews with former users, collection and revision of applicable drawings, utility identification and review, and radiological and chemical sampling. In some cases, sampling will be postponed until actual decommissioning, for accessibility or safety reasons. The data acquired from the characterization will principally support demolition activities and waste characterization requirements.

Engineering data requirements consist of utility and structural information. Specifically, the locations of all utilities and any necessary reroutes must be identified. Structurally, the characterization effort must ascertain whether the

Building 146 drum assembly will rotate. The drum has not been turned since the 70's, and seal integrity and the opposite filter banks are items of concern. Existing drawings will be collected for reference and will be annotated to identify the as-left facility condition. Historical records will be reviewed to identify any abandoned utilities and any facility modifications which could affect decommissioning.

Knowledge regarding types and quantities of contaminants is essential for decommissioning operations and waste handling. Radioactive waste may be either low-level or transuranic, while chemical contamination may result in hazardous or mixed waste. Potential contaminants have been identified from the remedial action work plan, operating summaries, decommissioning summaries, and historical interviews. Radionuclides of concern are U-235, U-238, Pu-238, Pu-239, Tc-99, Am-241, Am-243, Np-237, Th-232, and Pa-231. Chemical concerns include asbestos (146 HEPA filters), metals (146 HEPA filters), PCBs (lighting ballasts), perchlorates (ductwork, 146 filters), and picric acid.

Because the data address waste management and safety concerns, exact readings are not as important as bounding readings. The data should identify thresholds for waste categories or personal protective equipment requirements.

A significant amount of data currently exist for this project (Marshall 1994). This information was obtained during a Laboratory-wide project to quantify special nuclear material holdup in ventilation systems. These data indicate that sizable portions of the process exhaust would be classified as transuranic waste. The project will decontaminate the ductwork during decommissioning to minimize the volume of transuranic waste. Accordingly, during decommissioning the removed ductwork and decontamination waste will be characterized for waste disposal purposes. This approach also recognizes the difficulty and expense of sampling exhaust systems prior to removal. Likewise, HEPA filter sampling is best left until actual removal, at which time the filters may be sawed into pieces and samples obtained more easily.

Additional data will be collected to measure radioactivity in systems not addressed during previous holdup measurement campaigns. Measurements will be made using nondestructive assay methods with Sodium Iodide and Germanium detectors. Items likely to be free of contamination will nevertheless be surveyed to verify that no unexpected radioactivity is present. Appropriate engineering controls will be used during decommissioning to protect uncontaminated materials.

Except for one small spot of contamination on the floor of Building 146, there have been no historical releases within either Building 146 or 324. The walls and floors should be free of contamination. The long-range alpha detector (LRAD), an experimental system developed at Los Alamos (Rawool-Sullivan et al. 1994), and conventional gas-proportional instruments will be used to systematically survey the structures to verify that the material is uncontaminated.

Facility processes did not involve hazardous wastes listed under the Resource Conservation and Recovery Act (RCRA). The RCRA facility investigation work plan does identify metals as a potential contaminant of concern, so the Building 146 filters will be sampled for metals. Sampling for metals, like the surveys for radioactive constituents mentioned above, will be performed at the time of filter removal. Building 146 has been sampled for perchlorates. This sampling will be repeated after the drum has been turned. Historical records suggest that picric acid was used for some experiments. Building 146 will be tested for picric acid before and after turning the drum. During disassembly, duct systems will routinely be tested for perchlorates.

The HEPA filters contain asbestos, and the roofs of both buildings may contain nonfriable asbestos-contaminated material. The roofing material will be tested for asbestos. Lighting systems will be inspected for PCBs during disassembly, and fluorescent bulbs will be handled as hazardous waste.

TABLE II

HEALTH AND SAFETY

The Laboratory and project adhere to rigorous health and safety practices. A system is followed in which we develop work packages consisting of technical work procedures and special work permits, i.e., radiation work permits (RWPs), augmented with task hazard analyses (THAs). The THA fully defines specific tasks, identifies protective measures, and informs workers of hazards. These work packages supplement the project plan and site-specific health and safety plan. The process also employs

a graded approach in procedure development.
For example, the work package for routine decontamination activities consists of an RWP and a THA. More difficult operations, such as hood and glovebox removal, also have a work procedure in addition to the aforementioned permit and THA. Because the exact hazards and sequence of activities can vary among hoods and gloveboxes, the THA is modified when warranted.
The last type of work package addresses unique, higher-hazard systems, for which a detailed work procedure is prepared. Again, the procedure is augmented with RWPs and a THA. Because the Laboratory reviews and approves all work procedures, but not all THA revisions, this last category invariably receives additional scrutiny from project managers. Regardless of type, all daily work activities are tied to the specific governing work procedure-THA package, and this information is recorded by the site safety officer. Thus far, the project has recorded one lost workday case due to infection of a small cut.
The Laboratory provides an extensive radiological protection program for the project. The program consists of radiological engineering, dosimetry, bioassay, and health physics coverage of operations. An ALARA (i.e., as low as reasonably achievable) Committee reviews all relevant work procedures. Total dose received by all personnel to date is approximately 40 mrem.
The TA-21 Decommissioning Health and Safety Plan also is followed for filter building characterization activities. Characterization activities requiring documentation are 1) the perchlorate and picric acid testing procedure, THA, and RWP; 2) the drum turning THA and RWP; and 3), the structure survey procedure, THA, and RWP

DECOMMISSIONING TECHNIQUES

The project follows current, accepted industry practices. Because alpha contamination is the radioactive hazard in question, remote systems are unnecessary, but health, safety and environmental practices are nonetheless rigorous. For example, at the start of the project, the exhaust system for Building 3 was cut off, the stack capped, and portable HEPA systems were brought in to control general and process ventilation. These steps were required, since the building lacked an efficient filtration system, and dismantlement activities could have resulted in increased emissions. The net result was that during decommissioning, site emissions were significantly reduced by means of a filtration system that was more efficient than that used at the facility during forty years of operations.
Also, at the start of remediation, an extensive hood and glovebox residual-uranium assay was performed. The data was necessary for reasons relating to safeguards and waste transportation and disposal. Measurements were performed in situ by the Laboratory's safeguards assay group using portable field instruments. Air sampling stations were installed around the site perimeter to collect data on fugitive dust emissions.
The general decommissioning sequence consists of system electrical disconnects, acid line and piping removal, hood and glovebox removal, exhaust system removal, asbestos removal, concrete floor sawing, utility piping removal, final system disconnects (i.e. electrical and fire protection), and building demolition.
For the demolition of Building 3, the Laboratory rented a hydraulic shear and trackhoe. Although renting equipment is common in the commercial sector, the practice had not been used before by the Laboratory due to the potential for contamination. The risk of contamination was low, and the advantages of increased productivity, improved worker safety, and effective waste segregation and minimization clearly outweighed the contamination risk. Building 3 was demolished using the shear in August 1994, and the equipment was cleaned and returned without incident. Figure 3 shows the shear in operation. Additional air monitoring stations were placed to monitor emissions.
Fig. 3.
Building 4 presents several unique challenges. The process exhaust ductwork runs the exterior length of the building on both sides and is constructed of fiberglass-coated stainless steel. Each side contains approximately 300 g of enriched uranium. Removal will require secondary containment and work at a height of 15 ft to 25 ft above the ground. One portion of the utility tunnel is reputed to have a very deep pit, currently covered with steel plating and asphalt, formed by a long-term, low-volume hydrofluoric acid leak.
Some new technology is being developed and applied to the project; however, only

proven technologies are considered. As previously noted, portable nondestructive assay methods are used for determining glovebox and ductwork holdup. Additionally, the LRAD is being used for concrete characterization and for the free release of items.

The Laboratory has issued a contract to demonstrate an innovative duct lining technique to either fix contamination inside ventilation systems or remove the contamination. A fabric liner soaked with commercially available strippable coating is everted into the duct using a pressurized canister. After curing, the liner may be removed to decontaminate the duct. Our goal is to decontaminate transuranic waste ductwork to levels low enough to allow recycling.

WASTE MANAGEMENT

Wastes generated on the project are classified as low specific activity or nonradioactive for transportation purposes and as low-level waste (LLW) for disposal purposes. The project waste volume estimate is 2000 yd3 of LLW. Additionally, radioactively contaminated asbestos has been generated (50 yd3), as have small amounts of mixed waste. Waste is disposed of at the Los Alamos LLW disposal facility. During the demolition of Building 3, most waste was placed into 20- x 8- x 8-ft standard shipping containers. Considerable compaction was achieved, and the entire container was disposed of.

Laboratory and Department of Energy policy precludes the free release of any material with detectable activity above background, even when the surface contamination is below release guidelines. While some materials have been released to a municipal landfill following demonstration of no detectable activity, waste minimization activities primarily emphasize volume reduction through on-site compaction and recycling of contaminated scrap metal. Concrete will be cleaned using a shot vacuum system, and the remaining slabs will be crushed and used as onsite fill. Through recycling, steel decontamination, and concrete crushing, low-level radioactive wastes from decommissioning Building 4 should be reduced by 60% compared to those generated at Building 3.

Soil remediation is coordinated with the Laboratory's remedial action project. Sampling and other activities also are coordinated to ensure data applicability and cost effectiveness.

COST AND SCHEDULE

The Building 3 and 4 South decommissioning was originally scheduled to last for three years, with a total project cost, including assessment, of $7.5 million. By accelerating the remediation schedule to two years, fixed costs are reduced significantly. Currently, the project is scheduled to be completed in September 1995, with a total project cost of $6.4 million. This does not include the costs for disposing of LLW, as the Laboratory waste management groups are funded directly. The filter building characterization effort will cost approximately $250,000.

LESSONS LEARNED

The main lesson learned to date involves the discovery, during system disassembly, of perchlorates in the Building 3 process exhaust system. Use of perchloric acid had not been identified during the assessment phase, when many records were reviewed and former operators interviewed. Perchlorates are shock and temperature sensitive, although they may be handled safely when wet. Experts from Oak Ridge National Laboratory were called in to assist in solving the problem. Considerable time and money was saved by using their proven techniques instead of developing solutions internally (Phillips et al. 1994). Perchlorate sampling and analysis were performed in the field using a portable ion-specific electrode system. Dismantlement required steaming two 3- x 3- x 20-ft sections of ductwork that joined to form a central upsweep that ran through the building attic and onto the roof. The system was disconnected in the attic and lowered to the floor, and the large section of ductwork was cut into smaller sections and rinsed in tanks of water.

Another important lesson learned is that the observational approach is very effective from both cost and schedule perspectives. By minimizing characterization activities, initial expenses and time to completion are reduced. Moreover, involving the people who will be doing the physical work in the work planning simplifies the techniques used and guarantees the feasibility of the chosen techniques.

ACKNOWLEDGMENTS

This work is funded by the U.S. Department of Energy and is being carried out under the Los Alamos National Laboratory Environmental Restoration Project.

ABSTRACT

The West Valley Demonstration Project (WVDP) is located at the Western New York Nuclear Service Center (WNYNSC), approximately 40 miles south of Buffalo, New York. The WNYNSC reprocessed over 600 metric tons of irradiated fuel between 1966 and 1972; this reprocessing operation also produced more than two million liters (600,000 gallons) of high level wastes stored in subsurface tanks. In 1980, Congress passed the West Valley Demonstration Project Act authorizing the Department of Energy to conduct a high level waste management project on the WNYNSC site. The two million liters of liquid wastes are to be processed and solidified by vitrification, then transported to a federal repository for disposal.

An analytical tool has been developed for use in the decontamination and decommissioning (D&D) planning process. This tool is being used specifically to develop viable facility closure scenarios that, through pathway analysis, will allow identification and selection of D&D criteria for the WVDP and the WNYNSC. The criteria development process is unique because the WNYNSC is home to the only commercially licensed irradiated fuel reprocessing facility ever to operate within the United States. This process is more complex because the Department of Energy and the State of New York both have defined roles in the site decommissioning, through the 1980 Act and the Operating License. To complete the project, the Act requires the DOE to decontaminate and decommission facilities used for the WVDP to criteria prescribed by the Nuclear Regulatory Commission. To terminate the operating license, New York State must also meet prescribed criteria set forth by the NRC.

INTRODUCTION

Background

The Western New York Nuclear Service Center (WNYNSC) near West Valley, New York was the site of the only commercial nuclear fuel reprocessing facility ever operated in the United States. The reprocessing facility operated from 1966 to 1972 and generated approximately two million liters of high level radioactive waste (HLW), which is stored in underground tanks at the site. The plant was shut down in 1972 for modifications and upgrades, but was never brought back on-line.

The processing facility was licensed by the Nuclear Regulatory Commission (NRC) to operate under Operating License CSF-1, Docket No. 50-201, with the New York State Energy Research and Development Authority (NYSERDA) the licensed owner of the site and facilities, and Nuclear Fuel Services (NFS) the licensed operator. In response to a request by the AEC (Atomic Energy Commission), the New York Atomic Research and Development Authority (predecessor to NYSERDA) amended the operating license application, indicating the recognition and acceptance by the State of New York of the perpetual responsibility for caring for the waste stored at the site.

In 1980, the United States Congress passed Public Law 96-368 called the West Valley Demonstration Project Act (the Act), authorizing the DOE "...to carry out a high-level liquid nuclear waste management demonstration project at the Western New York Nuclear Service Center in West Valley, New York." The West Valley Demonstration Project (WVDP) was established to demonstrate that HLW from the reprocessing of spent nuclear fuel can be managed safely in the United States. The Act directs the

DOE to: (i) solidify the HLW; (ii) develop containers suitable for permanent disposal of HLW; (iii) transport the solidified HLW to a federal repository for permanent storage; and (iv) dispose of the low level radioactive waste (LLRW) and transuranic (TRU) waste produced during the project. It also requires the DOE to decontaminate and decommission (D&D) the tanks and other facilities used during the solidification process, and "...any materials and hardware used in connection with the project in accordance with such requirements as the Commission may prescribe."

Purpose

The purpose of this paper is to describe a tool for use in developing D&D criteria for completion of the WVDP. The WVDP Act requires DOE to decontaminate and decommission project facilities in accordance with such criteria as the NRC may prescribe. With respect to the WVDP, it is important to assure that the standards developed are applicable to the decommissioning responsibilities of the DOE and New York State, and that both parties are subject to manageable and realistic criteria. During 1993, decommissioning planning for the WVDP was initiated by defining plausible regulatory options for the DOE to satisfy its project responsibilities, as well as identifying possible regulatory options for NYSERDA, the site owner. Although the DOE is not subject to the specific regulatory requirements that are imposed upon NYSERDA, there are agreements in place to ensure that, upon Project completion, there is an orderly transition from DOE operation to NYSERDA operation. It was decided to begin D&D planning by "scoping" the possible end results of decommissioning, thereby identifying areas of concern and uncertainty that could be factored back into the earlier planning process. A summary of last year's scoping effort is presented in the following section.

REGULATORY OPTIONS

A key aspect of project decommissioning is the prescription of D&D criteria; this task is the responsibility of the NRC. The NRC will execute this responsibility in a manner consistent with its rules, regulations, and policy. Since there is a Part 50 operating license for the facility, the NRC is most likely to identify WVDP D&D criteria consistent with the potential regulatory options for the facility. Four regulatory options have been identified as those most likely and available for implementation at the WVDP. They are:

- License Termination
- Amending the Existing License
- License Conversion
- Rulemaking

These four options represent possible long-term regulatory solutions for completion of the WVDP, and provide a general "target" for D&D planning. The long-term solution will be dependent on the Record of Decision (ROD), which will be issued after completion of the Environmental Impact Statement (EIS), scheduled for October 1996.

D&D SCENARIO AND CRITERIA DEVELOPMENT APPROACH

Results of Regulatory Option Review

The four regulatory options can be evaluated relative to possible closure scenarios for the diverse facilities at the WVDP, and the resulting combinations in terms of the regulatory options can be assessed. For example, license termination would require that waste and facilities be removed from the site to satisfy site release requirements. However, at this time there is no repository available to receive much of this waste, rendering this regulatory option somewhat impractical. To more thoroughly evaluate the interrelationships between individual facility closures and possible final regulatory solutions for the WVDP, a matrix evaluation tool has been developed to permit the systematic evaluation of facility-closure combinations, referred to as D&D scenarios.

Matrix Overview

The matrix is a tool for qualitatively evaluating the various factors influencing a process. The matrix looks at environmental, programmatic, regulatory, and administrative impacts. In addition, the matrix process allows for the site to be evaluated at the facility/equipment level, instead of the entire site as a unit. For example, in the matrix, an evaluation for shipping HLW to a federal repository for permanent disposal would be based on the feasibility of such a facility in the decommissioning phase, rather than on the desirability of that option based on environmental concerns. If the facility/closure option is not feasible under the matrix evaluation, only the facility is impacted, rather than the entire site. The matrix also reflects available information from the EIS and other pertinent

documents in the evaluation of facility - closure option combinations. Use of the matrix results in plausible D&D scenarios, which can then be evaluated further using pathway analyses. The resulting outcome of the pathway analyses is data that can be used to develop site-specific D&D criteria.

APPLICATION OF THE MATRIX TOOL

A matrix approach provides an alternate and practical solution for evaluating potential closure options for the WVDP following vitrification. The matrix approach involves selection of facilities and closure options for evaluation using predetermined screening criteria. The criteria address elements of significance to the project, e.g., safety, compliance, cost, community acceptance, etc. Each of these elements can be given a relative weighting when compared with other elements. This is followed by assigning relative ranking for a particular option. These values (weights and ranking) are applied to select facilities and options in a matrix format. Iterations and summation of the numerical scores lead to development of a short list of realistic options for individual facilities or for the project as a whole.

Although specific facilities, closure options, and screening criteria have been identified for the current application, it should be noted that each of these parameters can be modified to meet project needs. Trial runs with the matrix approach indicate that it represents an economical and viable solution for the current WVDP needs. The approach is flexible enough to cater to changes in the project environment and evolving regulatory requirements.

Following is an example to illustrate how this process can be utilized for selection of candidate D&D scenarios for the WVDP. Evaluation using this matrix approach follows the following sequence:

- Identify facilities for consideration
- Identify potential options for closure
- Decide upon the key factors that influence each option
- Assign numerical weighting factors (optional)
- Evaluate and determine the numerical value for each cell
- Tabulate results, round off, and simplify
- Compare results, select options with best scores
- Review and eliminate impractical options
- Prepare a short list of scenarios for further evaluation (pathway analysis)

Identify Candidate Facilities

Applying this approach at the WVDP, the first step in the matrix evaluation process was selection of facilities potentially requiring cleanup and/or removal. Eleven facilities were selected for evaluation in the matrix. These facilities include site buildings/areas having the greatest potential for radiological impact. These facilities were either used for vitrification of HLW or will have a significant impact on any D&D decision made for the site. Facilities included in the current analysis are:

- Process Building
- NRC-Licensed Disposal Area (NDA)
- State-Licensed Disposal Area (SDA)
- Low Level Waste Treatment Facility (LLWTF)
- High Level Waste Tanks
- Vitrification Building
- Liquid Waste Treatment System (LWTS)
- Chemical Process Cell Waste Storage Area (CPC-WSA)
- Radwaste Treatment System Drum Cell
- Lag Storage Areas
- Construction and Demolition Debris Landfill (CDDL)

Identify Candidate Closure Options

A closure option is determined by what activities are to be performed on a particular facility and what the outcome to the facility would be following completion of those activities. Ten closure options were chosen for evaluation. These options cover the range of possibilities and yet keep the number manageable:

1. Complete removal from site
2. Complete removal to new on-site storage facilities
3. Complete removal to existing on-site storage facilities
4. Partial removal to new on-site storage facilities

5. Partial removal to existing on-site storage facilities
6. Complete removal to new on-site disposal facilities
7. Complete removal to existing on-site disposal facilities
8. Partial removal to new on-site disposal facilities
9. Partial removal to existing on-site disposal facilities
10. Monitor and maintain

There are now eleven facilities to be evaluated against ten closure options, which results in numerous facility/closure option combinations, such as complete removal of one facility, partial removal of another facility, monitor and maintain a third facility, and so on. However, it is not cost-effective to develop D&D criteria for all 110 possible facility/closure option combinations. A method to reduce the number of facility/closure option combinations to those that are most plausible involves the use of screening criteria.

Screening Criteria

Screening criteria are the elements to be evaluated for a given facility and closure option. The major factors considered in the selection of screening criteria are environmental impacts, regulatory and institutional constraints, public desires, congressional support, technical feasibility, and costs. From these factors, nine screening criteria were selected for use in evaluating the facility-closure option combinations. These criteria were considered appropriate because they address issues of mutual interest to the DOE and New York State, the active role of the state and the local community in the decision-making process, and the safety and cost-related aspects that are considered in all evaluations. The nine screening criteria are:

- Safety
- Compliance
- Long-Term Effectiveness
- Short-Term Effectiveness
- Reduction
- Implementability
- Cost
- State Acceptance
- Community Acceptance

Prior to beginning the evaluation, it is critical to ensure that the screening criteria are thoroughly defined and understood by all participants. Screening criteria may be weighted in the matrix based on their relative importance to each other, or may be evaluated without weighting factors.

Ranking

Ranking determines the importance of a screening criterion in a particular facility-closure option combination. For example, of all the facilities considered for complete removal, the Process Building represents the potential for highest occupational radiation exposure; therefore, this closure option would be rated poor (low score) for safety in this particular situation.

Each facility/closure option combination was ranked for each of the nine screening criteria. The screening criteria were assigned a value between 0 and 5 (0 not being viable and 5 being good), based upon the importance and applicability to a particular situation. The ranked values for the nine criteria for each facility/closure option combination are then totaled to determine the overall score for that combination. Any criterion given a 0 for a particular facility/closure option combination (for example, implementability for "complete removal from site") results in a zero for the entire combination, thereby dropping that combination from further consideration.

Matrix Completion

Figure 1 shows a portion of a matrix completed during a trial run by the process described in this report. The first step in completing the matrix was to list facilities and closure options in a row and column format as the variables. A numerical value (ranking) was noted in the matrix cell; the upper left matrix cell represents a numerically assessed comparative value of "0" for "Complete Removal From Site" of the "Process Building." This illustrates the rejection of a facility/closure option combination that is not viable because of a zero assigned to one of the screening criteria. This also applies to complete removal of the NDA. Fig. 1.

The first matrix cell in the column for "Monitor and Maintain" the "Process Building" was assigned a numerical ranking of "18." This ranking is the sum of

assessed values for each of the nine screening criterion described previously. For example, this cell shows a numerical value of "2" for Safety, a value of "1" for Community Acceptance, and so on. The rationale for arriving at this value was provided in the previous section. The argument to assign a low value of "2" for Safety was that this option could involve greater potential for exposures, industrial accidents, resulting contaminations, etc. Similarly, a low value of "1" for Community Acceptance represents the unacceptability of this option to the local community; we have assumed the community would not be very receptive to any waste or facilities associated with waste to be maintained on-site.

Although a value assigned for each criterion listed in a cell is subjective (dependent on the individual evaluator), it tends to be normalized under the given constraints and in comparisons with the other closure options. As the evaluation progresses, the evaluator may decide to revise a previously assigned value, thus leading to further normalization. It is this iterative process, involving reasoning, that eventually leads to convergence of individual assessment results.

Scenario Development

The process starts with a tabulation of the results in each cell and a summation to get a total picture. The table leads to a short list of closure options that are viable for each facility. Those options with the highest scores are evaluated further. These highest ranking closure options are reviewed for each facility and a determination is made as to whether the option is prudent to implement. For example, it will not be prudent to demolish a facility because it is shown to be an economical choice, and then construct another to support monitoring and maintaining of another facility. Thus the evaluation involves a "reality check;" evaluations take a realistic view of the surrounding conditions and environment.

Theoretically, the "preferred closure option" for each facility should be that option having the highest value in the matrix. However, in developing scenarios that would include similarly ranked facility/closure option combinations for each facility, we elected to eliminate those facility/closure option pairings that required actions that were not in concert with the preferred closure options taken for other facilities on site. This approach enabled us to focus on those options that made sense in the overall scheme of site D&D.

In summary, the highest ranking options are reviewed for each facility and a determination is made as to which options make sense considering what is being done with the other facilities on site. The result of such an interactive approach is that the closure options with the higher rankings will not be chosen for a particular scenario if the choice does not make sense in the overall D&D process. The compilation of plausible facility/closure options results in a "D&D scenario" that represents a possible site configuration, or goal, for decommissioning. D&D scenarios are further evaluated using pathway analysis. The resulting outcome of the pathway analyses is data that can be used to develop site-specific D&D criteria. As previously discussed, a preliminary matrix run has been completed, and the resulting D&D scenarios are being used to set up and test the pathway analysis program. The current plan is to perform a matrix run using a wider range of participants from other organizations that were not involved in developing the preliminary matrix, and to use the resulting scenarios for pathway analysis.

CONCLUSION

Using a matrix approach to analyze complex issues involving regulators and federal and state agencies is neither new nor uncommon. Experiences to date in developing and piloting this matrix tool have shown a number of benefits in using this type of an approach. Some of these benefits are as follows.

Benefits

Easy to Use: A process employing a matrix approach is quite simple to understand and easy to use.

Implementable: Because of its simplicity, adaptability to varied situations, and cost-effectiveness for the evaluation, it is easier to implement than other more quantitative methods.

Ownership: Since the evaluators have direct first hand knowledge and involvement in the process, they have a sense of ownership and are more likely to support the results and implementation.

User Friendly: By developing a computer program to run the analysis, we have further simplified it and made it user friendly.

Wider Range: It addresses several areas of interest to evaluators with different

backgrounds, and it can be used by a wide range of individuals.
Involvement: It is one of the few methods where project stakeholders can directly provide their input or run the analysis for themselves. It provides a vehicle for discussion and can be used to solicit input in a timely manner. The decision makers are more likely to approve the results because of the stakeholders' early and continued involvement and understanding of the process.
Economical: The process requires neither advanced computer software nor technology to implement. The costs associated with the evaluation are minimal.
Iterative: Several iterations can be performed to suit varied needs or to adjust to changes in the regulatory or political environment more quickly and at a fraction of the cost of quantitative methods.
Acceptance: This approach has been used frequently by federal, state, and regulatory agencies, and by commercial groups; it finds wide acceptability with users and regulators.

ABSTRACT
Environmental restoration efforts in the government and private sectors are currently challenged with remedial decisions for a variety of hazardous and mixed waste matrices. Soils and sludges require the application of remedial technologies to separate out hazardous organics, metals or radionuclide contaminants to meet applicable regulatory cleanup criteria. Destruction technologies which typically complete thermal, vapor extraction and stripping technologies chemically alter organics to destroy them through oxidation into carbon dioxide , water and in some cases acid gases. The most commonly used oxidation processes are incineration, catalytic oxidation, regenerative oxidation and flameless oxidation. Flameless thermal oxidation is an attractive VOC destruction alternative because it combines many of the advantages of the various flame-based methods but avoids most of the problems inherent to those methods. Its packed bed design operates by preheating an inert ceramic matrix to 1600-1800F and then passing the premixed organic vapor stream (plus additional air and fuel as needed) through the bed to effect uniform and nearly complete oxidation. Because the destruction matrix is inert and non-catalytic, halogenated and sulfonated compounds do not affect system life and since it is flameless, its efficiency of oxidation is not impacted by a flame's inherent instability The large thermal mass of the oxidizer bed accommodates significant moisture content and fluctuations in organic stream concentrations without effecting process efficiency.
This paper presents several designs for remedial systems which can be enhanced by incorporation of flameless thermal oxidation for very effective VOC abatement and heat recovery for process reuse. Specifically discussed are enhanced designs for 1) low temperature thermal desorption, e.g., for the removal of volatile (VOC) and semi-volatile (SVOC) organics from soils, sludges or other solid matrices; 2) in situ vapor extraction (SVE) e.g., for the removal of spilled organics from the vadose and saturated zones of soils; and 3)heated air/steam stripping, e.g., for removal of volatile organics from surface and ground waters. Towards the realization of such enhanced remedial systems, several planned small-scale demonstrations at DOE sites are discussed, specifically 1) a demonstration of a Thermatrix ES-300H oxidizer in an SVE chlorinated organic destruction application at the Savannah River

Site; 2) a demonstration of a Thermatrix GS-100M oxidizer as the secondary combustion chamber of the Plasma Arc Furnace at DOE's CDIF facility in Butte, Montana; and 3) a proposed technology development program through DOE's Morgantown Energy Technology Center to produce an innovative, non-incineration thermal treatment system to remediate mixed-waste contaminated solids at DOE facilities.

COMMON REMEDIAL TECHNOLOGIES AND THE VOC WASTESTREAMS THEY GENERATE FOR TREATMENT OR DISPOSAL

Environmental restoration efforts in the government and private sectors are currently challenged with remedial decisions for a variety of hazardous and mixed waste matrices. Soils and sludges require the application of remedial technologies to separate out hazardous organics, metals or radionuclide contaminants to meet applicable regulatory cleanup criteria. Surface and ground waters that have become contaminated by contact with hazardous, radioactive or mixed waste constituents must also undergo processing to achieve "clean water" status as defined by regulatory contamination limits. In nearly all cases where mixed waste is involved, either the hazardous or radioactive constituent must be removed from the waste, e.g., hazardous organics removed to leave a radioactive-only waste, to allow for compliant disposal at either a RCRA or radioactive landfill.

The present paper promotes the enhancement of several remedial technologies which have found widespread application in hazardous and mixed waste treatment at site remediations: 1) low temperature thermal desorption, e.g., for the removal of volatile (VOC) and semi-volatile (SVOC) organics from soils, sludges or other solid matrices; 2) in situ vapor extraction, e.g., for the removal of spilled organics from the vadose and saturated zones of soils; and 3)heated air/steam stripping, e.g., for removal of volatile organics from surface and ground waters. Furthermore, this paper describes the role that recuperative flameless thermal oxidation can play in not only enhancing the operation and performance of these "separation" technologies but also in the very high destruction and removal efficiencies (DRE) for volatile organics it can achieve.

VOC DESTRUCTION OPTIONS FOR REMEDIAL ORGANIC WASTESTREAMS

Destruction technologies which typically complete thermal, vapor extraction and stripping technologies chemically alter organics to destroy them through oxidation into carbon dioxide , water and in some cases acid gases. The most commonly used oxidation processes are incineration, catalytic oxidation, regenerative oxidation and flameless oxidation.

Flame-based incineration has been a widely used method of VOC destruction but has recently come under greater regulatory scrutiny and constraint. With incineration, liquid or vapor organics pass through a highly reactive flame zone and are converted to non-hazardous products or easily neutralized species. Due to the inherent instability of flames however, this process is often incomplete, with the formation of undesirable products of incomplete combustion (e.g., phosgene, dioxins).

For many applications catalytic oxidation is an improvement over flame-based incineration. Organic destruction takes place more rapidly in the presence of a catalyst than in a homogeneous gas stream. Or alternatively, the same destruction rate can be achieved at lower temperatures. Catalysts can perform well with a wide variety of hydrocarbons, although most are poisoned by sulfur and halogen containing compounds. While incineration is typically used with rich organic streams, catalytic oxidation is often preferred for the destruction of streams with moderate to lean fume content. Streams with varying richness may cause sintering or deactivation of the catalyst surface.

Regenerative oxidizers are used primarily in low-concentration organic stream applications. They typically feature a flame-based combustion chamber interconnecting two or more fixed beds. The inlet and exhaust flows are alternately diverted across the beds through complex valving. The incoming organic stream is preheated in one bed while the heat released during oxidation is captured by the other bed(s) as the exhaust gases exit the system. An oxidation chamber connects the beds and is heated by flame burners or electric elements. Regenerative oxidizers typically achieve 80 -98% heat recovery which aids in the efficient destruction of highly dilute organic streams. Due to the alternating nature of the flow distribution network and the design of the oxidation chamber, DREs are typically <99%. In order to prevent overheating, regenerative oxidizers must add large amounts of dilution air to process rich streams.

Flameless thermal oxidation (FTO) is an attractive VOC destruction alternative

because it combines many of the advantages of the various flame-based methods but avoids most of the problems inherent to those methods. Its packed bed design operates by preheating an inert ceramic matrix to 1600-1800F and then passing the premixed organic vapor stream (plus additional air and fuel as needed) through the bed to effect uniform and nearly complete oxidation (See Fig. 1.). Because the destruction matrix is inert and non-catalytic, halogenated and sulfonated compounds do not affect system life and since it is flameless, its efficiency of oxidation is not impacted by a flame's inherent instability The large thermal mass of the oxidizer bed accommodates significant moisture content and fluctuations in organic stream concentrations without effecting process efficiency. The following table presents performance data from commercial and laboratory unit testing.
Fig. 1.
TABLE I
The recuperative design takes flameless thermal oxidation one step further. Instead of introducing organics directly to the bed, the organics enter the oxidizer through a series of tubes running vertically through the bed. Upon exiting the tubes near the top of the bed, the organics enter a reaction zone and are oxidized. As the oxidized vapor is directed back down through the bed toward the exhaust outlet, its heat is imparted to the incoming organic vapor rising vertically through the tubes which increases the efficiency of the overall process. This "single pass" design overcomes two major problems associated with regenerative thermal oxidation, specifically the absence of any volume of unreacted fume to degrade DRE and the elimination of a need for complex valving or indeed any internal moving parts. Our experience with a 6500 scfm scale recuperative oxidizer in the paint applications industry confirms this performance expectation with respect to heat recovery, high DRE (>99.99%) and trace to non-detectable criteria air pollutants emissions. (<2 ppm NOx; <10ppm CO).
Recuperative flameless thermal oxidation (RFTO) offers several other advantages which significantly enhance remedial applications. RFTO is designed to accommodate low concentration, moderate to high flow vapor streams which are typical of many remedial separation technologies, e.g., SVE and air/stream stripping of groundwater. RFTO as a destruction method routinely achieves greater than 99.99% DREs for the halogenated (and non-halogenated) hydrocarbons typically found in ground-spilled hazardous organic remediations. Along with excellent DREs, RFTO produces only trace to non-detectable oxidation byproducts (e.g., carbon monoxide and nitrogen oxides), easily meeting current air emission standards. Depending upon the concentration of organic vapor entering the recuperative oxidizer, the efficiency of heat recovery would allow for excess heat utilization in such applications as heated air/steam generation for enhanced SVE or groundwater treatment or in the case of thermal desorption, preheating and inerting of the kiln interior for safe, efficient separation of organics from soils and sludges.
Before discussion of enhanced remedial system designs, it will be useful to look more closely at the recuperative FTO design and the benefits to be derived from it.
RFTO DESIGN AND ITS BENEFITS
A typical recuperative flameless thermal oxidizer consists of a refractory lined alloy steel shell, a refractory lined tubesheet, heat exchange tubes, a preheat burner, a gas introduction port and an exhaust port. The vessel, above the tubesheet, is filled with ceramic packing. The ceramic packing is located both inside and outside of the heat exchange tubes. (See Fig. 1.)
In operation the recuperative reactor is first preheated. This is accomplished by firing a burner into the top chamber of the reactor. The burner is fired only long enough to heat the top 16 inches of the packing to above 1400F. The alloy tubes within the packed bed are kept cool during the preheat process by flowing a small amount of air through them. At the end of the preheat stage a temperature gradient exists in the packed bed, from >1400F at the top of the bed, to several hundred degrees at the bottom of the bed.
After preheating, a mixture of air, fuel, and organic compounds to be destroyed is introduced into the reactor, in the area below the packed bed called the plenum. The plenum is separated from the packed bed by a refractory lined tubesheet. The plenum area is kept cool by the continuous flow of cool reactant gases into this area. From the plenum, the gases are directed into the heat exchange tubes. As the influent gases flow through the tubes, they pick up heat from the hot exhaust gases flowing counter current on the outside of the tubes.

As mentioned above, the tubes are filled with ceramic bed media. The bed media within the tubes serves two functions. Its first purpose for the packing inside the tubes is that it aids in the heat exchange process. Since the gases are optically thin, heat transfer by radiation would be very inefficient. However, heating the gases by forced convection makes the heat exchange to the gases much more efficient. The second purpose for the bed is to act as a flame arrestor. This is accomplished by increasing the gas velocity to a value higher than the flame velocity of the mixture, and also by quenching any flame that may be present.

The overall heat exchange mechanism starts with the hot exhaust gases heating the packing on the outside of the tubes. This is occurs primarily by forced convection, although radiation and conduction do help to a much lesser degree. Heat is then radiated and conducted from the packing to the outside of the tube walls. Heat is conducted from the outside tube walls to the inside tube wall, where it is radiated and conducted to the bed media within the tube. The heat is then absorbed by the cool incoming gases through forced convection.

When the gases reach the top of the tubes, they have reached combustion temperature. Combustion occurs as the gases emerge from the tubes and continues into the open chamber above the tubes. This creates a pool of chemical radicals in the top chamber, which leads to the establishment of a well stirred reactor region. Due to the presence of the high concentration of radicals in this area, uniform combustion occurs very rapidly.

The products of combustion then flow down through the packed bed on the outside of the heat exchange tubes. As the hot exhaust gases flow through the packing, they give up some of their heat to the packing through forced convection. The exhaust gases then exit the reactor at the exhaust port and are directed to the stack where they are discharged to atmosphere.

Thus inherent to the recuperative design is the heat retention, transfer and reuse potential which enhances the efficiency of processing organic vapor streams of low concentration. The 60 - 65% heat recovery in operation also allows for excess heat to be available from such low concentration streams for use in the separation phase of the remedial process. And since thermal processing is maintained at 1600 - 1800F, conversion of organics is essentially complete while formation of nitrogen oxides is minimized. It should be mentioned also that non-recuperative ("straight through") designs of flameless thermal oxidizers also offers significant heat recovery and reuse. Thus for moderate to high concentration remedial organic streams which exceed the desired conditions for processing with the recuperative system, the addition of a heat recovery unit (e.g., waste heat boiler) to a straight through thermal oxidizer can effectively process the stream while providing heat recovery and reuse potential.

ENHANCED REMEDIAL SYSTEMS UTILIZING RFTO

The above described benefits of recuperative flameless thermal oxidation can not only provide very effective VOC abatement but also increase the efficiency of the remedial processes themselves. The following presents several designs for remedial systems to demonstrate the benefits of incorporating the recuperative oxidizer design with the realization that the straight-through-with-heat-recovery design can be substituted if appropriate (e.g., higher contaminant concentrations; low system flow conditions).

Enhanced Indirect Fired Thermal Desorption

Thermal desorption is typically an ex-situ remedial process for the physical separation of organic contaminants from soil, sludge, sediments or other solid matrices. In this process thermal energy is applied either directly or indirectly to volatilize organic compounds from the contaminated solids. Operating temperatures vary (typically between 500-850F) and the thermal processing is designed for separation rather than destruction of organic contaminants. Once volatilized, the organics as a vapor stream are processed through some type of air pollution control device, e.g., captured by adsorption on carbon or condensed, or subjected to further treatment to convert them into environmentally acceptable species. Perhaps the most common thermal desorption design is the rotary kiln or dryer. This design consists of a horizontal cylinder heated either directly (e.g., by blowing hot gas over the waste medium) or indirectly (e.g., by blowing hot gas over the rotary drum walls) and operate either on an incline or by rotation. Processing capacities of 5 - 55 tons per hour are reported. The effectiveness of desorption processing is a function of the chemical composition of the waste feed, its physical characteristics, as well

as feed rate, temperature and residence time.
In the proposed design organic-contaminated solids are fed into an indirectly fired rotary kiln and heated to 500 - 850F. (See Fig. 2.) The hot desorbed organic vapor stream is processed for particulate and the captured solids transferred to the treated solids handling area. The filtered organic vapor stream then enters the recuperative oxidizer where supplemental air is added if necessary. Within the oxidizer the organics are converted to CO2 and H2O. The hot oxidizer effluent vapor stream is then split, the majority going through a gas cleaning process (e.g., scrubbing of acid gases) if necessary and then discharged to atmosphere while a split stream at 700 - 1000F is returned to the kiln where it is used as a preheating and inerting carrier gas in the ongoing desorption processing. In this way the heat value of even low concentration organic contaminants is recovered and used to increase the efficiency of the overall process.
Mobile Enhanced Soil Vapor Extraction
Soil vapor extraction (SVE) is a process for the removal of VOCs and some SVOCs from the subsurface soil zone located between the land surface and the top of the water table. When operating, SVE transfers organic contaminants from soil and interstitial water to air and entrained and condensed air streams which require further treatment.
During SVE air is drawn through the soil, passing through the soil particle pore spaces, following paths of least resistance and carrying contaminating organic vapors with it. In turn, condensed-phase organics will vaporize and replace the exiting organics. Thus this dynamic vaporization process establishes a dynamic equilibrium of condensed and vapor- phase organics until all of the condensed-phase organics have vaporized and pass through the higher permeability soil volume. This dynamic vaporization process can be enhanced through the use of heated air or steam in the injection wells.
In practice SVE operates with two sets of wells. One set, the vapor extraction wells, are operated under negative pressure and provide the motive force for vapor transport through the soil. The other set, the air vent or injection wells serve to replace the removed air and enhance the flow and control of vapor transport. The extraction wells are powered by vacuum pumps or blowers with in-line liquid collection or vapor condensation capacity. The removed, organic-laden vapor is typically processed in one of three ways: adsorbed on activated carbon; thermally destroyed by incineration or catalyzed oxidation; or condensed through refrigeration.
The design proposed here is for a mobile enhanced SVE system with several unique features. (See Fig. 3.) Organic vapor removed through extraction wells is destroyed in a recuperative style oxidizer, the heat of combustion recovered and used to generate heated air or steam in a waste heat boiler. Ongoing vapor extraction can then be enhanced by using this heated air or steam in the injection wells. In addition, if organic condensate is separable from the aqueous phase in the knock-out pot, it can be vaporized in a heat exchanger and reintroduced into the oxidizer for destruction. A significant body of past performance data supports the expectation that the air emissions from the oxidizer will be 99.99% DRE or better for contaminant organics, with NOx , CO and products of incomplete combustion at trace to non-detectable levels.
Fig. 2.
Fig. 3.
This mobile unit as designed would allow localized remediation of small organic spills or contaminated areas at site remediations. Using the heat of oxidation to generate steam or hot air for injection makes efficient use of the heating value of the organic contaminants, enhances the efficiency of volatile organic removal and promotes the extraction of more difficult organics (e.g., dense non-aqueous phase liquids).
Enhanced Groundwater Extraction and Treatment
Groundwater contaminated with volatile organics is typically remediated by first pumping water from a recovery well into the top of a packed stripper column or stacked tray assembly. In the packed tower design an air stream is directed up from the base of the column countercurrent to the water which is falling down from the top. As the air rises and comes in contact with the water, the organics transfer to the air stream and are carried out the top while the treated water drains out the bottom of the tower. The mass transfer of organics from water to air is driven by

the mechanical energy imparted by the forced air and the large surface area. The ultimate efficiency of removal is dependent upon the specific stripper design and dimensions, as well as physical and chemical characteristics of the organics involved. Increased efficiency of removal can be effected to some degree by preheating the water and thus enhancing the removal of less volatile compounds. In the case of organics with low miscibility with water, e.g., halogenateds, steam stripping is commonly used. Steam stripping is also more effective than air stripping when the water contains very high concentrations of volatiles, e.g., when DNAPLS are present. Steam stripping columns are usually run counterflow steam to water and allowance is made for immiscible phase separation and decantation both in the stripper overhead products and column bottoms. Further advantage is gained in steam stripping by the formation of minimum boiling azeotropes. Such azeotropes form at temperatures below the boiling point of the organic compounds present and are removed with the steam vapor exiting the column. For example, 1,1,2-trichloroethylene forms an azeotrope with water that boils at 86C while the boiling point of the pure compound is 113.7C.

Either style of flameless thermal oxidizer can be coupled with air or steam stripping contaminant separation methods as the VOC abatement step but the coupled system with the greatest overall advantage would be the recuperative oxidizer/steam stripping design. The recuperative oxidizer would be preheated to prepare it to receive organic vapor and to generate heat for the waste heat boiler and in turn to generate steam for the preheater and stripper. During operation, groundwater is pumped from recovery wells through the preheater and into the top of the stripper column. Steam generated in the waste heat boiler is delivered typically at 1 atm and 100C with a 10 - 30 mole percent of feed steam consumption. The overhead vapor exits the stripper, undergoes decanting and then enters the recuperative oxidizer where the organics are oxidized. The heated effluent from the oxidizer passes through a waste heat boiler prior to being quenched and scrubbed for acid gases and finally released to atmosphere. The recovered heat is used to continue generating steam for the preheater and stripper while the treated groundwater effluent from the stripper can serve as the water source for steam generation. Any free phase organic liquids pumped from recovery wells or resulting from liquid/liquid separation can be reintroduced to the stripper column and processed through the oxidizer. This coupled groundwater extraction and treatment system thus offers efficient heat recovery and reuse as well as effective VOC abatement performance to enhance groundwater remediation.

PLANNED DOE TECHNOLOGY DEMONSTRATIONS

Several small scale demonstrations of coupled remedial/FTO technology are planned in the near future at several DOE sites. The objective of these demonstrations is to gain field performance data from which the benefits of such coupled technology can be compared with other remedial alternatives.

Coupled SVE/Flameless Thermal Chlorinated VOC Abatement at Savannah River Site

A demonstration of a Thermatrix ES-300H oxidizer in an SVE chlorinated organic destruction application is planned this spring at the Savannah River Site in Aiken, South Carolina. A skid mounted, electrically heated 5 scfm oxidizer will be coupled with a rotary lobe blower at a preexisting vapor extraction well in the A/M Area of the site. After system optimization, up to 10,000 ppmv of combined perchloroethylene, trichloroethylene and trichloroethane will be processed through the oxidizer continuously over a several week period. Gas samples from the inlet and outlet of the oxidizer will be taken for analysis. Analytical data will indicate the DRE achieved for each compound, the presence of any products of incomplete combustion and the quantity of acid gas (HCl) generated.

Coupled Plasma Arc Furnace/Flameless Thermal Oxidizer at the CDIF Facility

The Retech, Inc. plasma arc centrifugal treatment system installed at DOE's Component Development and Integration Facility (CDIF) in Butte, Montana will be the site of another demonstration in late spring. The plasma arc system is designed to destroy organic material through high-temperature oxidation and to immobilize inorganic material into a low-leachable glass ceramic matrix. Currently, off-gas containing acid gases, moisture and particulate from the primary processing chamber passes through a gas-fired secondary combustion chamber, high energy scrubber, a series of filters and finally catalytic reactor to reduce NOx emissions to the atmosphere. The objective of the planned demonstration is to evaluate the

feasibility of a Thermatrix flameless thermal oxidizer replacing the secondary combustion chamber. It is anticipated that total hydrocarbons, CO and NOx emissions will be reduced below current emission levels due to the demonstrated superior performance and control of the flameless thermal oxidation process over flame processes.

Proposed Design of "Non-incineration" Thermal Treatment System to Morgantown Energy Technology Center

Thermatrix has proposed a technology development and verification program to the Morgantown Energy Technology Center, in response to the Research Opportunity Announcement entitled "Applied Research and Development of Technologies for Environmental Restoration and Waste Management." The objective of the proposed program would be to produce an innovative, non-incineration, thermal treatment system to remediate mixed-waste contaminated solids at DOE facilities. The first phase of testing would verify the capability of Thermatrix's flameless thermal oxidation technology to effectively treat low concentration hazardous organic vapor streams similar to off-gases from solid, low-level mixed waste (LLMW) organic separation treatment processes like thermal desorption and soil vapor extraction. If successful, the second phase of testing would develop a pilot scale thermal treatment system by coupling a rotary kiln thermal desorber with a recuperative style flameless thermal oxidizer and wet scrubber. After this system has been verified functionally by processing clean sand, it would be demonstrated in a simulated LLMW (non-radioactive) mode using non-rad soil or sand spiked with hazardous liquid organics and then with actual low-level mixed waste soil or solids. If successful in these demonstrations, a final effort would design full scale thermal desorber/Thermatrix FTO systems scaled up from pounds-per-hour pilot design criteria to tons-per-hour processing capacities appropriate to specific DOE waste inventory volumes.

CONCLUSIONS

Remediation of organic-contaminated soils, sludges, surface and ground waters currently utilizes separation technologies which are energy intensive and typically leave a residue requiring further handling, e.g., destruction or off-site disposal. Flameless thermal oxidation, especially with heat recovery, offers an innovative approach to enhancing the efficiency of routine remedial technologies as well as superior VOC abatement performance. Designs for enhanced thermal desorption, mobile soil vapor extraction and groundwater steam stripping extraction and treatment are presented which by incorporating a recuperative oxidizer into the operating system promises significant heat recovery, effective destruction of organic contaminants (>99.99% DRE) and only trace to non-detectable criteria air pollutant emissions. Such enhancement of routine remedial methodologies can provide the remedial manager with more cost effective, energy efficient and better performing tools with which to tackle the many hazardous and mixed waste environmental restoration challenges.

Albuquerque, NM, USA

ABSTRACT

Grout injection tests employing permeation grouting methods are underway to evaluate two grout materials for in situ barrier construction. Performance goals have been established to determine whether permeation of the materials within unconsolidated soils will provide competent subsurface barriers of sufficient lateral extent and hydraulic integrity to meet the U.S. Department of Energy (DOE) environmental restoration needs. The grout materials are a montan wax-based particulate grout developed in Germany and a sodium silicate chemical grout developed in France. Field tests are underway at a site in Richland, Washington, adjacent to the DOE Hanford Reservation. The results of earlier laboratory and field tests are presented and the ongoing field study in Washington is described. The preliminary results suggest both

grouts may be suitable for addressing containment/stabilization needs within the DOE complex under certain conditions. The suitability of the grout depends on the site conditions and the performance requirements (durability, residual hydraulic conductivity, etc.). Traditional grout permeation methods are unsuitable for introducing the montan wax material under most soil conditions due to the relatively high viscosity of the material and difficulty in controlling the breaking of the emulsion. Permeation grouting with montan wax may be suitable for stabilizing buried wastes with high void ratios. Other application technologies such as jet grout and soil mixing were not evaluated in this study but are being used in Germany and are the preferred method for introducing montan wax grout. The penetration of the sodium silicate material using permeation grouting was more successful but questions still exist as to the competency of the barrier produced. The post-injection characterization studies planned for the Spring of 1995 should address the remaining uncertainties.

INTRODUCTION

Two grout materials of European origin are being studied at a site near Richland, Washington to evaluate their ability to permeate unconsolidated soils and reduce the hydraulic conductivity. The two grout materials are a montan wax emulsion developed in Germany and a glyoxal-modified sodium silicate grout developed in France.

The materials were first identified in 1992 by the International Technology Exchange Program (ITEP), an Office of Technology Development program (1). One of the objectives of ITEP was to identify innovative environmental remediation and waste management technologies in other countries for possible import to the United States to expedite the clean up and waste management needs within the DOE complex. As part of this effort, a survey of German environmental technologies was performed by Golder Associates Inc., under contract to Sandia National Laboratories and the DOE Office of Technology Development.

The lack of enforced environmental regulations in the former German Democratic Republic and the concentration of industry in the western part of the country has resulted in serious environmental problems throughout the country. In 1991, the Federal Environmental Agency estimated there were 146,400 suspected contaminated sites in Germany; 99,300 in western Germany and 47,100 in eastern Germany (2). The sites consist primarily of old waste dumps, industrial areas and military bases. The agency estimates that 10 to 20% of the sites will require remediation to reduce public health risks to acceptable levels.

Because of the numerous sites that require corrective measures, remediation will not be completed for many years. As a result, containment and other mitigation measures that could be put in place quickly are being considered to prevent problems from getting worse until a final solution is found. Based on this situation, a number of companies, institutes and joint ventures are developing technology for constructing in situ containment barriers (low permeability regions) to reduce or arrest contaminant flow and transport. Two of the concepts under development and testing are a montan wax emulsion developed by Vereinigte Mitteldeutsche Braunkohlenwerke AG (MIBRAG) and a glyoxal-modified sodium silicate grout developed by the French chemical company Socit Franaise Hoechst.

The idea to use montan wax to construct containment barriers came about because of the serious environmental problems in the Bitterfeld area. There are several industrial waste disposal pits where leachates are entering the local aquifer contaminating the drinking water supply. Site remediation may take many years to accomplish because of the volume of material involved and the large associated costs. In an attempt to address this problem, MIBRAG began testing the feasibility of creating containment barriers by injecting a montan wax emulsion in unconsolidated soil adjacent to contaminated areas using permeation grouting methods (3). The early results were promising and additional government funded demonstration projects are underway.

MIBRAG was privatized in 1994 and is now owned by a consortium of US and British companies. The wax production company, Romanta GmbH, was not part of the privatization scheme and is currently under the control of the ministry of finance. The environmental division from MIBRAG responsible for developing the subsurface barrier technology was transferred to Romanta.

Montan wax is a fossil plant wax with properties similar to natural plant waxes such as those found in carnauba palms. It is a hard, high-melting point, non-toxic material used in carbon inks, emulsions, polishes and lubricants. It is actually a

mixture of waxes, resins and asphaltene-like materials composed of C-24 to C-32 carbon chain esters of long chained acids and alcohols. Montan wax grout is a suspension-type grout consisting of a stable emulsion of montan wax, water, and an emulsifier. The emulsion is formed by injecting a stream of melted (95-98oC) wax and emulsifier into water at the same temperature and then rapidly cooling the mixture to 50oC. Both ionic and non-ionic emulsions can be formed. To break the emulsion in a field application, a small amount of bentonite clay is added (approximately 2-5% by weight) just prior to injection, which binds the emulsifier and allows the emulsion to break. The resulting wax/bentonite mixture forms a highly viscous material that can significantly reduce the permeability of the soil matrix.

The modified sodium silicate grout developed by Socit Franaise Hoechst has been extensively tested in the laboratory at the Hoechst facilities in Paris and at the Technical University of Clausthal (Germany) but has not previously been field tested as a barrier material. However, the material (sold under the trade name of Klebogel) has been successfully used (particularly in near-surface tunnel construction) in Europe and the U.S. as a soil strengthener in unconsolidated soils.

The sodium silicate grout consists of four components: an alkaline liquid consisting of silicon dioxide, sodium oxide, and water; an acidic liquid consisting of glyoxal and additives; an aqueous suspension of non-agglomerated silica particles in an alkaline medium; and water. The grout is prepared by successively the components to water. The setting time and viscosity of the grout can be controlled by altering the proportions of the four components.

The DOE Office of Technology Development began evaluating montan wax and the glyoxal-modified sodium silicate grouts in 1992. The project is funded under the In Situ Remediation Integrated Program and performed by Golder Federal Services, Inc. and Sandia National Laboratories. Initial activities involved laboratory tests to assess the effectiveness of the grouts in reducing hydraulic conductivity in unconsolidated soil and their resistance to common types of industrial and hazardous wastes. Field testing was initiated in 1993 at Sandia National Laboratories in Albuquerque, New Mexico. Single-borehole injection tests using permeation grouting techniques were performed to evaluate the penetration characteristics of the grouts over a range of soil types and conditions. Additional field tests are currently underway at a site in Richland, Washington near the DOE Hanford Reservation.

This paper describes the results of the laboratory and field tests and provides a preliminary assessment of the potential applications of the materials within the DOE complex. Emphasis is given to describing the most recent field test at the Richland, WA site.

RATIONALE

A recent estimate of the quantity of buried waste within the DOE complex is 2.1 million m3. Various types of buried waste are present at the Hanford Site, the Savannah River Site, the Idaho National Engineering Laboratory, Oak Ridge National Laboratory, and the Rocky Flats Plant. Approximately half of all DOE buried waste was disposed of before 1970. The regulations at that time allowed the commingling of different wastes (i.e., transuranic, low-level radioactive, and hazardous waste). As a result, much of the waste is believed to contain both hazardous and radioactive components. The waste is present in different forms and conditions, including trenches, pits, storage pads, and other structures.

Containment systems, or subsurface barriers, are a potentially important component of DOE's goal of bringing all DOE facilities and sites into compliance with applicable laws and regulations for protecting public health and the environment. While DOE's goal is to eventually clean up all contaminated sites, the remediation of some sites may be delayed due to technical difficulties, cost, or schedule considerations. In these situations, it may be necessary to use temporary measures to mitigate the impact of the contamination until a permanent solution can be implemented. In some cases, subsurface barriers may be applicable for containing known or potential contamination long enough to allow planning, scheduling, and budgeting for remediation or the development of new technologies. Chemical and particulate grouts are of interest since they provide a means of creating an in situ containment system that will retard further movement of contaminants until they can be safety and effectively removed.

In addition to containment, barrier technology can also be used as a backup measure for cleanup activities and as a means to enhance the performance of other remediation technologies. Subsurface barrier materials can also be used to improve

the efficiency of other remediation technologies, such as pump-and-treat, chemical fixation, and vapor extraction systems, by directing and focusing the containment plume to the treatment area and/or limiting the volume of the soil or ground water to be treated.

TEST RESULTS

The grout study is being performed in three phases of increasing scale and scope: laboratory tests; single-borehole field tests; and multiple-borehole field tests. Permeation grouting is the only delivery method used in the study, i.e., the performance of the grouts when delivered via jet grouting, soil mixing, etc., was not evaluated. Permeation grouting was the recommended method for injecting both types of grout at the initiation of the project. Recently, jet grouting has replaced permeation grouting as the recommended method in Germany.

The first two phases have been completed and the results are summarized below. The multiple-borehole tests are ongoing. Grout injection was completed in late 1994 and the post-injection characterization activities are scheduled for early 1995. The completed activities are described and preliminary observations concerning grout performance are provided.

Laboratory Tests

The two objectives of the laboratory tests were to 1) characterize the extent the grouts reduce the hydraulic conductivity of unconsolidated soils and 2) assess the compatibility of the grout materials with typical waste forms.

Soil samples from three sites within the DOE complex were used for the tests: the Buried Waste Integrated Demonstration (BWID) site at the Idaho National Engineering Laboratory; the Mixed Waste Landfill Integrated Demonstration (MWLID) site at Sandia National Laboratories, and the Underground Storage Tank Integrated Demonstration (USTID) at Hanford. The results are documented in a report entitled Laboratory Test Results for Evaluating the Performance of Montan Wax and Sodium Silicate Barrier Materials in Unconsolidated Soils (4).

Standard methods and procedures were used to determine the grain-size distribution, bulk density, permeability, and mineral composition. A preliminary estimate of the groutability of the soils was made based on general groutability criteria (Table I), grout viscosity (Table II), and the laboratory permeability measurements (Table III). The groutability of the BWID soil was expected to be poor, based on the low hydraulic conductivity (10-5 cm/sec) and high percentage of silt (>>90%). The USTID and MWLID soils, with their relatively high conductivity (10-2 cm/sec and 10-4 cm/sec, respectively) and lower percentage of fines (approximately 5% for both soils) were expected to be groutable with the lower-viscosity montan wax formulations and the sodium silicate formulation.

TABLE I

TABLE II

The results of the hydraulic conductivity tests for the ungrouted and grouted samples are shown in Table III. Grout was injected into the base of 15 cm diameter soil samples and allowed to cure for 48 hours before testing. The montan wax and sodium silicate grouts were able to permeate the USTID and MWLID samples, however, neither grout could permeate the silty clay samples from the BWID site because of the high percentage of fine material in the samples. Both grouts significantly reduced the hydraulic conductivity of the USTID and MWLID soils. The source of the variability in the post-injection conductivity has not been identified. One possible explanation is sample disturbance; the grouted samples were transferred from a stiff-walled triaxial cell to a flexible-walled cell and the handling of the sample may have resulted in creation of pathways (e.g., along the grouted-soil/sample-sleeve interface). Another reason may be incomplete permeation of the samples by the grout. This could result from soil heterogeneity and/or small differences during sample preparation. Additional laboratory tests are underway with revised procedures that minimize the potential for sample disturbance and sample variability.

TABLE III

The compatibility of the grout with the waste forms and leachates that may be encountered is an obvious criterion for a subsurface barrier. A test program to evaluate the resistance of the grouts to chemical degradation was undertaken based on earlier studies by the EPA. Spooner et al. (6) evaluated the compatibility of a number of grout materials with various classes of chemicals. The chemicals used were considered to be representative of a majority of the leachates present in hazardous

waste disposal sites. The EPA study evaluated the effect of the chemicals on the setting time and durability of the grouts.
The chemical compatibility testing in this study was limited to an evaluation of grout durability. It consisted of immersing grout/sand cylinders in chemical baths and observing any changes. The chemicals are listed in Table IV along with the functional groups they represent. The samples were constructed by mixing approximately 20% grout with 80 % sand and compacting the mixture to a final density of 2.8 g/cm3. The specimens were immersed in the chemical solutions for 28 days. Visual observations were made on a daily basis to detect physical changes (e.g., swelling, shrinkage, softening, color changes).
TABLE IV
With the exception of the specimens in the ethylene glycol, the samples containing montan wax grout were largely unaffected by the chemical groups. Most showed some deterioration or softening, primarily around the periphery limited to the first few mm of the surface. The results suggest that, with the exception of the glycols, the durability of the montan wax would should be favorable for most industrial wastes. The sodium silicate specimen also performed well in all but the sodium hydroxide solution. The latter results are consistent with the EPA study.
Single Borehole Tests
Single-borehole field tests were performed at the MWLID site at the Sandia National Laboratories. The objective of the tests was to obtain information on the injectibility of the montan wax and sodium silicate grouts over a range of soil conditions. Eight boreholes were used to perform the tests, four boreholes for each of the grout types. Grout injection was attempted at multiple-levels within each of the boreholes in order to intersect a range of soils types from low permeable silts to highly permeable coarse sands and gravel deposits.
The movement of the grout within the soil was monitored using downhole geophysical tools including resistivity and neutron moisture probes. Typical response curves for each tool are presented in Fig. 1. In this example, resistivity decreases and moisture increases are associated with the arrival of the grout front at the geophysical monitoring borehole. The penetration distance of the grouts from the injection borehole typically ranged between 1 m and 2 m for the sodium silicate and montan wax grouts.
Fig. 1.
The tests results suggest that both the sodium silicate and montan wax grouts can be injected in unconsolidated soils with conventional grout permeation methods, provided the soils have sufficiently high conductivity. Montan wax grout permeation was limited to the higher-conductivity zones. Attempts to inject the grout into lower-conductivity soils resulted in unacceptable injection pressures, or the grout traveling up the borehole annulus to the surface. The minimum hydraulic conductivity for permeation grouting appeared to be approximately 5 x 10-4 cm/sec for both the sodium silicate grout and the montan wax grout. The results of the single-borehole tests are presented in a report entitled Preliminary Results of Permeation Tests Using Montan Wax and Sodium Silicate Barrier Materials in Unconsolidated Soils at the Mixed Waste Landfill Integrated Demonstration Site (MWLID) (7).
Multiple Borehole Tests
The objective of the multiple-borehole tests was to demonstrate the feasibility of constructing subsurface barriers under field conditions that met certain performance goals. The primary goal was to produce a continuous horizontal barrier with a hydraulic conductivity of 10-6 cm/sec. The appropriateness of this level of performance for actual barrier applications will depend on the site-specific needs and the thickness of the emplaced barrier. For some applications, such as the use of grouts to redirect groundwater flow, the contrast in the hydraulic conductivities between the grouted and ungrouted soils is more important than absolute values, and hydraulic conductivities of 10-5 cm/s or higher may be adequate.
The test site is located in an area adjacent to the municipal landfill for the City of Richland, Washington. The site is located approximately 2 km northwest of Richland. Reconnaissance tests suggested the site provided a zone of sufficient permeability and lateral continuity for the implementation of the multiple-borehole injection tests. The test site was located outside and immediately north of the permitted portion of the landfill. The on-site evaluation and preliminary soil sampling was completed in April 1994. Laterally continuous, poorly-graded medium grained sands were located at a depth of 5 m below the ground surface. The medium

sands were underlain by finer sand and silt. Initial laboratory grout permeation tests were performed on soil samples from the site and hydraulic conductivities of the medium sand and fine sand were measured at 9.1 x10-2 cm/sec and 7.7 x 10-3 cm/sec, respectively.

Geologic data for the vicinity of the test site were available from the Richland Landfill Development and Closure Plan (8). Near-surface soils at the site are part of the Pleistocene Hanford formation, and are sand-dominated. The total thickness of the Hanford formation at the site is approximately 15 m. The depth of the water table is approximately 38 m below surface.

Figure 2 illustrates the general layout of the test site. The site is divided into three areas, one for preliminary injection tests to test the formulation and grout injection equipment, and two other areas for the montan wax and sodium silicate multiple-borehole tests. The location of the injection boreholes and geophysical monitoring holes are shown in Fig. 3. Drilling was initiated with four boreholes at the outer margins of the test site drilled to a maximum depth of 30 ft. Split spoon samplers were used to complete a detailed stratigraphic log of the site. The results were used to select the target depth for grout injection. The interval between 3 and 4 m depth was selected. Following drilling, the boreholes were converted to geophysical monitoring access holes. Four grout injection boreholes and sixteen geophysical monitoring holes were completed in each of the two test locations. The grout injection boreholes were completed with 3.8 cm diameter tube manchettes with grout ports at 0.3 m intervals between the 3 and 4 m target depth.

Fig. 2.

Fig. 3.

Baseline logging of the geophysical monitoring boreholes was performed prior to the grout injection tests, to provide additional site characterization data and baseline information for comparison with later geophysical responses caused by the introduction of grout. Downhole logging tools used included neutron moisture and conductivity tools.

The tube manchette method was used to inject the grout into the soil formation (Fig. 4). The grout delivery system consists of PVC casing with grout ports drilled at selected locations and covered with an expandable rubber sleeve. The casing is placed in a borehole and the annular region backfilled with a cement-bentonite slurry to provide intimate contact between the casing and the surrounding soil. A grout tube with a pair of straddle packers is used to isolate ports at the desired depth. The grout injection pressure is increased until the annular grout surrounding the injection ports is fractured providing a pathway for the grout to enter the soil. The grout injection pressure is reduced to prevent further fracturing of the soil.

Fig. 4.

In general, grout was injected in one borehole at a time to facilitate the monitoring of grout movement. Grout "take", pressures, and flow rates were continuously monitored. Following initial fracturing of the annular grout, injection pressures were limited to approximately 2.1 kPa per m of depth to avoid uplift and fracturing of the soil formation. This pressure is approximately equal to the lithostatic pressure and is commonly used by the grouting industry for permeation grouting.

Geophysical monitoring in adjacent boreholes was performed frequently using the neutron and conductivity tools during the early stages of injection. Grout was injected until: 1) geophysical data indicated that the target permeation distances (radius of 5 m) and thickness (0.75 m) had been met; 2) 5300 l of grout were injected; 3) the pressure required to inject grout exceeded the limit; or 4) grout appeared at the ground surface. There were 15,000 l of each grout type available for the tests.

Food-grade powdered dyes were added to both the montan wax and sodium silicate grouts to identify the materials during post-injection sampling and excavation. The dye colors were varied during injection. In general, two color changes were made in each borehole to later identify the movement and interaction of the grout fronts. In some cases, injection was performed in more than two phases and additional dye changes made. The initial color was different in each of the boreholes.

Permeation grouting with the montan wax grout was largely unsuccessful. Grout was observed flowing from the surface along or near the borehole annulus. The annular region around the borehole was resealed with additional cement-bentonite slurry and

allowed to cure. This resulted in the grout flowing to the surface along new pathways. Following several additional attempts to prevent grout movement to the surface, additional injection boreholes were drilled. New sleeves were installed with injection ports at 0.3 m intervals to provide additional locations to inject the annular sealing material. The new sleeve design and installations procedure resulted in increased take however the montan wax eventually flowed to the surface. The upward movement of the montan wax grout was observed in all but one of the injection holes. Hydraulic fracturing of the soil is suspected in this case.

The break time of the montan wax emulsion depends on the type and amount of bentonite clay that is added to the emulsion and the amount of mixing that occurs. The presence of natural clays in the soil can also affect its performance. Once the emulsion breaks, the grout viscosity increases dramatically and further movement through the soil is not possible, even in the coarse sands at the site. Prior to the field tests, laboratory tests were performed to select a bentonite clay that would result in a sufficient set time for the grout to move radially 2 - 3 m from the borehole. A sodium bentonite clay was eventually selected, however, the break time (for all the clays tested) was highly dependent on the amount of agitation the mixture received. Under field conditions, it was very difficult to control the mixing time and amount of agitation. As a result, the break time was likely to have varied and the lack of permeation may be the result of the grout setting soon after it was injected into the soil. Similar problems have been encountered in the German montan wax grout program where they have largely abandoned permeation grouting for other application methods, e.g., jet grouting.

In general, the sodium silicate grout was successfully injected using the tube manchette method although the direction and distribution are uncertain. There were two occurrences where grout flowed to the surface but the situation was corrected by resealing the borehole annulus. Grout was detected by the geophysical measurements at distances of over 1 m from the point of injection, however, there was no indication that the target distance of 3 m was achieved. This suggests that there was a significant vertical component to grout movement unless the geophysical tools failed to detect the presence of the grout. Visual inspection of the grouted region during excavation of the area in the Spring of 1995 is expected to resolve these issues and provide additional information on the behavior of the materials. In addition to visual inspection during site excavation, a number of hydrologic tests will be performed. They include small-scale permeability tests with Guelph permeameters and, in areas where the grouted soil area is of sufficient extent, large-scale permeability tests will be performed using a sealed double-ring infiltrometers.

CONCLUSIONS AND RECOMMENDATIONS

The field tests at the site in Richland, Washington are ongoing, however, the initial data suggest the injection of the montan wax grout using permeation grouting was largely unsuccessful for creating a laterally extensive barrier. Data from the sodium silicate grout test are more promising but the geophysical monitoring devices did not detect the presence of the grout in several locations. Post-test characterization to evaluate barrier continuity, size, and hydraulic performance, is planned for Spring 1995.

The inability to construct a subsurface barrier with montan wax grout using permeation grout does not necessarily preclude the grout from further consideration for applications within the DOE complex. As mentioned earlier, the German program has largely abandoned permeation grouting for jet grouting. Jet grouting is already being used in the US to construct groundwater barriers, for example, 20% of the jet grouting applications performed by Hayward Baker are for water control including horizontal bottom sealing of powerplants (9). Soil fracturing techniques, such as the FRACTOOL technology developed by Golder Associates, and the soil-saw developed by Haliburton are other promising application methods that should be considered and evaluated as delivery systems for montan wax grouts. Montan wax should also be considered as an additive for other types of grouts such as cement grouts. A grout consisting of cement, sand, fly ash and montan wax has successfully been used in a metro tunnel in the United Kingdom to control groundwater inflow.

The application of geophysical methods to monitor grout emplacement has been largely successful and the tools should be considered when designing similar types of studies. The methods are attractive due to their relatively low costs and the ability to provide real-time information on the location of the grout front.

DIRECT CONVERSION OF PLUTONIUM METAL, SCRAP, RESIDUE, AND TRANSURANIC WASTE TO GLASSDIRECT CONVERSION OF PLUTONIUM METAL, SCRAP, RESIDUE, AND TRANSURANIC WASTE TO GLASS

Jeff Rudolph
Oak Ridge National Laboratory

ABSTRACT
A method for the direct conversion of metals, ceramics, organics, and amorphous solids to borosilicate glass has been invented. The process is called the Glass Material Oxidation and Dissolution System (GMODS). Traditional glass-making processes can convert only oxide materials to glass. However, many wastes contain complex mixtures of metals, ceramics, organics, and amorphous solids. Conversion of such mixtures to oxides followed by their conversion to glass is often impractical. GMODS may create a practical method to convert such mixtures to glass.
Plutonium-containing materials (PCMs) exist in many forms, including metals, ceramics, organics, amorphous solids, and mixtures thereof. These PCMs vary from plutonium metal to filters made of metal, organic binders, and glass fibers. For storage and/or disposal of PCMs, it is desirable to convert PCMs to borosilicate glass. Borosilicate glass is the preferred repository waste form for high-level waste (HLW) because of its properties. PCMs converted to a transuranic borosilicate homogeneous glass would easily pass all waste acceptance and storage criteria. Conversion of PCMs to a glass would also simplify safeguards by conversion of heterogeneous PCMs to homogeneous glass.
Thermodynamic calculations and proof-of-principle experiments on the GMODS process with cerium (plutonium surrogate), uranium, stainless steel, aluminum, Zircaloy-2, and carbon were successfully conducted. Initial analysis has identified potential flowsheets and equipment. Major unknowns remain, but the preliminary data suggests that GMODS may be a major new treatment option for PCMs.

INTRODUCTION

The Glass Material Oxidation and Dissolution System (GMODS) is a recently invented process (1,2) for the direct, single-step conversion of plutonium-containing materials (PCMs) to glass. PCMs include excess weapons components, scrap, residue, and transuranic waste. GMODS can convert mixtures of metals, ceramics, organics, and amorphous solids directly to glass.

The end of the cold war has resulted in excess plutonium metal, scrap, residue, and the prospect of significant future (as well as significant current) quantities of transuranic wastes from operations and decommissioning of facilities. Some of the high-plutonium-assay PCMs may be stored should the plutonium be needed for national security or energy. Other PCMs will be declared waste. Consequently, multiple incentives exist to convert PCMs to glass:

Storage and disposal risks are minimized by converting PCMs to a glass that is stable, insoluble, and nonburnable.

Criticality risks are minimized by converting PCMs to a glass containing neutron poisons so nuclear criticality is avoided by chemical composition, not by geometry.

Nuclear materials accountability and safeguards are simplified and made more reliable when plutonium is stored as homogeneous glass in numbered containers. (Measurements of plutonium quantities in heterogeneous PCMs is difficult.)

STRAWMAN CRITERIA

If PCMs are to be converted to glass for storage or disposal, a set of glass performance criteria are required to define goals. For disposal, there are two sets of criteria: 1) waste management criteria and 2) safeguards criteria. Waste management criteria depend upon the disposal site (3,4). There are four sets of waste management criteria: 1) mechanical (package dimensions, handling mechanisms, etc.), 2) chemical (chemical waste form behavior, hydrogen gas generation, etc.), 3) allowable heat generation rates, and 4) nuclear criticality. The safeguards criteria are designed to prevent unauthorized diversion of plutonium. Storage criteria are similar except long term performance (>100 years) is not required.

Mechanical, thermal, and chemical waste form performance criteria have been developed for the acceptance of HLW glass (3). These criteria provide a conservative basis for defining appropriate criteria for a PCM borosilicate glass.

Nuclear criticality and safeguards criteria depend upon plutonium concentrations; thus, the requirements for the final glass are also dependent on plutonium concentrations. Plutonium concentrations at which different criteria come into effect are not currently fully defined and will depend upon both technical and institutional factors.

The nuclear criticality waste acceptance criteria (WACs) are designed to prevent nuclear criticality over geological time. If the plutonium concentration in the waste is sufficiently low, nuclear criticality is not a concern. If the plutonium concentrations are high, criticality criteria may be satisfied by the addition of depleted uranium to the final glass to ensure long-term avoidance of criticality (5,6).

In a repository, plutonium is generally immobile, but nuclear criticality is a concern over geological time frames because plutonium decays to highly enriched 235U. Selective dissolution and precipitation of uranium in groundwater over geological time creates the potential of concentrating uranium and initiating criticality events if the original uranium is highly enriched. Geological evidence shows that past naturally occurring nuclear reactors have been created by these mechanisms when the uranium enrichment levels exceeded several weight percent 235U. In contrast, no evidence exists of naturally occurring reactors at lower enrichment levels. The former scenario can strongly limit the quantities of plutonium per waste package (5) and the spacing of waste packages in a geological repository.

Plutonium in light-water reactor (LWR) spent nuclear fuel (SNF) is allowed in geological repositories, although 1 % of the heavy metal in a SNF assembly is plutonium and the total fissile content of the SNF heavy metal is typically 1.4 %. The basis for plutonium acceptance is that it is mixed with depleted 238U. This prevents nuclear criticality. When the plutonium decays to 235U, it is born into a world of 238U and is isotopically diluted by that 238U. For PCMs with higher concentrations of plutonium, the repository licensing and acceptance philosophy for SNF may be used as a basis for repository acceptance of highly loaded plutonium waste forms by incorporation of depleted uranium into the waste form. A waste with a ratio of about 1 part plutonium to 50 to 100 parts uranium will have nuclear

characteristics similar to
LWR SNF
The second plutonium concentration related set of criteria are for safeguards. Three categories of safeguards may exist (these are currently being defined) for PCMs.
1. The International Atomic Energy Agency (IAEA) has developed a set of criteria (7) defining when safeguards are not required for PCMs. If the plutonium concentration is sufficiently low, potential diversion of the waste for the recovery of plutonium is not credible.
2. If the plutonium concentration in the waste is higher, some form of standard safeguards are required.
3. If the concentration of plutonium is sufficiently high, arms control concerns may require mixing the PCMs with radioactive materials to make plutonium recovery difficult. The United States Academy of Sciences (8) has proposed that if excess plutonium is to be disposed, it should meet a spent fuel standard; i.e., excess plutonium should be no more accessible than plutonium in SNF. This set of recommendations is part of the ongoing discussions concerning international control of nuclear weapons and nuclear weapons materials. Several methods to achieve this goal have been defined. The United States Department of Energy is currently determining if or at what concentrations of plutonium in a waste should the spent fuel standard be applied (9). This implies that at some concentration of plutonium in the PCMs, some quantity of radioactivity may be required to be added to the waste to make plutonium difficult to recover.
The criticality criteria suggest that as the plutonium concentration of the wastes increases, at some point low-enriched uranium may need to be added to produce an acceptable waste form. The safeguards criteria suggest that as the plutonium concentration of the wastes increases, at some point sources of radioactivity may need to be added when producing a waste form. There are two sources of depleted uranium in the United States: depleted uranium at the uranium enrichment plants and low-enriched SNF. In this second category, there exist 2100 t of Hanford-N SNF with an initial enrichment of 0.95-1.08 % which is badly degraded and may require treatment before it can be accepted for geological disposal. If criticality criteria are the only concern, adding the clean depleted uranium to PCMs during waste processing may be appropriate. If nuclear criticality criteria and spent fuel standard safeguards criteria are concerns, adding Hanford-N SNF or an equivalent to the PCMs during processing may be necessary. The Hanford-N SNF provides both the depleted uranium and the radiation source.
GMODS PROCESS DESCRIPTION
The basic concept of GMODS is based on adding unprocessed PCMs (with plutonium in multiple chemical forms), glass frit, and a sacrificial oxide directly to a glass melter. GMODS may be operated in a batch mode (Fig. 1) with all waste-processing operations preformed in sequence in a heated pot. The starting point for conversion of PCMs to high-quality glass is the melter filled with molten lead-borate glass in a ratio of 2 mol of lead oxide or more per mole of boron oxide.
Fig. 1. GMODS batch processing of PCMs to borosilicate glass.
In the first step, PCMs are fed to a molten lead-borate glass bath. Conventional molten glasses dissolve wastes made of oxidesbut not wastes containing metals or organics. Molten lead-borate glass has unique properties. Metals in the feed chemically react with the lead oxide in molten lead-borate glass, thus forming metal oxides and lead metal. These metal oxides dissolve into the lead-borate glass. The boron oxide in the molten glass assists the rapid dissolution of metal oxides, including any protective oxide layers on the metals into the molten glass. Organics are oxidized to carbon oxides and steam with lead metal as the by-product. Example chemical reactions in the molten lead borate glass are:

$$Pu + 2PbO \rightarrow PuO_2 + 2Pb \quad (1)$$

$$Zr + 2PbO \rightarrow ZrO_2 + 2\,Pb \quad (2)$$

$$2Al + 3PbO \rightarrow Al_2O_3 + 3Pb \quad (3)$$

$$3Fe + 4PbO \rightarrow Fe_3O_4 + 4Pb \quad (4)$$

$$C + 2PbO \rightarrow CO_2 + 2Pb \quad . \quad (5)$$

The lead metal from these chemical reactions separates from the molten glass and sinks to the bottom of the melter. There it forms a separate layer of molten lead. Dense reactive metals (e.g., plutonium metal when added to the molten glass) may partly react and dissolve into the glass and may partly sink through the glass and descend into the lead. Plutonium melts at a low temperature (638C). If the molten

plutonium metal enters the molten lead, it dissolves into the lead. The dissolved plutonium is then oxidized at the lead-glass interface and extracted in oxide form back into the glass.
The lead-borate glass, with its dissolved PCMs, is not a high-quality glass. To create a high quality glass, two more steps are required. Glass additivesprimarily silicon oxide (SiO2)are fed to the melter where they mix with the molten lead-borate glass and then produce a lead borosilicate glass. This is in the same family of glasses as is crystal used in elegant, expensive glassware.
After formation of lead borosilicate glass, excess lead oxide in the glass is removed by adding carbon to the glass to create a borosilicate glass that is chemically similar to HLW borosilicate glass and which has similar desirable properties in terms of waste management. The resulting chemical reactions yield gaseous carbon oxides exiting the melter and lead metal separating from the molten glass and sinking to the bottom of the melter. Lead oxide may be removed from the dissolution glass for multiple reasons: a) better final waste glass, b) reduction of the volume of the waste glass, and c) avoidance of the costs to provide added sacrificial lead oxide. Studies (10) indicate that many glasses that contain lead are not hazardous. Some lead can remain in the glass to improve glass properties. The product borosilicate glass is poured from the melter into cylinders or converted into marbles.
After removing the product glass from the melter, boron oxide and lead oxide are added to the melter to replace materials that have gone into the final glass product. The lead at the bottom of the melter is reoxidized back to lead oxide by the addition of oxygen.
2Pb + O2 2PbO .
(6)
The resultant lead oxide mixes with the residual glass to create a new batch of molten lead-borate dissolver glass. The production cycle is then repeated as new wastes are added to the melter.
PRODUCT DESCRIPTION
The product composition will depend upon the feed material. Typical glass compositions for high plutonium/uranium glasses are shown in Table I. These numbers report experimental work at Savannah River Laboratories (11) in development of actinide glasses.
TABLE I
The glass-product form can be logs or marbles. Logs provide a well-defined product form that fills a product canister. Marbles allow inspection of the glass product and recycle of off-specification materials. Marbles can also be converted into glass logs with small, simple glass melters or by filling the containers with marbles and heating the marbles to consolidate them at temperatures below normal molten-glass conditions. This option also allows separate production of marbles from different PCMs and combining the marbles and then melting them together within the final waste package.
GMODS EQUIPMENT DESCRIPTION
Cold-wall, induction-heated glass melters appear to be the preferred choice of vitrification equipment for most GMODS applications. In a cold-wall melter, a thin layer of frozen glass separates the molten glass from the melter wall. This separation prevents glass corrosion of the furnace lining. The higher temperatures (1400C) possible with such melters allow the use of glass formulations with higher waste loadings and/or the production of more durable glasses. The high waste loading per unit volume minimizes cost.
Cold-wall, induction-heated melters are used industrially to melt titanium and super alloys. They are being modified for radioactive waste processing in France (12) and Russia (13). The French have an operating melter with a throughput of 50 kg/h and are developing a 200-kg/h melter. The French melters have also been used to melt Zircaloy hulls and hardware into ingots. The melters have the capacity for bottom gas injection and may be emptied by tilting the furnace or using bottom freeze valves. Similar melters for hazardous flyash are being developed with capacities to 800 kg/h.
THERMODYNAMICS
The thermochemical properties of the PbO-B2O3 system are the basis for GMODS. The abilities to oxidize metals and to dissolve metal oxides are directly related to the thermochemical activity of PbO and B2O3. This system was assessed by Slough and

Jones (14). These authors used the Gibbs energy values reported by Kapoor and Frohberg (15). In this work, we also have used the data of the latter.
The processing of metals in GMODS involves both oxidation and dissolution into a PbO-B2O3 glass. The overall free energy change for the process will include the free energy change for the oxidation, plus the free energy change for the dissolution. The final dissolution product will be at least a ternary system involving PbO-B2O3-metal oxide. No data are available about such systems on which to base a calculation on the distribution of species for the entire process. It may be possible to perform calculations on ternary and higher systems using thermodynamic solution models. Until that work is done, the best guide to treatability of a material by GMODS is the oxidation of the metal by PbO.
The best way to compare the relative ease of oxidizing a given metal is to use oxygen potentials. Oxygen potential is described in units of energy and is defined as RT ln PO2. Figure 2 shows plots of oxygen potentials for forming a number of metal oxides. This figure shows the important feature that any metal oxide that is higher than another can oxidize the metal in a lower position. Here, we are concerned about the ability of PbO to oxidize metals. Figure 2 shows that any metal, Sn, Fe, Zn, Cr, U, Pu, Al, etc., that lies below the PbO:aPbO = 0.1 line will be oxidized when the activity of PbO is 0.1. In this figure, only Cu2O lies above the PbO lines. However, Zhou et al. (16) have shown that copper in the +2 oxidation state, as in CuO, is stable in 2PbO.B2O3 glass. The stability of oxidized copper in this glass must be due to the combination of oxidation and dissolution and not oxidation alone. Other metals, such as Ag, Au, Pt, and Pd do not form oxides that are stable at high temperatures, and they are not included here. Noble metals dissolve into the lead. The oxygen potentials for the formation of ZrO2 are similar to those of Al2O3.
Fig. 2. Oxygen potential diagram.
Some metals, such as U and Pu, can form more than one oxide. The highest oxides are thermodynamically stable as far as oxidation is concerned. However, the overall oxidation and dissolution may result in a lower oxide in the borate glass. Tests of UO2 oxidation and dissolution resulted in a black product which is most likely to be U3O8 rather than UO3, which is red.
Carbon may be introduced into GMODS either as waste to be treated or to reduce PbO to Pb with the production of carbon dioxide (Eq. 5). The equilibrium constant for this reaction is ~3 108 at 1000C; therefore, even when the PbO activity is quite low, carbon will be oxidized.
EXPERIMENTAL RESULTS
A series of small-scale experiments have been initiated a) to demonstrate process chemistry and b) to provide process and equipment design data. The data include solubility and density, viscosity, and chemical reaction rate measurements.
The solubility of various oxides in lead-borate glasses with molar compositions from PbO:B2O3 to 4PbO:B2O3 was investigated. High solubility is required for high waste loadings in the glass and rapid dissolution of oxide layers on metals in the feed. For uranium oxide, the highest solubilities in the lead borate dissolution glass were with an initial glass molar composition of 2PbO:B2O3. This particular lead-borate glass, when heated to 1020C, dissolves in excess of 20 wt % UO2 + 20 wt % ZrO2. Other experiments showed similar solubility for Al2O3.
Preliminary chemical reaction tests demonstrated the conversion of uranium, Zircaloy-2, aluminum, cerium, and stainless steel to dissolved oxides in the dissolution glass with production of lead metal. Experiments have also demonstrated oxidation of carbon with production of metallic lead and gaseous carbon oxide release. Dissolution rates are being investigated systematically for candidate metals and materials such as carbon. Quantitative data are incomplete; however, qualitative observations for Zircaloy, aluminum, stainless steel, and carbon confirm that satisfactory dissolution rates in the 2:1 PbO:B2O3 glass can be expected. Of these, only carbon has been measured. Under static conditions, the rate of mass loss from a cylindrical carbon rod was 0.1 g/(cm2*h) at 1000C.
Measurements of the mass of the lead regulus that results from the oxidation-dissolution reaction indicate similar rates for aluminum and Zircaloy. The metal cerium, which is chemically similar to plutonium, also produced a similar amount of lead.
Glass viscosities and densities were measured over a range of temperatures and viscosities in a platinum viscometer. Low viscosities are required to ensure rapid

mixing and reaction of PCMs with the lead-borate glass. The results (Table II) indicate that the lead borate system is a low-softening-point glass with low viscosities in the range of 700 to 900C. This implies that the actual dissolution-oxidation step can be conducted below 1000C.

TABLE II

Added experiments are planned to measure glass physical properties (viscosity, density, thermal conductivity, and heat capacity) and chemical reaction rates for various materials as a function of glass compositions and temperature. Major experimental work remains to demonstrate the process.

EXAMPLE FLOWSHEET

Based on theory and experiment, a set of flowsheets was developed for the conversion of PCM to glass. One flowsheet was for the direct conversion of plutonium metal to glass using a single vessel. Table III summarizes this particular flowsheet. The final glass is a plutonium storage glass with 10% plutonium. This plutonium concentration ensures criticality control by composition rather than geometry.

TABLE III

CONCLUSIONS

GMODS is a new process for converting PCMs in metal, ceramic, amorphous solids, and organic forms directly to a borosilicate glass. Preliminary experiments have been initiated using cerium as a substitute for plutonium. Tests have also been initiated with other materials that may be in PCMs. The preliminary experimental data indicate the potential for GMODS to be a workable process for PCMs. However, significant process development work is required and major work remains to demonstrate engineering feasibility.

If GMODS can be developed into a successful process, it creates the option to convert most PCMs into a homogeneous, transuranic glass. This has multiple benefits. Safeguards would be simplified by conversion of heterogeneous materials to homogeneous glass. Nuclear criticality safety for higher concentrations of plutonium in wastes would be assured by chemical composition. Waste management would be simplified by creation of a single, high-quality waste form acceptable in any repository.

ABSTRACT

The recent rebirth of interest in nuclear transmutations is mainly due to a significant progress in the accelerator technology now permitting us to achieve sufficient target currents and thus neutron yields. These neutrons of adequate spectrum shape (e.g. a hard one) can be used for transmutation of nuclear materials (actinides - fertile and/or fissile ones, fissile products or spent nuclear fuel). In view of supposed safety and economical advantages the idea of a symbiotic nuclear energy system, consisted of an Accelerator-driven fuel Regenerator (AR) and a number of LWRs serviced by it, is the subject of this study. In the AR the regeneration of spent fuel with simultaneous fissioning of plutonium, both from ca. 3 LWRs can be carried out. At higher inventories, the abatement of respective minor actinides (e.g. 237Np, Am) and a partial abatement of fission products, can be performed too. In addition to the above, it should be emphasized that a reduction of environmental impact of nuclear energy with nuclear technology is of particular importance for the deployment of the former in view of its possible positive psychological effect. Summarizing, the advantage of the present concept of accelerator-driven transmutation of waste based upon then operating reactors, lies in efficient slowing-down of the rapid world wide build-up of nuclear waste at reasonable investment expenses.

INTRODUCTION

One of the causes conditioning the spread of negative social attitudes towards nuclear energy seems to lie in the unavoidable and deep discrepancy between the time scale of exhaustion of traditional energy sources and human (political, economic, social and personal) time horizons. The latter are simply inadequately short as compared with the former - distant and vague though unavoidable. Simultaneously, the apparently less important aspects of investigations, like environmental and social impacts of developing technologies only very recently were gaining their well deserved attention. A symptom of change is the search for new solutions of the very sensitive item coupled with nuclear energy - the nuclear waste. The recent rebirth of interest in nuclear transmutations (1) is mainly due to a significant progress in the accelerator technology now permitting us to achieve sufficient target currents and thus neutron yields. One proton of energy 1 GeV impinging upon a heavy (e.g. Pb) target (Fig. 1) can produce about 30 fast neutrons. These neutrons of adequate spectrum shape (e.g. a hard one) can be used for irradiation of nuclear materials (actinides - fertile and/or fissile ones, fissile products or spent nuclear fuel) (2). Thus being, the fertile nuclides can be transmuted into fissile ones, then these when being fissioned are producing energy while the radioactive fission products are transmuted into stable ones. The feasible in this way re-use of spent fuel reduces the environmental impact of the nuclear fuel cycle.

Fig. 1.

Therefore, the present work is an attempt to demonstrate the concept of

Accelerator-driven Regenerator (AR) as an environmentally benign solution, which should help in the deployment of nuclear energy.

GENERAL CONSIDERATIONS

The same premises that are substantiating so deeply future-oriented research, as that one in the field of spallation neutrons applications (the seek of new energy sources to meet future energy needs and abatement of nuclear waste) oblige scientists to more and more integral approach in these analyses. First, one must recognize the need of efficiency of undertakings and at the same time be conscious that just the economical incentives are motivating most human actions at social level. Thus in order to cope with the tasks that have been facing us, the studies should first of all, though - by necessity - roughly, deal with economical aspects of emerging nuclear energy systems.

Economical Questions

Unfortunately, in fact till now, there are no unquestionable, truly reliable and complete economical evaluations of existing energy sources, not to mention the emerging ones. That pessimistic opinion results from the observation that till now the energy prices do not include the whole of externalities which in reality are (or will be) paid by the society (in the future even by the whole mankind at global scale). The proposal of carbon tax is an example of first still not successful attempt to internalize such costs. Simultaneously, the respective dispute and very distant perspectives of its implementing indicate the gap between the existing and strict economical calculus. Thus, the results of economic studies of accelerator driven systems are so uncertain that one can doubt whether detailed analyses are now useful. The main sources of errors lay in the uncertainties of:

capital cost of long term investments, i.e. the interest and discount rates that determine this main component of costs,

price of uranium, determined by its demand which depends on the growth rate of nuclear power industry influenced, in turn, by public attitudes, various political factors etc.,

back-end costs somehow determined by the readiness of society to spent means for reduction of its true or imaginary threats,

electric power demand depending on the global (and also local) economic development and demographic growth.

The above factors can vary in a very wide range over the decades that separate nowadays from the time of commercialization of the use of accelerators for the energy purposes. Even though, since a simplified analysis is better than nothing, the approach presented below deserves an attention.

The spent nuclear fuel is to be rejuvenated, what should bring higher gains (equal to the fuel share in the electricity costs) thanks to the two benefits (2):

1. Direct reutilization of unburned fissile nuclides contained in the fuel;
2. Avoidance of one fuel cycle.

Both features merit some emphasizing, in view of their positive environmental effect. When discussing the AR economics one should not forget that the contribution of uranium raw material to the cost of electricity from nuclear power does not exceed recently 3-5%. Therefore, alone the production of fuel in accelerator systems cannot bring an income, which might compensate immense investment costs of spallators, well exceeding the ones of LWRs. Thus one can conclude, that accelerator systems must be confined neither to sole fuel nor to mere energy production, but transmute the nuclear waste too (3).

The essence of AR economics (4) is illustrated in the self-explanatory Fig.2.

Fig. 2.

Thus one can see that symbiosis of a certain minimum number S (support ratio) of LWRs with the AR is essential for the latter to be economic. In other words - the AR must resolve the problems of fuel cycle of several (say, 3) LWRs. The dependence of S on some physical parameters of the AR is discussed below in the item Reactor Physics Issues.

Environmental Aspects

In our concept of the Accelerator-driven Regenerator being used for rejuvenating of the burned-up fuel it is performing a triple function:

first - the "augean" one of a symbiont co-operating with S fission reactors for transmuting (fissioning) their actinides and (partly) fission products i.e. de-poisoning and deactivating the nuclear reactor waste;

second - of a device producing net energy from fissions;

third - of a breeder of fissile material in the fuel supplied for regeneration.
In the present discussion the most important postulate is the consideration of environmental impact of the whole energy system the AR is part of. This signifies that confining oneself to the analyzing of impacts of the sole device without taking into account those stemming from other inseparable elements of the system is a serious error that can falsify the assessment of the whole concept.
Therefore, in the case of accelerator-driven fuel regeneration one should compare the change in the impacts when to the system of S (symbiotic) fission reactors is added alternatively: -one AR or - one LWR reactor.
Then let us accept the following assumptions:
the LWR's environmental, health etc. impact is taken as unit;
the impact of the LWR fuel cycle alone amounts to 90% of the total impact, whereas the impact of an AR is equal of that of LWR;
the fuel regeneration reduces the impact of respective fuel cycle by 1/3.
The above assumptions are quite conservative. In spite of doubling the energy production per fuel cycle (i.e. per amount of the mined uranium, fabricated and reprocessed fuel), decay and transmutations of radioactive nuclides in the irradiated fuel, a reduction of the impact not to 1/2 but merely to 2/3 has been assumed. Also in spite of lack of danger of the uncontrolled supercriticality the impact of the AR has been assumed as equal to that of LWR's. In such circumstances the change in the overall impact of the whole energy system which resulted from the above discussed alternative solutions is presented for two representative values of support ratio S in the TABLE I
As it can be seen from the Table I the implementation of an Accelerator-driven Regenerator as a fuel rejuvenator can be environmentally benign.
Reactor Physics Issues
The connection between the design premises and physical properties of the transmutation system should be discussed first. One of the most important parameters of the system is the conversion ratio Cr, in general defined as a number of bred fissile nuclei per one net destroyed fissile nucleus in the system. It is to be calculated from the formula:
Eq. (1)
where:
symbolizes integration over all neutron energies and volume of the system,
F neutron flux,
cfe sum macroscopic capture cross section of all fertile nuclides in the system,
afi sum macroscopic absorption cross section of all fissile nuclides,
As it is shown below, this is just the factor directly determining the number of LWRs served by a given transmuting system. As far as assemblies of high fission contribution are concerned the connection between S and parameters of such AR system and symbiotic LWRs of equal power, is (4):
Eq. (2)
where CrR regards LWR, and usually varies within 0.6-0.67.
The formula (2) is illustrated in Fig. 3.
Fig. 3.
One can see that in order to serve, say, at least 3 LWRs by the AR, Cr should amount to 2-3. In the efforts to have an optimum AR, distinct for instance, by efficient transmutations of Transuranics (TU), one must never forget that since only fissioning is recognized as a definitive way of getting rid of TUs, the rate of transmutation per power unit is absolutely limited.
The process, thus inseparable from energy release, has a well fixed intensity (per energy unit) and thus its whole rate is directly determined by the size i.e. the power of the device.
In this view, the optimization efforts should rather consider other factors than the rate of transmutation i.e. first of all those facilitating the fulfillment of safety requirements and the optimum use of the accelerator. Among the former the most important postulate seems keeping the neutron multiplication factor keff below a certain value recognized as a safe one. In turn, the constancy of over the time of transmutation is desirable in order to have all the time the optimum load of accelerator. This state keff const can be approximately assured if the amount of fissile inventory in the system is kept unchanged, i.e. provided Cr 1.
But, as one can see it in Fig. 3, an AR of Cr = 1 can support no symbiotic LWRs at all.

Therefore, some other solution must be found.
Namely, the circumstances when Cr of the system as a whole remains equal to 1, but at the same time the value of S will be well above 1. This apparently contradictory requirement can be achieved by a diversification of the media filling the assembly. Generally, in hard spectra, a high fissile breeding rate can be expected in the spent fuel because of a relatively low mean enrichment in there. Instead, if into the system a certain additional fissile material is added, its increased burnup rate will compensate the breeding in the regenerated fuel, thus making the Cr of the system drop to 1. This might be done with Pu recovered from the burned-up fuel of symbiotic LWRs (after the second cycle, when no more regeneration is possible, because of the radiation damage in the fuel). The higher concentration of fissile material in the outer zones can simultaneously assure the desirable flattening of the power density distribution in the assembly.
Obviously a more diligent calculations might provide us with results of still higher degree of accuracy and reliability, yet these obtained at this initial phase of working out the present concept are presented below. An exact evaluation of Pu + minor actinides (MA) balance in the whole symbiotic system is foreseen in the nearest future.

CALCULATIONS AND RESULTS

Neutronics

The complexity of neutron transport phenomena makes impossible an exact description of physical reality in the respective calculations. Thus quite significant simplifications are inevitable. The problem lies in the right selection of them or in the avoidance of those which threaten with inadmissible errors in given circumstances.
The phase space of parameters of Accelerator-Driven Regenerator has been investigated in search for areas of Cr 1 at simultaneous safe k values, arbitrarily assumed not to exceed 0.95. The neutron transport calculations were performed on the model of cylindrical target/blanket system (Fig. 4) driven by a proton accelerator.
Fig. 4.
The neutron yield due to spallation has been assumed to be 30 neutrons (of fission spectrum) per 1GeV proton. In order to have flatter power distribution the concentration of fissile material has been increasing in the zone of fuel rejuvenation. The space devoted to the spent fuel + additional Pu and MA, has varied from 4% vol. in inner layers up to 28% in the outer ones. The remaining volume up to 90% has been filled with liquid lead as a cooling medium while construction materials occupied the 10% everywhere.
The amount of additional Pu and MA corresponded to its tenfold content in the fuel to be rejuvenated. The external neutron reflector of lead has been assumed.
For both actinides and fission products, the transmutation calculations for U/Pu fuels were performed with modified code BISON. This program uses ANISN code for neutron transport calculations and Bateman's method for time-dependent evolution of nuclide chains. The pertinent nuclear data 42-group set has been based on JENDL-3 library except for fission products evaluated from ENDF/B-6. In view of pretty high neutron multiplication in the system (keff ca. 0.94) the neutron transport in high energy region above 15 MeV has been neglected. The performance of the system is presented in the Table II.
TABLE II
As it has been announced above, in addition to a suitable enrichment of rejuvenated fuel, one should examine the changes in fissile products concentration, especially those radioactive ones and reactor poisons. Some radiotoxic or poisoning fission products can be transmuted into non-harmful isotopes, due to neutron capture during irradiation. Unfortunately, the lack of yields of fission products for all significant fissile nuclides (eg. 241Pu and 238U), in many cases deprive our preliminary assessments of any reliability. Thus only some less doubtful are presented in the Table III. where the initial concentrations in the spent fuel and the respective changes in result of the rejuvenation are given. They were based on the rejuvenation time assuming sufficient build up of fissile material. The 10 year cooling time of LWR's fuel before irradiation was also assumed.
TABLE III
The concentration of the most important stable poison 149Sm (and of some other ones too) was assessed to be decreased, although changes for specific nuclides differ considerably and some nuclides even are building-up. Nevertheless, it should be

reminded that FP activity, increases less than linearly with the burnup, and the rejuvenation finally results in doubled energy production from the fuel. Thus, the radioactivity per released energy is decreased, non mentioning the waste volume, just substantiating the proposed concept of reduction of the nuclear waste.

CONCLUSIONS

The proposed methodology gives rise to some remarks. In addition to the necessary completing the yields of fission products, it should be noticed in connection with the neutronic calculations, that an exact consideration of resonance self-shielding should be introduced. A correction for these effects, though a moderate one for hard spectrum media, that prevents us from an overestimation of neutron capture in 238U i.e. of fissile breeding, will result in a certain reduction in fissile materials concentration. Similarly, the component of high energy neutrons (>15MeV) should be considered, esp. in view of their contribution to the radiation damage. Also the reliability of the whole system, thus its load factor can prove lesser than the one of LWR and the price of rejuvenated fuel lower than expected. Nevertheless, since the structure and composition of the assembly are far from being optimized, a margin for further improvements in its performance still remains.

The influence of the pertinent geometry, requiring a 3-D code coupled to the burnup one and, at minor scale, also the distribution of newly bred fissile material within a rejuvenated fuel rod also demand evaluation. A desirable, more homogeneous power distribution during its future exploitation should be expected. This positive effect can be achieved due to higher rate of neutron captures in the outer layers of the rod due the captures (mostly) occurring in self-shielded resonances.

In conjunction with the economy of the AR, one should admit that it cannot be quite completely evaluated, at least until a recognized methodology of internalization of environmental costs of energy conversions is elaborated.

As for transmutations of fissile products and of actinides some deeper insight might be desirable too. In this case an objective function should be selected (e.g. the biological hazard potential) which would consider the risk associated with each particular nuclide i.e. among other its (radio) toxicity, probability of spreading out, entering the food chain etc. On such basis the final sum effect of the rejuvenation process could be reliably estimated.

All the above ways to raise the reliability of evaluations remain in the close plans of the authors.

On the basis of presented approach and results the concept of fissile fuel rejuvenation, is revitalized. Certain simplifying assumptions and a preliminary character of calculations notwithstanding, the possibility is demonstrated of a reduction of general hazard from nuclear energy system, with the help of an accelerator at reasonable investment effort. This advantage is due to a symbiosis of the AR with then just operating reactors. Therefore, the concept of Accelerator-driven fuel Regenerator, proven as environmentally benign, should help in deployment of the nuclear energy. This, in turn, should find a right reflection in the support of farther pertinent research. Besides, it should be emphasized that a reduction of environmental impact of nuclear energy with nuclear technology is of particular importance in view of its possible positive psychological effect. Summarizing, the advantage of the proposed concept lies in efficient slowing-down of the rapid world wide build-up of nuclear waste at reasonable investment.

Molten Metal Technology, Inc.

ABSTRACT

Quantum-CEP (Q-CEP) is an innovative and patented technology developed by Molten Metal Technology, Inc. (MMT) that can process radioactive and mixed waste streams to decontaminate and recover resources of commercial value while achieving significant volume reduction and radionuclide stabilization. MMT is currently in the process of commercially deploying Q-CEP in the government and commercial radioactive markets. To this end, MMT has formed two relationships with market leaders: Martin Marietta Corporation and the Scientific Ecology Group (SEG), a Westinghouse subsidiary. M4 Environmental, L.P., a 50/50 partnership between MMT and Martin Marietta Corporation, was formed to deploy Q-CEP applications in the U.S. Department of Energy (DOE) and U.S. Department of Defense (DoD). A Q-CEP demonstration facility is currently under design and construction for the processing of DOE mixed waste in a privatized mode. MMT has also joined forces with SEG to deploy Q-CEP systems for processing spent ion exchange resins from nuclear power plants worldwide. A U.S. facility is currently under construction and will be operational by the end of 1995.

This paper outlines a wide range of CEP/Q-CEP's processing results including RCRA wastes, spent ion exchange resins and contaminated scrap metal. These results highlight the technology's unique features in processing radioactive and mixed waste:

1. Waste Minimization Performance: RCRA wastes are recycled into commercially valuable products: gases, ferroalloys and ceramics. Processing of mixed waste streams leads to complete destruction of hazardous contaminants and the potential formation of one or more decontaminated product streams such as fuel gas and/or metal alloys.
2. Environmental Performance: Processing of RCRA wastes leads to environmental performance surpassing regulatory standards. Destruction Removal Efficiencies (DREs) 99.9999% have been consistently demonstrated. NOX and SOX were not detected to 3 ppm (analytically limited). Dioxins/furans were not detected to the targeted regulatory limit of 0.1 ng/Nm3 toxicity equivalent (TEQ). All ceramic products passed Toxicity Characteristic Leaching Procedure (TCLP) tests.
3. Controlled Radionuclide Partitioning: Processing of contaminated scrap metal results in metal decontamination >99%, with current experimental demonstrations limited by the lower detection limit (LDL) of the analytical equipment. Commercial processing of spent ion exchange resins will result in gas decontamination factors >107.
4. Final Form Stabilization: Multiple high temperature glass compositions have been developed for Q-CEP applications. SEM/EDX results showed radionuclide incorporation into final form. Radionuclide incorporation into stable high chlorine content glass structures outperforming high-level nuclear waste reference glasses in PCT and TCLP durability testing has been proven.
5. Volume Reduction: Volume reduction from processing contaminated scrap metal is specific to individual scenarios and dependent on the initial form of the waste material. Processing of spent ion exchange resins results in volume reductions >30:1. Preliminary calculations indicate volume reductions >100:1 may be achievable while processing DOE mixed low level waste streams (MLLW), such as organic sludges and combustible debris.

MMT operates a variety of experimental and demonstration-scale CEP systems and has demonstrated long-term operability and reliability to commercial and government customers. Over 40 customer-established performance-based criteria covering environmental performance, product quality, and operability were surpassed with third-party oversight and validation by a major German chemical manufacturer. An on-stream factor >90% was achieved.

Q-CEP RESEARCH, DEMONSTRATION AND COMMERCIAL FACILITIES

Catalytic Extraction Process (CEP) is an innovative and proprietary technology that allows waste material of a wide range of composition (organic, organometallic, and

inorganic) to be recycled into products of commercial value, such as synthesis gas, hydrogen chloride, metal alloys, and specialty ceramics. At the core of CEP is a liquid metal bath which acts as a catalyst and solvent in the dissociation of the feed and the synthesis of products. Upon introduction to the bath, feeds dissociate into their constituent elements. Addition of co-reactants enables reformation and partitioning of desired products. The catalytic and solvation effects of CEP, together with the thermodynamically controlled reaction pathways, allow the technology to achieve superior environmental and waste minimization performance. Q-CEP is the application of the CEP technology to process radioactive and mixed waste streams. Targeted radionuclide partitioning leads to decontamination and recycling of a large portion of the waste components to commercial products (e.g., synthesis gas) with high resultant volume reduction through radionuclide concentration into a stable condensed phase.

MMT has engaged in technical development of Q-CEP and is currently in the process of commercially deploying the technology to the government and the commercial radioactive market. MMT has formed two significant partnerships to enable quick deployment of Q-CEP: 1) A Martin Marietta Corporation/MMT limited partnership -- M4 Environmental, L.P. --is designing and constructing a demonstration unit for application to DOE wastes; 2) MMT and the Scientific Ecology Group (SEG), a Westinghouse subsidiary, are jointly constructing a Q-CEP facility to process radioactively contaminated spent ion exchange resins.

A variety of experimental and demonstration-scale CEP and Q-CEP units have been operated for both research and customer needs. MMT's Recycling-Research & Demonstration Facility in Fall River, MA, has been the primary site for technology development and customer demonstrations. Fall River houses four bench-scale units, five pilot-scale units, seven physical models and a commercial demonstration prototype unit. The facility is fully permitted by the Commonwealth of Massachusetts for recycling demonstrations using hazardous and non-hazardous materials as CEP feeds. At Fall River, MMT has carried out a range of demonstrations on RCRA materials and has received recycling certifications from the Massachusetts Department of Environmental Protection for the processing of RCRA-listed and characteristic feeds. MMT has also carried out radioactive surrogate and common isotope testing at the Fall River facility. Testing on low-level radioactive materials, and particularly spent ion exchange resins, has taken place at MMT's demonstration facility in Oak Ridge, TN. MMT is expanding its "hot" testing capabilities by deploying with M4 demonstration-scale Q-CEP units to process low-level waste and mixed low level waste.

Technical development and commercialization of Q-CEP was partly sponsored by the DOE. From 1993 to date, MMT has been awarded a total of $19 million under a Planned Research and Development Announcement (PRDA) (1). Contract sponsored activities focused on demonstration of Q-CEP chemistry, recovery potential and final form stability, development of a conceptual engineering design, and application of Q-CEP to contaminated scrap metal and mixed low level waste. Under the agreement with SEG, MMT is constructing at Oak Ridge a Q-CEP commercial facility for processing radioactively contaminated ion exchange resins from nuclear power plants. The Q-CEP system, designed for high volume reductions (>30:1), is targeted for operation in 1995.

An extensive demonstration run was successfully completed for the recycling of biosolids waste provided to MMT by a major German chemical manufacturer. The run demonstrated the long-term operability of the CEP system with respect to on-stream factor and steady-state operation. This prototype campaign also demonstrated CEP's utility for on-line recycling of a commercial-grade synthesis gas. A number of operational performance criteria for on-stream factors, steady-state operation, and product quality and consistency were established jointly by the customer and MMT. Based upon on-site third party customer validation, more than 40 operational criteria were met and surpassed (Table I). Steady-state operation was successfully demonstrated and product quality and consistency met the needs for on-line recycling. An on-stream factor >90% was achieved (2).

TABLE I

Q-CEP PROCESSING OF RCRA WASTE

CEP has been demonstrated on a range of RCRA listed wastes as well as characteristic and RCRA-like surrogate material (Table II) including high-molecular weight aromatics, chlorinated organics, organically-bound nitrogen species (isocyanates),

plastics, and organometallics. Table II data are from waste processing using the Fall River demonstration unit. The technology's environmental performance has been demonstrated during actual waste processing to meet and surpass current and proposed regulatory standards. Specifically, DREs >99.9999% were achieved for principle organic hazardous constituents (POHCs). NOX and SOX were not detected in the product gases to detection limits of 3 ppm. Condensed phase non-leachable products, both ceramic and metal phases, of marketable composition were generated. Dioxins were not detected to the targeted regulatory limit of 0.1 ng 2,3,7,8 TCDD TEQ/Nm3.
Currently the effectiveness of hazardous waste treatment technologies is regulated by the EPA by measuring the concentration of hazardous materials in the after-process wastewater and non-wastewater. All processes have to ensure that organic constituent concentrations in individual wastewater and non-wastewater streams are lower than the regulated limits set by EPA. CEP demonstrations surpass the current limits even when compared with the Best Demonstrated Available Technology (BDAT). CEP was recently approved by EPA (on October 24, 1994) as a non-combustion technical equivalent (BDAT) for eight RCRA-listed isocyanate waste codes (K027) for which incineration had previously been mandated as the commercially available BDAT technology.
The environmental performance of CEP has also been demonstrated on chlorinated waste streams containing some of the most difficult to destroy hazardous constituents (3). The results of demonstration-scale processing of RCRA-listed waste F024 (chlorinated aliphatics) indicated that hazardous organic constituents in the feed were not detected in ceramic, metal and scrubber water, thereby surpassing the BDAT standards for all effluent streams (Table III). Destruction Removal Efficiency (DRE) on multiple organic hazardous constituents exceeded 99.9999%, which surpassed the current regulations mandating DREs >99.99% (Table IV). Trace constituents were not detected to the targeted regulatory limit of 0.1 ng/Nm3 TEQ (Table V).
TABLE II

TABLE IV
TABLE V
Q-CEP APPLICATION TO SPENT ION EXCHANGE RESINS
Nuclear power plants in the United States generate over 200,000 ft3 of spent ion exchange resin. Ion exchange resins are widely used in nuclear power plants for water purification. Regeneration of the contaminated ion exchange resin is not economically feasible, due to the large volume of contaminated liquids generated and other market barriers. The resin waste stream represents the largest waste stream in both volume and activity for nuclear power plants. Disposal has been hampered by the recent closure of the Barnwell, S.C. radioactive waste disposal facility to many of the nuclear power plants. A technology providing volume reduction and stabilization offers significant economic and safety benefits to nuclear power plants.
Surrogate Testing: Prior to hot testing, MMT performed demonstration runs on non-radioactive resin at the Fall River demonstration unit to study CEP efficiency in organic resin conversion. Gas-phase detection of the resin (polystyrene-divinylbenzene polymer) is limited by sampling protocol; hence, a modified method was used to calculate DRE. Using styrene as a decomposition product, the calculated DRE was >99.9999% (below the LDL of 1.2 ppb). As a confirmation, the destruction efficiency for the resin was also calculated by comparing the number of moles of benzene rings in the solid feed with the number of moles of benzene rings in the gas phase. This analysis also resulted in a DRE >99.9999%.
Bench-Scale Testing: A range of "hot" tests using commercial spent ion exchange resin have been performed at SEG's facility in Oak Ridge using bench-scale Q-CEP systems. A representative total Curie balance is shown in Table VI for the gamma-emitting radionuclides in the resin supplied by SEG. A radionuclide closure of 105 7% was measured.
TABLE VI
The bench-scale testing has demonstrated decontamination factors leaving the reactor system 104 (limited by analytical). The commercial facility is designed for decontamination factors >107. Table VII shows representative decontamination factors achieved in the bench-scale tests exiting the reactor system but excluding the gas handling train (i.e., HEPA filter). Decontamination factor is defined as DF = Activity In / Activity Out.
TABLE VII

Commercial facility: The Q-CEP-IER commercial facility, jointly operated by SEG and MMT, will be capable of processing up to 400 High Integrity Containers (HICs) or 80,000 ft3 of IER per year. The facility will operate two Q-CEP systems in a batch mode, which will prevent commingling of customer waste. A customer batch of one or more HICs will be processed and a stable final form contained in a steel container will be returned to the customer. Volume reduction is determined by operating parameters such as customer batch size, resin composition, and curie content. The design specifies that volume reductions will be at least 30:1 while on-going optimization of operating parameters is expected to lead to higher volume reduction ratios.

Q-CEP APPLICATION TO CONTAMINATED SCRAP METAL

Previously published studies have demonstrated the ability to partition radioactive components, such as uranium and plutonium, from the metal phase into a vitreous phase via melt refining (4,5,6,7). Residual concentrations ranging from 0.05 ppm to 2 ppm were achieved using diffusion of oxidizing, vitreous-forming agents to partition the radioactive components. Successful partitioning to less than 10 nCi/g levels (approximately <0.1 ppm) has been demonstrated for uranium- and plutonium-contaminated metals. Q-CEP offers the potential for superior performance, as the techniques involved in melt refining are completely incorporated and enhanced in Q-CEP technology. Specifically, Q-CEP incorporates active radionuclide partitioning through select co-reactant additions (e.g., oxygen) and enhanced mass transfer (e.g., convection), while melt refining is based upon "passive" diffusion-based partitioning. MMT has demonstrated the capabilities of Q-CEP to process contaminated scrap metal under the DOE sponsored development programs.

Bench-/Pilot-scale Testing on Surrogates: Q-CEP processing of radioactive wastes was first demonstrated using surrogates in the Fall River facility. Hafnium and cerium were chosen as the surrogates of radionuclides uranium and plutonium based on similarities in oxidation free energy, density, and method of incorporation into glass (8). Theoretically, these elements will be oxidized and captured in the ceramic phase. Bench-scale tests were carried out varying experimental parameters including metal charge (nickel and iron), glass composition (a matrix of calcium alumino/borosilicates), temperature, and bath carbon level. Initial contamination levels ranged from 350 ppm to 900 ppm. Table VIII shows representative decontamination factors from the processed metal samples. The results indicate successful removal of hafnium and cerium from the "contaminated" metal phase, with demonstrated decontamination factors >99% (LDL limited). Overall mass balance closure >97% has been demonstrated.

TABLE VIII

Bench-Scale Testing of Contaminated Scrap Metal: MMT continued Q-CEP experiments in the bench-scale units at Oak Ridge using depleted uranium (U) and uranium/cerium (Ce) mixtures. The experimental program included optimization of the ceramic phase capture of these species. The primary experimental design parameters evaluated were glass composition, and initial form/loading of the contaminant (Table IX). Samples were taken both from the metal surface and throughout the interior and analyzed for uranium and cerium content. The ceramic phase, reactor crucible, headspace insulation and gas handling train were also subjected to radiochemical analyses. Greater than 95% curie closure was achieved.

TABLE IX

Scanning electron microscopy (SEM) and Energy Dispersive X-ray Diffraction (EDX) were performed on selected glass samples to investigate the nature of incorporation into the ceramic phase. Results indicated that both U and Ce were partitioned to the targeted phase (glass). Figure 1 shows representative results demonstrating the partitioning and capture of uranium in the vitreous phase. These EDX results were originated from a Q-CEP experiment in which the initial iron metal charge contained 1000 ppm uranium. This EDX clearly shows that U is present in the glass phase along with the calcium, aluminum and silicon (note that peaks have been labeled). Uranium decontamination is further quantified by Neutron activation analysis (NAA) studies. In an iron-aluminosilicate-uranium system, decontamination of uranium was found to be 99.77% (LDL limited), which demonstrated consistent findings with surrogate tests. Decontamination measurement was limited by the analytical lower detection limit, which was on the order of 0.1 ppm (dependent upon the contaminant and metal). Thermodynamic calculations indicate that the residual contaminant concentration in the metal should be several orders of magnitude less than the detection limit of

NAA. To verify the stability of the glass formed, PCT and TCLP tests were performed on a series of synthesized glasses that contained various amounts of RCRA metals and uranium. All glasses were shown to be significantly more durable (i.e., less leachable) than high-level nuclear waste reference glasses.
Fig. 1
Q-CEP APPLICATION TO LOW LEVEL MIXED WASTE
Volume Reduction: Volume reduction calculations have been carried out based on Q-CEP of DOE MLLW streams. Major waste streams include soils, inorganic sludges, organic sludges, combustible debris, and inorganic debris. The ceramic phase, which captures the radionuclide contaminants, is expected to be the only solid phase which may require disposal. In the absence of a de minimis standard, decontaminated metal has restricted reuse applications within the DOE complex. Given an achievable de minimis standard, free release into the commercial sector would also be allowed. The synthesis gas product, which captures essentially all carbon and hydrogen in the feed, may be used within the processing system for energy generation. The volume reduction varies from 2:1 to greater than 100:1, depending on the initial form and composition of the feed material.
TABLE X
A recent DOE sponsored evaluation of Integrated Thermal Treatment Systems (9) for application to DOE mixed wastes showed that a Q-CEP system would have the lowest total life cycle costs (TLCC) compared to eighteen alternative systems including incineration, vitrification, and plasma treatment. Q-CEP offers a one-step process that simultaneously achieves organics conversion, metal recovery, and radionuclide immobilization. Q-CEP's broad feed acceptability and robust nature dramatically reduces the feed pretreatment and characterization requirements and the need for post-processing stabilization. This streamlined system design lowers capital and operating costs, and enhances overall system volume reductions.
CONCLUSIONS
Currently no single commercially available technology dominates the huge market of low level and mixed radioactive waste generated and stored in the United States and abroad. Q-CEP can be applied to a wide range of low level radioactive and mixed waste feeds, effectively partitioning and stabilizing radionuclides while destroying hazardous constituents. Furthermore, Q-CEP may be able to reduce radioactive levels in recovered materials to below background levels, which may facilitate establishment of de minimis standards. Q-CEP applications to DOE and commercial radioactive waste problems has been demonstrated and outlined in this paper. Current commercialization programs will deploy the technology to both the government and commercial sectors. A Q-CEP facility accepting spent ion exchange resin from nuclear power plants is targeted for operation in 1995. A mixed waste demonstration facility to process DOE wastes in a privatized mode is also under design and construction for 1995.

A METHOD TO DEAL WITH BIOSPHERE TRANSFERS TO ACHIEVE DOSE CALCULATION IN HLW SAFETY AND PERFORMANCE ASSESSMENT

Elisabeth Leclerc-Cessac

FRANCE

ABSTRACT
Dose limits are usually provided by safety authorities to perform radioactive waste disposal safety assessments. It therefore involves a radioactive transfer modelling through the biosphere to provide dose calculation. This paper described the methodology used to identify and to characterize the biospheres consistent with long-lived radionuclide repository and the dose conversion factors associated. Present national data, reconstruction of past climates and present analogue biospheres were used for biosphere determination. Temperate and tundra biospheres were first studied.
Then, bibliographic study and statistical analysis allowed us to select transfer parameter values and their associated uncertainties for both biospheres. Comparison experiments and chemical analogue determination seemed to be a good opportunity to balance data lacks.
The biosphere model used to calculate the dose conversion factor in a temperate biosphere is shortly presented and its validation is in progress by international comparison. The possible ways of integrating the climate-dependent biospheres in a global safety calculation are then discussed.

INTRODUCTION

The french National Agency for Radioactive Waste Management (ANDRA) is studying several concepts of long-lived radioactive waste repositories in deep geological formation. French rules use indeed dose limits and dose is one of the criteria used to conduct performance assessment and to discriminate between different deep repository systems. The usual way to calculate dose is to determine a biosphere conversion factor which allows to calculate an effective dose (in Sv/year) received by man from an activity (in Bq/year) released in a river or an aquifer after migration through geologic barriers. The biosphere conversion factor comes from biosphere modelling in which biosphere transfers through main food-chains are determined. This calculation needs a lot of radionuclide-, scenario- or site-dependent parameters. The main work consists in selecting values for each transfer parameter and giving associated uncertainties for the biosphere. In a long-term perspective consistent with a HLW repository, various biospheres must be studied which are representative of climatic changes at least over a 160,000 year period (1). In this context, a food-chain associated to each of the six major biospheres has to be characterized and the transfer parameter values determined. Then the plausible ecosystems will be further integrated in a global model. Considering all these assumptions, we have developed a global method which is explained below: first our study consists in defining temperate and other biosphere scenarios, relevant parameters are then determined and the biosphere modelling allows to calculate a conversion factor.

SITES AND CRITICAL GROUPS

Context

We have to characterize the different transfers along several food chains and to specify the critical group associated. The Basic Safety Rule (2) (R.F.S.III.2.f.) edicted by the French Nuclear Installation Safety Directorate and the ICRP 46 (3)

recommend to take into account a critical group "representative of those individuals in the population expected to receive the highest dose equivalent, and relatively homogeneous with respect to the location, habits and metabolic characteristics that affect the dose received [...] The habits and characteristics of the group should be based upon present knowledge using cautious, but reasonable, assumptions."
With respect to these two hypothesis -present technological level and pessimistic assumptions-we chose an agricultural critical group and obviously an agricultural scenario. Main basic food chains which transfer radionuclide, to the critical group are indeed typical and traditional agricultural food chains (see Fig. 1).
Fig. 1.
Farmers are therefore supposed to receive the highest effective dose because of their high self sufficiency level with respect to the global population but also because of their numerous outdoor activities (ploughing, harvesting,...), which involve possible external exposure and inhalation of soil particles. The critical group is able to drink water directly from the release compartment. This assumption appears plausible in the case of an aquifer because, in France, some farmers use a well in their land from which they irrigate fields and water animals and from which they might draw water to drink.
We tried then to adjust site-dependent parameters to the chosen sites such as climatology (obviously just for temperate biosphere), pedology and hydrography. Relevant to the Basic Safety Rule, we had to consider hypothesis "homogeneous with respect to the location" so we had to study first local ecosystem and social behavior. We then adapted these data in order to be pessimistic to answer safety recommendations.

REAL DATA FROM A TEMPERATE BIOSPHERE

Level of human dietary intake have been determined from a national survey (4) and the mean data regarding farmer population were chosen in order to be consistent with the critical group described above. Mean animal feed consistent with a mean production were calculated from national data.
Agronomic parameters were reviewed with local conditions and habits.
Climatic parameters representing statistical means measured by the French Meteorology Institute were chosen as nearest as possible to the defined site.

Methodology Used for Other Biospheres

The main difference between temperate biosphere modelling and long-term biosphere modelling relies on the level of site-specific characterization such as edaphic and hydrologic features which are impossible to predict. In this context, we decided to use present analogues of past french climatic states to build the plausible food chains and the relevant critical group.
The methodology developed to determine and describe the plausible future biospheres likely to exist in France was the purpose of a previous paper. We first used past data to characterize the plausible vegetations over a glacial-interglacial cycle. Present analogues then help us to describe the food chain and the specific critical group. The tundra biosphere study was based, for example, on the reindeer breeders of Lapland (1960's).
It is also possible to characterize agricultural practices which are used in temperate environments and which may be adapted to colder biospheres. We can imagine, for example, cultures in greenhouses. New parameter values will be adapted to this specific situation. These other ways are now under study and will be compared with the other approach, i.e. the traditionally living critical group. This part of the work and the previous one are the subject of exchange between experts.

RADIONUCLIDE- AND SITE-DEPENDENT PARAMETERS

We had then to select the values of radionuclide-dependent parameters (distribution coefficients and concentration factors) and the associated uncertainties. We chose to use both bibliographical study and experiments.
Twenty five radioelements (H, C, Cl, Co, Ni, Se, Sr, Zr, Nb, Tc, Pd, Cd, Sn, I, Cs, Sm, Eu, Ra, Th, Pa, U, Np, Pu, Am and Cm) corresponding to about fifty five radionuclides for high-level radioactive waste disposals were chosen to be studied.

First Step

Thus, a complete study for temperate value selection began. An equilibrium between the different biosphere compartments was assumed and constant concentration factors were considered.
The method consisted in scanning international bibliography and selecting values

from articles and reviews. Experiments adapted to our temperate conditions were chosen. Then, for each radioelement and each parameter, a statistical analysis was conducted to advise the mean and variation interval corresponding to the best fit of the distribution. Values distribution were examined and plotted with a statistical code named Statgraphics Plus (5). The best distribution fit (lognormal or loguniform) was then selected taking into account the highest Kolmogorov-Smirnov test signification level. Kolmogorov-Smirnov test calculates maximum distance between the sampled distribution function and the fitted distribution function. This test was selected because it tests all the values and not only the mean and is valid whatever chosen fit model. The Chi-square goodness-of-fit test is not appropriate if the expected number of observations in the different classes of values is small (smaller than 5).

The geometric mean and the fit for the parameter values were therefore determined. A lot of data for temperate biosphere and for several radioelements (iodine, caesium, radium, selenium, uranium ...) were obtained but there were data lacks for a few radioelements like protactinium, niobium, zirconium, samarium or europium. There was a similar problem for other biospheres. A lot of data exist concerning caesium and strontium behavior in tundra biosphere, for example, but there is not many information about other radioelements. Another approach needed to be developed.

Data Lacks Balance

A collaboration with french National Institute for Agronomic Research (INRA) was intended to balance some data lacks and to understand radionuclide behavior performing experimental studies on soil-to-plant transfer. Soil is indeed an important compartment because of its connections to many pathways like water-to-soil, soil-to-plant, soil particle human inhalation and human external exposure. Another particularity of the soil is the possible accumulation of some radionuclides with time. We then considered radionuclide accumulation in soils because it appeared to be an important compartment which influences radioelement biodisposibility and so soil-to-plant concentration factors. Parameter sensitivity analysis have indeed shown that this biosphere compartment and river or aquifer flow rate participate more than other factors to the dose.

We therefore focused these experiments on soil-to-plant transfer and used three radioelements very different in their chemistry and soil behavior, i.e. technetium, nickel and niobium. The present available results concern only the technetium. In the biosphere and especially in aerated soils, this element is mostly present under TcO_4^-, a very mobile and poorly sorbed oxidized form. However, in the long-term, local reducing conditions and microbial activity promote the reduction of Tc, and the low mobile form TcO_2 which is easily complexed by organic matter tends to predominate. This work studied more particularly the uptake of Tc99 from freshly contaminated soils to rye-grass and winter wheat. Echevarria et al. (6) showed that the rate of soil contamination had a significant effect on the total amount of Tc99 recovered in rye-grass (the more soil Tc99 concentration is high, the more plants uptake this element) and the total uptake of Tc99 was always the same percentage which validates the concentration factor notion. Soil-to-plant concentration ratios ranged from 10 to 400 depending on the plant species and variety and also on the plant organ. Maximum accumulation of technetium in plants is generally found in leaves. Concerning wheat, high concentration factor values are found for leaves (600 kg in soil/kg in plant) compared to concentration factors for grains (less than 1) which allowed us to precise concentration factor for the edible part.

Plants showed a great potential for the removal of Tc from contaminated soils. Technetium contaminated plants could be hidden in soil after harvest and the bioavailability of this "organized" technetium has been shown to be similar to inorganic technetium.

Other experiments are conducted to compare soil-to-plant transfer under temperate biosphere conditions and under colder conditions with the same radioelements. To simulate colder conditions, we chose two soils developed under mountain climate with high organic matter content and plants are grown in pots which are placed in a growth chamber (16h light, 80% humidity, 15C day and 5C night).

In parallel with experiments, we also try to determine chemical analogues with a bibliographical study to balance data lacks. We pointed out, for example, the similar chemical behavior between palladium and nickel and between the two lanthanides europium and samarium and the actinide americium. We can therefore use nickel data for palladium data lacks and americium data for lanthanides.

The current experiments try to answer the question: are transfer parameters values influenced by climatic conditions (temperature, soil characteristics...)? If they are, we will try to determine the differences with temperate biosphere. If they are not, we will take the temperate values for tundra and other biospheres.
Tundra biosphere parameter values were determined and a comparison with temperate biosphere is conducted. A lot of data have been found for caesium and the same behavior has been shown: caesium migration depends on organic matter content in soils both in temperate and tundra biosphere.
More, we must point out important parameters with a sensitivity analysis and focus our attention on these parameters. The distribution coefficient Kd, for example, seems to be very important. As Kd is influenced by soil characteristics, we will try to incorporate this influence in the model.

BIOSPHERE MODELLING: CONVERSION FACTOR CALCULATION

Radionuclide pathways between each biosphere compartment can be modelled by simple equations of radioactivity transfers characterizing compartment concentrations which allow, with knowledge of level of consumptions and of dose factor values, to calculate ingestion dose. Dose factors are given by ICRP 61 (7).
We have to determine a conversion factor for each biosphere.

Temperate Biosphere

ANDRA has developed, in eighties, a one dimension code named AQUABIOS. This code integrates basic radionuclide transfer equations.
Results of AQUABIOS have been compared with other code calculations at BIOMOVS international exercises until two years. The BIOMOVS II Complementary Studies exercise consists of a set of test cases for the assessment of the radiological consequences of the release of radionuclides to a terrestrial biosphere. The release may occur in a biosphere deep soil, a river or a near surface aquifer. Many other codes involved in the exercise are compartment models employing first order linear kinetics to calculate the distribution of contaminants in the biosphere. The most obvious distinction is the number of "dynamic" compartments in each model. Aquabios code provides basic modelling with a low number of compartments compared to others. Only the deterministic phase of the exercise has been set up. Final results will be available at the end of 1995. Based on the same data and scenario describing a well-defined biosphere, calculations show that Aquabios results do not differ a lot with other codes. But it must be remembered that there is no way in which the participating models can be characterized as correct or incorrect on the basis of these results.

Other Biospheres

As we have explained earlier, the tundra biosphere was the first biosphere developed in the long-term perspective because of all the available data, owing to numerous studies conducted all over the world after the nuclear tests since 1950. The tundra modelling conducted to the determination of 21 transfer parameters associated to a traditional food chain and five major equations, mathematically formalizing the transfer pathways in water, fish, soil, plants and reindeer.
Some data are selected only for 19 radioelements among 25 and we are only able to characterize the whole transfer parameters for caesium.
The method developed for the temperate biosphere will be used to select the transfer parameter values and the associated uncertainties.
The use of chemical analogues and an elaborate knowledge of transfer processes in temperate biosphere will allow to balance data lacks for tundra biosphere.
The other ecosystems should be analyzed this year in order to determine their climatic characteristics and their critical group.

Integration of Successive Biospheres

The possible ways of integrating the different biospheres in a long-term safety calculation is the objective of the study of long-term evolution of the biosphere. In this context, for each typical biosphere, transfer processes must be determined, then relevant parameter values must be selected and finally a dose conversion factor must be calculated. Two approaches are then possible to integrate the biospheres: a statistical or a deterministic approach.
The first one uses regression equations with past and present observations to obtain the most probable extrapolation. Each biosphere is an entity with an occurrence probability at each time in the future. The second one implies a global system modelling (climate-biosphere) and uses equations believed to represent the long-term physical, chemical and biological processes governing the climate system.

CONCLUSION AND PERSPECTIVES

Our global methodology is described in Fig. 2. Future actions will consist in making a sensitivity analysis of the transfer coefficients to the conversion factor in order to determine the most important parameters. We will therefore be able to adjust the parameters to the site local conditions. We also have to analyze different probabilistic events like an accidental intrusion by man and other scenarios as well in a deep aquifer, exploratory drill...

Another important development to be performed will consist in integrating all the selected biospheres in a new model.

A PRELIMINARY PARAMETRIC PERFORMANCE ASSESSMENT FOR THE DISPOSAL OF ALPHA-CONTAMINATED MIXED LOW-LEVEL WASTE STORED AT THE IDAHO NATIONAL ENGINEERING LABORATORY*

T. H. Smith
G. L. Anderson
Idaho National Engineering Laboratory
Lockheed Idaho Technologies Co.
J. Myers
IT Corporation

ABSTRACT

A preliminary parametric performance assessment (PA) has been performed of potential waste disposal systems for alpha-contaminated mixed low-level waste (ALLW) currently stored at the Idaho National Engineering Laboratory. The radionuclide-confinement performance of treated ALLW in various final waste forms, in various disposal locations, and under various assumptions was evaluated. Compliance with performance objectives was assessed for the undisturbed waste scenario and for intrusion scenarios. Some combinations of final waste form, disposal site, and environmental transport assumptions lead to calculated doses that comply with the performance objectives, while others do not. The results will help determine the optimum degree of ALLW immobilization to satisfy the performance objectives while minimizing cost.

INTRODUCTION AND BACKGROUND

A preliminary parametric performance assessment (PA) has been performed by Smith et al. (1) of potential waste disposal systems for alpha-contaminated mixed low-level waste (ALLW) currently stored at the Transuranic Storage Area (TSA) of the Department of Energy's (DOE's) Idaho National Engineering Laboratory (INEL). The ALLW contains 10-100 nCi/g of transuranic (TRU) contamination and was generated primarily from 1970 through 1989.

The containers of ALLW are stored together with the containers of TRU waste. The volume of ALLW is estimated to be 24,413 m3, about 40% of the total waste stored at the TSA (ALLW plus TRU waste). The waste is awaiting retrieval from storage, segregation into TRU waste versus ALLW, treatment, and disposal.

This PA was conducted for the Private Sector Participation Initiative (PSPI), which supports the DOE in evaluating possible private sector treatment of the ALLW. The PSPI is in its early stages. Several feasibility studies on private sector treatment have been completed, but a final waste form (FWF) and a disposal site have not yet been selected.

The purpose of this study was to provide preliminary evaluations of the radionuclide-confinement performance of treated ALLW in various FWFs, in various disposal locations, and under various assumptions. The study examined the effects of several parameters on performance of the overall disposal system (consisting of the FWF, containers, engineered barriers, and the disposal site). The performance was evaluated in terms of projected receptor doses and the other performance objectives of DOE Order 5820.2A, Chapter III.

The principal emphasis was on the performance of potential FWFs for the ALLW. Three categories of FWF (cement, glass, and ceramic) were addressed by evaluating the performance of two limiting FWFs for each category.

Performance at three disposal sites was evaluated to illustrate the effects of site characteristics on the performance of the total disposal system. Several other parameters were investigated, both singly and in some combinations, to determine the effects on the calculated receptor dose. Not every combination of parameters was evaluated, however.

This study is a preliminary parametric PA. It is preliminary in that it is not the formal PA that will be prepared after a disposal site and the FWF(s) have been selected. It is parametric in that several parameters were varied to observe their effect, rather than examining in detail one FWF and one disposal site. At this early time in the PSPI, the evaluation of a wide range of options was needed to provide guidance on the selection of an FWF(s).

The study was performed in two phases. In the first phase, PA computer runs were performed using an initial set of assumptions and parameter values. In the second, the earlier results were evaluated, then additional runs were made using refined assumptions or expanded ranges for some parameter values. The complete set of earlier runs was not repeated using the revised assumptions or parameter values.

This study has several potential uses:

It will help the PSPI determine the optimum degree of ALLW immobilization to satisfy the performance objectives of DOE Order 5820.2A, while minimizing cost

The results indicate the margin of compliance with the performance objectives and how the margin depends on various parameters

The study identified key parameters for which better data are needed.

THE WASTE

Most of the ALLW was generated at the Rocky Flats Plant; the remainder, at several other DOE facilities, including the INEL. The waste consists of a wide variety of solid materials (e.g., sludges, paper, metals) contaminated with small amounts of TRU radionuclides and other actinides. Some of the ALLW, particularly the small fraction that is remote handled (RH), also contains fission products and activated metals.

Most of the ALLW is mixed waste; i.e., it contains chemically hazardous constituents per the Resource Conservation and Recovery Act (RCRA). Treatment will be required under RCRA's Land Disposal Restrictions.

Shipping records for the waste are incomplete, particularly concerning radionuclide information. As a result of this situation and the uncertain split of the waste between ALLW and TRU waste, there is some uncertainty about the inventory of radionuclides in the ALLW. Based on a set of assumptions, a simplified, limiting inventory was developed for use in the PA. For the second phase, a refined inventory for part of the waste was used for some computer runs.

Glass, cement, and ceramic were considered logical candidates for the FWF that will be chosen for the ALLW. To evaluate a wide range of potential variations within these three categories, two limiting FWFs were selected for evaluation from each category. Of each pair, one represents the more favorable characteristics in terms of contaminant immobilization; the other represents the less favorable characteristics. Table I lists the FWFs evaluated.

DISPOSAL SITES

The disposal location for the treated ALLW has not been designated. To illustrate the effects of disposal site characteristics on the performance of the disposal system, three arid Western sites were used. Characteristics that are representative

of the following sites were chosen: the Subsurface Disposal Area at the INEL, Site 14 in the central part of the INEL, and the Radioactive Waste Management Site of the DOE's Nevada Test Site. The sites are referred to herein as Sites A, B, and C, respectively.
Site A was studied because it is adjacent to the TSA. Site B was selected because its underlying sedimentary beds are among the thickest at the INEL. Site C was picked because it has virtually no groundwater flow.
The study of a disposal site in this PA does not imply that the site will be the actual disposal location for the ALLW.
TABLE I
SCENARIOS, TRANSPORT PATHWAYS, AND EXPOSURE ROUTES
To assess the performance of ALLW disposal systems, two scenarios were evaluated. The first is the undisturbed waste scenario. (See Fig. 1). After 100 yr of institutional control, members of the public were assumed to use a drinking water supply well located 100 m downgradient from the edge of the disposal unit. The full range of transport pathways was considered for this scenario. However, based on other studies, it was concluded that a) groundwater transport with a full range of exposure routes and b) atmospheric transport of radon with inhalation exposure would be the dominant contributors to dose. These pathways were evaluated (see Fig. 2).
Fig. 1.
Fig. 2.
The second scenario is the intrusion scenario, which is assumed to occur after the loss of institutional control. The scenario has three parts. (See Figs. 1 and 2.) In the intruder-drilling scenario, an intruder drills a well directly through the source zone (the waste disposal pit). The drilling crew suffers exposure to the radionuclides in the exhumed waste/soil mixture from external radiation and inhalation. In the intruder-excavation scenario, waste/soil mixture is excavated during construction activities. Onsite workers are exposed by external radiation and inhalation. In the intruder-agriculture scenario, some of the waste/soil mixture is exhumed by the drilling or excavation activities just described. The mixture is spread over the ground surface, resulting in exposure by direct radiation and inhalation. In addition, radionuclides are taken up by crops and are ingested with foodstuffs of plant and animal origin.
The treated waste was assumed to be buried in a large pit. The waste stack height was 22.7 ft (6.9 m), corresponding to eight 55-gal drums. The top of the uppermost drums was 5 ft or 9 ft below grade (two cases), with the void being backfilled with soil. An 11-ft-thick, multilayer cover was emplaced over the backfill. The cover was designed in accordance with Nuclear Regulatory Commission (NRC) and Environmental Protection Agency (EPA) guidelines to help ensure its integrity up to 500 yr. After that time, it was assumed not to be present. (The belowgrade backfill was assumed to be present for all times.) Thus, the total thickness of geologic material over the waste was 16 ft or 20 ft in the two cases studied.
ANALYSIS OF PERFORMANCE
Conceptual models were developed to describe the dominant physical and chemical processes assumed to occur in the various scenarios and transport pathways.
The conceptual models were implemented by a suite of numerical models. For the intruder scenario, the Generation-II (GENII) package of computer codes was used. For the groundwater transport pathway in the undisturbed waste scenario, the Variably Saturated 2-Dimensional Flow and Transport code (VS2DT) was used to model the flow of water through the source zone. The Disposal Unit Source Term (DUST) code was used to model the release of radionuclides and transport within the source zone. Flow and transport in the unsaturated zone (below the waste disposal pit) and in the saturated zone were evaluated using analytical solutions. Finally, exposure routes were evaluated using the Dose Integrated Over Ten Thousand Years (DITTY) code of the GENII package. For the radon transport, analytical solutions were used.
The performance-related characteristics of the six FWFs, such as leach rates, were estimated using a combination of the limited existing laboratory data and theoretical calculations. Site characteristics were estimated using a combination of questionnaires completed by site representatives and data in published reports.
RESULTS
About 45 runs were made, using the numerical models, to evaluate performance in the undisturbed waste scenario and the intrusion scenarios. The matrix of runs is given in Table II.

The results are also given in Table II and are compared against the performance objectives listed at the top of each column. (The additional performance objectives that are not listed in the table were met in all cases that were evaluated.) The rationale for each run is summarized in Table III.

CONCLUSIONS

The key observations and conclusions from this preliminary parametric PA of the ALLW are presented below. The first group of observations and conclusions relate to the process followed in the study.

The second group relates to the results obtained. The number of cases examined in the study was rather largeabout 45, depending on how one countsbut was still limited. To broaden their usefulness, the following observations and conclusions were extrapolated somewhat to cover the results expected from cases that were not specifically evaluated but are believed to be predictable with a high degree of confidence based on the results of closely related cases.

Process-Related

Completing the preliminary parametric PA at this early time in the PSPI resulted in compiling information, developing simplified models, and performing scoping analyses, all of which are expected to prove useful to the PSPI.

The lack of formal selection of a FWF was compensated for by evaluating the performance of limiting examples of each of the three principal categories of FWF. This approach illustrated the likely range of potential behavior of the FWF.

The lack of formal selection of a disposal site was compensated for by evaluating the performance at three possible sites and varying several key site parameters. This approach illustrated the likely range of potential behavior of the disposal site.

As a check on the conservatism of the assumptions and parameter values used, they were compared against those in five related assessments. The comparison indicated that, on balance, the study was not on either extreme in terms of conservatism or nonconservatism, when the ranges of parameter values used here were considered.

TABLE IIb

TABLE IIc

TABLE IIIa

TABLE IIIb

Results-Related

Compliance with the performance objectives depends not only on the FWF and the disposal site, but also on the overall conservatism of the set of assumptions in the PA.

For the undisturbed waste scenario:

- The results depend particularly on the assumed values for the leach rate of the FWF, the infiltration rate, and the Kd values.
- The dominant radionuclide contributing to dose is the Am-241 decay chain.
- At Site C, any FWF would be expected to comply.
- At Site A or B, nearly all FWFs would be expected to comply under nearly all assumptions. Possible exceptions are the PCC and FUETAP FWFs or untreated waste under quite conservative assumptions (more conservative overall than those investigated herein).
- The performance of the untreated waste is nearly equal to that of PCC, suggesting that little benefit is expected in this scenario from cementing the waste. (It is noted, however, that conservative assumptions were used concerning the adsorption of radionuclides in cement.)
- Most of the cases at Site A were evaluated using a comparatively low infiltration rate and taking credit for travel time through the underlying fractured basalt. However, these nonconservatisms were slightly more than compensated for by the conservatism of not taking credit for adsorption of radionuclides in the source zone.

For the intrusion scenario:

- To the accuracy of these analyses, the intrusion scenario results are independent of the location of waste disposal.
- The results depend particularly on the depth of burial (belowgrade), cover longevity, and radionuclide concentration in the FWF.
- The dominant radionuclides contributing to dose are Cs-137 and Am-241 during the early period studied (e.g., 100 yr postclosure) and the Pu-239 and Am-241 decay

chains for the later period (500 yr postclosure).
- For the intruder-drilling scenario, all FWFs and burial depths studied satisfy the performance objective. (The one exception was the highly unlikely refined-inventory case in which the intruder drills into the RH waste, rather than into a homogeneous mixture of RH and contact-handled (CH) waste.)
- For the intruder-excavation scenario, all FWFs and burial depths studied satisfy the performance objective. (The one exception was the case with TRU waste, not ALLW).
- For the intruder-agricultural scenario, all FWFs fail to satisfy the performance objective for the 5-ft burial depth (16-ft cover). If the burial depth is increased to 9 ft (20-ft cover), all FWFs pass except IEB and IEB4. If the refined inventory is used, IEB passes and the dose from IEB4 is 110 mrem/yr, barely over the 100 mrem/yr limit of the performance objective.
- Under the assumptions used in this scenario, improved immobilization of the radionuclides into a more concentrated FWF degrades the intrusion performance by concentrating the source term. However, a more precise analysis of the inhalation exposure route would reflect the likely larger particle sizes of improved FWFs subjected to drilling or excavation, resulting in a lower calculated dose to intruders.

FOLLOW-ON STUDIES

In a third phase of the PA work, the preliminary parametric evaluations are being refined in several areas, some of which are described below.

FWF performance for hypothetical disposal of the INEL ALLW at two additional DOE sites, the Hanford Site and the Savannah River Site, is being evaluated. The effect of engineered features on disposal system performance is being explored. The waste inventory of nonactinide radionuclides, which strongly affect the dose in the intruder-agricultural scenario, is being refined. The effect of retardation of radionuclides due to chemical reactions in the cement FWFs is being evaluated. Finally, the particle size distribution of the FWF residue after disruption due to drilling and excavation is being explored.

As the project to provide treatment of the INEL ALLW moves forward, performance evaluations are expected to provide continuing support.

EVALUATION OF POTENTIAL HAZARDS RELATED TO RADIOACTIVE WASTE DISPOSAL

Peter W. Brennecke
Bundesamt fur Strahlenschutz
Federal Republic of Germany

ABSTRACT

According to the German disposal concept, all radioactive waste has to be emplaced in a repository constructed and operated in deep geological formations. The required safety of a disposal mine must be demonstrated by a site-specific safety assessment that in particular includes the system geology, repository design, and waste packages.

To get a more detailed insight into the evaluation of the isolation potential of the site-specific geological barrier, it is meaningful to perform additional investigations into the radiotoxicity and chemotoxicity. Thus, an evaluation including the hazard potential of organic and inorganic substances being the major constituents of waste packages to be disposed of becomes possible.

INTRODUCTION

The need for safety assessments of waste disposal systems stems from the necessity to realize protection objectives. As waste disposal methods have become more technologically based, through the application of more highly engineered design concepts, through more rigorous and specific limitations on the types and quantities of waste to be disposed of as well as through experience and technical knowledge gained in disposal site operation, it follows that assessment scopes and procedures also must become more sophisticated.

In the past most investigations predominantly focuses on radioactive constituents of

the waste and on respective assessments of radiological consequences and impacts. However, the radionuclides being contained in the waste does only form the minor mass fraction. The major mass fraction is made up by non-radioactive organic and inorganic material including toxic and/or hazardous substances. Thus, the occurrence of chemotoxic substances has to be acknowledged and be taken into account in addition to hitherto existing safety assessments of radioactive waste disposal.

RADIOACTIVE WASTE DISPOSAL CONCEPT

From the very first beginning, the radioactive waste disposal policy in the Federal Republic of Germany has been based on the decision that all kinds of radioactive waste are to be disposed of in deep geological formations. Near-surface disposal is not practiced because of the high density of population, climatic conditions, and the existence of appropriate deep geological formations. The Bundesamt fur Strahlenschutz (BfS, Federal Office for Radiation Protection), among other things, is legally responsible for the establishment and operation of federal installations for disposal of radioactive waste.

Disposal Sites

According to the German disposal concept, all radioactive waste has to be emplaced in a repository constructed and operated in deep geological formations. As liquid and gaseous wastes are excluded from disposal in such a mine, only solid or solidified radioactive waste is accepted. Two sites are presently considered for disposal of low and intermediate level waste:

1. In the abandoned Konrad iron ore mine in Lower Saxony, it is planned to dispose of radioactive waste with negligible heat generation.
2. The emplacement of waste in the former Morsleben.salt mine in Saxony-Anhalt which was operated as a repository for short-lived low and intermediate level waste with low alpha emitter concentrations has been resumed.

The planned Konrad repository is assigned to accept radioactive waste with negligible heat generation, I. e. waste packages which do not increase the host rock temperature by more than 3 K on an average. Iron ore, I. e. coral oolite, at a depth of 800 m to 1,300 m is the host rock for this repository. Waste packages will be disposed of in drifts with an excavated volume of about 1,100,000 m3 allowing an em-placement of about 650,000 m3 waste package volume. Operation of the repository is scheduled at least 40 years. A total activity in the order of 1018 Bq and an alpha emitter activity of about 1017 Bq are anticipated in this facility.

In the former German Democratic Republic an abandoned salt mine located near the village of Morsleben was re-used for waste emplace-ment. From 1981 until 1991, radioactive waste with a total emplace-ment volume of approximately 14,500 m3 and about 6,700 spent sealed radiation sources were disposed of. Of this, the activity of alpha emitters amounts to 1.6 x 1011 Bq and that of beta/gamma emitters amounts to 4.8 x 1014 Bq. Subsequent to German unity the Morsleben facility has the status of a federal repository, the continuation of its former license being now limited by law until June 30, 2000. Until then, according to present planning, a radioactive waste volume of 40,000 m3 is envisaged to be disposed of. The estimated maximum activity of alpha emitters amounts to about 1013 Bq, that of beta/gamma emitters to about 1016 Bq. Operation has resumed smoothly on January 13, 1994.

Due to these planning data and marginal conditions the major bulk of low and intermediate level waste, i.e. radioactive waste with negligible heat generation, is intended to be disposed of in the planned Konrad repository. This is in particular relevant to alpha-bearing waste. The operation of the Morsleben repository will in the first instance contribute to the discharge of interim storage facilities.

Safety Criteria

The objective of radioactive waste disposal in repositories is to ensure that waste is handled and stored in such a way that the protection of man and environment from harm caused by the ionizing radiation is guaranteed. The basic aspects which must be taken into account to achieve the protection objective of disposal are compiled in the Sicherheitskriterien fur die Endlagerung radioaktiver Abfalle in einem Bergwerk/Safety Criteria for the Disposal of Radioactive Wastes in a Mine (1). These criteria qualitatively specify the measures to be taken in order to achieve the protection objective of disposal and define the principles by which it must be demonstrated that this objective has been reached.

The safety criteria permit a certain latitude of judgement. Such margins gradually diminish in the realization of a repository project. This process is predominantly determined by a site-specific safety assessment. Within the scope of such an

assessment the required safety of a repository in the operational and post-closure phase must quantitatively be demonstrated including the derivation of requirements on the design and construction of the facility as well as on the waste packages to be disposed of.
Nevertheless, the protection objective can only be achieved by an iterative process drawing together more and more detailed information obtained as the respective repository project progresses through its various phases of investigation, planning, detailed design and performance assessment, thus assuming more and more concrete forms.
Waste Acceptance Requirements
Persuant to the safety criteria (1), the safety of a repository in the operational and post-closure phase must be proved within the scope of a site-specific safety assessment. Such an assessment comprises the undisturbed performance of the planned facility, assumed incidents, the thermal influence upon the host rock, the nuclear criticality safety and the radiological long-term effects in the post-closure phase. The results of the respective Konrad safety assessment have been converted into both the design of the surface and underground facilities of this planned repository, and a system of waste acceptance requirements (2). They describe the general basic aspects and the general requirements to be fulfilled and then develop into more specific requirements on waste forms, packagings, radionuclide-specific activity limitations, documentation and delivery of waste packages to the repository. A survey on the structure of these requirements is given in Table I. The Konrad waste acceptance requirements can only be compiled in a final form after the license for this facility has been granted.
TABLE I
The structure of the Morsleben waste acceptance requirements (3) is similar to that of the Konrad requirements. Nevertheless, there are two decisive differences:
1. The operation of the Morsleben repository is regulated by the respective license granted on April 22, 1986, and by further documents pertinent to the license. This represents the legally binding framework which must be adhered to. The waste acceptance requirements includes both marginal conditions prescribed in the license and results of additional safety assessments which keep the above-mentioned framework. According to this, at first sight, the Morsleben requirements appear to be rather complicated.
2. The Morsleben waste acceptance requirements clearly distinguish between requirements on solid radioactive waste and on sealed radiation sources. Such a difference is not explicitly made within the Konrad requirements; they are formulated in a more general sense.
The fulfilment of the waste acceptance requirements ensures that the protection objective of radioactive waste disposal is met, i.e. radiation exposures will not exceed limiting values given in the Strahlenschutzverordnung/Radiation Protection Ordinance, and no undue radiological hazards will occur.
MIXED WASTE
Radioactive wastes including the full range from short-lived low to high level waste and spent fuel elements collectively present a very broad variety of chemical, physical and radiochemical characteristics, constituents and intrinsic hazards. Of this, mixed waste is defined to be waste that possesses both radioactive and non-radioactive constituents the latter being toxic and/or chemically hazardous. Well-known types of mixed low level waste are, e.g., liquid scintillation cocktails or fluids, miscellaneous laboratory chemicals, chlorinated organics and chlorofluorocarbon solvents. For many years, these non-radioactive constituents have been considered to be of minor concern. It has been implied that if mixed waste is disposed of in an adequate and safe manner in terms of its radioactive constituents then it will have also been disposed of safely in terms of its non-radioactive constituents. However, this is not necessarily true: radioactivity will decay, but toxic and/or chemically hazardous constituents may be persistent and their hazard potential may remain constant with time. Thus, implications arise and are implied on the disposal of mixed waste, using either near-surface or deep geological repositories. Further complications arise if different sets of regulations apply to the radioactive and non-radioactive constituents (4). In such circumstances, the ability to manage this waste has been somewhat limited.
Mixed waste particularly originates from research, development, demonstration and production activities in the defense area (4). Although this major source does not

exist in Germany, the arising of specific waste streams containing non-radioactive hazardous constituents cannot be excluded and must be taken into account. Such waste may originate from research establishments, medical/academic institutions, industrial facilities or the operation of nuclear power plants. Nevertheless, up to now, no necessity emerges for mixed waste to be regulated and handled separately from those wastes that are purely radioactive or hazardous. According to the German approach to radioactive waste disposal, mixed waste was considered within the planning work performed for the Konrad repository project and respective site-specific safety assessments were carried out. The results are reflected in both the Konrad waste acceptance requirements and an assessment of the chemotoxicity of that waste intended for disposal in the Konrad repository.

Thus, due to the Konrad waste acceptance requirements (2), the general basic requirement on waste packages

- "Prohibition of mixing non-radioactive waste which is to be disposed of in compliance with the Abfallgesetz/Waste Law with radioactive waste"

and the basic requirements on waste forms

- "No self-igniting or explosive materials are permitted"
- "Possible chemical reactions between the radioactive waste, the immobilization material and the packaging must be limited to a safety-related permissible level"

must in particular be fulfilled. These requirements are further detailed as well as appropriate checks and distinctive examinations are described within the quality assurance for waste packages (5). According to that the following quality assurance measures are applied:

The mixing of radioactive waste to be disposed of with non-radioactive waste is excluded according to distinctive regulations on the types and origins of radioactive primary waste to be treated using qualified conditioning processes, appropriate control measures by the waste conditioner, and subsequent independent inspections (performed according to BfS) of the conditioning process. Unallowed mixing would also in all probability be detected in the course of sampling inspections performed for waste packages not conditioned by qualified conditioning processes.

In order to specify further the basic requirements, characteristic values and test criteria have been deduced. The characteristic value for explosive materials is given by the content of explosives in the waste. Details, e.g. concerning permissible explosive materials, are regulated by the Sprengstoffgesetz/Explosive Substances Law. Furthermore, in accordance with this law, small masses of up to 3 g per 200 litre volume are considered to be permissible. It is to be anticipated that according to the distinctive regulations in the Sprengstoffgesetz permissible masses of explosives are kept, if contained in the waste. Nevertheless, if there should be any other hints, the primary waste will be examined and its contents of explosives be controlled.

Thus, the application of these specific tests ensures that only waste packages fulfilling the above-mentioned requirements will be accepted for disposal. In this way, it has been possible to develop a meaningful and practicable procedure for the safe handling and disposal of mixed waste.

RADIOTOXICITY AND CHEMOTOXICITY

In order to improve the predictive modeling capacity of safety assessments for the post-closure phase of a repository, safety assessment methods and procedures become more and more sophisticated. Thus, not only radiological aspects and radiotoxicities have to be evaluated but, in addition, the assessment of Chemotoxicities and the hazard potential of organic and inorganic constituents of radioactive waste to be disposed of has been performed.

A very comprehensive investigation into the chemotoxicity of radioactive waste (excluding vitrified fission product solution, cemented hulls and ends, and fines from reprocessing of spent fuel elements as well as spent fuel elements) was conducted for the Konrad repository project (6). Appropriate lists of chemotoxic substances, e.g. the International Register of Potentially Toxic Chemicals and compilations of the International Program on Chemical Safety and the International Agency for Research on Cancer as well as specific German ordinances on drinking water and sewage sludges were analyzed and respective organic and inorganic chemotoxic substances identified. Within a subsequent comprehensive inquiry into the actual and/or potential occurrence of those substances and into the elements and compounds which are the constituents of the waste packages to be disposed of, the

waste generators and conditioners submitted the data being necessary for an assessment of chemotoxicity. Thus, organic and inorganic compounds as well as radioactive and non-radioactive elements could be accumulated in a step-by-step procedure. Finally, an assessment of the chemotoxic organic and inorganic constituents was made considering the site-specific conditions in the post-closure phase of the Konrad repository.

Specific emphasis was given to the organic constituents. Table II lists chemotoxic organic compounds and typical representatives for which reaction types, reaction rates, and solubilities were needed to evaluate possible chemical and radiochemical-reactions in the post-closure phase.

TABLE II

It should be pointed out that in this table not only those compounds are compiled which are part of existing radioactive waste but, in addition, those chemotoxic organic compounds which may in future possibly be present in the waste. Thus, an assessment of a broad variety of chemotoxic organic constituents could be performed. As a result it was concluded that hydrolysis is the dominating factor concerning decomposition. According to the long-term safety assessment, it would take about 300,000 years for the water from the emplacement levels of the Konrad repository to enter the biosphere. This transfer time is long, even compared with the half-lives of the environmentally persistent chlorinated organic compounds. The chemotoxic organic compounds will therefore be safely hydrolyzed before reaching the biosphere, and there will be no need to limit the concentration of those organic compounds in the radioactive waste intended for disposal in the Konrad repository.(6)

Concerning the inorganic constituents, an assessment was based on the dilution of the saline and alkaline water from the repository on its way to the biosphere. It was assumed that the waste packages be dissolved in 106 m3 of host rock water ("repository water") in the post-closure phase. For chemotoxic inorganic elements only dilution in the "repository water" was allowed. Sorption and desorption, retardation effects as well as concentration-dependent solubility limits were not taken into account. As a result, it could be shown that the concentration of chemotoxic inorganic elements in the "diluted repository water", should it reach the biosphere, approaches the concentration limits of the German drinking water standards only in the case of a few elements, e.g. silver, cobalt, chromium, copper and nickel, being of common use in every day life.

In addition to these findings, comparisons were made as to the total of radioactive wastes:

- Chemotoxicity vs. its radiotoxicity.
- Radiotoxicity vs. 3 wt% natural uranium ore radiotoxicity.
- Chemotoxicity vs. the chemotoxicity of the mined repository volume.
- Chemotoxicity vs. the chemotoxicity of of the total repository area.

Time frames extend from 10 years up to 10 million years after the repository has been sealed (6). From that it may be concluded that the radiotoxicity of the radioactive wastes dominates the chemotoxicity for up to 100,000 years. After the first 1,000 to 10,000 years, the hazard potential of the radioactive wastes in the Konrad repository is lower than the hazard potential of the same repository. filled with natural uranium ore of 3 wt% U. The toxicity of the mined repository volume is less than the chemotoxicity of the radioactive wastes. The simple assessment with the "dilution model" demonstrates that no unacceptable hazards are associated with the chemotoxicity of the waste packages. Thus, the presence of inorganic and organic chemotoxic substances in the repository poses neither a new nor an inacceptable hazard potential to man.

For the Konrad repository the results of these assessments may be summarized as follows (6):

1. The chemotoxicity of the radioactive wastes stays distinctly below the radiotoxicity up to a time frame of about 100,000 years, when the radioactivity has decayed to such low levels that the radiotoxicity matches the already low levels of chemotoxicity,
2. The concentration of chemotoxic inorganic elements in the "diluted repository water", should it reach the biosphere, approaches the concentration limits as stated in the drinking water standards only in the case of a few elements.

In conclusion, it may be said that the chemotoxicity of the radioactive waste including mixed waste to be disposed of in the Konrad repository poses an acceptable risk to the public and that no new, hitherto unknown hazard potentials arise from

the chemotoxic organic and inorganic constituents of the waste. No additional requirements on the waste packages have been deduced from the above-mentioned assessments. However, it should be kept in mind that this advantageous result in particular stems from Konrad being a deep geological repository. As to a near-surface repository, appropriate limitations and requirements on the chemotoxic constituents of the radioactive waste are to be expected.

PROSPECTS

The approach to evaluate the potential hazards of waste by performing toxicity investigations shall not exclusively be reserved for radioactive wastes, but should exemplarily be applied as well and with even more justification to hazardous and/or purely chemotoxic wastes.

Thus, experience and knowledge gained in radioactive waste disposal planning work may advantageously be transferred and used in non-radioactive waste disposal activities, e.g. in order to reduce or avoid the necessity for later remedial actions.

ABSTRACT

The useful lifetime of thin-film composite (TFC) polyamide membranes used for the processing of variable aqueous waste at Chalk River Labs (CRL) by spiral wound reverse osmosis (SWRO) is about 3000 hours. This service lifetime is achievable through regular cleaning cycles which range between 70 to 200 m3 of waste treated. After 3000 hours of service the SWRO membranes deteriorate rapidly, and more frequent shutdowns are required for chemical cleaning cycles. The overall rejection efficiency of the SWRO membranes at an operating pH of about 6, and a volumetric recovery of 85%, decreased from about 99.5% with 3000 hours of service, to 95% after 4000 hours. Rapid increases in pressure drop due to increased deposition of foulants in deteriorated membrane areas were noted after 3000 hours of field service. Presently the crossflow microfiltration system is operated at pH 7 and removes 45% of the gross b/g contaminants and 70% of the a radioactivity. Iron concentrations are reduced to below 1 mg/L from 50 mg/L, which minimizes fouling due to ferric

hydroxide precipitates on the TFC membranes. About 60% of b/g in the permeate stream is present as 137Cs radioactivity.
The combined removal efficiencies for critical contaminants employing both microfiltration and reverse osmosis operations are as follows:

a : 99.9%;
b/g : 99.6%;
PO43-: 99.1%

INTRODUCTION

In the mid 1970's, AECL Research, at the Chalk River Laboratories (CRL) site, built a Waste Treatment Centre (WTC) for treating low-level solid and aqueous liquid wastes. The objective was to demonstrate processes for converting Canadian Deuterium Uranium (CANDU) wastes to a form suitable for disposal. The liquid waste streams are effectively volume reduced by a combination of continuous crossflow microfiltration (MF), spiral wound reverse osmosis (SWRO), and tubular reverse osmosis (TRO) membrane technologies. Backwash and chemical cleaning wastes from the membrane plant are further volume reduced by evaporation. The concentrate from the membrane plant is ultimately immobilized in bitumen using a thin-film evaporator in a shielded cell. The ability of the MF/SWRO technology to remove impurities non-selectively makes it suitable for the treatment of radioactive effluents from operating nuclear plants, with proper membrane selection, feed characterization, system configuration, and system chemistry control.
Currently, there are two streams routinely treated at CRL. One originates from the Decontamination Centre (DC waste) and the other collects waste from the Chemical Drain (CD waste) system. A total of about 2200 m3 of blended liquid (low to intermediate-level) waste are currently treated by the membrane plant annually. The current overall volumetric recovery of the two stage (concentrate-staged) reverse osmosis train employing SWRO and TRO is 96.6%. On a 35 m3 batch of waste treated there would be 0.7 m3 of backwash concentrate and 1.17 m3 of TRO concentrate sent to the evaporator for further volume reduction in a small evaporator, and subsequent immobilization with emulsified bitumen in a thin-film evaporator (see Fig. 1; (1)). The bituminized product from the facility occupies 0.175 m3. Hence, the overall volume reduction of the fresh feed through the integrated plant (employing both membranes and evaporation) is about 200.

MICROFILTRATION SYSTEM

In crossflow filtration (also called tangential flow or inertial filtration), pressure drives only part of the feed through the medium; the remaining feed flows tangentially along the surface of the medium, continuously sweeping particles from the medium's surface back into the feed. Generally, crossflow filters are operated as surface filters and have pores that are smaller than the particles to be removed. Crossflow microfiltration (MF) is the most recent advancement in membrane system technology. The removal efficiency of a MF membrane is significantly higher (10-100 times) than a conventional filtration process. MF systems operate as a barrier filtration device to remove particles, suspended solids, and microorganisms from a feed. By using a microfiltration membrane as the separation medium, particles in the 0.1 to 10 m range can be removed. The MF system employed at CRL is a model 40M1 manufactured by Memtec America Corporation and has been in operation since 1988 June. The original membranes were replaced after four years of service in 1992.
The crossflow MF system at CRL contains 40 filtration modules, approximately 6 cm in diameter by 50 cm long. Each filter module contains polypropylene hollow fibre membranes arranged in a shell-and-tube geometry. The total membrane surface area available for filtration in each module is about 1 m2. The nominal filter pore size is 0.2 mm. The system is configured as two individual systems of 20 m2 operating from a common surge tank. Each bank of 20 modules is further divided into two stages of 10 modules operating in series.
Feed flows tangentially across, over, and around the hollow fibre membranes at a sufficient crossflow velocity to keep the solids in suspension, thus minimizing deposition and fouling. A small fraction of the total feed flow (about 10%) passes through the membrane into the center of the tube or lumen, and exits as filtrate. The unfiltered portion of the feed is recycled to the system surge tank. The inlet feed pressure to the first stage is typically 300 kPa. The differential pressure across each stage is normally 40 to 50 kPa at a crossflow rate of 245 to 285 L/min. At a filtrate production rate of 25 L/min/bank, the transmembrane pressure (TMP) drop, which is the average feed pressure minus the filtrate pressure, is in the

range of 20 to 100 kPa.
To maintain the designed filtrate rate, and remove accumulated suspended solids in a concentrated form, the Memtec unit utilizes a patented gas backwash. Air at high pressure (700 kPa) is periodically introduced into the filtrate side of the system, and instantaneously expanded through the hollow fiber into the feed, thereby releasing accumulated solids from the membrane surface. Feedwater is then used to flush remaining solids from the system. The duration of the backwash sequence is approximately 90 seconds. Initiation of backwash is accomplished automatically by a panel-mounted timer, or manually by a push button. Chemical cleaning of the system is performed on a periodic basis, usually with an alkaline detergent. Chemical cleaning is required when the transmembrane pressure (TMP) exceeds 100 kPa at normal filtrate production rates of 15 to 25 L/min or if the crossflow pressure drop across the feed channel exceeds 80 kPa.

SPIRAL WOUND REVERSE OSMOSIS SYSTEM

Reverse osmosis (RO) is a technology that is well established for the production of potable water from brackish water or seawater. It has been successfully used to produce high-purity water for the electronics, pharmaceutical, and power industries. Because of its versatility to remove ionic impurities, particulates and colloids, organics, microorganisms and pyrogenic material from water, RO has attained a prominent role in water purification (2).
In reverse osmosis treatment, feedwater containing dissolved and suspended solids is pumped into the system at a desired feed pressure greater than the osmotic pressure of the solution. The feed stream is pumped into a pressure vessel containing one or more membrane elements connected in series. The feedwater then flows into the channels between the membrane sheets. These feed channels are composed of a plastic netting which breaks up the flow into small turbulent areas above the membrane surface.
Immediately above the membrane surface a concentration boundary layer forms whose thickness depends on feedwater ionic strength, particulate level, and flow in these small turbulent areas. The water and ions are transported by a solubility-diffusion process to the permeate water carrier. The purified water or permeate is recovered at atmospheric pressure. The remaining water, dissolved solids and particulates form the reject stream. The pressurized concentrate or retentate is dropped to atmospheric pressure through a back pressure regulating valve, immediately downstream of the system.
The performance of an RO membrane is usually described in terms of permeate flow, or "flux", contaminant rejection efficiency, and volumetric recovery. Permeate flux refers to the amount of flow across the membrane per unit area, at a particular operating pressure and dissolved solids concentration. The flow of water across the membrane is proportional to the effective pressure (applied pressure minus the osmotic pressure of the solution). Increasing the applied pressure will increase the permeate flow without increasing the solute flow.
Rejection is the relative change in contaminant concentration from the feed stream to the permeate stream. RO membranes are not absolute barriers, and some small percentage of the solute (typically about 0.5%) does pass through the membrane. The amount of solute transport is a function of the membrane type and is proportional to the differential concentration across the membrane.
SWRO membrane types can be broadly classified as cellulosic or noncellulosic. Cellulose acetate membranes are still widely used because of their resistance to fouling, and their low cost. They are, however, easily damaged by bacterial attack and have relatively low rejection efficiencies. Noncellulosic membranes, such as the Filmtec SW30HR membranes used at CRL, have a wider pH range and exhibit high solute rejection efficiencies. The SWRO configuration achieves a large specific surface area per unit volume, which is typically 1000 m2/m3. This can be compared to 165 m2/m3 for plate modules and 335 m2/m3 for tubular modules.
The ratio of permeate to feed in a RO system is referred to as recovery. To achieve high volumetric recoveries (up to 85% currently employed at CRL), it is necessary to stage the concentrate stream or recycle the concentrate for reprocessing. This is normally accomplished in a tapered system design. For instance, a two-stage system may have four pressure vessels in the first stage, feeding two vessels in the second stage. The tapered configuration compensates for feed flow loss by permeation, therefore maintaining optimum cross-flows in both stages.
The CRL system is a three-stage 5:3:1 tapered system with 10 cm diameter by 6 m long

pressure vessels. Each pressure vessel contains 6 Filmtec SW30HR membrane elements. The system is fed with a Goulds 3333 multi-stage centrifugal booster pump. Typical feed crossflows are maintained in the range of 35 to 50 L/min, with an inlet pressure of about 2700 kPa.

PRETREATMENT BY MF SYSTEM

There are many non-radioactive contaminants in the combined CD/DC waste stream. The most deleterious of these contaminants (from a downstream scaling perspective on the SWRO system) is iron. Although the MF system is not normally expected to provide significant rejection of chemical contaminants, iron removal to about 3 mg/L in the filtrate is required upstream of the SWRO to prevent excessive iron oxide fouling (3). Thus the MF system must be capable of removing iron if it is to be a suitable pretreatment option for the SWRO system.

The turbidity of the feed stream to the plant can be reduced from 200 NTU to less than 0.5 NTU, and the silt density index (SDI) can be reduced to less than 3 with the MF system alone (4. A turbidity removal efficiency of between 98% and 99.9% has been noted consistently for the MF system since the start of operations in 1988. It has been found, however, that filtrate from the microfiltration pretreatment process can be somewhat unstable for the types of wastes processed at CRL. Rapid increases of turbidity and silt density index (SDI) occur after the filtrate has been pH adjusted down to 6. It is thought that the increase of turbidity of the filtrate may be associated with instability of colloids at the operating pH of 6, and to the presence of polyvalent cations in solution.

EFFECT OF FEED pH ON MF REMOVAL EFFICIENCY

Pretreatment, such as pH adjustment, is used to maximize soluble contaminant precipitation. One of the objectives of this study was to determine the impact of feed pH on the removal efficiency of various contaminants by MF. The feed pH was altered by the addition of sodium hydroxide or nitric acid in the conditioning feed tank.

Fig. 1a.
Fig. 1b.
Fig. 1c.
Fig. 1d.

Figure 1a shows the effect of feed pH on the removal efficiency, e, of the gross a component of the combined CD/DC waste stream. It is evident that e increases substantially by raising the feed pH value from 6 to 8. The removal of gross a is virtually complete when the feed pH value remains above 8.

Figure 1b shows the removal efficiency of gross b/g for the same range of feed pH values. Although there is some scatter of the data, it is evident that e increases between pH 6 to 9, and remains invariant at about 90% thereafter. Normally it is undesirable to elevate the pH to 9 upstream of the MF system from a pH value of about 4, due to the prohibitive cost associated with adding large quantities of chemicals. Moreover, it would be necessary to reduce the pH back to 6 upstream of the SWRO system to prevent scaling by hardness ions such as calcium and magnesium. Hence, the MF system at CRL is usually operated at a pH of about 7, which results in a b/g removal efficiency of about 40% (Fig. 1b)[and an a removal efficiency of about 70%] (Fig. 1a).

The removal of b/g emitters elevated the contact radiation field on the MF cartridges. The contact radiation field with the MF cartridges increased from 10-4 to 10-1 Gy/h (10 to 104 mR/h) as the gross b/g concentration in the feed stream varied between 10 to 105 Bq/mL (2.7 E-4 to 2.7 E0 mCi/mL).

Of the longer-lived b/g emitters, the radionuclide that is most efficiently removed is 144Ce. Figure 1c shows the removal of 144Ce by the MF system in the evaluated pH range of 6 to 11. It is apparent that e increases with a pH ranging between 6 to 8. Thereafter, it is relatively constant, and virtually all of it is removed in the MF pretreatment step. A large component of the radiation field on the MF cartridge filters is due to the presence of 144Ce.

Iron oxide fouling was found to be present in the SWRO system at CRL. It is caused by the oxidation of ferrous to ferric ions and the subsequent precipitation of ferric hydroxides in the module (5). With the presence of sequesterants and chelating agents in the DC (EDTA, sodium hexametaphosphate), iron can exist in a complexed form, thereby causing it to stay in solution and not be removed by MF. Therefore, iron removal can be quite variable, and is dependent upon the concentrations of these compounds in the feed solution. Figure 1d shows the removal

efficiency of iron in the MF system, which increases from about 20% at a pH of 6, to 99% at a pH of 8. At the normal operating pH of 7, about 50% of the iron is removed, although iron concentrations to a level of less than 0.1 mg/L have been achieved. Generally, iron concentrations are lowered to less than 3 mg/L, which minimized ferric fouling downstream in the SWRO system.

Table I shows the removal efficiencies of both the MF and SWRO systems for various critical contaminants that are present in the CRL waste streams. The radionuclide most effectively removed by microfiltration is 144Ce with an average removal of 70.7%. Soluble contaminants such as 137Cs are not removed by the MF system. The overall removal efficiency for both the MF and SWRO systems ranges from 96.8% for 137Cs to 99.6% for gross b/g, and 99.9% for gross a. The overall removal efficiency of the most critical nonhazardous contaminant, PO43-, is 99.1%.

PERFORMANCE OF THIN FILM COMPOSITE MEMBRANES FOR LIQUID WASTE PROCESSING

The permeation flux was normalised to an applied pressure of 2.76 MPa and a feed temperature of 25oC using a method given by Bukay (6). The observed permeation flux (OBF) was normalised for temperature using a temperature correction factor (TCF) obtained from the membrane manufacturer, and an effective pressure using equation (1).

Eq. (1)

Fig. 2.

Figure 2 shows the overall normalised permeation flux for the plant-scale system. The data were obtained for the original thin film composite polyamide membranes installed in June 1991. These membranes were replaced in February 1994 after about 4000 hours of service. After the initial flux decline, which took place over the first 50 hours of operation, there was a subsequent gradual flux decline which took place over the next 3900 hours.

The flux decline with time observed in Fig. 2 is the result of concentration polarization and/or surface fouling. Surface fouling occurs when there is deposition of submicron particles on the surface, as well as crystallization and precipitation of smaller solutes. It is manifested when rejected solids are not transported from the surface of the membrane back to the bulk stream. In general, there are five types of fouling: namely membrane scaling, fouling by metal oxides, device plugging, colloidal fouling, and biological fouling (5). The different types of fouling frequently occur at the same time and can influence each other. Unfortunately, the interactions between types of fouling are poorly understood.

The chemical scale on the fouled CRL reverse osmosis membranes is comprised primarily of aluminum, silica, calcium, phosphorous, and to a lesser extent iron and sulphur. Calcium hydroxylapatite and octacalcium phosphate scale have been identified as a major fouling species on the SWRO membranes. Clay and aluminum silicate-based scale is thought to account for the initial large flux decline associated with concentration polarization, and represents the scale which is the most difficult to remove by standard chemical cleaning procedures. Precipitates approaching 10 m in diameter have been observed on the surface of the membrane, and these precipitates are hard to dissolve in even the most concentrated acids. This is further supported by the observation that alkaline cleaning chemicals at pH 12 are the most effective for permeate flux restoration where silica solubilizes to silicic acid (7). The precipitates in the 54 membrane elements of all three SWRO stages are similar in chemical composition.

While operating, TFC membranes take on an anion charge on the surface. This causes cationic foulants, such as aluminum and ferric hydroxides, along with cation coagulant polymers, to be attracted to it. Further, because of the high flux rates on composite TFC membranes, fouling occurs faster and is more noticeable than with other membranes (8).

The scatter of the data shown in Fig. 2 is not due to errors in measurement; rather, it is the result of permeation flux declines during a given run, and the subsequent recovery after a chemical cleaning with the appropriate solvent. A least squares curve fit was plotted through the data points in Fig. 2. It shows that the combined total flux (for all 54 elements) decreased from about 55 L/min at start up, to 25 L/min after about 4000 hours of service. The effectiveness of the cleaning solutions decreased noticeably after about 3800 hours of operation. The frequency of cleaning increased from 300 m3 to every 80 m3 of liquid waste treated as the membranes aged.

The most effective cleaning solution for the CRL scales was Memclean, an alkaline-based detergent containing EDTA. The most effective antiscalant chemical in the SWRO

system was Pretreat Plus which is manufactured by King Lee Technologies (San Diego, CA). The average throughput between chemical cleanings was maximized with the use of this antiscalant. Secondary wastes from cleaning accounted for about 5% of the annual waste feed volume to the plant. Acid-based cleaning solutions were generally not effective for removal of the scale-forming compounds. Silica scale was not effectively removed from the membranes with any of the cleaning chemicals that were investigated here, and it seems that the silica scale formed a tightly adherent layer immediately on top of the membrane surface.

During the final 200 hours of operation the performance deteriorated very rapidly. The permeation flux increased only marginally even after an aggressive chemical cleaning, and it became apparent that a change of membranes was required to keep up with the production of the waste. The system was shut down and new membranes were installed in all stages.

Chemical scaling on reverse osmosis membranes can be controlled and minimized by selecting optimal crossflow velocities through the SWRO system and by the use of a 5 mm cartridge filter upstream of the high pressure feed pumps. Pilot-scale studies at CRL have shown that a 50% increase in crossflow velocity can reduce the decline of permeation flux by a factor of 2 for the combined waste streams currently being treated. A 5 mm cartridge filter has been effective for the removal of scales such as silica and phosphorous even before volume reduction with reverse osmosis. This is due to the fact that unstable precipitates are formed after pH adjustment of the MF filtrate with acids. Antiscalant additives and pH adjustment appear to be secondary parameters in comparison to the dramatic impact of crossflow velocity.

Fig. 3.

Figure 3 shows the pressure drop across the three stages of the SWRO system over the lifetime of the original membranes, and the first 100 hours on the new membranes. During the initial 3000 hours of operation the average pressure drop across the system increased from about 500 kPa to 1250 kPa. This increase was attributed to clay and silt deposits in the brine channels of the system. In support of this hypothesis, Kronmiller (7) notes that the presence of silt and particulate (known to be present in CRL waste) are trapped in the membrane and not easily removed. He observed that as these foulants build they erode the membrane surface and break the spiral wound package.

During the final 1000 hours of operation there were large fluctuations in the average pressure drop, the amplitude of which sometimes exceeded 2200 kPa. However, there was still sufficient applied pressure to overcome the osmotic pressure of the waste water at 85% recovery. Aggressive chemical cleanings were performed to restore the flux (Fig. 2), and increase the net effective driving pressure to the system by lowering the system pressure drop (Fig. 3).

The significant increase in system pressure drop between 3000 hours and 3200 hours again is attributable to colloidal silt and scale buildup on the membranes and in the brine channels. During this period of time the concentration of silica-based colloids in the Decontamination Centre waste stream was significantly higher than usual. Permeate rates were acceptable during this period so the pressure drop was tolerated. Aggressive alkaline cleans using Memclean at 3120 hours and again at 3170 hours brought the pressure drop back to more normal values of about 1200 kPa.

Another performance indicator that can be used to assess the SWRO, is the overall removal efficiency of conductive ions. Figure 4 shows the conductivity removal in the plant-scale SWRO system over its service life. During this time the feed conductivity ranged from 100 to about 1000 mS/m, while the permeate conductivity was between 0.6 and 20 mS/m. In general, the permeate conductivity was below 10 mS/m except when there were upsets due to the over-addition of nitric acid.

Fig. 4.

Figure 4 shows that during the initial 3000 hours of operation the conductivity removal was steady at about 99.5%. In those cases where the removal efficiency was lower than 99%, the presence of excessive nitrate and sodium ions in the permeate following a chemical cleaning was the cause. These monovalent ions have low rejection efficiencies and the plant would have been temporarily overloaded with these monovalent ions immediately after a cleaning cycle. This would result in a reduced overall rejection efficiency. After these cleaning chemicals had been flushed from the system (at 1200 hours for example), the rejection efficiency would be restored to about 99.5% overall.

Conductivity removal decreased sharply after about 3000 hours of operation. During

the last 1000 hours the average conductivity removal decreased from 99.5% to about 95% (Fig. 4). A rejection efficiency of 95% is very poor for TFC polyamide membranes.

The many aggressive chemical cleanings that were required to restore the permeation flux (Fig. 2) may have had a detrimental effect on the membrane integrity, resulting in the considerable loss of membrane rejection performance. Physical abrasion of the polyamide rejecting layer over time may have also been a contributing factor. After 4000 hours of service the membranes were replaced because of the frequency of cleaning and the low overall removal efficiency being achieved.

CONCLUSIONS

Feed pretreatment upstream of reverse osmosis by microfiltration is critical for the removal of iron and suspended solids foulants. By conditioning the feed to a pH in the alkaline regime the precipitation of metals is optimized. About 70% of the alpha radioactivity is removed and about 50% of the gross beta/gamma radioactivity is rejected in the MF backwash when the system is operated at a pH value of 7.

The permeation flux of the SWRO system was maintained for about 3000 hours of service with regular cleaning cycles after every 100 - 200 cubic metres of liquid waste are treated. After about 3000 hours of service the membranes degraded, which resulted in a decrease of the overall rejection efficiency from 99.5% to 95%. Cleaning solutions account for about 5% of the waste feed processed annually through the plant. The chemical scale found on the fouled reverse osmosis membranes is comprised primarily of aluminum, silica, calcium, phosphorous, and to a lesser extent iron and sulphur. Calcium hydroxylapatite or octacalcium phosphate scale have been identified as the major fouling species on the membrane. Colloidal silica foluling contributes primarily to the initial large flux decline observed during the first 100 hours of operation.

The combined removal efficiencies for critical contaminants after treatment of the waste with both microfiltration and reverse osmosis are as follows:

- a: 99.9%;
- b/g: 99.6%; and
- PO_4^{3-}: 99.1%.

ABSTRACT
Oak Ridge National Laboratory (ORNL) will be using chabazite zeolite in the near future to improve wastewater treatment processes. The zeolite, a nonregenerable ion-exchanger, will be used to remove both radioactive strontium and cesium from 70 million gallons of process wastewater generated per year at ORNL. This process will replace the ORNL Process Waste Treatment Plant and improve wastewater treatment efficiency, improve the quality of the wastewater discharged to the environment, and reduce secondary waste generation. A commercially available ion-exchange system was leased to perform pilot-scale testing and provide the data necessary for full-scale plant design. Results of the study indicated that the commercial system performed well with the zeolite and that previous smaller-scale column tests adequately predicted the zeolite performance achieved in the commercial- scale columns. Filtration systems and zeolite sluicing procedures were very effective in pilot-scale tests. The mass transfer zone length for contaminant removal, calculated using the Rosen model, was comparable to that determined from smaller-scale column tests. The full-scale zeolite system is likely to be constructed in the 1999 time frame and will be one of the largest wastewater decontamination applications utilizing zeolite in the world.

INTRODUCTION
In previous development studies, many different flowsheets were evaluated for removal of radioactive strontium and cesium from Oak Ridge National Laboratory process wastewater (1,2). The wastewater has a groundwater-like composition with components shown in Table I. The chabazite zeolite system was chosen because of the many process advantages it offers from the standpoint of waste reduction, safety, environmental protection, and operating simplicity. Use of the zeolite system will reduce solid waste generation by more than 40%, eliminate the use of concentrated acids and bases, improve radionuclide removal, reduce dissolved salt concentrations, and eliminate several unit operations.

Laboratory and small-scale column tests were previously performed to determine equilibrium and kinetic data for the zeolite (3). The pilot tests were performed to evaluate physical operating characteristics of the system and validate previous small-scale column test results. A commercial ion-exchange system was leased from a private-sector service company and used in treatment of actual wastewater. This test program involved determining optimum procedures for sluicing of spent zeolites from the operating vessel, demonstrating the effectiveness of prefiltration equipment, and determining the mass transfer zone (MTZ) length for the commercial system for comparison with the MTZ determined with small-scale columns.

One of the problems encountered in previous small-scale and near-full-scale column studies at the Process Waste Treatment Plant is the occurrence of "contaminant bleed." Contaminant bleed is characterized by high effluent concentrations of radioactive contaminants after a column has been returned to service following spent media removal and reloading with fresh zeolite. This is caused by elution of contaminants from residual spent zeolite which was not removed from the column during sluicing. This behavior can reduce the in-service duration of a column and can result in release of wastewater which exceeds contaminant discharge limits. The extent of contaminant bleed is largely determined by the degree of success in removal of spent zeolite by sluicing. Many factors can influence the efficiency of zeolite removal including column design, operating procedures, and the condition of the zeolite. If sluicing is not effective, extraordinary and expensive measures must be taken to remove spent zeolite from the column. The pilot tests were designed to evaluate the efficiency of zeolite sluicing and the subsequent extent of contaminant bleed.

The MTZ specifies the minimum depth of the zeolite needed to achieve the required decontamination factor for the wastewater being treated. The MTZ length is important for determining the minimum column bed depth for the full-scale system. Though the zeolite removes both strontium and cesium, the MTZ length to be used in system

design is based on strontium breakthrough. This is because equilibrium behavior of the zeolite results in lower loading capacity and quicker column breakthrough for strontium. The strontium MTZ was determined for small-scale columns (7.6 cm diameter, 91 cm length) in previous studies (3). Since the MTZ length changes for different column geometry and internal design, it was important to determine MTZ length for the pilot-scale column.

In small-column studies, granular anthracite prefilter columns were found to be effective for removal of suspended solids from process wastewater prior to treatment with zeolite. Pilot-scale columns were loaded with the same anthracite material to prevent fouling of the zeolite bed and to demonstrate large-scale performance.

Pilot Plant System Description

The pilot system, leased from a private service company, was modular in design and constructed for nuclear power plant wastewater treatment applications. A flow diagram for the system is shown in Fig. 1. The system consisted of three skid mounted stainless steel columns, each with a diameter of 0.91 m (36 in) and a capacity of 0.85 m3 (30 ft3). A skid mounted control system was also provided which included the circulation pump, flow controller, and valving manifold. The columns were designed for down-flow ion-exchange or granular media filter applications and were equipped for backwashing, air sparging, flow control, flow totalizing, and sluicing of media into and out of the columns. Two of the columns were used as prefilters and were loaded with granular anthracite while the third column was loaded with chabazite zeolite. The system was equipped with a process wastewater influent and an effluent header with tie-in for service water and service air. The control skid was housed in a shelter to protect the electrical and electronic components. The system, referred to as the Zeolite Demonstration System (ZDS), was assembled within the diked containment area surrounding the ORNL Bethel Valley Storage Tanks (BVSTs). The system was connected to one of the 1.32 106-L (350,000-gal) collection tanks used as an equalization tank for the PWTP. The two columns to be used as prefilters were connected in parallel such that either could be in service while the other was being backwashed. The column to be used for the zeolite was located downstream from the prefilter columns. The flow indicator/totalizer was installed downstream from the zeolite column so that its operation would not be compromised by suspended solids in the feed wastewater. Since collection of system effluent for filter backwash was not feasible, filters were backwashed using untreated wastewater. Suspended solids concentration of the untreated wastewater was typically low enough so as not to present significant problems from slight breakthrough when the filter was returned to service.

Fig. 1.

The two prefilter columns were loaded with 0.57 m3 (20 ft3) of granular anthracite. The third column was loaded with 0.43 m3 (15 ft3) of 20 50 mesh natural chabazite zeolite. All three columns were loaded dry and backwashed at a flow rate of approximately 3.2 L/s (50 gal/min) for about 40 min to remove fines. The system was operated at a flow of 1.26 L/s (20 gal/min) to coincide with the flow per unit area used in previous small-scale column tests, approximately 1.9 Ls-1m-2. A wastewater residence time of 5.6 min was provided at this flow rate.

TEST RESULTS

Sluicing and Contaminant Bleed Evaluation

Two of the three sluicing tests performed were successfully completed. The procedure provided by the service company that supplied the pilot system was used. In the first test, using a combination of air and water for the sluicing operation left the column virtually free of all but a few grains of spent zeolite. During the exhaustion cycle leading up to the second sluicing test, extremely high suspended solids concentration was encountered in the wastewater due to an abnormality in BVST system operation. The suspended solids broke through the anthracite prefilters and accumulated in the zeolite bed. This caused the zeolite to stick together and become difficult to mobilize from the column. With manual spraying of the column interior, removal of the zeolite was eventually accomplished. In a third sluicing test, the condition of the wastewater was back to normal and the sluice was very successful. In previous small-scale column studies, the lack of clearly visible amounts of spent zeolite did not mean that contaminant bleed would not be encountered. Traces of spent zeolite not visible after sluicing caused contaminant bleed which continued for several hundred bed volumes throughput. At the beginning of the second and third

exhaustion cycles in pilot tests, frequent samples of the system effluent were taken to determine the extent of contaminant bleed. In both cases, the effluent radionuclide content was below the discharge limit for 90Sr (37 Bq/L or 7.1 pg/L) at the beginning of the exhaustion cycle. Elution of the traces of spent zeolite left in the column did not significantly elevate the 90Sr concentration of the column effluent. This was true for the two successful sluicing operations and for the case where manual spraying and removal of the spent zeolite was necessary. These results indicate that contaminant bleed will not be encountered in large-scale columns if spent zeolite sluicing is performed effectively.

The conceptual design for the full-scale system had included an acid cleaning system for rinsing of the zeolite column internal surfaces to elute the contaminants from spent zeolite left in the vessel. Though alleviating the contaminant bleed problem, this system added several hundred thousand dollars to the project cost and would have generated a secondary waste, the spent acid solution. The findings of the demonstration test allowed elimination of the acid cleaning system from the final system design.

Prefilter Effectiveness

As shown in the demonstration, one of the keys to effective removal of spent zeolite is the efficient performance of clarification and filtration equipment in removal of suspended solids from the wastewater. If removal of suspended solids is not complete, the solids accumulate in the zeolite, causing agglomeration and adhesion of zeolite to vessel walls. For the pilot study, granular media filters using anthracite were effective in two of the three tests. In the first exhaustion cycle, the jet mixers installed in the 1.32 X 106-L equalization tank were deenergized to allow the tank to act as a crude clarifier for removal of suspended solids. This simulated the expected operation of the full-scale zeolite system, which will include clarification as well as filtration. The prefilters performed well during this exhaustion cycle, and the spent zeolite sluiced easily from the column. During the second exhaustion cycle the jet mixers were energized, which simulated poor clarifier performance for the test. Several days were allowed for displacement of the accumulated solids in the equalization tank before restarting the zeolite system. However, suspended solids content remained high and caused breakthrough of the filter columns and accumulation of sludges in the zeolite column. Accumulation of these solids causes the zeolite to agglomerate and stick to the walls of the vessel. After the normal sluicing procedure, visual inspection of the column revealed a large quantity of spent zeolite caking the interior of the vessel. The vessel interior was washed down by a mild jet spray of water while pumping the sluice line with a double diaphragm pump. This procedure successfully removed the zeolite. This test indicated that breakthrough of prefilter columns cannot be tolerated for the full-scale system. Manual spraying the interior of a full-scale column would be a much more difficult, time-consuming, and costly process. This can be avoided in the full-scale system by avoiding accumulation of sludges in equalization tanks and by providing a well-designed clarification system to remove the bulk of the suspended solids prior to the granular media filters and the zeolite system.

Contaminant Breakthrough Data

The influent and effluent sampling data from two exhaustion cycles were successfully used to determine the breakthrough characteristics of the zeolite. A total of 2.4 106 L (5633 bed volumes) of process waste were processed during the first exhaustion cycle. Column breakthrough data are shown in Fig 2. For the graph, each data point for the gross beta concentration of the feed wastewater was averaged with the previous three data points to dampen the fluctuation in concentration and give an improved indication of breakthrough. The gross beta concentration of the wastewater was effectively reduced to acceptable levels during the first several days of operation. On the third day, a sudden increase in gross beta concentration occurred at a throughput of 591 bed volumes. During the next 48 hours, the gross beta concentration gradually decreased to acceptable levels. At a throughput of 1580 bed volumes, the fractional breakthrough (effluent gross beta concentration/influent gross beta concentration) began to increase to a consistent level of 30 to 40%, where it remained until the throughput of the system reached 4630 bed volumes. At this point, the effluent gross beta suddenly increased to levels that far exceeded the influent concentration. Gross beta concentrations gradually fell to levels corresponding to 40 to 50% breakthrough, at which point the test was terminated at a

throughput of 5630 bed volumes.
Upon investigating the concentrations of other cations in the zeolite effluent wastewater (the analytical results for which were several weeks behind the radiochemical results), it was discovered that an increase in sodium concentration from 30 to 170 mg/L coincided with the sudden 200% fractional breakthrough. It is well known that sodium concentration strongly influences the equilibrium between zeolite and other cations in the wastewater (4). In this case, the increase in sodium concentration caused elution of contaminants from the zeolite, resulting in high effluent gross beta concentrations. High sodium concentration is caused by periodic addition of salts to the process wastewater feed. Based on this behavior, it will be important during zeolite system operation to carefully monitor and control sodium concentration of the plant feed wastewater to avoid sudden variations. Elimination of the current softening and ion-exchange processes at the PWTP will eliminate the periodic fluctuation in feed sodium concentration. Thus, control of wastewater sodium concentration is not expected to be difficult when the full-scale zeolite system is operational.
A total of about 12,000 bed volumes was processed during the second exhaustion cycle, though part of this throughput was accumulated during recirculation of the tank contents. Breakthrough data are shown in Fig. 3. A sudden drastic increase in effluent gross beta concentration caused by an increase in sodium concentration occurred at a throughput of 4200 bed volumes. The fractional breakthrough declined rapidly over the next several days to a level of less than 30%. At a throughput of 6000 bed volumes, a steady decrease in gross beta concentration for the system feed was noted. This behavior was due to the diversion of the wastewater feed to the alternate collection tank resulting in recirculation of wastewater in the pilot plant feed tank and the subsequent exponential decay curve. The process waste feed was diverted back to the ZDS feed tank at a throughput of about 11,500 bed volumes. Final breakthrough was confirmed at a throughput of 12,000 bed volumes. By deducting the approximate volume of water recirculated, the actual throughput processed was 8900 bed volumes.
MTZ Length
An important objective of the pilot testing was to determine the length of the MTZ and compare it with MTZ lengths determined from smaller-scale column tests. At any time in the loading process, a column can be divided into three zones: a saturated zone, an MTZ, and an unused zone. The solid loading in the MTZ is near saturation in the direction of the water inlet end of the column and near zero toward the outlet end. The MTZ moves down the column during loading, and breakthrough occurs when it reaches the end of the column. Ideally, the MTZ will occupy a relatively short fraction of the column length, so that nearly all of the column is saturated at the time of breakthrough, when the column must be taken off stream and changed out with fresh zeolite. Experiments using columns 7.6 cm in diameter and 91 cm in height gave strontium MTZ lengths ranging from 10 to 30 cm depending on wastewater velocity. The Rosen long-bed solution, presented below, adequately predicted these MTZ lengths in an earlier study (3).
The long-bed solution of Rosen is a simplified model which accounts for both equilibria and flow rate variations (3,5). This model was used to determine MTZ length for the ZDS column using the data collected in the second exhaustion cycle. Rosen solved the partial differential equations for unsteady-state column adsorption for the case of a linear isotherm (5). Distribution coefficients for strontium and cesium were constant over the concentration ranges encountered at ORNL, as long as the calcium and sodium concentrations were constant. Typical strontium and cesium concentrations were below 10-6 eq/L, while calcium and sodium concentrations were generally on the order of 10-3 eq/L (3).
Fig. 2.
Fig. 3.
The Rosen solution for long beds is
Eqs. (1-4)
The above equations were applied to the data collected from the second exhaustion cycle in the following steps:
1. The superficial velocity through the bed was calculated with a bed diameter of 0.91 m and flow rate of 1.26 L/s.
2. The film mass transfer coefficient was found. From a study by Robinson (4), the film mass transfer coefficient (kf) for this same system was determined to be 0.006

cm/s at a lower velocity of 0.0914 cm/s. Since kf is proportional to the cube root of the Reynold's number of the particle (Rp1/3), a ratio may be written to determine kf at the appropriate velocity.
3. A log-log plot of Kd versus total salt concentration in solution from other zeolite treatment studies gave a fairly straight-line relationship (shown in Fig. 4); thus Kd could be determined from the figure.
Fig. 4.
4. A time (or position) in the bed was assumed to calculate the length of the MTZ. Since the Rosen solution is valid only for "long beds," a position near the end of the bed was assumed. For the second exhaustion cycle, breakthrough occurred at about 3 million liters. At a flow rate of 1.26 L/s, the corresponding time was about 40,000 min, so t = 30,000 min was chosen. By working only with the ratios of Y:X and O:X given in the Rosen solution, the diffusivity, DA, could be eliminated.
5.Expressions for both ratios mentioned in step 4 were determined as a function of bed length, z. A bed length, z, was assumed and CA/CAo calculated from Eq. 1. Results from this exercise showed CA/CAo to be approximately 95% at z = 40 cm and 5% at z = 60 cm. Thus, the MTZ at time 30,000 min was about 20 cm. In earlier small column tests (6), the length of the MTZ between 70 and 5% breakthrough was 15 cm, which agrees reasonably well with the results obtained in this demonstration. However, the lengths of the MTZs should not necessarily be consistent between the small column and the demonstration test, since the feed water compositions and therefore the Kds were not the same.
For a system which displays equilibrium behavior characterized by a constant Kd, such as this one, the MTZ exhibits "square-root spreading" as it moves along the bed. For example, by comparing the length of the MTZ at the end of a 3-m-long bed versus a 1.5-m-long bed, the MTZ should be 20.5, or 1.414 times as long. This is in contrast to a system with a favorable isotherm, where the MTZ does not spread. Based on our results, the square-root spreading factor should be applied when scale-up design is done for the full-scale columns from the pilot-scale data. The bed depth of the full-scale zeolite system is 3 m compared to the bed depth of 0.67 m for the pilot-scale. The spreading factor of the MTZ due to the bed depth difference is 2.13 [(3/0.67)0.5] resulting in a predicted MTZ length of 42.6 cm (2.13 20 cm) for the full-scale system. This MTZ is only 14% of the total bed height indicating that good zeolite utilization will be obtained for the full-scale system.
CONCLUSIONS AND RECOMMENDATIONS
Pilot-scale testing of a chabazite zeolite system was performed to validate small-scale column test results, evaluate operating characteristics, and predict performance of a full-scale system. Sluicing tests performed after each exhaustion cycle indicated that spent zeolite can be sluiced easily and completely from zeolite vessels as long as adequate prefiltration of wastewater is accomplished. The granular anthracite prefilters performed adequately when wastewater was pretreated by clarification. Contaminants which elute from tiny quantities of spent zeolite left in the column (unseen during visual inspection) did not reach significant concentrations in the system effluent. The pilot testing also illustrated that the radioactive strontium concentration in the zeolite column effluent was greatly influenced by sodium concentration. Sudden increases in sodium concentration of the wastewater must be prevented; otherwise, premature breakthrough of strontium from the zeolite system could result. Breakthrough data and the Rosen model were used to determine a MTZ length of 20 cm, which was comparable to the MTZ for smaller-column tests. The pilot test results indicate that a full-scale zeolite system can be expected to perform well as long as suspended solids and sodium concentrations of the wastewater are maintained at low concentrations.

ABSTRACT
We have investigated the properties of cement paste made with a newly developed admixture to verify its suitability for solidifying incombustible radioactive waste. This new inorganic admixture is an alternative to the organic compounds used so far to raise the fluidity of cement paste. The paste obtained using this flew inorganic admixture has the low viscosity necessary for filling the voids between wastes. The distribution coefficients for plutonium and americium in the system of water and powdered cement paste containing the inorganic admixture are over 10,000 ml/g. We carried out various tests on the property of the solidified product, and the results indicate that good integrity is maintained for a long time.

INTRODUCTION

Immobilized radioactive waste must offer long-term integrity when disposed of in a repository. The immobilized waste contains radioactive nuclides, so excess release of these nuclides must be avoided. Many procedures for the solidification of waste have been developed, and some have been put into actual use in radioactive waste treatment facilities (1,2). Cement is an attractive material for this type of disposal, since when solidified it has great integrity and thus offers the potential for containment of radioactive nuclides for long periods. When cement is used for this purpose, however, it is necessary to include an admixture in the mix of cement, water, and aggregate so as to obtain a paste with high fluidity.

We have developed a number of cements for use in waste solidification (3,4). Generally, organic admixtures have been used to obtain the required fluidity, but it is thought that organic admixtures might decompose after long periods in a repository atmosphere. Carbon dioxide generated by the decomposition process may damage the immobilized product, such as by cracking of the cement phase. In order to avoid this type of concern, we had developed a inorganic admixture, for calcium aluminate system, which yields a high-fluidity cement paste (4). In the case of using this inorganic admixture for another cement material system, for example blast furnace slug, the cement paste was slowly stiffened, and lost the fluidity immediately. We have developed another type of new inorganic admixture for blast furnace slug system in order to solve the stiffening time and the immediate fluidity.

The requirements of a cement-based material used to immobilize waste are listed below.

The material should have good integrity under disposal conditions.

The cement paste must have high fluidity in order to fill the voids between particles of solid waste.

The product should be capable of containing radioactive nuclides for long periods.

The additive we selected contains no organic component, so the first requirement is satisfied. We carded out various tests, both to measure the property of the material selected and to confirm having the other requirements for cement paste.

MATERIALS

The cement formulation investigated in this work are listed in Table I. We used blast furnace slug to ensure mild heat generation. A three-components admixture is used to maintain paste fluidity and promote paste hardening.

PROPERTIES

The Effect of Inorganic Admixture on Dispersion of Dement Particle

Generally, cement particles condense in water because they lack an electric charge. The particles can be dispersed by the addition of sodium lignosulfonate. We found that the addition of inorganic admixtures containing sodium phosphate, instead of sodium lignosulfonate also dispersed the particles (Fig. 1). These additives generate no carbon dioxide under disposal conditions. We selected a combination of these inorganic compounds as an admixture for high-fluidity cement paste so as to ensure long-term durability.

Properties of Cement Paste

We investigated the properties of cement paste including the chosen inorganic admixture by measuring consistency and stiffening time. Two admixtures were chosen for these tests, one consisting of sodium phosphate only and the other containing sodium phosphate, an inorganic carbonate, and calcium aluminate. The sodium phosphate and inorganic carbonate enhance fluidity, while the calcium aluminate promotes hardening of the cement paste.

Consistency is expressed in terms of the time taken for all the paste to flow out of the test cone shown in Fig. 2. This is the method specified by the Japan Society of Civil Engineers. Rapid loss of fluidity causes the difficulties to operate the solidification system. Figure 3 shows the consistency of the two types of cement paste.

To use of three-components admixture gives longer-term fluidity than the sodium phosphate alone; it is possible to adjust the fluidity period from 20 seconds to three hours, which is adequate for use in the immobilization of solid waste.

The stiffening time of the cement paste was measured by implementing the proctor needle penetration test (as defined by the American Society of Testing Materials). Figure 4 shows the results of the test. Proctor needle values of pressure for initial and final stiffening time are used in the figure; initial and final stiffening times are defined as pressure values of 3.5 MPa and 28 MPa, respectively. Generally, rapid stiffening leads to the formation of voids or cracks in the cement product, and slow stiffening requires large curing area. To avoid this problem, it is necessary. to adopt a stiffening time of over 10 hours or so. The initial stiffening time when only sodium phosphate is used as the admixture is 54 hours. Consequently, we added calcium aluminate to promote paste hardening. With the three-components admixture, which includes calcium aluminate, the initial and final stiffening times are 21 hours and 24 hours. This stiffening time is satisfy to avoid large curing area in the plant. We thus decided that this three-component admixture containing sodium phosphate, an inorganic carbonate, and calcium alurninate was the best.

Product Properties

We investigated the two of the mechanical properties of the solidified product, compressive strength after 28 days curing and bleeding ratio, based on the cement paste described in Table I. When the water/cement ratio ranges from 0.38 to 0.47, the compressive strength after 28 days curing is from 31 to 41 MPa. These values indicate that no degradation of compressive strength occurs when the three-component admixture is added. The bleed on the waste was found zero. These results lead us to conclude that this water/cement ratio is suitable for the immobilization of solid waste. Using batch experiments, we measured distribution coefficients to investigate the radioactive containment of this cement material. Powdered cement grout was the initial solid phase. Plutonium, americium, and carbon were added to the solution. The distribution coefficients of plutonium and americium are found to be over 10,000 ml/g, and the value for carbon is 1,000 ml/g (Table II). These large values for plutonium and americium result from the cement products, which make the solution basic. They satisfy the requirements for containing radioactive nuclides in cement materials.

Immobilization of incombustible waste

Immobilization tests were carried out with various types of simulated waste in 200-liter drums. Figure 5 shows the immobilization test equipment. Pipe waste immobilization tests were implemented using pipes of 13 mm. in diameter and 800 mm.

in length. A total of 804 pipes were arranged lengthwise in a 200-liter drum. The drum was not vibrated during injection of the cement paste, and the rate of injection was 12 liters per minute. A filling ratio of 99.4 vol. % was obtained. If the drum is vibrated, a higher filling ratio might be obtained. These tests indicate that the cement containing the inorganic admixture to maintain fluidity is a superior of material immobilization for solid waste.

CONCLUSION

We investigated the properties of cement materials containing the new inorganic admixture that we have developed. The cement paste was found to have sufficient fluidity for immobilization of waste, and it has the potential to contain radioactive nuclides. Our results suggest that cement including sodium phosphate, inorganic carbonate, and calcium aluminate is suitable for the immobilization of solid waste.

Av. del Libertador 8250
(1250) Buenos Aires, Argentina

ABSTRACT

This study is related with spent ion exchange resins beads (irradiated and non irradiated) embedded in cement matrices. Matrices containing sulphate resistant cement, blast furnace slag, zeolite and irradiated and non irradiated resin beads have been studied using SEM (Scanning Electron Microscopy) and X Ray diffraction techniques. EXRDA (Electron X Ray Diffraction Analysis) techniques were also used in this study.

Hydration has been developed at room temperature and has been interrupted with isopropyl alcohol at 3, 7, 14 and 28 days.

A durability study was also done. Eighteen months old samples were submerged in a synthetic sea water solution at 70 C during a period of four months.

From the results observed in these samples it is inferred that matrices containing blast furnace slag and zeolite present a better performance related to: removal of the calcium hydroxide from the matrix avoiding its undesired presence on the solidified product; diminution of the blast furnace slag content, which means that it is acting as a sacrifice material so protecting the zeolite; stability of the zeolite, allowing it to function as an inorganic ion exchanger particularly effective for Cs 137. The addition of Na(OH) in a concentration 1,5 Molar in the studied compositions produced no substantial improvement of the solidified product.

INTRODUCTION

Ion exchange resins are used for decontamination of different liquid streams in nuclear power plants. Management of spent ion exchange resins comprises the following actions: waste characterization, treatment, immobilization in a suitable matrix, waste form characterization, interim storage and final disposal in a repository. The purpose of these actions is to obtain a solidified and adequately contained end product and to meet the acceptance criteria related to: mechanical and

chemical stability, low leaching rates and radiation and thermal resistance.
With this objective, several formulations were designed. There was observed that an acceptable product is obtained using a matrix containing sulphate resistant cement and blast furnace slag in a 1:9 ratio. This matrix accepting 12 weight percent of dry resin. The blast furnace slag acts as a sacrifice material consuming the Ca(OH)2 produced on cement hydration.
Another interesting option is the inclusion of zeolites in the formulation. Zeolites are minerals naturally abundant in our country. They are natural pozzolanas of volcanic origin composed of hydrated aluminosilicates containing sodium, potassium and calcium. They present high thermal stability and resistance to high pH's. The inclusion of zeolites produces the following:

A better confinement of radionuclides, being particularly selective for caesium. As a consequence, lixiviation is lowered.

Utilizes the Ca(OH)2 set free by cement matrix hydration to form binding compounds.

Improves rheological properties of the paste.

The main disadvantage of zeolite is its reactivity in cement matrix. This is a pozzolanic reaction and can be limited by factors like temperature, calcium hydroxide availability and pore water.
There was observed that an acceptable product is obtained using a matrix containing sulphate resistant cement, blast furnace slag and zeolite in a 10:75:15 ratio.
Durability can be defined as the resistance of materials to physical, chemical or physico-chemical aggressions, being them of internal (intrinsic) or external (extrinsic) nature.
The aggressive environment can degrade the matrix by means of two different mechanisms. The first is dissolution (filtration, leaching, etc.) of soluble components. Dissolution starts at surfaces and propagates through the interior producing an emptying and a weakness of the structure. The second is chemical transformation. Chemical reactions may involve the formation of compounds of lower density that produce expansion stresses that may crack the matrix. If a chemical reaction occurs through solution the products can occupy the pores but if reaction occurs at a solid surface (solid-liquid reaction or topochemical reaction), expansive stress may deteriorate the structure.
Between the different types of chemical aggressions these can be mentioned: sulphate and chloride attacks, sea water and soft water attack, carbonation, alkali-carbonate and alkali-aggregate reactions.
Most common physical aggressions are freezing and thawing and drying and wetting cycles.
Porosity, pore structure and diffusivity of cement matrices exert a relevant control on the ingress of potentially deleterious substances.
In addition to avoiding the ingress of these substances, it is important to reduce the content of vulnerable phases in the cement pastes. Some vulnerable phases are: calcium hydroxide and hydrated tricalcium aluminate. Some of the compounds that produce expansive stresses are: Ettringite ($3CaO.Al_2O_3.3CaSO_4.32H_2O$ - very common), Gypsum ($CaSO_4.2H_2O$ - common) and Thaumasite ($CaSiO_3.CaSO_4.CaCO_3.15H_2O$).
EXPERIMENTAL PROCEDURE:
Samples of twelve different cementitious compositions were prepared. To simulate the waste, a mixed resin bed was prepared using LEWATIT M500 KR/OH (anionic exchanger) and LEWATIT S100 KR/H (cationic exchanger) in a 1:1 ratio. This resin bed was treated using $NaNO_3$ and pH was then adjusted using NaOH.
Part of this bed was irradiated using Co^{60} gamma radiation with a total dose of 108 rads. This is equivalent to the total irradiation dose expected until complete decay of the involved radionuclides. Samples were prepared using irradiated and non irradiated resin beds.
Hydration was developed at room temperature and was interrupted with isopropyl alcohol at the approximate ages of 3,7,14 and 28 days.
Table I shows the eight elementary compositions used. The other four correspond to matrices with irradiated resins that had the same composition of their counterparts with non irradiated resins. Samples with numbers 2,4,6 and 8 were prepared with non irradiated and irradiated resin beds. For each of these compositions the labeling has the subscript a) for non irradiated and b) for irradiated resins.
TABLE I
RESULTS

The following summarizes the results of this study:-Composition 1: Sulphate Resistant Cement (ARS) + Blast Furnace Slag (BFS): At the age of seven days the sample is compact. Hydration products cover ARS and BFS particles. We can see calcium silicate hydrate (CSH) of types I,II and III at the first stages and types II and III later. The diffraction pattern shows gehlenite (2CaO.Al2O3.SiO2.8H2O) and Ca(OH)2. The later increasing in content as hydration develops.

Composition 2a: ARS + BFS + Resin Bed (not irradiated): At the age of seven days the sample is compact. Three different zones can be distinguished: the bead, the matrix and the interface between them. Beads of approximately 500 mm appear separated from the matrix. Most of the beads show an irregular surface. Between the resin beads and the matrix there is a 30 mm gap, showing that a contraction followed the setting of the mix. Some of the beads are cracked and show solid paste inside their cracks, showing that the cracks existed prior to mixing.

Composition 2b: ARS + BFS + Resin Bed (irradiated 108 rads): At the age of seven days the sample is compact. Beads appear contracted with approximately 30 mm of gap between the matrix and them. Cracked beads have material in their crevices. Hydration products are CSH types I and II at the beginning of hydration and types II and III later.

Composition 3: ARS + BFS + Zeolite: Hydration is slower than in the first case (composition 1: ARS + BFS). At 14 days the sample is compact. Cement peaks (C3S, C2S, C4AF) decrease their heights as hydration develops. The principal hydration product is CSH type II at the first stages and type III later. There appears also CaCO3. Zeolite peaks correspond to clinoptilolite, heulandite and quartz. The height of the first two and the blast furnace slag broad peak decrease slowly.

Composition 4a: ARS + BFS + Zeolite + Resin Bed (not irradiated): The addition of zeolite improves workability. At the age of fourteen days the sample is compact. Blast furnace slag and zeolite peak heights diminish with time. There is a 30 mm gap between beads and matrix and the bead surfaces show less irregularities than in the composition 2a case.

Composition 4b: ARS + BFS + Zeolite + Resin Bed (irradiated: 108 rads): At the age of seven days the sample is compact. Beads appear separated from the matrix and their surface is less irregular than in the composition 2b case. Some beads appear cracked with solid paste inside crevices. Hydration products present are CSH types I, II and III. No Ca(OH)2 is detected. At the interface zone we observed needle like and sheet like structures (see Fig. 3).

Referring to recent experiences in Winfrith (AEA Technology), the effect of Na(OH) addition in the mix water was studied. According to this experiences, in a blast furnace slag plus ordinary Portland cement paste, the addition of Na(OH) would accelerate the hydration of Blast Furnace Slag. The effect of this is to reduce the availability of calcium ions which can exchange on the resin bead and thereby also reduces the amount of crystals formed which have the deleterious effect on the cement system. The concentration used was 1,5 molar in the mixing water.

Composition 5: ARS + BFS + Na(OH): At the age of three days the sample is compact. Addition of Na(OH) to the BFS + ARS mix accelerates hydration. Cement phases extinguish more quickly than in the composition 1 case. CaCO3 and Ca(OH)2 are detected. SEM observations show CSH of types I and II, prevailing type II. Needle like structures are profuse.

Composition 6a: ARS + BFS + Na(OH)+ Resin Bed (not irradiated): At seven days the sample is compact. The following phases appear: C3S, C2S, C4AF and CaSO4.2H2O. Also CaCO3 and Ca(OH)2. There is a 30 mm gap between the beads and the matrix. The interface matrix-bead is composed of a smooth and continuous surface.

Composition 6b: ARS + BFS + Na(OH)+ Resin Bed (irradiated 108 rads):At the age of seven days the sample is compact. Addition of Na(OH) accelerates hydration and beads appear with little irregularities. Crevices in some beads seldom contain paste inside. Observed phases are CSH types I,II and III and Ca(OH)2. The interface zone presents needle and globular like structures; also Ca(OH)2 hexagonal crystals.

Composition 7: ARS + BFS + Zeolite + Na(OH): At the age of three days the sample is compact. Addition of Na(OH) to the mix accelerates hydration. The CSH type III is predominant. The Ca(OH)2 appears in small quantities and extinguishes with time. The blast furnace slag and the zeolite react because their peaks diminish with time.

Composition 8a: ARS + BFS + Zeolite + Na(OH) + Resin Bed (not irradiated): At the age of fourteen days the sample is compact. Ca(OH)2 appears in small quantities.

Composition 8b: ARS + BFS + Zeolite + Na(OH) + Resin Bed (irradiated: 108 rads):

At the age of three days the sample is compact. Addition of Na(OH) to the mix accelerates hydration. A 30 mm gap appears again between matrix and pearls. Some pearls have crevices but without paste inside them. No Ca(OH)2 is detected.
Table II shows the X ray diffraction results of eight compositions (the eight shown in Table I but with irradiated resins). The most abundant three crystaline phases are shown for each composition.
TABLE II
Table III shows the X rays diffraction results of the eight compositions shown in Table I that were submerged in artificial sea water solution at 70C during 4 months. The second column shows bulk compositions while the first column shows the reacted surface.
TABLE III
According to semiquantitative composition profile determinations, at a depth of 3 milimeters, elementary compositions resemble bulk compositions.
Some examples of scanning electron microscopy photographs are shown in Figs. 1 to 6.

Figure 1 (Magnification 95 x) shows a fracture surface of a sample of composition NO 4 at seven days of hydration. Two beads of exhausted ion exchange resins embedded in a cementitious matrix. Pearls have approximate diameters of 500 mm and there is a gap of approximately 30 mm between the bead surface and matrix, indicating a contraction of the pearls.

Figure 6 (Magnification 2080 x): surface of sample of composition NO 3 after hot sea water immersion showing crystals of Gibsite (CaCO3).
Fig. 6.
ANALYSIS
The most abundant components of hydrated cementitious matrices are amorphous calcium silicate hydrates (CSH phase). The other components are crystalline phases detectable by X ray diffraction techniques and unreacted fractions of cement, blast furnace slag and zeolite.
Table II shows the X rays diffraction results for the different compositions examined. The three most abundant crystalline phases are indicated in order of preponderance.
An important characteristic feature of the X ray diffraction pattern is the extensive and broad amorphous peak due to the vitreous BFS. This vitreous BFS is the slag capable of react in alkaline media to form binding compounds. The height of this peak depends on the content of amorphous BFS in the matrix and it is observed that this peak diminishes its height as hydration develops.
This fact is interpreted inasmuch as the slag that has reacted doesn't contribute any more to the broad peak height. Blast Furnace Slag delays Portland Cement hydration and consumes the Ca(OH)2 forming more CSH phase. Samples containing ion exchange resins appear more corroded and expanded after hot sea water immersion than samples with the same composition but without resins. The addition of Na(OH) accelerates hydration.
In order to obtain concentration profiles, semiquantitative analysis of element concentrations were performed using EDAX techniques. Most abundant elements were calcium, silicon and aluminum. Less common elements were sodium, potasium,

manganese, iron, magnesium and chlorine.
Significant variations are observed in the first millimeter and at a deep of three millimeters the concentration is the same as the bulk concentration.
Generally, the superficial content of chlorine is higher and the alkaline (sodium and potassium) content is lower than the corresponding bulk concentration. This indicates a solubilization of the later in the immersion solution.
Another important observation from EXRDA analysis is the reduction of the calcium/silicon ratio at the surfaces. Quartz also appears in the diffractograms as a secondary crystalline phase. Diffractograms doesn't show calcium hydroxide at surfaces,pointing out its dissolution and the corresponding reduction of the calcium/silicon ratio.
The prevailing phase at surfaces is the brucite or Mg(OH)2 which appears forming a uniform cover of hexagonal crystals of uniform size, even though their medium dimension varies upon sample composition. Another important phase at surfaces is CaCO3 in two crystaline forms; calcite and vaterite. This phases seem to form a protective layer against further attack.
The bead contraction reduces the contact area with the matrix, so reducing the pathways for radionuclide difussion. This contraction indicates that there is a margin for an eventual disruptive expansion of the beads.Ion exchange resins inclusion in the tested concentrations reduces slightly their resistance to saline atack.
The addition of Na(OH) in a concentration 1,5 molar in these compositions produced no substantial improvement of the solidified product. The corrosion effect of hot sea water is more relevant in samples prepared with Na(OH) in the mix water.
Zeolite reduces the dissolution of alcaline elements since their relative concentration reduction is lower in samples were this component is present.
CONCLUSIONS
From the results observed in these samples it is inferred that matrices containing blast furnace slag and zeolite present a better performance related to: removal of the Calcium Hydroxide from the matrix avoiding its deleterious effect on the solidified product; diminution of the blast furnace slag content, which means that it is acting as a sacrifice material to protect the zeolite from a complete reaction and stability of a zeolite fraction, allowing it to function as an inorganic ion exchanger particularly effective for Caesium 137.
The addition of Na(OH) solution in the mix water reduces the resistance of these samples to hot sea water attack.

ABSTRACT
Two methods impedance and viscosity were employed to predict the on-line compressive

strength of cemented radioactive waste. Influence of frequency change in the impedance method has also been studied. The two parameters used were water to cement ratio and the amount of simulated radioactive waste. The basic objective was to find mathematical correlation's by these two methods for the prediction of 7 and 14 days compressive strength. The reliability of these methods has also been studied. Two types of waste have been prepared. Waste 1 consisted of a constant amount of radwaste but varying water to cement ratio. Whereas in waste 2, water to cement ratio as well as the amount of radwaste was varied. The experiments were carried out using sophisticated equipment to get precise data.

INTRODUCTION

Immobilization of radioactive waste is an important environmental issue of concern for both public governmental considerations. Radioactive waste is primarily produced during the operation of nuclear reactors. It could also arise from medical, institutional and research power. Proper and safe disposal requires not only chemical, physical and radiological characterization to ensure safety, but also public acceptability and satisfaction.

Coolant water in a nuclear reactor gets contaminated by the radionuclides as it passes through the coolant channels. In order to reuse this water, different chemical separation techniques could be employed for the purification. The use of ion-exchange resins beds and filters are two common techniques to recover usable water.

Once these radionuclides are collected on the ion exchange resins, the use of cement to immobilize this waste has proved to be economical and safe. Different standards have been set up by different nuclear regulatory agencies, which have to be met in order to ensure public safety.

Process control has several advantages above final product testing. The fundamental idea is to control the process in such a way that the prescribed standards of the final product is ensured. In order to reduce the secondary waste streams, time, as well as costs, several non-destructive, on-line compressive strength prediction methods have been employed by different agencies. From the concrete building industries, a few well known method are: ultrasonic, rebound hammer, maturity and viscosity.

OBJECTIVES

This project was primarily designed to study the physical characterization of cemented intermediate and low level waste. Previous works done by Slate (1) and Lewis (2) have shown that the impedance and viscosity methods are most promising. Thus this project was specifically carried out to study these two methods. The basic objectives were to find the mathematical correlation's between strength and other parameters such as impedance, plastic viscosity, C/(W+R) ratio etc., so that strength could be predicted by simply applying these equations. In this manner, one can save time and cost. The secondary waste stream production can be reduced. Hence the quality of the final products can be controlled. Table I and table II indicates the samples compositions. The two parameters that have been employed were water-cement ratio and amount of radwaste. The reliability of the experimental apparatus was also an integral part of this report.

Table I

Table II

IMPEDANCE METHOD

It is a known fact that cement paste consists of a conductive substance such as water with various compounds. A cement paste also consist of hydrated products, for example gel water and solid products of hydration. If an electric circuit is complete, current will flow through the circuit and changes in the resistance can be measured as the process of hydration takes place. In the impedance method this idea has been utilized to determine any mathematical correlation between resistance (impedance) and strength of cemented radwaste. Impedance is the term used to describe the resistance offered by a substance to the flow of charges.

Mathematically: $Z = V/I$, Z= impedance, V= voltage, I= current.

The fundamental idea of using an electric circuit model to find relationship between strength and impedance came after the review of McCarter's report (3). In that report, McCarter has described investigations into a method for monitoring the temporal changes in gel-space ratio within cement paste employing wide-band frequency response. Upon realization of the fact that impedance of the cement paste could be used as an important parameter to predict strength, an impedance meter was

built at KEMA. The meter consists of a sinusoidal voltage source. It measure the voltage difference between the electrodes and the current which exists between the electrodes. From voltage and current the resistance is calculated and given in the input. The integrated circuits are designed in such a way that it treats imaginary part of the input as absolute. It achieves this via a root mean square (R.M.S) converter. An operator can select the band of frequency as well as resistance scale. In this experiment, via impedance meter, four different ranges of frequencies (0.1 kHz, 1 kHz, 10 kHz, 100 kHz) have been used.

VISCOSITY METHOD

Rheology is the study of the change in form and flow of matter. In general, rheology is concerned with materials whose flow properties are more complicated than those of a simple fluid like water (1). A non-Newtonian fluid is a fluid which does need a minimal shear stress to produce a shear rate. In other words the deformation starts as soon as the shear stress passes some critical value. Water is a Newtonian fluid whereas concrete is a non-Newtonian fluid. The Bingham plastic model is used to describe the behavior of a type non-Newtonian fluid. The general equation is of the form:

$T = g + hN$

where T= torque, g=yield stress, h=plastic viscosity, N=velocity.

A rheology meter has been used in this method. Rheology meter enables the users to measure viscosity and yield point of Newtonian and non-Newtonian fluids. An operator can pre-set the shear rate. Hence controlled shear rate is possible. The rheology meter consist of a 1.5 inch diameter cylinder. The height of the cylinder is 5.5 inch. The speed of the rotating bob can be controlled. The measuring bob experiences torque from the flow resistance of the fluid (i.e. viscosity of fluid). Hence shear stress offered by the fluid can be detected. The cylinder with fresh cement paste in it is attached to the rheology meter in such a way that the rotating bob sinks in it. Upon the activation of the rheolab, user can set different combination of speeds and time scale. Hence software is used to manipulate the obtained data. Upon the completion of test, the viscosity and yield stress can be obtained for the given sample.

RESULTS AND DISCUSSION

General

The experiments were done in three stages. Consequently the results are discussed in the same manner. The first stage was done to confirm McCarter's report and to see the overall behavior of the frequency on the resistance between two electrodes. In the second part of the experiment, the impedance method has been utilized for the prediction of compressive strength. And in the third and last stage viscosity method has been studied. Impedance and viscosity methods were done simultaneously. The relationship between strength and C/(W+R) has also been included to verify the current work.

Frequency Effects

In this stage the overall behavior of the frequency on the impedance has been studied. The range of frequency which has been used was 0.1 kHz, 1 kHz, 10 kHz, and 100 kHz respectively. Two electrodes made up of brass were inserted into the fresh cement paste, which was inside the mold. The electrodes were 93 mm apart. Current started flowing upon the completion of the circuit. Impedance was recorded for the first 24 hour of the curing stage. The sample composition for all the samples was as follows:

TABLE III

Certain phenomena have been observed. Figure 1 shows that impedance is not only a function of time but also frequency. The resistance decreases at least for the first 3-5 hours. Then gradually increases at approximately constant rate. As it is apparent from figure 1 that different bands of frequency do effect the impedance. Eight samples were made for this purpose. For each frequency, two samples have been utilized. Thus the curves shown in Fig. 1 for the four frequencies are the average of two respective frequencies. There was a significant difference among the impedance vs time curves for .1 kHz, 1 kHz, and 10 kHz. It has been noticed that as the magnitude of the frequency increases, the impedance decreases. This behavior can be explained by realizing the fact that higher frequency means higher number of charges (electrons) passing in a unit of time. Hence keeping all the other parameters constant, the current rate increases and consequently the impedance decreases. According to McCarter's report, the enhanced conductivity at higher

frequencies is due to surface conduction effects (due to enhanced charge mobility at higher frequencies) on the adsorbed gel water (3). When the cement paste was fresh (i.e. first 3-5 hours) there were lots of free electrons available for current. In other words the mobility of charge carriers was much higher. Hence impedance decreases for the first 3-5 hours. But as the chemical reaction takes place (i.e. process of hydration continues) and free ions form different inorganic substances via bonds, the number of ions or electrons decreases. The aqueous phase in the cement paste decreases as the gel absorbs water, which means that less number of carriers are available for current flow. Hence resistance increases.
Fig. 1.
Another behavior was noticed in Fig 1. For the frequency range of .1 kHz, the impedance reaches a stable state after 9 hours. In other words for that frequency range, more resistance cannot be noticed by the impedance meter. The frequency range has to be increased in order to make impedance change visible. For the case of the highest frequency (100 kHz in our case), this stage is reached after 25 hours. It is also apparent from Fig. 1 that there is a significant difference at the initial impedance values among the four frequency ranges. This suggest that for the correlation factor between strength and impedance, the ten minutes resistance can be easily used. It also indicates that any frequency could be used in the impedance method. This will enable the operator to predict the strength after 10 minutes. Hence one can save a considerable amount of time.
Another part of this experiment that was coupled with the above part (i.e. impedance vs time relationship for different frequencies) was to see the difference between the magnitude of the low and high frequencies. According to McCarter's report, the difference between the low and high frequency resistivity curves will thus represent the proportion of current flowing through the (adsorbed) gel water and will be a quantitative measure of the gel-space ratio within the paste (3).
Hence percentage frequency effect is a term describing the difference in the low and high frequencies. Mathematically:
((Pl - Ph)/Pl) * 100
where
Pl = low frequency
Ph = high frequency
In our case low frequency was 0.1 kHz and high frequency was 100 kHz. Figure 2 shows the PFE vs time relationship. Few things should be noticed. For the first hour the curve increases. This implies that the difference between the low and high frequency dominate the initial period completely. In other words the frequency effect is significant and increases due to the different nature of charge mobility and gel-space ratio at these two different frequencies. Gradually the PFE factor decreases indicating the strengthening of the cement and lower mobility of the charges (i.e. Ca2+, OH- and absorption of water) as the process of hydration takes place and hence the frequency effect gradually diminishes. After 25 hours PFE will be a constant since the resistance at low and high frequencies will be constant. Hence one can conclude from Fig. 2 that the first 6-8 hours are very important as far as the frequency effect is concerned.
Fig. 2
IMPEDANCE METHOD
Impedance is the quantitative measurement of the resistance offered to the flow of charges by a substance. Slate's report (1) has indicated that impedance value could be used to predict the strength of the cemented radwaste. Hence in this part of the experiment an impedance meter has been used. The sample composition used for this purpose was given in Table I and Table II. In order to calculate the accuracy in the results and to see the reliability and reproducibility of the method, three molds of each composition have been prepared. Hence in the category of waste 1, 21 samples were made (Waste 1 has a fix amount of radwaste but varies in water-cement ratio). And in each mold there were 3 prisms. Hence in each category of waste 1 there were 9 prisms. Five of them were used for 7 days strength and the remaining 4 were used for 14 days strength. After the preparation of each sample, the viscosity test has been performed. These tests were followed by impedance measurements. Ten minutes impedance values were noted. Seven and 14 days strength tests were performed. These values are the averages of the three samples of each category.
Fig. 3.
Fig. 4

The equations describing the curve fit for the 7 and 14 days strength prediction taking impedance (Z) as an independent variable are as follows:
S = 32.96 ln Z - 62.02 (7 days strength prediction) (1)
S = 27.87 ln Z - 38.54 (14 days strength prediction) (2)
The best curve fits for both equations were found to be logarithmic. In order to justify the logarithmic curve fit for the strength versus impedance data points, some important points need consideration. Three types of curve fit were taken into consideration. Those were logarithmic, power and linear. In order to see the best curve fit mathematically, the sample coefficient of determination r2 has been considered. (Values of r2 between zero and unity indicate the relative strength of the relationship between two given variables (4)). Consequently if the value of r2 is close to unity, it simply suggest that the regression equation will give quite accurate predictions. In our case, for the 7 days strength prediction, the following values were obtained:
Table IV
Hence the r2 values for the logarithmic equation is closest to one, thus justifying the best curve fit. Similar was the case for 14 days strength equations. Intuitively speaking, another phenomena explaining this logarithmic behavior between strength and impedance could be described by realizing the fact that relationship between the hydration process versus time and strength versus time are also more or less logarithmic. Hence one can conclude that since hydration is strongly coupled with impedance, the strength versus impedance curve will likely be logarithmic. Thus this combination of mathematical background with intuitive knowledge about cement paste behavior, justifies the above curves.
In the waste 2 category, the relationship between 7 and 14 days strength and impedance were found to be exponential. This difference between logarithmic curves in waste 1 and exponential curves in waste 2 could be explained by looking at the sample compositions of waste 1 and waste 2. In waste 2 the amount of radwaste is also changing. Thus this indicates that the change in the amount of radwaste affects the bond formation process during hydration. Different sets of chemical reactions take place due to the presence of different amounts of radwaste. Consequently this affects the charge mobility and hence the impedance. However the impedance method remains reliable. The sample correlation factor for 7 and 14 days were .909 and .918 respectively. The following equations, where Z = impedance, and graph shows the relationship.
S = 86.14 exp (-0.016 * Z) (7 days strength prediction) (3)
S = 99.34 exp (-0.017 * Z) (14 days strength prediction) (4)
Fig. 5
Viscosity Method
A rheology meter coupled with rheolab software has been used in this experiment. In the beginning of the experiment, several small tests were done to develop a general understanding about the viscosity method.
The viscosity measurement was divided into four intervals. These intervals were controlled by different shear rates. It has been noticed in the previous experimental work that the cement paste follows the Bingham model after going through a series of different shear rates. It has also been found experimentally that interval number 4 gives the best correlation factor. Hence as a part of test preparation all the samples were passed through these four intervals and only the measurement from the fourth interval was taken into account. The shear rate varies from 31.853 (1/sec) to 191.12 (1/sec). This variation of shear rate via rotating bob was pre-set for 30 seconds.
The objective here was to find the optimum mathematical model between 7 and 14 days strengths and viscosity. The relationships were logarithmic. The following two equations can be used to predict the 7 and 14 days compressive strength.
S = 36.18 ln m + 19.89 (7 days strength prediction) (5)
S = 41.76 ln m + 20.98 (14 days strength prediction) (6)
The following two figures illustrate the best curve fit with data points.
Fig. 6
Fig. 7
Both of these graphs behave reasonably well. Not only mathematically but also intuitively it makes sense. The sample coefficients, r2, were .993 and .994 for 7 and 14 days strength prediction equations respectively. Thus indicating an accurate estimate of the strength. Secondly, this best curve fit also indicates that if the

viscosity of the paste is less than approximately 0.2 (Pa.s), the strength will be zero, a likely behavior. If the viscosity of the fluid is very low, that indicates lots of fluidity (i.e. higher w/c ratio) and consequently the strength will be very small. Thus on both grounds, theoretical as well as practical, these graphs make sense.

In the waste 2 category, 7 and 14 days strength were found to be exponential again. The sample correlation factor were .945 and .962 for 7 and 14 days strength respectively. Hence both of the relationships, i.e. strength versus impedance and strength vs viscosity, were found out to be exponential. The following equations and figure illustrate this behavior.

$S = 15.36 \exp(0.45 * m)$ (7 days strength prediction) (7)

$S = 16.57 \exp(0.47 * m)$ (14 days strength prediction) (8)

Fig. 8.

It has also been found that the strength of the cemented radwaste decreases in a linear fashion as the amount of the radwaste increases. The following two equations shows the relationship, where R = amount of radwaste. Figure 7 shows this behavior.

$S = -2.61*R + 67.96$ (7 days strength prediction) (9)

$S = -2.91*R + 76.25$ (14 days strength prediction) (10)

Fig. 9.

Strength as a Function of C/(W+R)

Previous work at KEMA was done to find the strength prediction equation in terms of its contents, namely cement, water and amount of radwaste. A ratio had been developed for this purpose which is C/(W+R). KEMA's report (5), indicates the following equation and figure.

$S = 41.3 (C/(W+R)) - 17.3$ (28 days strength prediction) (11)

Fig. 10.

In order to check and compare the results obtained from this experiment with the previous work, similar graphs and equations have been produced. The only difference is that the following graph is for 7 and 14 days whereas the above graph is valid for 28 days. The equations and graph are as follows:

$S = 32.18 (C/(W+R)) - 7.32$ (7 days strength prediction) (12)

$S = 28.16 (C/W+R)) - 5.87$ (14 days strength prediction) (13)

Fig. 11 7 & 14 Days Strength Versus C/(W+R)

One can see that a similar relationship is obtained. Also, since the 7 and 14 days strengths are lower than the 28 days strength, the graph is less steep. As the number of days for the strength test increase, the graph becomes more steep, thus approaching like Fig. 10. Figure 11 verifies the validity of this experiment.

Also to understand the logarithmic nature of most of the results, two fundamental relationships have been tested. These were strength development and 7 and 14 days strength versus w/c ratio. The best curve fit for both of them were found to be logarithmic. The equation for strength development were as follow with the sample correlation factor of .953.

$S = 11.35 \ln(\text{days}) + 23.77$ (14)

Hence it indicates that most of the important relationships among cement parameters are related to each other logarithmically. As the process of hydration continues, it influences the strength, and resistance in a logarithmic fashion. Hence it is not surprising that most of the results were found to be logarithmic. Similarly, the equations describing the 7 and 14 days strength are as follows:

$S = -55.99 \ln(\text{days}) + 9.69$ (7 days strength prediction) (15)

$S = -49.25 \ln(\text{days}) + 20.55$ (14 days strength prediction) (16)

The following figures illustrate this behavior.

Fig. 12.

Fig. 13.

SOURCES OF ERROR

Even though every effort has been made to avoid any possible error, there were a few things which might have caused the deviation in the data:

1. It was noticed that during the impedance measurement the electrodes were sometimes not straight. Hence this would cause variation in the impedance value. A difference of 0.5 ohms was observed.
2. The accuracy of the weight machine was up to three decimal places. Sometimes four decimal places were required to make w/c ratio and other values as precise as possible. However this could not be obtained with the available balance. Hence this small difference in the samples might affect the overall measurements. However all

the samples were consistent
3. It has been anticipated that due to low resistance offered by the steel mold, the current might flow from there. Since the idea was to measure the resistance between the electrodes (in other words only through the cement), the impedance value will be the combination of steel resistance and cement resistance. A difference of 25% in the impedance value is possible. The basic idea behind this project was to see on the pilot plant basis whether impedance could be used to predict the strength or not. On commercial scale, this phenomena however will never happen in practice because of the larger distance between the electrodes.
4. The measuring cup in the viscosity method was sometimes tilted. Hence it could have shifted the cement paste on one side, which might have cause errors in the viscosity and yield stress.
5. Due to the tedious nature of sample preparation and measurement, the time interval between sample preparation and ten minutes impedance measurements could have varied five minutes. Hence it can affect the consistency of the ten minutes impedance measurements.
6. Random human errors could have occurred in recording weights, in samples preparation, in viscosity measurements, and in the impedance measurement.

CONCLUSIONS

This project was designed to study the feasibility of impedance and viscosity methods for the strength control of cemented radwaste. The fundamental objective was to obtain for optimum mathematical relationships between strength and other parameters on a laboratory scale. Both methods, impedance and viscosity, have shown reliable results.

In the impedance method the optimum relationship between strength and impedance was found to be logarithmic. The reproducibility of this method turned out to be very good. The average value of all the standard deviations in the impedance method is 3.23 ohms. This indicates that certainly impedance method could be used on an upgrade scale for compressive strength prediction. In the waste 2 category, the relationship between strength and impedance was exponential. Hence this shows that the variation in the amount of radwaste can play significant role chemically and electrically. Also it is important to realize that only one variable is required, namely impedance, to predict the strength.

In the viscosity method, the optimum relationship was found out to be logarithmic. Whereas in the waste 2, it was exponential. The reliability of this method is extremely good. The average value of its all standard deviations is .323 Pa.sec. Again only one variable is required to predict the strength. Both of these methods are not only efficient but also consume very short amounts of time to give results. Hence on the commercial scale, this factor can play a vital role.

The logarithmic and exponential nature of most of the results could be explained by realizing the fact that most of the fundamental parameters in cement paste are related to each other logarithmically. Two good examples will be strength development and strength and w/c ratio. Since these two parameters (strength development and w/c ratio) are strongly coupled with viscosity, impedance, it is likely that the other relationships will follow the same behavior. The strength versus c/(w+r) graph also follows the same behavior which has been obtained in the previous work at KEMA. Hence this also proves the validity and reproducibility of this research study.

RECOMMENDATIONS

1 The viscosity meter does not give accurate results for water to cement ratio below .40. A w/c ratio below 0.40 results in very stiff cement paste. During the measuring stage, the rotating bob creates a vacant space in which the cement paste does not return back. Hence the measurement will not be true. To avoid this one can shake the measuring cup to make sure that there is no space or some kind of instrument could be employed to remove the vacant space.
2 A remote technique for samples preparation and measurements will be preferable so that the consistency could be maintained throughout the experiment, more accurately.
3 In order to measure the resistance only between the two electrodes on pilot plant basis, some insulated materials for the mold should be used in order to avoid any kind of mold resistance effects.
4 Special care should be taken in order to make sure that the electrodes are straight into the samples. Some kind of clip could be used for this purpose.
5 A weight balance with greater precision and accuracy (i.e. 4 decimal places) would

be preferable.
6 More data points are encouraged in order to obtain smooth curves and to increase the range of applicability of the equations.

THE RADIOACTIVE WASTE TREATMENT PLANT OF THE PUSPIPTEK SERPONG NUCLEAR RESEARCH CENTER (INDONESIA) AND ITS INCINERATION UNIT
Jacques Eymeri
Jean-Christophe Gauthey
Technicatome
France
ABSTRACT
In the framework of its radioactive waste management activities, TECHNICATOME, a subsidiary of the French Atomic Energy Commission, developed, realized and commissioned a low level radioactive waste treatment plant for BATAN, the Indonesian Atomic Energy Authority.
Main processes implemented are: evaporation, compaction, incineration, cementation of liquid and solid waste.
The waste treatment plant and the different processes are described; particular emphasis is given to the incineration unit which was commissioned two years ago and which has been since that time fully in operation. The organization of the Project and work share between
INTRODUCTION
In order to reduce the amount of waste to be stored and to ensure storage satisfactory environmental safety conditions, selective treatments, adapted to the specific type of waste considered, are carried out in specialized installations.
For several years TECHNICATOME has been developing, building and putting into operation treatment and packaging processes adapted to different types of waste. By controlling the entire waste treatment process from production to storage, TECHNICATOME has been able to set up for BATAN (BADAN TENAGA ATOM NASIONAL, the Indonesian national atomic board), a radioactive waste treatment plant for its nuclear research center on the PUSPIPTEK site.
The installation was built in collaboration with BATAN, thus ensuring a transfer of the technologies required to enable the Indonesian staff to operate the installation.
PRESENTATION OF THE NUCLEAR RESEARCH CENTER
Within the PUSPIPTEK scientific center (research, science and technology center) BATAN (the Nuclear Energy Commission) is responsible for studying, developing and implementing nuclear energy processes. For this purpose, it is equipped with:
- a pluri-disciplinary reactor,
- a radio-isotope production laboratory,
- a reactor fuel production laboratory.

Waste produced by these different installations is treated by a waste treatment plant designed by TECHNICATOME and built in collaboration with Indonesian companies.
ORGANIZATION OF THE OVERALL PROJECT
This has been implemented as part of a joint project between TECHNICATOME and BATAN:
TECHNICATOME was responsible for overall engineering, supplying specific nuclear equipment, monitoring assemblies and tests.
BATAN was responsible for the infrastructure, erection and putting the equipment into operation.
INSTALLATION DESIGN PRINCIPLES

Waste Characteristics

Waste produced by the research installation located on the Center comprises:

liquid waste with an activity less than 5.4 108 Bq/m3 (2.10-2 Ci/m3),

semi-liquid waste (ion exchange resins: IER) with a maximum activity of 3.7 109 Bq/m3 (0.1 Ci/m3),

solid technological waste (plastic bags, gloves, cotton, paper), packaged in 100 l metal drums. This waste is separated by the producer:

- by type of waste (compactable, non compactable, alpha emitter),
- by activity, so that, the contact dose rates of the packaged drums do not exceed 0.25 m Gy/h (2.5 mRad/h),

biological waste with a maximum activity of 3.7 105 Bq/kg (10-5 Ci/kg) packaged in plastic bags,

items of clothing (clothing, masks) packaged in 5 to 10 kg plastic bags with a dose rate of under 2.5 10-2 mGy/h (2.5 mRad/h).

Installation Functions

The main purpose of the installation is to:

treat radioactive waste so as to produce waste packages consistent with existing storage standards,

carry out research and development work in the field of waste treatment.

The individual processes to which wastes are subjected depend on the type of waste involved. The table provided in appendix 2 shows the successive operations performed for different types of waste.

In order to carry out waste treatment of the following functions are available:

collect waste from different producers and transport it to the treatment station,

treat liquid waste by:

- evaporation (liquid waste) or incineration (combustible waste),
- packaging in a concrete matrix,

treat solid waste by:

- compacting (compactible waste), incineration (combustible waste) or placing in a concrete shell (other solid waste),
- packaging in a concrete matrix,

treat semi-liquid waste by:

- chemical pre-treatment,
- packaging in a concrete matrix,
- treating items of contaminated clothing in a nuclear laundry,

store the packages produced prior to being transported to the repository,

treat clothing.

Besides R & D studies are performed in the laboratories.

Basic Design Principles

The installation is comprised of three buildings:

the main building housing the processing equipment and administrative services,

a building containing the auxiliary units (various utilities, generator),

a building housing the package storage area.

The main building is comprised of two blocks:

a "cold block" containing the administration building, general technical facilities and the centralized control room,

a "hot" block sub-divided into distinct areas corresponding to differents types of process.

The entrances and exits to/from the "hot" block are provided with air locks:

"hot" and "cold" staff cloakrooms,

equipment air locks for each area.

TREATMENT OF AQUEOUS LIQUID WASTE

Purpose of Treatment

Treatment by evaporation makes it possible to obtain:

concentrate containing all the active matter which can be embedded in a concrete phase,

distillate free from active matter wich can be released into the environment.

Transport to the Plant

Liquid waste is transported from the storage tank (reactor, laboratories, workshops) to the treatment installation in an 8 m3 tanker.

Tanker design complies with the regulations governing the transport of dangerous materials in France. The vehicle is therefore authorized to use the public highway.

The tanker is provided with its own pumping system which ensures:

  the filling of the tanker from the producer's tanks,
  or draining into the treatment plant tanks.
A control console enables the operator to pilot transfer operations from the truck
The tanker is provided with all the necessary biological protection and safety equipment (overflow reservoir, gas filtration, ...) to ensure safe operation and the radiation protection of the operating personnel.
Waste Storage
Waste storage is ensured by four 50 m3 tanks each equipped with its own homogenization system either to collect the effluent or to perform mixing operations to ensure that the physicochemical characteristics of the waste comply evaporator requirements
Evaporation
The installation has a capacity of 750 l/h. The volume reduction ratio is 50. The dry condensate and distillate concentrations are 250 g/l and 2.5 10-4 g/l respectively.
The installation consists of:
  a tubular exchanger, with thermosiphon circulation, into which the waste to be evaporated is introduced. Live steam heating is used to ensure the vaporisation of liquid wastes,
  a setting tank at the exchanger outlet is used to separate the liquid and steam phases. The steam phase is fed into the separation column. The concentrate obtained is removed from the bottom of the tank,
  a separation column. The liquid carried over into the steam is separated from this steam by washing through the exchanger plates using a reverse flow of demineralized water,
  a condenser which ensures condensation of the steam phase and a cooling unit which is used to cool the distillates.
The distillates are stored in two 50 m3 tanks. These tanks are provided with sampling and chemical ratio measuring systems.
With the exception of the chemical reagent circuits, which are controlled locally, the system is controlled from the evaporator control room.
Evaporation operations are automatic. In the event of a malfunction, safety devices put the installation into a standby mode.
Waste Packaging
This unit is equipped to package the following waste in concrete shells:
  evaporation concentrates,
  ion exchange resins,
  solid non compactible waste and 200 l drums of already compacted waste.
Packaging is carried in a concrete matrix.
The unit is designed to operate 8 hours per day.
Operations are controlled from a console in the control room.
Concreting operations are automatic. In the event of a malfunction safety devices put the installation into a standby mode.
Storage
The following functions are ensured in the storage room:
  storage of concrete shells,
  storage of shells and drums of waste from other waste production centres,
  loading of shells and drums for transport to the repository.
Storage capacity is 1500 drums and 500 concrete shells. These are handled with a crane and pallet stackers.
TREATMENT OF SOLID WASTE
Purpose of Treatment
The purpose of solid waste treatment is to process:
  non combustible waste by compaction,
  combustible waste by incineration.
The wastes obtained (incineration ash, compact slabs) are then packaged into drums or concrete shells in a concrete matrix.
Transport to the Installation
The waste is transported by truck from its production site to the installation. It is packaged in 100 l metal drums. Wastes, which can be incinerated, are separated on the production site from other wastes.
Storage before Treatment
A special room is used for the storage of:

100 litre drums of non combustible waste,
empty 200 l drums into which the first drums are compacted,
100 litre drums of combustible waste.

Compaction of Drums Containing Non Combustible Waste

The 100 l drums of solid waste which cannot be incinerated are compacted into the 200 litre drums using a 600 kN hydraulic press.

This press is provided with a nuclear ventilation circuit to ensure containment during operations.

The installation is controlled and operated manually and locally.

Packaging the Compacted Units

After being filled with waste, the 200 litre drums are back-filled with cement grout and vibrated to ensure that the compacted waste is correctly packaged (see paragraphe 5.2.5.).

Incineration of Combustible Waste

The incineration unit burns:

solid combustible waste:

- cotton,
- polyethylene,
- PCV

combustible liquid waste:

- oil,
- scintillation liquids,
- tributyl phosphate (TBP) diluted in dodecane,

biological waste.

The installation has a capacity of 50 kg/h for solid waste and 20 kg/h for liquid waste.

The 100 l drums of combustible waste are transferred from the 100 and 200 l drum storage room to the incineration room (see 5.3.3.).

The contents of the drums are packaged in cardboard boxes containing 3.7 kg of waste. This is done in glove boxes.

The cardboard boxes are loaded automatically into the incinerator through a double air lock chamber.

The liquid waste to be incinerated is stored in a 1 m3 tank (waste not containing TBP) and in a 0.1 m3 tank (waste containing TBP). Wastes are then transferred into the incinerator after possible dilution, (to limit the quantity of TBP in the liquid waste to be incinerated).

Technological solid waste is packaged in plastic bags and stored in deep freezers. These bags are then packed into cardboard boxes in glove boxes and then fed into the incinerator.

The installation consists of:

a furnace with two chambers:

- a first chamber where oxygen reduced combustion takes place for solid waste (temperature between 800 and 1000C),
- a second post-combustion chamber where combustion occurs in gas produced in the 1st chamber during solid waste and liquid waste combustion operations. The temperature in this chamber is approximately 1000 to 1200C,

a dilution chamber to reduce the gas temperature to 180C by dilution in the ambient air,

a two-stage gas filtration unit:

- approximate filtration using a bag filter with automatic unclogging through a continuous flow of compressed air,
- filtration of radioactive particles using HEPA filters,

a gas washing unit to:

- cool the gas produced by filtration,
- neutralize the acid gases produced during combustion.

This unit consists of a venturi and a separation column.

an extraction assembly comprising:

- a gas reheater,
- gas extraction fan,

Gas activity is continually monitored before release into the atmosphere.

Waste incineration is performed in 6 day cycles. Each day includes a 6 hour period during which the unit incinerates waste and an 18 hour period during which the unit is maintained at a constant temperature (thermal standby).

Ash is removed from the furnace every day before incineration.
The unit is controlled from a control room equipped with a control panel.
The installation operates automatically. In the event of a malfunction, safety devices put the installation on standby.
Packaging Incineration Ash
Ash is removed from the first combustion chamber and the bag filters through an air chamber, where it is cooled before being recovered, with continuous confinement, in a metal drum which has been previously filled up with encapsulation materials.
Ash is embedded in cement using a drum-rotation mixer.
The drums are taken to a room (see paragraphs 5.2.5.1) while the concrete sets, before being taken to the storage room after the packages have been radiologically controlled.
TREATMENT OF COMBUSTIBLE LIQUID WASTE
This waste is delivered in carboys and transferred to the combustible liquid waste storage area (see paragraph 5.3.6.1.). Tanks containing liquid waste with TBP are separated from those without TBP.
The waste is incinerated as described previously.
TREATMENT OF SEMI LIQUID WASTE
Aims of Treatment
The aim of treating semi-liquid waste (ion exchange resins) is their cementation.
Transport to the Installation
The ion exchange resins are transferred from the storage tanks where they are produced to the installation by a 1.5 m3 tanker.
Storage of Ion Exchange Resins
Ion exchange resins are transferred by a hydraulic system into a 5 m3 tank where they are stored before packaging.
Packaging Ion Exchange Resins and Handling Packages
This is described in paragraphs 5.2.5. and 5.2.6.
TREATMENT OF LAUNDRY
Working clothing and gas masks used on the site installations, are cleaned in the laundry.
This treatment involves:
  sorting out contaminated laundry for treatment as solid waste (incineration/compaction),
  cleaning non contaminated laundry for re-use by the staff.
Laundry is sent to the station packaged in plastic bags in 100 l drums (5 to 10 kg load per drum).
Preliminary sorting operations involve measuring the dose rate in contact with the plastic bags. Bags with doses rate greater than a certain pre-determined value are sent to the solid waste treatment system.
The unit is composed of:
  washing machines,
  rotary driers,
  ironing presses,
  gloves boxes (used to open plastic bags).
Radiological controls are used to identify non contaminated clothing.
Decontaminated laundry is ironed using the ironing presses. A sewing machine is used to repair clothing.
The machines are controlled locally by an operator.
R & D LABORATORIES
The aim of these laboratories is:
  to improve waste treatment operations,
  to perform routine physico-chemical evaluation analysis.
They are equipped with standard physics and chemistry materials: PH-meters, spectrophotometers, conductivity meters, spectrometers, etc ...

REAL TIME NON-DESTRUCTIVE EVALUATION OF
MIXED WASTE AT HANFORD

T.J. McLaughlin
W.T. Hannah
E.L. Smith
Advanced Systems Technology, Inc.
1935 Butler Loop
Richland, WA 99352

ABSTRACT

Two shielded mobile Real-Time Radiography (RTR) units were designed, constructed, and mobilized to rapidly perform Non-Destructive Evaluation (NDE) of more than 1,400 drums and 200 large plywood ("B-25") boxes of mixed solid waste at Hanford in early 1994. NDE was used to better define the contents of each container of potentially mixed waste without opening them or unnecessarily exposing personnel or the environment to hazardous materials.

The purpose of the project was to determine, on a package-by-package basis, which containers were likely to contain hazardous constituents and to document the actual type of hazard.

NDE was accomplished by utilizing high-energy, collimated X-ray equipment that penetrated the containers onto an intensifier to produce an image of the materials in the container. A bipolar metal-ceramic X-ray tube with variable energy output was used to allow permanent recordings of the images of material of varying densities. Images were stored on VHS video tapes.

BACKGROUND

Advanced Systems Technology, Inc. (AST) was requested to assist Westinghouse Hanford Company in the characterization of containerized mixed waste for the Hanford Tank Farm Backlog Waste Program. AST was responsible for the design, construction, mobilization, and operation of mobile NDE systems for the remote examination of more than 1,400 207- to 320-liter drums and 200 B-25 plywood containers. The design incorporated the use of two different state-of-the-art Real-Time Radiography (RTR) systems, one for standard metal drums and one for large wooden boxes.

The purpose of the project was to assist Westinghouse Hanford Company to safely determine the contents of individual waste packages as a precursor to waste segregation and subsequent storage or disposal as mixed or low-level waste, respectively.

DESIGN CRITERIA

During the early stages of design, AST established a set of customer-driven criteria:

1. Hardware must be packaged into a mobile system for ease of transfer to customer facilities. Because the equipment may be moved frequently, stout equipment and transport systems must be provided.
2. To obtain the clearest X-ray image possible, provisions must be provided to tilt, turn, and rotate individual waste packages both vertically and horizontally.
3. Provisions must be provided to examine one-hundred percent of each waste package.
4. To meet the letter and intent of As Low As Reasonably Achievable (ALARA) goals, waste packages must move quickly through the process with little or no hands-on handling (hence the need for remotely-operated conveyors, close-circuit television systems, and X-ray shielding to limit radiation exposure to less than 0.5 mRem at the outside surface of the units).
5. The operator must have a reference system in order to document the exact location of individual objects in each waste package.
6. All NDE data must be capable of being recorded both on VHS tapes or CD-ROM discs.
7. If requested by the customer, the ability to mark and scan in a host of other data, such as waste generator records, for inclusion directly onto tapes or discs must be provided.

EQUIPMENT AND OPERATIONS

NDE equipment was provided in two trailers, one "drum" unit to handle up to 320-liter drums and one larger "box" unit to handle 10-cubic meter "B-25" boxes. The conceptual layout of the NDE box and drum units is shown in Figs. 1 and 2. Each unit contained the following equipment: collimated X-ray machine, shielded x-ray chamber, control console, two high voltage transformers, oil-to-air cooler, bipolar/metal

ceramic image intensifier tube with variable energy output and video camera, video display, remote video camera with monitor, video recorder, character generator, a Digital Imaging Database System, and a conveyor system with turntable.
Fig. 1. Conceptual layout of NDE drum unit.
Fig. 2. Conceptual Layout of NDE box unit.
Mixed waste was moved through the drum unit by placing the waste package through a side access panel (Fig. 3). Waste package numbers were recorded and a location template placed on the side of the waste package to enable NDT technicians to pinpoint the location of individual items. The drum was then moved through the unit remotely through an "L" shaped conveyor system where it was monitored via close circuit TV systems from the control room.
Once the drum reached the shielded x-ray vault (Fig. 4), radiography was initiated. Hydraulic systems in the vault provided for both vertical and horizontal movement. After the operator was satisfied with the results of the NDE, the drum then existed through the back of the unit where it was removed from the conveyor system. Control room operators recorded drum numbers directly onto VHS tapes. Operators had the option to highlight drum internals via computer-generated characters and lines. Interpretation of drum contents was documented via by operators into a sophisticated data input and compression system.
The box unit operated similarly to the drum unit except for larger hardware requirements and the need for boxes to be placed onto a conveyor and turntable system that was partially erected outside the end of the unit. In addition, the box unit was fitted with two shielded retractable walls used to house the X-ray system and intensifier. Boxes were conveyed into a large, shielded vault and the doors shut before RTR was initiated. Due to the depth of each waste package (2 m), NDE was performed twice on each box by conveying the box back out the end of the unit where it was turned 180 degrees on a turntable; radiography was then performed a second time. The conveyor system was again reversed once radiography was completed to remove the box.
WASTE ANALYSIS PLAN AND QUALITY ASSURANCE
All work was performed in accordance with the Waste Analysis Plan agreed to between the signatories of the Hanford Federal Facility Compliance Agreement: EPA-Region X, Washington Department of Ecology, and Department of Energy-Richland Field Office (1). The Waste Analysis Plan was based upon criteria established by the customer (2) and AST.
A Quality Assurance Project Plan (QAPP) was written for this project and included all NDE procedures, software requirements, document control processes, change control/change request systems, non-conformance report formats, data compression criteria, internal quality control checks, preventative maintenance, document control, calibration procedures, and materials identification and control (3).
Fig. 3. Mixed transuranic waste entering mobile NDE drum unit.
Fig. 4. Waste package on turntable in shielded NDE vault.
PERMITS, TRAINING, HEALTH AND SAFETY
AST developed a Health and Safety Plan that was fully protective of operators, technicians, observers, and nearby customer personnel. Since none of the waste containers required opening to determine their contents during this phase of the backlog waste program and sufficient shielding provided for X-ray equipment, all ALARA goals were met.
Approvals were obtained from the State of Washington Department of Health for the use of mobile X-ray equipment, including an operations permit from the Office of Radiation Protection (4).
Non-Destructive Testing (NDT) personnel were certified per the requirements of ASNT SNT-TC-1A (5) and included both Level II and Level III NDE technicians. AST operators were used that had previously provided NDE services on more than 13,000 low-level, mixed, and transuranic wastes nationwide.
Other job-specific training focused upon radiation safety fundamentals, use of installed radiation survey instruments, engineered safety features of radiation-generating devices, non-radiological hazards, and operating procedures and practices. Site-specific training included radiation worker, OSHA 1910.120 hazardous material (40 hour), and Hanford orientation. Full medical exams, including vision and hearing, were also provided for all personnel.
OBSERVATIONS
A large campaign of mixed wastes stored in drums and plywood boxes was safely

completed by remote evaluation via mobile real-time radiography. Due to the design and operation of the mobile NDE units, clear images of the contents of the waste containers were safely and quickly obtained and stored on VHS tape. Based upon NDE data, more than 1,600 containers were quickly and economically sorted and decisions made as to their ultimate disposition.

Other observations noted from this waste characterization campaign were as follows:

1. Custom-fabricated NDE equipment were fabricated and mobilized 3,000 miles in a relatively short period of time to meet ambitious schedules and expectations.
2. Throughput easily reached a minimum of 25 drums or 6 boxes per shift.
3. No unusual occurrences or safety incidences were noted.
4. ALARA goals were met.
5. The design allowed required minimum waste handling. Once placed onto the conveyor system, waste packages required no additional handling.
6. The x-ray images produced were extremely clear due to the design of the unit and the ability to x-ray individual waste packages in all planes. As a result, the presence of hazardous materials or excess liquids were easily noted.
7. If coupled with a Non-Destructive Assay (NDA) component, a complete mobile NDE/NDA system could be readily adapted for use in transuranic waste certification programs, such as those required by Waste Isolation Pilot Plant.

DEFENSIBLE ALPHA CHARACTERIZATION OF GLOVE BOXES AT D&D SITES

Mohini W. Rawool-Sullivan
R. D. Bolton
R. Marshall
Los Alamos National Laboratory

ABSTRACT

Hundreds of glove boxes contaminated to levels above transuranic (TRU) waste limits will be taken out of service at various nuclear facilities over the next few years. If the contamination is categorized as TRU waste, the costs associated with packaging, transportation, size reduction, storage, and eventual disposal are estimated at about $396,000 per box. These glove boxes are typically cleaned to below the low-level waste (LLW) limit of 100 nCi/g before being taken out of service, but current measurement technologies have inadequate sensitivity or accuracy or both to provide defensible measurement of the remaining low-level contamination. Given a defensible measurement protocol, these glove boxes could be disposed of as LLW with an estimated savings of $391,000 per box. Considering all the boxes to be disposed, the savings add up to many millions of dollars. Long Range Alpha Detection technology, developed at Los Alamos National Laboratory for site characterization, shows great promise for accurately measuring the low levels of contamination remaining in glove boxes so as to defensibly characterize them as LLW. In laboratory tests using a 1m by 1m by 0.66m mock-up glove box constructed from sheet metal and safety glass, we have demonstrated the ability to measure contamination levels as low as 0.0008 nCi/g.

INTRODUCTION

Decommissioned glove boxes, which have been previously used for direct handling of nuclear materials, must have their residual contamination levels measured to satisfy nuclear safeguards and waste disposal requirements. Safeguards requirements can be met if the uranium or transuranic element content of the glove box is measured and

reported to the nearest gram. DOE Order 5633.3 specifies a measurement uncertainty "goal" of 25%. Waste disposal measurement requirements specify that contamination levels should be defined in terms of the alpha-emitting activity per unit weight of the glove box. Glove boxes with greater than 100 nCi/g of alpha activity are declared as transuranic (TRU) waste while glove boxes with contamination levels less than 100 nCi/g are declared as low-level waste (LLW). Draft Revision B of DOE Order 5820 requires that measurements of glove box contamination levels made in support of disposal as LLW must have a "95% confidence level" that the waste does not exceed the threshold level for TRU waste.

In preparation for disposal, decommissioned glove boxes are cleaned of residual alpha contamination before they are disconnected from the exhaust ventilation system. Cleaning methods typically remove most paint and deposits and are successful in reducing residual alpha contamination to around the 100 nCi/g level. If in situ measurements indicate contamination levels are still above 100 nCi/g, further cleaning can be performed. If credible measurements can be performed in situ, glove boxes can be cleaned efficiently to LLW levels. Once the glove box is removed from the ventilation system, further cleaning is not possible for safety and economic reasons. Glove boxes removed from the ventilation system and determined to be contaminated above LLW levels must be disposed of as TRU waste.

At Los Alamos National Laboratory, the current cost of size-reduced packaging, transportation, and burial of a glove box classified as LLW is about $5,000 per glove box. If the glove box is declared TRU waste, the current cost of packaging, transportation, and disposal amounts to about $396,000 per glove box. Thus, having a nondestructive, in situ method for characterization of glove boxes will considerably reduce the cost of disposal.

CURRENT TECHNOLOGIES

Measurement methods that are currently used to determine contamination levels in glove boxes are based on counting gamma or alpha emissions from 235U or TRU isotopes. For gamma detection, sodium iodide or another scintillating material is used. The gamma detection techniques suffer from one or more of the following drawbacks:

- Non-uniform distribution of the contaminants,
- Insufficient detection efficiency, or
- Background interference.

In practice, measuring glove box contamination by gamma counting is only feasible once the glove box is removed from the work area to a low-background area. If the glove box is then found not to be cleaned to LLW limits, the glove box must be disposed of as TRU waste.

Alpha counting methods using both solid-state and gas proportional detectors have been used for monitoring the inside surfaces of glove boxes. Alpha counting methods provide excellent measurement sensitivity but are subject to measurement errors in practice. Because alpha particles have a range of only a few centimeters in air, measurements must be performed on virtually every square centimeter of the interior of the glove box. The accuracy obtained using manual alpha surveying techniques depends heavily on the skill of the measurer and the care exercised in covering all internal surfaces. It is difficult to position alpha detectors in hard-to-reach areas yet these areas are likely to have the highest contamination levels and are the most difficult areas to clean.

We believe that the Long Range Alpha Detection (LRAD) technology (1) developed at Los Alamos National Laboratory will provide the measurement breakthrough needed to defensibly measure alpha contamination inside glove boxes destined for waste disposal. This paper describes exploratory tests using a mockup of a glove box and a prototype glove-box monitor.

REVIEW OF LRAD TECHNOLOGY

The range of typical alpha particles in air at STP is about 3.5 cm. Over this distance, an alpha particle loses its kinetic energy by creating a proportional number of ion pairs. These ions have a lifetime on the order of seconds, so by using either an air current or an electrostatic field one can transport these ions a fair distance. If the ions are transported to an electrode, they can produce a small current proportional to the kinetic energy deposited by the original alpha. Thus, total current is proportional to the total amount of activity present. This ion transport and collection is the fundamental idea behind LRAD technology. Detector systems based on LRAD technology (2) have been built and successfully used to

monitor soil surfaces and objects.

LABORATORY TEST SETUP

To investigate the problems involved in glove-box monitoring, we built a prototype LRAD glove-box monitor and attached it to an all-metal mockup of a glove box constructed from Unistruts and sheet metal. The length of the detector was 15 cm and the inside diameter was 8.9 cm (3.5 in.). It had a single ion collection grid which was kept at +300 V. The dimensions of the glove box were 1m high x 1m wide x 2/3 m deep. The front surface had two 8.9cm (i.d.) holes to represent glove ports. On one of these glove ports, we mounted the prototype LRAD detector and a fan with a variable power source. On the second glove port we attached an 8.9cm (i.d.) electrostatic filter to keep ions generally present in the room from entering the glove box. The fan generated air currents throughout the glove box to draw ions created inside the glove box into the detector. In a real glove-box monitoring situation, we envision that air drawn out of one glove port and through the detector will be returned to the glove box through the adjacent glove port, thus preventing contamination from leaving the glove box. An artist's conception of the LRAD glove box monitor is shown in Fig. 1. This figure does not show the ion filter used in the laboratory tests, but it depicts how the airflow will be circulated in the final implementation.

SOURCE RESPONSE OF GLOVE BOX MONITOR AS A FUNCTION OF AIR FLOW

For this test we used a 125,000 dpm (56.3 nCi) 238Pu source. The net weight of the test glove box was 69.5 kg, which meant that the contamination level was 0.0008 nCi/g. To qualify as LLW, a glove box must register alpha activity of 100 nCi/g or less. Therefore, a contamination level greater than 71,201 nCi would be required to elevate this glove-box mockup into the TRU waste category. On each of the six interior surfaces of the glove box we chose five positions to place the radioactive source, as shown in Fig. 2. The "front" surface refers to the side of the box with the glove ports, as shown in Fig. 1. The "right" and "left" sides refer to right and left from the point of view of a person standing in front of the glove box.

Fig. 1.

Fig. 2.

The fan shown in Fig. 1 was connected to a Variac. We took data at three different settings. The air flows at these settings were ~0.22 m3/min (setting A), ~0.35 m3/min (setting B) and ~0.57 m3/min (setting C) when measured in front of the detection grid.

From Fig. 3 one can see that at a contamination level of 0.0008 nCi/g we measured "detectable" current well above the background in all positions and that the response for a given position varies as a function of airspeed. At an airspeed of 0.35 m3/min, the overall detector response is more uniform than at 0.22 m3/min, i.e., the difference between the largest and smallest response measured was less for settings of 0.35 m3/min than for 0.27 m3/min. At the highest (turbulent) setting of 0.57 m3/min, the response was less than or equivalent to the response obtained at 0.35 m3/min. Additional data taken with the source placed on the other five surfaces of the box gave similar results to those shown in Fig. 3. The clear response to a point source placed at various locations within the glove box gives rise to the possibility that hot spots can be localized by covering various locations inside the glove box with an alpha attenuating material.

Fig. 3.

A second method for localizing contamination hot spots within a glove box is suggested by the variation in detector response as a function of the locations as seen in Fig. 3. This variation is caused by differences in ion transport and detection efficiency due to the airflow differences throughout the glove box. By directing the airflow at various locations throughout the glove box, we can make the detector response more uniform and determine additional information as to the approximate location of contamination. To determine the improvement in detector response as a function of source location that can be realized in this way, we constructed an air inlet nozzle capable of directing a stream of air into specific locations within the glove box. With the source located on the top surface at position #2 and with the air inlet nozzle directed toward the source, detector response improved from ~27% to ~85% of the response at position #1. We repeated similar measurements when the source was at position #4 on the right wall and found similar improvements in detector response.

Fig. 3. Response of the glove-box monitor to the source (0.0008 nCi/g) at the five locations on the left surface, as shown in Fig. 2. The Variac setting of A corresponds to an airflow of ~0.22 m3/min, Variac setting of B corresponds to an airflow of ~0.35 m3/min, and Variac setting of C corresponds to an airflow of ~0.57 m3/min.

SOURCE RESPONSE IN A GLOVE BOX WITH A GLASS WINDOW

After modifying the all-metal glove box mockup to include a safety-glass window, we conducted a series of tests to determine the effect of this nonconducting material on detector response. For these tests, we used the same source placed at the five locations on all inside surfaces of the glove box as before. No loss of signal that could be attributed to the presence of the glass window was seen. Although we did not repeat the airflow tests, we believe that detector response could be improved, as before, if the airflow is controlled.

EFFECTS OF LEXAN ON DETECTOR RESPONSE

To investigate the effects that a material capable of supporting a large static charge, such as plastic, will have on detector response, we replaced the safety-glass window with a sheet of Lexan. The same 125,000-dpm 238Pu source was placed on the bottom surface in the five locations shown in Fig. 3. The detector response observed was lower in all cases. In particular, no response was observed when the source was placed near the Lexan wall because Lexan acts as a sink for ions, which collect on the surface as a static charge, thus giving an overall lower response. No response whatsoever was measured when ions were generated near the Lexan wall. To demonstrate charge saturation, we increased the source strength to 500 Ci. In the mock glove box this activity is equivalent to 7 nCi/g of contamination. We placed this source at location #3 on the bottom surface next to the LEXAN wall, a location where we did not obtain a response from the 125,000 dpm source.

The result from this test with the 500 mCi source is shown in Fig. 4. It took about 2 hrs from the time the source was introduced into the mock glove box for the response to level off at 5000 fA. This long rise time was due to charging of the Lexan wall, which finally became saturated with ions. The detector response returned to its normal background level of 160 fA as soon as the source was removed. In conclusion, although we failed to detect contamination at the previous 0.0008 nCi/g level when one wall of the glove box was made of Lexan, we did manage to detect contamination at the level of 7 nCi/g, which is still well below the TRU threshold of 100 nCi/g.

Fig. 4.

CONCLUSIONS

In summary, all of our preliminary tests show that LRAD technology, once fully developed, will provide a defensible way of measuring contamination within glove boxes. Government guidelines require that we be able to reliably determine with reasonable accuracy that contamination levels are below 100 nCi/g to dispose of the glove boxes as LLW. Our test results show that we can measure much lower levels of contamination. Glove box monitors based on LRAD technology operate in situ and are nondestructive. They give results in real time, which will enable the user to get immediate feedback on how well the decontamination of a given box is proceeding. These monitors may also be able to isolate hot spots by taking data as various areas inside the glove box are covered.

EFFECTS OF ATTENUATION PROPERTIES ON THE MULTI-DETECTOR OPTIMIZATION METHODOLOGY FOR RADIOACTIVE WASTE CHARACTERIZATION

Kaiss K. Al-Ahmady
Thomas E. Huston
Dept. of Nuclear Engineering Sciences
University of Florida
Gainesville, FL 32611

ABSTRACT
An optimization methodology has been previously developed to account for the spatial and statistical uncertainties associated with radioactivity assessment processes utilizing multi-response, non-destructive detection systems. The methodology is used to predict the optimal placement (or configuration profile) of detectors around a waste container in order to minimize spatial and statistical uncertainties. Radiation detectors located relatively close to a container of source materials are affected by an increased spatial uncertainty attributable to the unknown spatial distribution of source materials in the waste container. Detectors located relatively far from source materials are affected by greater statistical uncertainties arising from the random nature of radioactive decay and from fewer interactions within the detectors' sensitive volumes. The partial contributions of both spacial and statistical uncertainties to the assessment reliability depend on the measurement process and the assay system design. In this study, the optimization methodology is extended to account for source-and matrix-material radiation attenuation properties (which could be obtained from earlier chemical and physical waste characterization). The optimization methodology is based on minimizing a ratio--the End-Response Ratio--which is formulated to account for the combined effects of spacial and statistical uncertainties in the assessment process. The minimized End-Response Ratio corresponds to the optimal configuration (e.g., location of detectors) of the assay/detector system by utilizing local and global searching techniques. A computer code has been developed to facilitate application of the methodology. Use of the methodology leads to greater accuracy/reliability in the assessment results.

INTRODUCTION

Quantitative assessments of radioactivity have become widespread over the last fifty years and now exist in a number of fields. Such fields include but are not limited to industrial radiography, manufacturing quality control, power generation, diagnostic and therapeutic medicine, and radioactive waste management. The accuracy of a radioactivity assessment process is an important component to consider. Accuracy is especially important when results of the assessment are to be used to characterize radioactive waste materials before or after treatment/ handling, to make decisions related to health and safety, and/or to meet specific regulatory requirements. The accuracy of an assessment is affected by uncertainties inherent in the assessment process. Uncertainties in the assessment of radioactivity associated with nondestructive assay systems are attributable to instrumental and non-instrumental sources. Instrumental sources include uncertainties and errors in the assessment due to instrument limitations and configuration and to human factors involved in running equipment and interpreting results. Non-instrumental sources include uncertainties introduced by counting statistics, spatial and temporal distributions of the source activity in the container, and random phenomenon (e.g., involving radiation transport and interactions). Several optimization procedures have been employed to obtain better accuracy in assessment results. Shenhav and Ben-Haim (1) applied optimization principles to determine the minimum radioactive mass that can be detected by a nondestructive, passive assay system of randomly distributed materials. Yong et. al. (2) evaluated the uncertainty in radioactive waste inventory data by calculating the estimated range of activities and producing distributions for their predictions by numerical propagation of uncertain parameters through a model. Notea and Segal (3) applied a method based on developing a characterization function for the assay system that correlated measurable variables such as detector design parameters, detection limits, detector response and uncertainty. The method is limited to the expressible detector response and measurement uncertainty. Al-Ahmady and Huston (4,5) recently developed an optimization process for nondestructive assessment that is based on minimizing a function (the End Response Ratio, ERR) which accounts for both statistical and spatial uncertainties of the counting system. The value of the minimized function corresponds to the optimal assessment configuration.

In this paper, matrix and non-matrix radiation attenuation terms have been incorporated into the ERR optimization method to improve the design and performance of radioactivity assay systems for characterizing unknown and randomly distributed radioactive materials. The scenario investigated involves a single point source of radioactivity that can be at any random, unknown location within a cylindrical waste container. The contents of the container (source and matrix) result in attenuation

of the radiations being detected. A parametric study of the effects of different attenuations on the End Response Ratio for this scenario was performed. The results indicate that detector locations exist which allow uncertainties in the assessment process to be minimized (i.e., accuracy is improved). A computer program was developed to facilitate the investigation.

MATHEMATICAL CONSIDERATIONS

The ERR method incorporates both statistical and spatial sources of uncertainty in an unrestrictive assessment of randomly distributed radioactive materials. When a detector in the assay system is located relatively far from a radioactive source, statistical uncertainty in the detector reading increases because fewer interactions occur in the detector sensitive volume (leading to fewer counts). Radioactivity in the assessment process is represented by a randomly oriented point source that can be located anywhere within the confines of the container. If a source of unit activity is utilized for this treatment, the statistical uncertainty can be quantified by the standard deviation of the mean, S, of a set of n readings (counts) taken over equal time durations, t.

Eq. (1)

where si is the standard deviation of each element (i.e., reading) in the set and is given by Ci1/2. The term Ci represents the total counts recorded by the detector for reading i. The value of Ci can be estimated from,

Eq. (2)

where ti is the time interval of measurement i (assumed to be equal for all i here); n is the total number of elements in the set; and Fi is the Source-Detector Configuration SDC function. The function Fi represents the count rate expected to be measured for element i of the total set of readings and is determined by the geometry of the configuration utilized in the assay system. For the treatment examined here a simple SDC function F for a point kernel response is utilized. The detector count rate for uncollided particles (photons) for a unit-activity point source is,

Eq. (3)

where A is a constant which accounts for the detector's intrinsic efficiency and other conversion factors, N is the linear attenuation coefficient of the source-container matrix materials, D is the normal distance from the point source to the detector, a is the detector radius, a is the angle between the normal to the detector surface and the source direction, and d is the distance from the source point to the intersection point with the container surface of the line connecting the source point and detector.

The statistical uncertainty contributed to the assessment process is quantified by the ratio of the standard deviation (assuming Poisson statistics) in the overall detector(s) count mean to the count mean of the detector(s) for a complete set of readings. The complete set of readings is generated by spatial scanning over all possible locations of the unit activity source in the container volume and over all possible detector locations in the measurement volume. The measurement volume represents the space in which a detector(s) can be located. The source and measurement volumes are mutually exclusive since the testing is nondestructive. The statistical uncertainty contribution to the assessment process can then be expressed as,

Eq. (4)

where Ust is the statistical component multiplier of the ERR (5).

Spacial uncertainties are important when detector(s) are relatively close to the container surface and are caused by the unknown spatial distribution of the source material in the container. If source activity is being determined by the assessment, the value that is assigned to the activity will depend strongly on the location of the source in the container. Since the assessment is non-destructive, the point cannot be known and can theoretically be anywhere within the container. This unknown source location leads to a spatial uncertainty in the assessment process. The spatial component of the ERR was previously constructed from the ratio of the maximum to the minimum responses from the complete response set for the specific consideration. This component is based on the total detector counts for SDC functions of point kernel assay system configurations and can be represented by,

Eq. (5)

where Usp denotes the spatial uncertainty factor. By considering all possible source locations in the container and all possible detector locations (configurations), the

resulting set of counts per source location, per detector configuration is called the complete response set (4).
It is important to note that elements of the complete response set are assumed to be linearly independent of time, spatial distribution of unit activity sources, and the radioactive source mass. Linearity in source mass is valid when the radiation absorption characteristics of the non-source materials (including matrix materials, container material, and the medium between the detector and container) are constant or relatively constant over the assay time period. The linearity with the source spatial distribution exists if there is linear independence in the detector's responses to spatially distinct point sources of unit activity. The linearity in time is justified if the source activity remains constant over the testing period (4).
The statistical and spatial uncertainty components treated above are reasonably independent, therefore their contribution to the uncertainty of the assessment process can be evaluated from their product as,
Eq. (6)
where j is the number of detector configurations. If a constant time interval, t, is used for all the measurements then
Eq. (7)
The attenuation term in F can be studied to determine its effect on the ERR as a figure of merit to evaluate the best locations of detectors around the radioactive waste containers in the optimization process. The ERR can be perceived as a figure of merit which accounts for the overall contributions of spacial and statistical uncertainties. Larger values for the ERR indicate greater uncertainties; smaller values indicate less uncertainty. For a given source container, the detector configuration that results in the lowest relative value for the ERR will optimize the assessment since it will possess the least (relative) amount of overall uncertainty.
RESULTS AND DISCUSSIONS
A computer code has been previously developed (5) to facilitate implementation of the multi-response optimization methodology for radioactive waste management applications. Modifications have been introduced into the code in order to incorporate the effects of matrix material attenuations. The algorithmic format implemented in the code consists of objects that perform the following functions:
1. scan the radioactive waste container volume, as specified by the container geometry, to generate a sample set of the possible source spatial locations;
2. calculate the distance between every source point location and detector(s) location specified by the user; also calculate the attenuation distance between source to the container surface according to the SDC structure;
3. generate the complete response set {Ci} for all possible configurations according to sampled source points, number of detectors, and other considerations;
4. employ search techniques to determine Usp developed for each configuration;
5. compute the ERR for all configurations and determine the minimum ERR value in the set; and
6. employ a feedback routine to iterate over control variables until optimal values are obtained.
The modifications made to the existing program for this work involved addition of code to calculate the distance between the source point and the intersection point with the surface of the radioactive waste container located on the line passing through the point source and the point representing detector location. In this application, the code is used to perform a case study on a cylindrical radioactive waste container (drum); however, it can be adapted for other waste assessment optimization problems. Cartesian coordinates (x,y,z) were utilized in the scanning process; the waste container axis was taken to coincide with the z axis. The bottom center of the drum was taken to coincide with the origin.
Earlier analyses utilizing this optimization methodology (5) and container configuration showed that optimal placement of a detector system was achieved when detectors were placed at radially symmetric positions about the cylindrical container and at z equal to the midpoint of the drum length. The particular detector location depended on the number of detectors utilized in the assessment process. Step increments were applied in the three directions dx, dy and dz and were selected to be the same for all directions. As this increment becomes smaller the number of

calculations become larger and the code resolution increases. For scanning purposes, the container is assumed to be located within a closest fitting imaginary box when generating source points. The distance between each sampled source point and the drum center point, at each z increment, is compared with the waste container radius and rejected if it is larger. This technique excludes points which are not located in the drum, but which are sampled because of the scanning process. Due to results of previous runs (investigating optimum detector locations), the detector locations were restricted those lying in the plane given by z = 1/2 L, where L is the drum length. The code can be used to place detectors at any location in the measurement volume; however, run time increases.

Similar detectors are assumed in this example, and they are symmetrically located around the axis of the container at z = 1/2 L. The container used for this analysis was a 55-gallon drum of standard dimensions (~90 cm length and 60 cm diameter). The detector radius was assigned a diameter of 4.5 cm. The waste container cross section is uniform and is described by x2 + y2 = rO2, where ro is the radius of the container. A constant time interval is utilized for all measurements. A simple SDC configuration function F for a point kernel response is utilized. Distance D between detector point location (j) and source point location (i) is calculated by

Eq. (8)

where (xi,yi,zi) represents the source location and (xj,yj,zj) represents the detector location. The attenuation distance d in the SDC configuration function F is determined by substituting the parametric equations for a ray into the conical equations for a cylindrical surface and solving the resulting expression for the distance at which the ray intersects the surface. The ray was defined as originating at the source point and passing through the detector location.

The effect of different linear attenuation coefficients on the ERR was analyzed with the source configuration discussed above for a drum container. Linear attenuation coefficients investigated ranged from a theoretical value of zero (no attenuation) to one (the value approximately seen for photons in lead). Fig. 1 shows the resulting ERR plotted against the distance between the waste container surface and the detector for linear attenuation coefficients, u, ranging from 0.05 to 0.5cm-1. The minimum distance a detector can be located is zero, which represents a detector located immediately on the outer surface of the container. The y-axis of Fig. 1 gives the logarithmic (base-10) value of the ERR in order to show the wide range of values obtained. Although a minimum value of ERR vs. distance exists for each attenuation examined, the logarithmic scale does not clearly show it for all cases plotted. The introduction of attenuation into the analysis resulted in ERR values that spanned over more than 25 orders of magnitude for the attenuations plotted.

Figure 2 shows the relation between the linear attenuation coefficient and the log10ERRmin. The figure also includes plots of the components of the ERR, Usp and Ust. The figure illustrates the effects of attenuation on the statistical and spacial uncertainties and on the the combined uncertainties for the optimal configurations. As the attenuation increases, the spacial uncertainties (associated with the optimized ERR) become very large; however, the statistical uncertainties do not change dramatically. For the geometry examined, the spacial uncertainty component (associated with the minimum ERR) increased by over 40 orders of magnitude from zero to an attenuation of 1 cm-1. Since the ERR is simply the product of the spacial and statistical components, the log of the ERR is simply the sum of the log of the components. Since the optimal placement corresponds to the minimum ERR value of the set generated from different detector configurations, the introduction of attenuation into the system causes greater uncertainty in the assessment result compared no attenuation.

The effect of source- and matrix-material attenuation on optimal detector placement can be seen in Fig. 3 which illustrates how the optimal distance changes for different attenuations. The optimal distance to place the detectors so that uncertainty is minimized ranged from roughly 30-80 cm (for this case study). When matrix attenuation is negligible the optimal distance of the detectors is at the upper limit of the range cited (80 cm). As attenuation increases, the optimal distance is reduced as shown in Fig. 3. In generating data for this study, detectors were placed at 10 cm intervals. This protocol explains the lack of smoothness in the curve. Use of smaller intervals would have produced smoother results. The primary point to this figure is that attenuation affects the optimal placement of the

detector.

CONCLUSIONS
The effects radiation attenuation properties of matrix-materials on the deterministic ERR method of minimizing uncertainties in the assessment of unknown randomly distributed radioactive materials has been evaluated. Modification to the SDC function used in the optimization methodology was made by including an exponential attenuation term. Minimization of the End Response Ratio was performed to give optimal detector locations in the assay system. A computer program was developed to facilitate implementation of attenuation properties in the ERR method. The program consists of basic algorithms which: scan the radioactive container volume, calculate distances between the source and detector, calculate attenuation distances in the matrix materials, generate the complete response set according to the SDC configuration function, employ search routines for the minimum and maximum values of the response functions and the calculated ERR set, and finally relay feedback to determine the best assessment configuration. Matrix-material attenuations contribute to increase in the assay system uncertainty. Shorter distances between the detector and the waste container are thus required to provide lower uncertainties and consequently better assessment resolution for higher compared to lower radiation attenuations in the waste drum.

Savanna Army Depot Activity
ABSTRACT
One of the decontamination and decommissioning projects within the Department of Defense is the demilitarization of an aging stockpile of munitions. A large portion of the stockpile contains depleted uranium (DU) as an armor piercing core and so these munitions must be assayed for the presence of uranium in other components. The assay method must be fast and preferably easy to implement. The presence of DU is indicated by its alpha decay. The alpha particles in turn produce ions in the ambient air. If a significant fraction of these ions can escape the quantity of propellant, the ions can be detected instead of the alpha particles.
As a test of the feasibility of detecting alpha emissions from DU somewhere within a cartridge of propellant, we measured the transmission of ions through layers of real propellant. The propellant is in the form of graphite-coated cylindrical pellets. A 105-mm cartridge was modified for use as a pellet chamber. A check source served as an ion source. The ion detector consisted of a grid held at 300 V coupled to an ammeter. Results confirm that this is a promising technique for testing the propellant for the presence of DU quickly yet with sensitivity.
INTRODUCTION
The Department of Defense maintains a large inventory of munitions which contain

depleted uranium (DU) components. The DU component normally forms the core of the projectile assembly of the munitions, and is used because of its superior ability to penetrate enemy armor. As the stockpile of DU munitions ages, it will become necessary to safely disassemble the munitions, removing all explosive/combustible components and recovering other components for recycling. This process is known as demilitarization (demil). Of particular interest is the demil of 105-mm tank ammunition because this cartridge design has a section of the DU penetrator rod in direct contact with the propellant charge. The propellant consists of solid cylindrical pellets, each 1.5 cm long and 7.6 mm in diameter. Because the level of potential DU migration onto the propellant is expected to be low, a sensitive method of assay is required to segregate contaminated propellant. Given the large volume of propellant to be monitored, the assay method must also be expeditious-preferably in situ on the demil line-because a lengthy assay time could significantly add to the total cost of the demil project.

One indicator of the presence of DU is the presence of alpha particles emitted by the natural decay of uranium. Alpha particle activity can be detected via the ions that are created in air by the ionizing alpha radiation. The ions can survive much longer-and thus travel much farther from the source uranium-before neutralizing compared to the range of the alpha particles. For assay of a cartridge full of propellant, air is drawn through the pellets, transporting these ions to an ion detector.

An alternative assay would empty the pellets from each cartridge, spread the pellets on a conveyor, and scan the pellets for gamma-ray activity. This process is slower and might spread contamination.

ALPHA DETECTION

The ion detector consists of a metal grid across an air pipe. Ions caught on the grid as air passes through create a very small (femtoamps) current to ground. The response of the detector is on the order of seconds, the time necessary to transport the ions from the alpha particle to the detector. Detector requirements are simply a small voltage supply (300-V battery) for biasing the collection grid and a sensitive ammeter or electrometer. Similar detectors based on long-range alpha detection (LRAD) have been designed (1) and fielded by a team at Los Alamos National Laboratory (2).

The number of ions reaching the detector is proportional to the amount of DU present on the surface of the pellets. The ions can be absorbed or at least neutralized in collisions with the pellets before reaching the detector. This potential loss of efficiency at ion collection and hence of sensitivity to DU can affect the attractiveness of this nondestructive, in situ assay.

ION TRANSMISSION TEST

The transport of the ions through the propellant was tested at Savanna Army Depot Activity. Air containing fixed amounts of ionization is drawn through a steel 105-mm cartridge case. The loss of ions to attachment to propellant grains is measured as a function of depth of propellant in the case.

Test Apparatus

The test bench is illustrated in Fig. 1. The lower chamber held a 230Th check source which served as a source of ions. The front door on the chamber had a large cut-out, covered by a generic furnace air filter. The source disk was held in the center of the chamber by a stand. The TMA/Eberline source had an activity level of 6220 disintegrations per minute (dpm) in Sept. 1991 (essentially the same at present) over an active area of 4.4-cm diameter. To provide different activity levels, we made several masks. These masks consisted of sheet metal with circular punch-outs of graduated diameter. Diameters were chosen to provide variations in activity level in 660 dpm steps: assuming the activity was uniform across the original source. The data will call this assumption into question.

The pellet chamber consisted of an empty 105-mm cartridge, roughly 60 cm long. The bottom of the cartridge had a large hole, covered by a perforated metal sheet. This mechanical support for the pellets may have acted as an electrostatic filter for the ions passing through.

The pellets are graphite-coated, and therefore normally have a conductive surface. The packing fraction of the 7.6-mm diam., 1.5-cm cylinders was determined to be 60% in random pouring of the pellets. The layer of pellets would act as a grounded, conducting sponge that could filter ions. Qualified personnel transferred the propellant between storage and the cartridge during the operation, and data was

acquired in a separate bay behind 30-cm-thick concrete walls.
Fig. 1.
The 10-cm-diameter pipe monitor was bolted onto the cartridge. The signal grid was nominally 91 cm from the source disk. The sensitivity of the pipe monitor was determined in the lab to be 10 dpm per femtoampere (fA), similar to other LRAD pipe monitors (2). A 300-V battery was used to bias the grid. The battery was kept remote in the data acquisition bay in accordance with safety procedures. An Arnone electrometer (3) was secured to the monitor body and wrapped with black electrical tape. A BNC cable (and a grounding strap) was run out of the bay to a Keithley electrometer operating as a voltmeter. A PowerBook 180c ran the acquisition software.
A vacuum hose was connected with flanges directly to the top of the monitor. Approximately 1.8 m of this hose ran to a shop vac. A 10-cm-diameter chamber was inserted midway along the hose and contained a probe for measuring airspeed. There is some question as to the effect of turbulence within this chamber on the measured airspeed, as the chamber was not very long. A sliding opening assembly permitted control of the amount of vacuum and therefore the airspeed. Airflow was kept between 30 and 102 cm/s in a 10-cm diameter so that the response was relatively insensitive to airspeed (2).
TEST RESULTS
Figure 2 shows the response of the monitor with no propellant in the chamber. The data set taken at 45 cm/s airflow consists of two sets, separated by 90 minutes of delay. The lower value of the two points for 6220 dpm goes with the earlier set. Three observations are relevant.
1. The sensitivity (slope) changed during the delay, when the monitor and electrometer were moved and the electrometer was not physically secured. Ignoring the 6220 data (see #2), the slope below 3500 dpm is 66 dpm/fA, while above 3500 dpm the slope is 43 dpm/fA.
2. The source disk appears to have non-uniform deposition, with higher activity per unit area towards the periphery of the disk. Within each of the data sets, the 6220 data are consistently above what would be expected from extrapolating the lower activity data. This is also true to a lesser extent for the 4905-dpm activity, and the 4247-dpm area. Therefore, source strength must be considered nominal. We suspect that only the total activity of the 230Th source would be guaranteed to some tolerance by TMA/Eberline.
3. Better sensitivity was obtained with increased airspeed. The slope at 74 cm/s is 35 dpm/fA. Moreover, the measured airspeed was less stable at the lower setting. This may be a function of turbulence in the measurement chamber at that airspeed, or the load on the shop vac when the air vents just upstream of the vac were wide open. The half-minute to half-minute fluctuations in the data appeared to be proportional to the fluctuations in measured airspeed.
Figure 3 shows the response of the monitor when 5 cm of propellant covers the bottom of the cartridge. Data were taken for 145 fpm. The ratio of response for 5 cm vs no propellant is graphed in Fig. 4 for those activity levels common to the two sets of data. This ratio represents the average transmission of ions through 5 cm of propellant. The average is 25% with a (one-sigma) range of 21-29%. Thus one could anticipate that transmission of ions through 10 cm of propellant-an additional 5 cm-would be 25% of 25%, or 1/16. This would be close to the background of roughly 20 fA. Indeed, with 10 cm of propellant, a signal was obtained at background level even with an unmasked 6220 dpm source.
Fig. 2.
Fig. 3.
Fig. 4.
For a 5-cm layer, the airspeed was increased to 122 cm/s in an attempt to optimize the monitor sensitivity. The results are plotted in Fig. 5. Not much signal was recovered, and in fact the measurement with a 10-cm layer was checked at airspeeds approaching 152 cm/s without observation of any signal above background.
Fig. 5.
IMPROVEMENTS IN TECHNIQUE
We should be able to improve the technique enough to obtain a response of 10 dpm/fA (without propellant). The ion source/alpha source was separated by the perforated

metal sheet, which surely acted as an imperfect electrostatic filter. In real monitoring (and in the next phase of testing), alpha sources will be buried within or directly underneath any propellant.
Moreover, the use of triaxial cable would enable the electrometer to be separated from the detector head. Care should be taken in stabilizing air flow, at least for interpreting test results if not in actual disassembly usage. Lastly, test sources should be better defined as to intermediate activity levels, for example, through the use of a source set.
The next phase of testing will involve mixing a known amount of DU powder into some M30 propellant. We will learn the effect of reduced ion production by a single alpha particle due to pellets in the path of the alpha. This next phase will be carried out at Picatinny Arsenal in New Jersey.

CONCLUSIONS

A sensitive but fast method is needed to assay propellant from the demil of munitions containing DU. Alpha decay of the DU and subsequent ion production in air (the LRAD technique) provides a possible means of assay. In studying this technique, we have measured the transmission of ions through overlaying propellant.
A significant fraction of ions (25%) penetrates 5 cm of propellant. Therefore, assaying the DU within a batch of propellant is feasible through detection of the ions produced by the alpha decay of uranium. However, because no ions would penetrate a full 105-mm cartridge, the assay process must involve spreading the propellant within some container or conveyor belt. This still offers an improvement in the amount of time required to assay a quantity of propellant. Traditional alpha particle detectors detect the alpha particles directly and so are sensitive to DU contamination only on the top surface.
The next phase will use contaminated propellant to test the true efficiency of the detection method. If the efficiency is large enough, then only engineering problems relating to implementation on the demil line need be addressed.

ABSTRACT

The Multiple Assay Dual Analysis Measurement (MADAM) system is a combined low-level and transuranic waste assay system. The system integrates commercially available Segmented Gamma Scanner (SGS) capability with a multienergy x-ray and gamma-ray analysis to measure these two waste forms. In addition, the system incorporates a small neutron slab detector to satisfy safeguards concerns and the capability for automated high-resolution gamma-ray analysis for isotope identification. Since delivery of the system to this facility, an evaluation of the waste measurement characteristics of the system has been conducted. A set of specially constructed NIST-traceable standards was fabricated for calibration and evaluation of the low-level waste (LLW) measurement system. The measurement characteristics of the LLW assay system were determined during the evaluation, including detection limits for all isotopes of interest, matrix attenuation effects, and detector response as a function of source position. Based on these studies, several modifications to the

existing analysis algorithms have been performed, new correction factors for matrix attenuation have been devised, and measurement error estimates have been calculated and incorporated into the software.

INTRODUCTION

The Plutonium Facility at Los Alamos National Laboratory (LANL) is a U.S. national defense facility involved in the recovery and processing of plutonium and other transuranic elements. Wastes are routinely generated from many stages of pyrochemical and aqueous processing of plutonium and uranium, and from plutonium fuels fabrication. The processing steps generate a wide variety of leaner scrap and waste forms, such as plutonium oxide from burned residues, Pu-bearing salts from production/reduction and metal purification processes, impure plutonium metal, metal reduction slags, ash, ceramics, cleaning rags, plastics, HEPA filters, and other remnants and apparatus generated from processing and cleanup tasks. Solid wastes created from this processing are divided into two broad categories: transuranic (TRU) waste containing greater than 100 nCi/g and low-level waste (LLW) containing less than this amount. TRU waste is obtained from various processing and cleanup steps within the processing gloveboxes and may be packaged in containers ranging from small cans up to 55-gal. drums. LLW is derived from locations outside the gloveboxes where contamination is expected to be light. Both solid waste categories receive nondestructive analysis (NDA) to determine radioactive content. For low bulk density materials (< 0.25 g/cc) such as paper, plastics, ash, powders, etc, the analyses are performed using x-ray or gamma-ray analytical methods. Denser materials, such as metals, leaded gloves, and some plutonium salts, are measured with passive or active neutron counter analysis.

In general, measurements of low-density LLW utilize a combined L x-ray and gamma-ray analysis in which the contributions from 235U, 238Pu, 239Pu, 241Am, and fission products are collected to determine the total activity in the waste.(1-4) Because this technique does not correct for matrix attenuation or self-absorption effects, it is suitable only for low bulk density materials with diffuse contaminations of plutonium or uranium. The sample is rotated and vertically scanned before a single NaI detector to smooth the spatial response of the signal. Correlation factors for non gamma-ray emitting species may be incorporated into the software to account for radioactive species not directly detected by the instrument (1). This analytical method provides high sensitivity and reasonable accuracy for low-density materials. However, the method has several limitations. First, it is generally insensitive to unknown radioactive contaminants. That is, contaminants such as 237Np, 243Am, or 244Cm, which are often associated with plutonium processing, may not be revealed with this method. Failure to detect their presence can lead to significant underestimation of the total activity in the waste. A second limitation in the method concerns its susceptibility to density variations in the waste. In the past, matrix attenuation of the gamma-ray and x-ray signals in low-density LLW has been discounted as a relatively minor constituent in the overall measurement uncertainty. Typically, a standard with the same density as the average LLW density has been used to calibrate the instrument. However, as the variability in waste matrix types has grown and come under increasingly stringent regulatory requirements for more accurate measurements of LLW, corrections for matrix attenuation effects have become necessary. A third limitation on existing x-ray and gamma-ray analysis of LLW relates to the inability of these instruments to detect plutonium concealed within photon-shielding materials. The concern here is not that the radioactive content in the waste will be underestimated as discussed above, but rather that comparatively large quantities of plutonium (10s of grams) may be concealed within gamma-ray shielding materials such that they are invisible to the detector. For example, significant amounts of plutonium could be contained within relatively-thin lead shielding, thereby presenting a diversion scenario of significant proportions to safeguards analysts. At present, this vulnerability must be addressed by additional safeguards measurements before the waste items leave the facility.

To surmount these limitations on x-ray and gamma-ray measurements of waste, a new instrument has been developed jointly by personnel at the LANL Plutonium Facility and Canberra Industries, Inc. From the same measurement platform, the instrument can operate in either an SGS mode to analyze TRU waste and leaner residues or can be used in a multienergy analysis mode to measure LLW. In the multienergy analysis mode, the software inspects the 235U, 238Pu, 239Pu, 241Am, and fission product gamma-ray and x-ray spectral regions with the NaI detector as indicated above, and

additionally performs isotopic gamma-ray analysis using a high-resolution detector. In addition, a neutron counter measurement simultaneously examines the waste for the presence of radioactive materials that may be shielded from the gamma-ray analysis. A series of test measurements has been performed to determine instrument sensitivity, matrix and geometry effects, stability, and a more realistic assessment of the measurement uncertainty.

This paper will first describe the MADAM system in more detail. The important characteristics of the TRU and LLW measurement platforms will be discussed. In particular, the capabilities of the MADAM LLW measurement system will be reviewed in some detail. The SGS is typical of commercially available SGS assay systems so only a short discussion of this component will be given. The results of the evaluation of the neutron safeguards detector will be presented. Finally, a discussion of the advantages and disadvantages of the LLW measurement system will be presented.

SYSTEM DESCRIPTION

The frame for the new instrument was taken from an old SGS unit that was decommissioned and retrofitted to accommodate both low-level and transuranic waste containers. Its footprint is approximately 5 ft by 5 ft, although the dewar for the HPGe detector protrudes an additional 18 in. on one side. All power supplies, amplifiers, counter/timers, motion controllers, and other electronic modules are housed in one standard 180 cm high by 56 cm wide by 76 cm deep NIM cabinet. The computer, printer, and keyboard are mounted separately on an adjacent 24 in. by 24 in. desk.

The SGS measurement platform includes a collimated coaxial HPGe detector and a multi-position transmission source holder. The system is designed to accommodate container sizes ranging from small cans up to 55-gal. drums. The detector collimator is designed to provide a segmented analysis with 2-in. segments over the height of a 55-gal. drum. However, for assays of smaller containers, the collimator can be configured for 0.5-in. segments with the use of a specially designed collimator insert. The software automatically detects the presence of the collimator insert and alerts the operator if the proper parameter file is not selected. The transmission source holder contains a multi-position rotator which holds up to six different transmission sources, allowing the system to be easily configured for assays of many different radioactive isotopes. Selection of the proper transmission source for an assay of a particular isotope is made automatically based on the information entered in the isotope parameter file. The SGS analysis utilizes the standard two-pass assay technique with transmission and live-time corrections that has been in use for many years (5). The instrument will perform either a three-peak assay in which there is an assay peak, a transmission peak, and a rate-loss correction peak, or a four-peak assay in which there are two transmission peaks in addition to the rate-loss and assay peaks. Each peak is analyzed using three fixed regions of interest, one for the peak and a background region on each side of the peak. The SGS software contains many diagnostics checks to validate the operation of the instrument, including detector full-width half-maximum, amplifier gain, sample density, and rate limits on the transmission and live-time sources.

At this facility, low-level waste is normally packaged in 1 ft by 1 ft by 2 ft cardboard boxes. The new instrument is capable of measuring waste packaged in these containers and, in addition, can accommodate LLW contained in 30-gal. and 55-gal. drums. The measurement time for the cardboard boxes is 2 min. The instrument is programmed to directly measure 235U, 238Pu, 239Pu, 241Am, and fission products using a single 5 in.-diam by 2 in.-long NaI detector optically coupled to a photomultiplier tube. Shielding around the detector consists of a specially fitted 1.75 in.-thick lead cover surrounding the sides, head, and back of the NaI crystal, except where the 2.0 in.-wide vertical collimator allows x-ray and gamma-ray access from the sample. The collimator permits the entire length of the LLW container to be viewed throughout the measurement. This collimator arrangement, plus rotational and vertical scanning, permits smoothing of the detector's spatial response to the waste package. The LLW measurement electronics, consisting of a preamplifier, amplifier, high-voltage power supply, scaler, and Canberra System 100 MCA board, form an independent, stand-alone unit that controls only the LLW measurements. Periodic measurements of a shuttered 133Ba source mounted to the platform provide gain and intensity control for the detector. Table I contains a summary of the major components in the LLW measurement system.

The system is also capable of performing gamma-ray isotope identification in LLW

containers using the SGS coaxial HPGe detector. For LLW measurements, the 2-in. collimator is rotated to a vertical orientation, which allows the entire length and width of the LLW container to be viewed by the detector. The purpose of the high-resolution measurement is to detect unexpected contaminants in the waste. An analytical balance, calibrated from 0 to 30 kg, is also connected to the system computer in order to calculate the activity per unit gram of waste.
Finally, a small 1 ft by 1 ft by 4 in.-wide neutron slab counter, containing four 8 in.-long 3He detectors surrounded by polyethylene, operates during waste measurements. The internally-mounted amplifier converts the output of the 3He tubes to a TTL pulse train directed to the counter/timer which, in turn, is interfaced to the computer. The neutron counter is attached to the side of the measurement platform; its purpose is to detect the presence of plutonium that may be transparent to the NaI detector. Because this detector measures only total neutron counts, not coincidences, it is not intended to accurately assay the plutonium content in the waste. It is meant only to detect the presence of relatively large quantities of shielded material. The neutron measurement is performed simultaneously with both the SGS and the LLW assays. The user is alerted if the neutron count rate is above a predetermined limit entered in the configuration parameter files. Motor controllers for rotational and vertical positioning of the sample and shutter regulation for the gain source support the detection apparatus.
TABLE I
EXPERIMENTAL METHODS AND RESULTS
SGS Measurements
The SGS system is a direct adaptation of a commercially available SGS to the MADAM platform. Modifications to the commercial SGS software for the MADAM platform include the addition of the safeguards neutron detector and an automatic peak identification analysis using Canberra's Spectran-AT at the completion of the SGS analysis. The system is currently configured to perform assays for 239Pu, 238Pu, 235U and 237Np. The live-time correction is made using the 88 keV gamma from a 109Cd source mounted on the barrel of the coaxial detector. Two transmission sources, 75Se and 137Cs, are used to perform the transmission correction for routine assays. The assay and transmission peaks used in the analysis are shown in Table II.
TABLE II
Since the SGS is a standard NDA technique, the measurement characteristics of the system will be only briefly discussed. The performance of the MADAM SGS system was tested using a set of 239Pu SGS standards. The standards are constructed of plutonium oxide blended into a low-density diatomaceous earth matrix. The standard cans are 11 in.-high with a diameter of 4 in. Tests were performed with the 2-in. collimator and with the 0.5-in. collimator insert. The measurement precisions obtained with 10 and 100 g plutonium standards are shown in Table III for two measurement times. The precision is defined as one standard deviation in the measurement result. In addition, the detection limits for the isotopes the system is configured to assay were determined and are shown in Table IV. Detection limit is defined here as the detector response that is equal to three times the background signal under the assay peak. It is assumed that the error contribution from the transmission peak and the live-time peak will be small compared to the error in the assay peak at the detection limits. It should be noted that these detection limits are theoretical limits based on the detector response from ideal assay samples. In real assay situations, instrument sensitivities are limited by practical considerations such as matrix composition, sample heterogeneity, and acceptable error. Typical detection limits for 239Pu and 235U assays at this facility are in the range of 0.5 to 1.0 g.
TABLE III
TABLE IV
LLW Measurements
Until recently, the measurement methods used to assay LLW leaving the LANL Plutonium Facility were identical to the methods originally developed by Umbarger and Cowder (1,3) in the original MEGAS box counter. In the latest revision of the MEGAS counter, the MADAM system, a number of changes have been made to the measurement algorithms in order to better satisfy changing regulatory requirements. The original MEGAS concept was intended to make a simple "go/no go" decision regarding the specific activity of a waste package. The new changes have been implemented in an effort to provide more quantitative measurements and to apply an error estimate to

the measurement result.
The changes to the measurement algorithms include: a background subtraction routine, calibration as a function of box weight (density) to correct for matrix attenuation effects, and an error estimate that is provided with the final measurement result. In addition, a spectrum integral of the areas outside of all analysis regions of interest (ROIs) has been added to detect any unexpected isotopes that may not fall into the analysis ROIs. The current MADAM system is configured to measure 238Pu, 239Pu, 241Am, 235U, and to check for the presence of fission products. The analysis isotopes and the energy of the analysis ROI for each isotope are listed in Table V. Detailed descriptions of the original MEGAS analysis method are available in the literature.(1,3)
Spectra are recorded by the NaI and HPGe detectors while the LLW box is rotated and vertically translated in front of the detectors. Typical measurement times range from 2 to 4 min. The background is removed from the NaI spectrum by performing a channel-by-channel subtraction with a smoothed background spectrum. The background spectrum is stored on disk and is updated frequently through a menu option using administrative controls. Then integrals of the analysis peaks are determined and the spectral sum for unexpected isotopes is made. The HPGe spectrum is analyzed only if the box contains greater than 100 nCi/g, unexpected isotopes, or fission products.
TABLE V
Low-level waste standards were prepared for calibration and characterization of the MADAM instrument by Robert Marshall of group CST-1 at LANL. The standards were prepared by pipetting a known amount of a standard solution (2 molar nitric) onto filter paper. The solution was allowed to air dry for 1 to 3 hours in an open-face hood. The filters were then placed between two strips of adhesive-backed polyester film (FasCal PX 1071 Bright Chrome 1 Mil Polyester, Fasson Co., Painesville, Ohio) with seven evenly-spaced filter papers for each assembly. The strips were then heat-sealed in two envelopes of 4.5 mil polyethylene. The final dimensions of each standard are approximately 4.5 in. by 23 in. The end product consists of a set of six 239Pu standards ranging from 0.26 to 22 mg total plutonium, a set of six 238Pu standards ranging from 1.4 to 80 mg total plutonium, and a set of six 241Am standards ranging from 5.7 to 434 mg Am. The plutonium used to produce the 239Pu standards had a nominal 240Pu enrichment of 6%, and the plutonium used to produce the 238Pu standards had a nominal 238Pu enrichment of 83%. Each set of standards is sufficient to span the specific activity range from 5 to 100 nCi/g in boxes ranging from 5 to 15 kg.
Standard boxes were prepared by placing five 2 in.-thick, 1 ft by 2 ft slabs of a variable-density polyurethane foam (Last-A-Foam FR-3700, General Plastics Manufacturing Co., Tacoma, Washington) into the normal waste boxes used at LANL. The variable-density foam was chosen for the box matrix rather than simulated waste, such as clean plastics and paper, since it is a very controllable and reproducible matrix. The slabs are held apart by 7/16-in. spacers to allow the standards to be slipped into the boxes in many different positions. Boxes with weights of 3, 4.5, 9, and 14 kg were constructed for the calibration measurements. The specific activities and box weights reported in this paper do not include the carton weight in accordance with DOE LLW regulations at this facility. The LLW boxes add an additional 700 g to the total weight of the package.
The 235U standards were prepared by blending 93% enriched uranium oxide into a diatomaceous earth matrix. The blended material was then sealed in 14 polyethylene laboratory bottles. The ratio of uranium to matrix material is such that in a 250 ml bottle filled to approximately 80% there are 0.26 g of oxide. The waste boxes for the uranium calibration were constructed from the same variable-density foam matrix described above. In this case, the foam matrix material was machined to allow the uranium bottles to be inserted into the matrix in multiple positions with up to all 14 bottles in a box. This results in a calibration range of 0.2 to 2.8 g 235U for each box. Waste boxes with weights of 5, 8 and 12 kg were constructed for the uranium calibration.
Each set of standards was measured in multiple positions in each box. A volume-averaged calculation was used for the instrument calibration. The volume of the waste box was divided into smaller volume elements around the positions used in the calibration measurements. The results of each measurement were then weighted with the appropriate volume element and summed to get a volume-averaged response. A calibration constant for each isotope was determined for each box weight. A

least-squares polynomial fit to the data was then used to determine the calibration constant as a function of box weight. This provides a correction for the increased attenuation of the low energy x-rays as the density of the matrix material increases. In the lightest box, 3.0 kg, the effect of the matrix attenuation over the volume of the box is small. The response from the least sensitive to the most sensitive position varies by 8.3%. On the other end of the weight range, at 14.0 kg, the effect of matrix attenuation on the 17 keV plutonium x-rays is very severe. The response varies by over 800% from the least sensitive position in the center of the box to the edge of the box where the response is highest.

The errors that contribute to a LLW measurement were broken down into five major categories: statistical, calibration, matrix variation, isotopic variation, and geometric effects. The geometric variation includes both the change in detector response as a function of source location and the effects of matrix attenuation for a single matrix. The error contributions are summarized in Table VI. The matrix and geometric errors are presented only for the 17 keV analysis of 238Pu and 239Pu because the errors for the americium and uranium measurements performed at 60 keV and 186 keV respectively, are small.

The statistical error was calculated by assuming a normal distribution and using the calibration constants in conjunction with the expected response from all of the isotopes of interest. The statistical contribution from the background subtraction was included in the calculation. Statistical error is estimated as a function of measured activity for each isotope. Bias in the calibration was measured by remeasuring the standards in each box after all the calibration functions had been entered into the system. The bias averaged over the entire calibration range is < 1% while the maximum calibration bias for any combination of source and box weight was 12%. The one sigma uncertainties in the calibration constants due to random variations in the calibration measurements range from 0.5 to 1.5%.

TABLE VI

The error due to changes in the matrix composition was measured by constructing waste boxes with simulated waste materials. Three mock boxes were constructed for this purpose. The simulated matrices used were shredded paper, small polyethylene vials, and rubber gloves. A 239Pu standard was placed in the center of each box and the box was assayed. The errors shown are the measured differences in the assay value when compared to a similar assay performed in the foam calibration matrix with an equivalent weight. The errors shown represent the largest possible error since the source was located in the center of the waste box where changes in the matrix attenuation have the greatest effect. Significantly smaller deviations would be expected with the radioactive material randomly distributed throughout the waste box.

The error contribution due to changes in the isotopic composition of 239Pu material was calculated based on the correlation of the measured L x-rays to the total activity for various material types found at the LANL Plutonium Facility. Errors in the measured total activity as large as 60% can result due to variations in the isotopic composition of the different material types. However, this source of error is not expected to provide a significant contribution to routine LLW measurements. A large majority of the materials processed at the Plutonium Facility have isotopic ratios very similar to that of the calibration material. Only rarely are 239Pu material types of significantly different isotopic composition expected to be encountered.

Finally, the geometric error was estimated by measuring a 239Pu source in various locations in each box, including folded lengthwise and placed in the top or bottom of the box. The %RSD reported in Table VI was determined by assuming the measured range in the response to be 2 standard deviations. Thus 95% of all measurements fall within the measured range. For example, in the 14 kg box, the measurements ranged from 12 nCi/g in the center of the box to 110 nCi/g at the extreme edge of the box with no matrix material between the source and the side of the box. The box had a nominal activity of 29.7 nCi/g. If the measurement at the edge of the box is not included, the next largest measurement is 30.2 nCi/g, reducing the standard deviation to 15%. Because the 2-in. foam slabs constrain the position measurements, it is not possible to get a uniform volume sampling of the box.

The sensitivity of the LLW measurement system was estimated based on the system response determined from the calibration and the geometric and background error statements. The sensitivity is reported as the detector response from a source equal

to three standard deviations above the background signal. In this report, the activity is defined as the total activity. A significant contributor to the total activity of plutonium is the beta decay of 241Pu. Unfortunately, this decay mode does not produce any radiations that can be directly measured by the MADAM system. The total activity must be correlated to the measured L x-ray activity using average isotopic compositions for material in the Plutonium Facility and specific isotope activities. The estimated sensitivities are shown in Table VII. These sensitivities are based on a 120-sec. measurement time and represent the expected sensitivity for a point source located in the center of a waste box, the position of least sensitivity. Thus, the results shown in Table VII demonstrate the worst-case detection limits for the instrument.

TABLE VII

Neutron Counter and Isotope Identification

The efficiency and geometric variation in the response of the neutron counter were measured using a 252Cf neutron source with a known activity. The measured efficiency of the neutron counter with a neutron source located on the center of the platform is 0.34%. Monte Carlo calculations using MCNP indicate the efficiency for a 240Pu neutron distribution should be approximately 5% higher. Also, calculations indicate that the slab is slightly undermoderated. The response could be increased by about 50% by adding additional polyethylene to the face of the slab. The geometric variation in the neutron detector response has a maximum deviation of -45% over the volume of a LLW box.

The response of the neutron detector to plutonium was measured using cans of plutonium oxide placed in the position with the lowest sensitivity. From this series of measurements, the minimum sensitivity of the neutron counter is estimated to be approximately 5 g of plutonium (6% 240Pu) for a 120-sec. measurement. The minimum detectable quantity will be somewhat higher for plutonium metal. This value is more than sufficient for the safeguards function that this slab counter is intended to perform. These measurements were made in the relatively high background, approximately 33 totals/sec, of the basement of the Plutonium Facility. In the lower neutron background of the LANL CMR building where the second MADAM unit is located, the minimum sensitivity is reduced to approximately 1 g of plutonium.

The HPGe detector will be used in combination with Canberra's Spectran-AT for isotope identification purposes. This feature will not be used routinely, but will be used for boxes that have activities above the 100 nCi/g limit and for boxes that are found to contain fission products or unexpected isotopes. When a box is flagged for one of the above reasons, a Spectran-AT compatible file is created from the HPGe spectrum taken during the LLW analysis and saved to the disk. These files can be analyzed later by the NDA lab supervisor. If the count rates are not high enough to produce a useable HPGe spectrum in the short LLW assay time, the boxes are set aside for counting at a later time. Measurements have shown that an overnight count of 10 hours is more than sufficient to measure 239Pu gamma-rays in a waste box with an activity level of 90 nCi/g to better than 5%.

In addition, the isotope identification feature has also been incorporated into the SGS analysis. The HPGe spectrum from each segment is summed to produce a spectrum accumulated over the entire container. A Spectran-AT analysis is then automatically performed on the summed spectrum after the SGS analysis has been completed. The purpose of the Spectran analysis is to identify any unexpected radioactive contaminants in the waste container.

DISCUSSION

The MADAM system has several advantages over many existing gamma-ray analysis systems. The capability to perform two different measurement techniques from the same measurement platform provides an important advantage for facilities or operations with limited floor space. The addition of the isotope identification feature using the HPGe detector and the simultaneous safeguards measurement with the neutron detector are two very useful features in facilities tasked with safeguarding nuclear materials. The most impressive feature is the capability to screen a large number of waste boxes in a short time while retaining good sensitivity. The LLW analysis system can perform an assay in two minutes with detection levels below 1 nCi/g for all isotopes of interest in the Plutonium Facility.

While the high specific activity of the plutonium L x-rays provides very good sensitivity for plutonium contamination, the low energy L x-rays interact strongly with the matrix material. As discussed previously, the analysis error increases

rapidly with box weight due to the attenuation of the L x-rays inside the waste matrix. This limits the LLW analysis to low-density matrices. Analysis of the NaI spectrum from the LLW measurement allows some determination of the type of material in the box, such as a 238Pu material type versus weapons grade plutonium or uranium. However, limitations in the NaI analysis prevent simultaneous assays of these material types. At the Plutonium Facility, these waste streams are carefully segregated so this does not pose a serious problem. A further limitation of the material type determination occurs at very low activity levels. For specific activities below approximately 10 nCi/g, differences in the low-energy signatures from 238Pu and 239Pu become very small. As the specific activity decreases below this level, the probability of misidentification becomes much greater. Additionally, with these very low specific activities, an isotopic ratio determination with the HPGe becomes impossible. Since a large fraction of the total activity in plutonium and uranium comes from beta emitters which are not directly measured, any change in the isotopic ratios from that of the calibration materials will lead to measurement errors which can be quite large in some cases. If the isotopic ratios of the material are known, correction factors can be applied to the results; however the exact isotopic ratios are not generally known for any given waste box.

CONCLUSION

A new NDA system has been developed to assay LLW and TRU waste generated from plutonium and uranium processing operations from the same measurement platform. The LLW measurements have been improved by the addition of algorithms for matrix correction, background subtraction, and error estimation. The addition of a small neutron counter to the measurement platform provides the capability for a safeguards measurement to be performed during the gamma-ray analysis to check for the presence of shielded fissile material. Isotope identification software has been added to both the LLW and TRU waste assay systems to aid in the detection of unexpected radioactive contaminants. The LLW assay system is capable of quickly screening low-density waste while retaining good sensitivity. The results of this paper show that improvements to the LLW assay system allow quantitative LLW measurements to be performed from this measurement platform with realistic error statements associated with the assay.

ACKNOWLEDGMENTS

We would like to thank the staff of the Los Alamos National Laboratory Plutonium Facility NDA laboratory for their support and help in obtaining the data presented in this report.

A NEW DEVICE FOR MEASURING THE SOLID FRACTION IN SLURRIES OR THE MOISTURE IN STABILIZED NUCLEAR WASTE

U. vonWimmersperg
Brookhaven National Laboratory
Upton, NY 11973

ABSTRACT

Retrieval of nuclear waste from storage tanks typically requires the mobilization and suspension in the supernate of solids that have settled to the bottom. This can be achieved by means of a mixing pump. During this operation it is important to be able to monitor the progress of particulate suspension. A new method is reported here for determining the solid to liquid volume ratio, using a radio-frequency probe. The method is immune to the effects of pressure differentials which occur during slurry agitation and exhibits linearity over a wide range of solid fractions. The probe is compact and robust, so that it can be employed were access is limited and where there are mechanical stresses and corrosive environments. This device is also expected to be cost-effective as a reliable long-term monitor of moisture in nuclear waste.

INTRODUCTION

The retrieval of nuclear waste from storage tanks can frequently be effected by slurry pumps. In cases where solids have settled out below a liquid layer, agitation can be used to prepare slurries by means of the dynamic suspension of particulates. It is the need to monitor this process of particulate suspension that motivated the development of the device described in this paper. However, since the technique employed provides a measurement of the liquid to solid ratio of the medium, the determination of moisture is an alternative application.

Ionic conductivity provides the physical parameter for the determination of the liquid to solid ratio in a slurry. Aqueous solutions exhibit conductivity in the form of ion currents. The presence of solid particles in such a liquid reduces the cross sectional area available to ion currents. Rather than exposing conducting electrodes to probe such an electrolytic medium, an insulated radio frequency (RF) coil was used to sense electromagnetic energy loss via ionic currents. Among the advantages of using a RF probe which is hermetically sealed in a dielectric casing, are mechanical robustness and immunity to corrosion, electrolytic effects and surface contamination.

Initial tests of such an RF probe have been conducted in slurries containing weight fractions in the range 30% to 60% of iron oxide powder in saturated aqueous sodium nitrate solution. Ionic current energy losses were determine at frequencies in the range 1MHz to 20MHz using a Q meter. It was found that the best sensitivity for the slurries tested and the coil configuration used (10 turns of 3mm thick copper wire spaced over a length of 50mm on a cylinder of 50mm diameter) occurred at 9MHz. However, the frequency chosen was not a critical value and comparable measurements could have been obtained over the range of frequencies quoted above.

The volume fraction of fV and the mass fraction fM of solids in a slurry can be defined in terms of the solid volume VS and density rS, and the liquid volume VL and density rL as follows:

$$fV = VS/(VS + VL)$$

$$fM = rSVS/(rSVS + rLVL)$$

It was found that the effective Q of the coil and slurry combination decreased with decreasing solid fraction. This is what is expected as a result of the consideration above, since lower solid content in the slurry implies Q loss through increased ionic current. It was also found that within the 5% accuracy of the measurements performed, the relationship between the volume fraction fV and Q was perfectly linear over the range of slurries tested:

$$fV = m\,Q + c \text{ where } m \text{ and } c \text{ are constants.}$$

The mass fraction showed a dependence on Q as follows:

$$fM = (m\,Q + c)/([1-a]mQ + [1-a]\,c + a)$$

where a rL/rs

The relation between fM and Q is thus not linear, except in the fortuitous case when the density of the liquid and solid phases in the slurry are equal. The observed linear relationship between fV and Q appears to be compatible with the ionic current loss model.

It is expected that this simple RF probe, which can be operated directly with an off-the-shelf commercial Q-meter, will solve the need to monitor slurry formation in real time. The device is small enough to pass through restricted tank apertures and is not affected by dynamic pressure gradients such as occur in stirred slurries.

Calibration of the probe only requires a measurement to be taken in drained liquid which is free of solids. It may be convenient to install a two-coil probe in which one coil is fitted with a filter screen that admits only liquid, so that automatic calibration is provided. Such RF probes are, of course, not limited to the monitoring of stirred slurries and can also serve as long term monitors of humidity in moist sediments.

SYSTEMS APPROACH TO ASSESSING DOE FACILITIES
Christopher L. Munson
Parsons Engineering Science
Charles E. Shipler
Westinghouse Hanford Company
ABSTRACT
Facility and system assessments are needed throughout the DOE complex, and are regularly performed for operating, shut-down, and surplus facilities to supply information for determining the best utilization of these facilities. The DOE has adopted the Capital Asset Management Process (CAMP) which includes a standardized inspection activity to assess DOE facility assets. However, to date there has been a lack of a standardized approach which could be followed in performing large-scale facility and system assessments incidental to the CAMP program. This detracts from the assessments' effectiveness, especially when an appropriate systems engineering approach is not used. Through experience attained in the preparation of large-scale engineering assessments for diverse facilities and systems, a standardized approach is presented which ensures the application of systems engineering to DOE facility assessments. This approach addresses DOE Orders and Site Contractor requirements. The recommended approach consists of a simple four step process. These four steps include 1) definition of requirements, 2) data compilation, 3) data evaluation, and 4) conclusions and recommendations. Case studies are presented which demonstrate the application of the approach to various types of assessments of nuclear facilities.
INTRODUCTION
The current need for facility assessments is apparent throughout the DOE complex. The needs prompting these assessments range from ensuring continued operations to planning for decommissioning. The DOE, and its predecessor, the AEC, constructed facilities for the production, processing, and management of various chemical and radioactive materials. These facilities were often constructed rapidly with a single mission objective, and often without adequate consideration of eventual decommissioning needs. Changes in long range plans, or unanticipated needs for certain materials, have caused many facilities to operate beyond their original design life and/or outside the originally intended operational bounds. As the DOE mission shifts from material production to environmental restoration, the use of existing facilities must be considered, notwithstanding the extreme changes in facility utilization this shift can cause. Many facilities were constructed so that consideration of optional missions is practical. However, outdated equipment and support systems may preclude their use. A well defined and executed assessment can supply information to determine, based on life cycle costs, the economic advantages of using a facility, maintaining the facility in a "cold shutdown" condition with only minimal surveillance and maintenance, or decontaminating and decommissioning the facility.
OBJECTIVE
The objective of this paper is to identify the key elements of a facility or system assessment that must be accomplished so that the assessment will be effective, and useful in developing life-cycle costs. The successful application of these elements will provide the life-cycle technical and economic results needed to make effective decisions with respect to future activities.
The approach presented was developed in the course of preparing detailed engineering assessments for a number of DOE facilities at the Hanford Site. As such, the approach is best suited to the preparation of large-scale engineering assessments. These assessments go beyond the scope of the basic asset inspections included in the Capital Asset Management Process (CAMP) that has been established by the DOE as an integral part of facilities management (1). CAMP is the ultimate vehicle by which DOE capital assets will be managed and which will support and justify budget and planning requests. Accordingly, the approach for facility and system assessments

presented here is intended to provide guidance for preparation of the complex engineering assessments that will supplement the integrated facilities management process now being established throughout the DOE complex.

APPROACH

The preparation of an effective assessment requires four elements. These four elements are as follows:

1. Definition of Requirements: This element involves defining the objective of the assessment; identifying the applicable regulations, codes, and standards; and preparing any checklists needed for the execution of the assessment. Two methods of defining the requirements are readily available at DOE facilities. The first is the use of the Standards/Requirements Identification Documents (S/RIDs) and the other is the use of a Surplus Facilities Inventory and Assessment (SFIA) checklist. To date, both of these methods have been limited to selected facilities which are identified by DOE or the Defense Nuclear Facility Safety Board (DNFSB).
2. Data Compilation: This element consists of compiling all available information pertinent to the objective of the assessment. In most cases this includes obtaining historical operating documentation and facility drawings, interviewing plant staff who were at the facilities during operations, inspecting facilities and systems visually or using non-destructive methods, and obtaining laboratory reports from any relevant sample analyses.
3. Data Evaluation: This element is performed based on the objective of the assessment. For assessments with well-defined checklists (such as those solely designed to establish compliance with regulations) the evaluation is a simple comparative analysis of the checklist against the accumulated data. In more complex assessments, this step may involve the preparation of a seismic analysis computer model, mass, energy, or chemical balance calculations, and evaluation of utility requirements, for example.
4. Conclusions and Recommendations: This element summarizes the data comparisons and evaluations performed above and provides the information needed for a life cycle analysis. The key items which must be included in the conclusions are the results of any risk or safety assessment activities, determination of compliance with environmental regulations, definition of operating and/or surveillance requirements, and any other applicable results which may affect operational or maintenance cost estimates.

This approach incorporates "systems engineering" in that the four elements have been found to specify all of the key functions and functional requirements needed to successfully complete DOE facility assessments. The relationships among the four elements and the various sub-tasks within elements are well defined in accordance with a rigorous systems approach.

Figure 1 graphically depicts the four elements discussed above and their functional breakdown.

Fig. 1.

CASE STUDIES

Three case studies are presented below which illustrate various applications of the assessment approach discussed above. Each of these assessments was performed using this approach, albeit sometimes in a iterative manner.

Case Study #1: Miscellaneous Tank Evaluation

In response to potential safety concerns, an assessment of 50 miscellaneous underground tanks at the Hanford Site was initiated. These tanks are all underground and most still contain some quantity of radioactive or chemically hazardous waste in either a sludge or liquid form. The tanks were used for a variety of purposes. Many were catch tanks used to collect spills or leaks incurred during waste transfers from facilities. Other types include vault tanks used for acidification of caustic waste prior to uranium extraction, and experimental tanks used in the support of the Hanford Site Hot Semi-works facility, and lime-filled neutralization tanks for treating acidic process condensates.

To perform an adequate assessment of equipment which could not be inspected, it was necessary to establish a methodology which would ensure that all applicable safety concerns could be addressed without introducing unnecessary conservatism into the final safety assessments. Another unique aspect of this assessment was in evaluating the appropriate ownership of these tanks with respect to both the Hanford operating contractor divisions and the applicable governing regulatory agency and statute,

i.e., CERCLA or RCRA.
Step 1: Definition of Requirements
The objective of this assessment was straight-forward: evaluate the expected inventory of the 50 miscellaneous tanks and determine the safety issues associated with this inventory. Due to the extensive work done in identifying safety issues for the large single and double shell tanks at the Hanford Site, the safety parameters were readily available.
Step 2: Data Collection
Data collection was the key step in this assessment. Many of these tanks had been interim isolated during the late 1970s and early 1980s; however, operational records prior to these periods were often incomplete or unavailable. Available historical records were collected and examined, site interviews were conducted, processes at facilities associated with these tanks (tank farms and material production and research facilities) were characterized, and process flow diagrams were prepared.
Step #3: Data Evaluation
This element involved compiling the data for each of the 50 tanks and preparing tank-specific data sheets. These data sheets included pertinent design information on the tank, such as location, size, operating life, and associated facilities; historical information on waste receipts; sample data (where available) on existing inventory; process flow diagrams to determine possible waste intrusions; and estimates of chemical and nuclear inventory. From these data sheets a safety checklist was completed. For example, tanks which received relatively large quantities of plutonium were evaluated for criticality. Tanks with a high inventory of organic materials were evaluated for toxic gas generation and flammability.
Step 4: Conclusions and Recommendations
Based on the results of the safety and environmental evaluations, a prioritization matrix was developed. This matrix gave those tanks with the possibility of having immediate risk to on-site personnel under a no-action scenario the highest priority for remedial activities. Tanks which posed environmental risk through the potential intrusion of regulated waste into soils or groundwater were given the next highest priority. Tanks which posed a risk to workers upon entry (such as opening risers) were identified for future planning. This prioritized list provided recommendations for developing a follow-on program plan for the surveillance and restoration of these tanks.
Case Study #2: T Plant Viability Assessment
The T Plant facility complex is located in the 200 West Area of the Hanford Site and has been proposed to function as the long-term decontamination support facilities for the site. T Plant is a canyon facility and was constructed in 1944 for the extraction of weapons grade plutonium. By 1956 the facility had ceased its original plutonium production mission, and had begun operation as a maintenance and decontamination support facility. The thick concrete walls and open deck configuration of this facility allowed versatility in the receipt, decontamination, and repair of large equipment items, such as pumps and other processing equipment. Mission changes at the Hanford Site from defense-related nuclear production to waste cleanup and environmental restoration drives the need for a variety of solid waste processing capabilities. As noted above, T Plant is proposed as the decontamination facility within the scheme of solid waste processing activities. To accomplish this mission, the 50 year old facility must be shown to be structurally sound and must be outfitted with adequate support systems (safety, material handling, environmental protection, and utilities). To provide this assurance, a viability assessment was performed.
As with the miscellaneous tank project, the T Plant assessment followed a four step process. However, this process used much different data collection and evaluation methods and resulted in a more detailed and comprehensive set of recommendations.
Step 1: Definition of Requirements
The objective of this assessment was to determine the viability of T Plant to perform as a decontamination facility in support of the solid waste disposal division mission. The requirements were developed through two methods. The first was the preparation of S/RIDs. The S/RIDs for T Plant consisted of an 18 volume set of requirements for all systems and safety and environmental administrative requirements. This set of requirements provided the applicable regulations, codes, and standards needed to assess the facility. The second method for developing requirements included the definition of a facility mission. Although the ideal

mission was to provide full service decontamination capabilities for the Hanford Site, it was recognized that more cost effective scenarios exist in which T Plant would operate in a limited role, and other planned facilities, such as the Waste Receiving and Processing (WRAP) modules, could be used for the remainder of the projected waste stream.
Step 2: Data Collection
Data collection was a multifaceted activity. One key element of the data collection was gathering information to estimate the projected solid waste stream requiring decontamination/treatment by T Plant over the 30 year environmental restoration phase of the Hanford Site. This was performed through an intensive effort of document and equipment drawing research, site interviews, and equipment inventory database consultation. The second element of the data collection was obtaining copies of all pertinent plant documents (drawings, operating records, seismic analyses, vendor literature, procedures, permit applications, and previous assessments). The final element of the data collection effort consisted of walk-throughs and detailed inspections of the T Plant buildings and systems. Material handling systems, building structure and seismic response, safety systems, mechanical and electrical utilities, secondary waste management systems and facility environmental compliance were inspected by experts in these various functional areas.
Step 3: Data Evaluation
This element was accomplished by making individual evaluations of each major plant system. The experts assigned to the various functional areas each prepared a system description, referencing essential drawings, operating history, procedures, etc. Next, the systems were evaluated for compliance with DOE orders, applicable codes and standards, engineering practices, and for expected viability over the 30 year working life of the facility in terms of operational, maintenance, safety, and environmental factors. A detailed time and motion analysis for receipt and shipping of solid waste, and a seismic analysis were two of the many rigorous evaluations accomplished in this element.
Step 4: Conclusions and Recommendations
Based on the system descriptions and evaluations, detailed recommendations were made for necessary system upgrades, equipment replacement, and facility renovations required to bring the systems and buildings into compliance and make them viable for extended future operations. Ongoing and previously planned upgrades were kept in retrospect. For example, substantial secondary containment and leak detection upgrades for the liquid waste handling system, canyon crane refurbishment, restoration of the modified canyon roof to its original configuration, various HVAC system upgrades, installation of fire suppression and early warning fire detection systems, etc., were recommended.
Case Study #3: 340 Facility Compliance Assessment
The 340 Facility is located in the 300 Area of the Hanford Site, where fabrication of uranium fuel elements was accomplished historically. Currently, the 300 Area is used for various research and development programs for environmental remediation. The 340 Facility manages radioactive and non-radioactive liquid wastes generated throughout the 300 Area. Wastes are transferred to the 340 Facility chiefly through two process sewer systems. Radioactive wastes are collected in agitated, underground vault tanks and periodically sampled for analysis. Within 90 days, the collected radioactive wastes are transferred to railroad tank cars and shipped to 200 Area tank farms for long-term storage. Non-radioactive wastes are collected at the 340 Facility in open retention basins, the effluent from which was formerly discharged to a local process trench, and currently discharged to the Treated Effluent Disposal Facility at the Hanford Site.
Step 1: Definition of Requirements
The objective of this assessment was to provide an environmental compliance evaluation of the 340 Facility as regards requirements for the receiving, storing, handling and transferring of radioactive and non-radioactive liquid wastes. The compliance assessment was based on the applicable requirements of the Washington Administrative Code (WAC) for hazardous and mixed waste facilities, federal regulations for airborne emissions and aboveground and underground storage tanks, and site contractor (Westinghouse Hanford Company) guidelines.
An interesting aspect of this study was the additional identification of requirements the 340 Facility would need to comply with to become a RCRA Part B

permitted facility.
Step 2: Data Collection
Data collection for this assessment centered on the identification of environmental requirements based on the site contractor's Environmental Review Compliance Assessment Inspection Checklist and guidelines given in the site contractor's Environmental Compliance Manual. Review of the checklist and manual indicated that their organization and content would be adequate to assure a rigorous assessment. In addition to the key data collection task of identifying federal, state, and site contractor requirements, relevant documents and drawings of the 340 Facility were reviewed, plant staff were interviewed, and site visits and inspections of facility systems were conducted as needed.
Step 3: Data Evaluation
Data evaluation began by filling out the checklist provided by the site contractor for facility environmental compliance. Due to the complexities of multiple federal, state, and site contractor requirements identified in the course of filling out the checklist, a matrix cross referencing the requirements was developed. This matrix listed references of applicable federal and state regulations, the references of corresponding site contractor requirements, description of the individual requirements, and then an evaluation of compliance or non-compliance with each requirement, along with accompanying comments.
Step 4: Conclusions and Recommendations
Based on the requirements compliance matrix, a list of compliance deficiencies was developed. This list was broken down by facility systems, including sampling and monitoring systems, storage tanks, storage areas, etc. Some notable deficiencies that were identified concerned continuous monitoring and sampling systems for airborne radioactive effluents, and lack of integrity assessments for underground storage tanks. Specific recommendations were made for correction of each deficiency, with rough estimates of costs for the corrective measures.
Also, conclusions were drawn as to what actions would be required to permit the 340 Facility as a RCRA facility. Major storage tank replacements with double shell tanks, sampling and monitoring system upgrades, secondary containment upgrades, etc., were shown to be required, along with preparation of additional documents for permitting purposes. Recommendations were made that these upgrades would probably not be cost effective, and that alternatives to the long-term use of the 340 Facility be considered, along with request of a waiver to operate the facility as is in the interim.
CONCLUSIONS
Preparation of effective facility and systems assessments requires a consistent approach that will ensure that adequate definition of requirements, data compilation and evaluation, and drawing of conclusions and recommendations are accomplished. A systems engineering approach as outlined has been shown to adequately meets these needs, regardless of the kind of assessment to be performed. Properly prepared, assessment results can be effectively used to develop life-cycle costs, and can provide valuable input to the DOE complex-wide Capital Asset Management Process currently being established.

SYSTEMS APPROACH, INTEGRATION, AND PROJECT MANAGEMENTFOR SUCCESS ON ENVIRONMENTAL RESTORATION PROJECTS
John S. Patten
Vortec Corporation
Collegeville, PA
Norman W. Jetta P.E.
Jetta System Engineering Services
Malvern, PA
ABSTRACT
Mixed waste environmental restoration projects are presenting new requirements in technical management to companies and government agencies. These requirements reflect new technical, schedule, and cost challenges which must be met in an environment far different than that previously encountered by civil or "works"

projects. Existing skills and techniques for conventional engineering design may be insufficient. This paper presents a techniques for project management for environmental restoration projects involving multidisciplinary technologies, "first time" design, and innovative equipment operation.

TIMES CHANGE - TODAY'S PROJECT FRAMEWORK

Things are not what they used to be. Environmental Restoration (ER) projects are different. They are different for the government, different for the those designing solutions, and different for those implementing solutions. The framework for these projects, as well as the life cycle of concern, has changed, and the new framework needs to be clarified. Those who implement these projects, as well as those who must procure these services must know what to expect.

Because some of the resources to accomplish ER are similar to those used in works/civil projects, (for instance land filling) specification of the approach/effort for ER is quite similar. However, because many of the solutions required for the remediation of mixed waste are leading edge technologies (for instance vitrification), it may be more appropriate to look to the system engineering model for guidance. Examining the elements of each shows why.

"Works" and Environmental Restoration Projects

Works/civil projects:

Deal with the known - roads, strength of materials, flood plains, soil structure, landfills.

Proven solutions - no development for new technologies required.

Basically have one decision maker - a city water commission, an office of the Corps of Engineers, a developer, and industrial plant manager.

Have a clear definition of job - build a bridge from A to B, dredge the channel, build a landfill for a city of 30,000.

The scope is finite - design and build (one contractor), design or build (two contractors).

Life cycle defined - structure to last 30 years, landfill to operate for 15 years.

Liability circumscribed - covered by insurance, governmental body assumption of liability.

ER projects on the other hand:

Deal with the unknown; for example at WMS '95 topics will address

- "Rebar Corrosion Due to Carbonation in Structural Reinforced Concretes for Near-Surface LLW Repositories", J. Torok
- "Alternate Conceptual Models in the Saturated Zone at Yucca Mountain", L. Lehman, T. Brown
- "Credible Future Climate for the Nevada Test Site for the Next 10,000 Years", J. Cochran, J. Emery

Require leading edge solutions - Hanford Tank Wastes.

Decision making Is fragmented - Stakeholders, government, private business, citizens

Magnitude of the problem may not be bounded - quantity of waste, toxicity time period, number of waste streams.

Life cycle takes on new meaning - half life greater than 1000 years, administrative controls capability 500 years hence.

Specter of "LIABILITY"

- Lawyers will not be stopped by contracts regarding liability,
- Our lawyers are smarter than your lawyers, and the
- Deep pockets concept.

Example - Vortec Vitrification Demonstration Plant Project

This Technology Demonstration Contract is for design and construction of a high throughput (25 tons/day) combustion melting system to be used in a 30 day demonstration of the vitrification of a low level mixed waste. The decision makers were DOE and DOE support contractors.

The final waste stream characterization of the several sources considered resulted from a system engineering definition accomplished through an iterative analysis. The design soil waste stream was the worst case which could be encountered tempered by a "cost and reasonableness" criteria relative to radionuclide levels.

Phase 1 involved developing a system concept through trade studies, surrogate soil testing, and interaction with a number of potential host sites. Phase 2 involved the detail design for a particular host site (Hanford), but late in Phase 2 Hanford

withdrew support and a new site was required. Phase 2A will involve selecting another site while Phase 3 will implement the construction and 30 day demonstration of the solution. In all phases, analyses, tradeoffs, and iteration of answers have been required. In no case have the requirements lent themselves to being resolved by a "plug in and grind out" approach.

Example - Hanford Low Level Tank Waste

In this case, the magnitude of the problem may never be bounded because there are too many unknowns, not only in terms of the waste but also for the appropriate technology to use in remediation, the business/contractual manner in which the remediation will be carried out, the life cycle for assurance of environmental protection, and that old specter-- "LIABILITY" (whose?, when?, why?). The government is in the early phases of developing parallel approaches of: 1) selecting an A&E contractor for implementing what may be a conventional design/build civil project with operation to be defined at a later date; 2) while in parallel selecting a company that will sell a "complete remediation service" covering technology development, design, build, and operation on a fixed price basis.

Approaches Have Changed

In the old way of handling civil projects, there was "design then build". When dealing with the government, the rules are quite precise. In general, the effort was accomplished on "cost plus" contract. Any modifications were fairly straightforward, but in any event usually never required innovative development.

Most of today's senior management with the engineering firms (or in government offices) involved in ER gained their experience with "works" and civil projects. They still try to define a solution with a one pass design, "Our General Spec.", and supporting standard specifications and drawings in the atmosphere of the "cost-plus" contract inefficiencies and perceived large government budgets.

Contract cost goes up because ER projects are not standard, mixed waste stream definitions are imprecise, and pressure to improve public health and safety quickly encourages a "do something" mindset.

The "old way" to civil projects may have a small role in ER but only where cost effective, proven design definitions exist.

A better way, the systems engineering approach, provides a high confidence, reduced risk method because it provides a disciplined methodology controlled by decision points based on established success criteria. It can, exercised properly, result in a lower life cycle cost for obtaining results while satisfying the real needs of the stakeholders. The major benefit is that it will produce results which solve the ER problem.

Not yet totally accepted by the A&E sector, the system approach has long been used in the aerospace community and is gradually being implemented in the industrial community. It is being explored in the ER community as the DOE Tank Waste Remediation System Program opportunity (Commerce Business Daily, 8/18/94) acknowledges.

UNDERSTANDING SYSTEMS

The Characteristics of the System

A process is not a system. Adding a computer to equipment does not define a system. Systems are more than just processes or computers. Systems consist of any or all of the following; process, methods, equipment, and software. The identifying feature of a system is that it is defined by the interfaces. This emphasis on interfaces distinguishes a process from a system. Interfaces may be physical (mechanical, electrical), informational, human interface, environmental, and timing. The importance is that success at the interfaces brings together equipment, software, and individuals into a combination that works.

System engineering provides a problem solving approach where perceived complexity can be simplified, options can be analyzed and implemented to close on solutions, and the methodology will be iterated until solutions meet requirements based on success criteria. Concepts transition into designs, designs into equipment, and costs flow from budgetary estimates into firm costs for implementation.

As illustrated in Fig. 1, integrated system design demands: establishing requirements; solving problems functionally; iterating to close on a solution; and then translating results to designs as specified by drawings, specifications, and other documentation. This approach provides higher confidence for achieving objectives because the discipline dictates that all variables, not just those that are part of the design, be addressed.

Fig. 1.
System engineering requires not only understanding the methodology, but also requires creativity, an open mind, and fresh approaches.
The Role of Creativity
Creativity is essential to modern Systems Engineering Management because the technology is changing quickly and many approaches, which previously were not feasible, can now be implemented. A positive approach to analyzing these new situations is required and particularly in ER projects because to date, mixed waste remediation approaches have not resulted in easy answers with existing technology. Roadblocks in thinking will assure that the inefficiencies of the old ways will prevail, and project success will be questionable.
Creativity, like systems, is an iterative approach. Creativity implies an absence of preconceived ideas (open mind) and positive approach (can do attitude).
An open mind will accept that there are many solutions to a problem which will meet the functional requirements. A positive approach will provide the motivation to follow through to success.
Communications, System Projects, and the Microcomputer
Excellent and speedy communications are necessary in the system engineering approach so that needs and data can be delineated in timely fashion to those who must take action.
The one practical tool that can be most important to the Project Manager and the Team, so that data and information is readily available and can be transferred quickly, is to have microcomputers for all team members. It is not necessary that the computers be networked although that will obviously improve communications; if everyone uses the system. The major benefits of the microcomputer will be that once the information is in, it will be available for use as often as required, and it can improve productivity Thus, a table with data developed for characterizing the soil (compounds, values) on the Vortec Vitrification Demonstration Plant Project is not only communicated to the design engineers, but it is also easily accessed and inserted into the monthly and final reports,, and it can be quickly available to respond to either the customer or a refractory supplier.
THE ER PROJECT- ACHIEVING SUCCESS
Two critical phases in ER projects require the most attention to achieve success. They are:
  Phase 1 - System Concept
  Phase 2 - Detailed Design
Phase 3 - Implementation, when the design is installed, operated, and the environmental remediation accomplished, while important, is not considered critical (until things fail to go as planned) because it is totally dependent on the first two phases. In this phase, correction of problems will be have the highest cost impact and can contribute heavily to schedule delays. It is therefore extremely cost effective to devote the most attention in Phases 1 and 2 to items which historically have contributed the most to problems encountered in Phase 3. In general, these have been in the area of requirements, interfaces, and organization.
To provide the greatest help to the executives and Project Managers involved with ER projects, this paper will focus on critical issues in the first two critical phases of the project.
Phase 1, System Concept Definition, is the investigation phase where the remediation problem is analyzed and approaches are synthesized to select a concept which will meet the needs of the customer. The system requirements and the major subsystem requirements are defined. Data is collected, and all functions are analyzed. Systems analysis to quantify waste characterization, quantities, and throughputs are accomplished. Interfaces and critical technical issues are identified, and a baseline system concept for achieving the remediation is developed. The baseline concept scopes the cost of remediation.
Phase 2, Detailed Design, is the pre-implementation phase that results in the drawings and specifications that define the design of the system and equipment for remediation. Where there are existing proven methods to accomplish the remediation, the exact method in which the remediation will be carried out is specified in detail during this phase.
In Phase 3, the design is implemented either by fabricating and installing the designed system or by procuring the proven method necessary to achieve the desired results.

Techniques for use in Phases 1 and 2 which will enhance the probability for success in Phase 3 will be described in the following sections.

Phase 1 - System Concept Definition

This phase is possibly the most critical part of the project because the basic requirements are established. The objective of the effort and the criteria for completion are defined. Reviews of successful projects show that either, or both, of these items are never established, or they are unclear resulting in contractual debates. Requirements may change later, but the basic needs initially established identify the analyses to be conducted and the data to be collected.

There are three major tasks which can be achieved in this phase to enhance success. They are establishing Project Manager and the Team, developing the system requirements, and bounding the technical parameters.

The Project Manager and The System Engineer

Some organizations use Project Management as an executive development path for managers, and as a result they may have non-technical individuals manage ER projects. If the executive management understands the risks, and the associated costs, then this is an excellent technique for training future executives.

A higher confidence, reduced risk approach is to have a technically strong Project Manager with the necessary people skills. Because successful Project Managers need to provide guidance in technical approaches and problem resolution required on ER projects, purely administrative experience may not provide the "horsepower required". It is not always possible to obtain both qualities in one individual, and therefore it will be necessary to choose management over technical skills and support the Project Manager with a technically strong System Engineer.

The System Engineer must understand the total requirements before addressing the hardware, software, and interfaces of the project but is guided by these items while developing the requirements. The System Engineer, while concerned with all technical aspects of the project, usually has different skills than the classic Project Engineer. The Project Engineer historically has been concerned with the equipment aspects of a project. The System Engineer must be constantly aware of all the interfaces affecting the solution and not just the design engineering factors. Having engineered a "works" project may not meet the technical skills criteria in a leading edge project where the technical requirements may demand an understanding of air pollution control, nuclear parameters, physical characteristics of barriers, chemical interactions, mass and thermal balances, as well as complete engineering documentation.

There are two intangible characteristics the Project Manager and the System Engineer must possess. Both must be goal driven and output oriented. In a project where timely communications are imperative, it does no good to provide information to those who need it only when it is "complete". System engineering is an iterative and dynamic approach. One cannot wait for "completeness."

Many times the best available information and necessary assumptions must be used pending "complete" information.

On the Vortec Vitrification Demonstration Plant Project, it was not possible during Phase 1 to define the offgas from the melter so that the air pollution control system (APCS) could be developed because a site and waste stream had not been selected. Thus, a worst case soil was defined from the available characteristics for candidate sites. The "available" characteristics were used because the waste streams at candidate sites were themselves undefined. As a result, the APCS included acid gas cleanup. This equipment was removed when the selected host site did not have chlorinated hydrocarbons in the waste.

Finally, recognize that the most qualified Project Manager for one phase of a project may be totally inadequate for another phase. For this reason, it is imperative that senior management not take the selection process lightly.

Selecting the Team

Naming the project team is also an important decision. Many emphasize the need for management commitment and support as the Number 1 reason for project success. While important, many success stories continue to illustrate the ability to achieve the project objectives on time and within budget in spite of lack of management commitment. The specific reasons are debatable. However, a strong team and Project Manager that are goal directed and output oriented seems to be one reason.

Team capability includes a liberal amount of creativity. The role of creativity was stressed earlier. If it is lacking, roadblocks in thinking will assure that the

inefficiencies of the old ways will prevail, and project success will be questionable.

For all but the smallest project, the core team (those directing the overall efforts which are continuous throughout the project), must be dedicated to the project substantially full time. In Phase 1, these people, in addition to the Project Manager and System/Engineer, are key system analysts (heat balances, pollution control, waste chemistry, or other). An important, but little noticed key contributor, is a lead designer that can rapidly synthesize approaches and translate concepts into drawings.

The System Requirements Document

The System Requirements Document (SRD) defines functional requirements, design constraints, interfaces, and the acceptance criteria. It is the guiding document for all technical needs on the project and the key element in preventing technical surprises. It contains much more information than "Our General Spec." for civil projects because of the attention to function and interfaces. Finally, it indicates when the job is finished with the acceptance criteria. Because of its importance, it must be reviewed and approved by the customer to insure that the project is headed in the proper direction. To contribute to an on-schedule project, periodic review and feedback by the customer will allow the SRD to achieve "mid-course corrections".

Formats for the SRD vary. If one has not been specified by the customer or by the contractor's internal policies, an acceptable format is one which defines "requirements from top to bottom and from left to right". That is, the document will define requirements at the system level and for each major subsystem (top to bottom). It will also contain a sequence of events (timeline based description of operation) which establishes requirements beginning with the system initial conditions and ending with the completion of operations (left to right).

Bounding the Technical Parameters - Identifying the Drivers

The process and equipment are sized based on the Mass and Energy Balance of the system. When radionuclides are contained in the waste stream, the nuclear energy effects must be included. Developing a mass and energy balance is part of basic engineering, but it takes on added meaning in ER projects because of the need to account for hazardous materials before, during, and after the process. Therefore, the Mass and Energy Balance not only is necessary for sizing equipment, it is also an auditing tool and will aid in the Safety Analysis of the system.

The other types of analyses vary according to the technical content of the project. While initial analyses can be defined at project start, many will be defined as a result of analyzing the unknowns. Enough analytical effort must be achieved to designate the technical drivers. These may not necessarily be the ones identified at the start of the project. Because the drivers are primarily associated with cost and schedule, it is important to begin obtaining budgetary subsystem and system costs to develop implementation costs.

Phase 2 - Detailed Design

The most important items which will affect Phase 3 success (other than the design) are:

- The implementation cost
- The definition of subsystem/equipment interfaces
- Design oversights

The effects of these problems can be alleviated by:

- Technical Parameter and Equipment Cost Tracking
- Actively cooperating with suppliers to obtain more cost effective solutions and shorter schedules
- Interface Control Documentation
- "Red Team Reviews" before the preliminary and final design reviews

Proven techniques, requiring no special Management Information Systems, are described for accomplishing these tasks, and they are easily implemented.

Technical Parameter and Cost Tracking

The microcomputer is the tool for simplifying the effort. It will serve two purposes (among many) in technical parameter and cost tracking which are: 1) to store the Equipment List with the necessary data in spreadsheet form; and 2) to store other data and information about the system, subsystems, specifications, and drawings. This provides suppliers with the latest design information.
